The technique of placing an intraosseous line is straightforward. A specialized intraosseous needle or, if not available, a standard 16- or 18-gauge needle, a spinal needle with stylet, or bone marrow needle is inserted into the anterior surface of the tibia 1 to 2 cm below and 1 cm medial to the tibial tuberosity (avoiding the epiphyseal plate). The needle is directed at 90 degrees to the anteromedial surface of the tibia, just distal to the tuberosity (see Fig. 48-6 and E-Fig. 48-1). When the needle passes through the cortex into the marrow, a sudden loss of resistance is sensed. Successful placement has been achieved if the needle is in the marrow cavity, as evidenced by the needle standing upright without support. If the needle has slipped into the subcutaneous tissue, its upright position cannot be maintained without support. Free flow of the infusate without significant subcutaneous infiltration should also be demonstrated. The technique has a small complication rate,<sup>34</sup> although possible complications include osteomyelitis, fat and bone marrow embolisms, and compartment syndrome. To avoid these potential complications, intravenous access should replace intraosseous access as soon as possible. The onset of action and concentration of most drugs after intraosseous administration are comparable with venous administration.<sup>35</sup> A relatively new device, the EZ-IO

(Vidacare, Shavano Park, Tex.) provides the most rapid means for intraosseous access (see E-Fig. 48-1).

### ENDOTRACHEAL MEDICATION ADMINISTRATION

In the absence of other vascular access, medications including lidocaine, atropine, naloxone, and epinephrine (mnemonic LANE) can be administered via the endotracheal tube.<sup>36,37</sup> The use of ionized medications such as sodium bicarbonate or calcium chloride is not recommended by this route. The peak concentration of epinephrine or lidocaine administered via the endotracheal route may be less compared with the intraosseous route. For example, the peak drug concentration of epinephrine after endotracheal administration was only 10% of that after intravenous administration in anesthetized dogs. The recommended dose for epinephrine via the endotracheal tube is 10 times the intravenous or intraosseous dose or 0.1 mg/kg for bradycardia or pulseless arrest.

The volume and the diluent in which the medications are administered through an endotracheal tube may be important. When large volumes of fluid are used, pulmonary surfactant may be altered or destroyed, resulting in atelectasis. The total volume of fluid delivered into the trachea with each drug administered should not exceed 10 mL in children and 5 mL in infants and neonates.<sup>38</sup> However, administering an adequate volume of a drug is important to reach a large area of mucosal surface beyond the tip of the endotracheal tube for absorption. Absorption into the systemic circulation may be further enhanced by deep intrapulmonary administration by passing a catheter beyond the tip of the tracheal tube deep into the bronchial tree. The risk associated with the endotracheal route of drug administration is the formation of an intrapulmonary depot of drug, which may prolong the drugs' effect. This could theoretically result in postresuscitation hypertension and tachycardia or the recurrence of fibrillation after normal circulation is restored.

### MONITORING DURING CARDIOPULMONARY RESUSCITATION

A basic clinical examination is vital during cardiac arrest. The chest is carefully observed for adequacy of bilateral chest expansion with artificial ventilation and for equal and normal breath sounds. In addition, the depth of compression and the position of the rescuer's hands should be constantly reevaluated in performing chest compressions by palpation of a major artery. Palpation is essential in establishing absence of a pulse and in assessing the adequacy of blood flow during chest compressions. Palpating the peripheral pulses may be inaccurate, especially during intense vasoconstriction associated with the use of epinephrine.

An indwelling arterial catheter, when available, is a valuable monitor in assessing the arterial blood pressure. Specific attention should be paid to diastolic blood pressure as it relates directly to adequacy of coronary perfusion during CPR. In addition, arterial access allows for frequent blood sampling, particularly for measurement of arterial pH and blood gases. Pulse oximetry can be used during CPR to determine the O<sub>2</sub> saturation and may be of value in assessing the adequacy of cardiac output, as reflected in the plethysmograph. The ECG can suggest metabolic imbalances and diagnose electrical disturbances.

The ETCO<sub>2</sub> monitor provides important information during the course of resuscitation. Because the generation of exhaled CO<sub>2</sub> depends on pulmonary blood flow, it can provide a useful indicator of the adequacy of cardiac output generated by chest compressions. As the cardiac output increases, the ETCO<sub>2</sub>

increases and the difference between end-tidal and arterial CO<sub>2</sub> becomes smaller.<sup>39</sup> In animal models, ETCO<sub>2</sub> during CPR correlates with coronary perfusion pressure and with ROSC.<sup>40,41</sup> In adults during cardiac arrest, an ETCO<sub>2</sub> greater than 10 mm Hg is positively associated with ROSC and hospital survival.<sup>42,43</sup> When the ETCO<sub>2</sub> is less than 10 mm Hg, efforts should be taken to enhance the quality of chest compressions (push hard, push fast, release completely, minimize interruptions, and optimize hand position). A reduced ETCO<sub>2</sub> may occur transiently in the presence of adequate chest compressions after administration of epinephrine owing to an increase in intrapulmonary shunting.

Temperature should be monitored during and after CPR. The resuscitation of the child with hypothermia as the cause of cardiac arrest must be continued until the child's core temperature exceeds 95° F (35° C). A glass bulb thermometer measures the temperature to very low values. Repeated measurements of core body temperature should be made at several sites (rectal, bladder, esophageal, axillary, or tympanic membrane) where possible, to avoid misleading temperature readings from a single site, because local body temperature may vary with changes in regional blood flow during CPR. Hyperthermia should be aggressively treated in the periarrest period, because postarrest hyperthermia is associated with worse outcomes in children.<sup>44</sup> Evidence suggests a benefit to induced hypothermia after resuscitation from cardiac arrest in adults<sup>45,46</sup> and after perinatal hypoxic or ischemic injury.<sup>47</sup> The data available to support the use of hypothermia in infants and children after cardiac arrest is from case series and retrospective studies. Pending results of a randomized controlled trial (Therapeutic Hypothermia After Pediatric Cardiac Arrest), clinicians may choose to control a child's temperature in the range of 91.4° to 95° F (33° to 35° C) for 12 to 48 hours after resuscitation with slow subsequent rewarming (see section on Postresuscitation Stabilization).

## Medications Used during Cardiopulmonary Resuscitation

### α- AND β-ADRENERGIC AGONISTS

In 1963, only 3 years after the original description of closed-chest CPR, Redding and Pearson<sup>48</sup> demonstrated that early administration of epinephrine in a canine model of cardiac arrest improved the success rate of CPR. They also demonstrated that the increase in aortic diastolic pressure with the administration of α-adrenergic agonists was responsible for the improved success of resuscitation. They theorized that vasopressors such as epinephrine were of value because the drug increased peripheral vascular tone and, hence, coronary perfusion pressure. The relative importance of α- and β-adrenergic agonist actions during resuscitation has been widely investigated. In a canine model of cardiac arrest, only 27% of dogs that received a pure β-adrenergic receptor agonist along with an α-adrenergic antagonist were resuscitated successfully, compared with 100% of dogs that received a pure α-adrenergic agonist and a β-adrenergic antagonist. Other investigators have demonstrated that the α-adrenergic effects of epinephrine resulted in intense vasoconstriction of the resistance vessels of all organs of the body, except those supplying the heart and brain.<sup>49</sup> Because of the widespread vasoconstriction in nonvital organs, adequate perfusion pressure and thus blood flow to the heart and brain can be achieved despite the fact that cardiac output is very low during CPR.<sup>49-51</sup>

The increase in aortic diastolic pressure associated with epinephrine administration during CPR is critical for maintaining coronary blood flow and enhancing the success of resuscitation.<sup>52,53</sup> Even though the contractile state of the myocardium is increased by the use of  $\beta$ -adrenergic agonists in the spontaneously beating heart,  $\beta$ -adrenergic agonists may actually decrease myocardial blood flow by increasing intramyocardial wall pressure and vascular resistance during CPR.<sup>54</sup> By its inotropic and chronotropic effects,  $\beta$ -adrenergic stimulation increases myocardial O<sub>2</sub> demand, which, when superimposed on low coronary blood flow, increases the risk of ischemic injury.

Any medication that causes systemic arterial vasoconstriction can be used to increase aortic diastolic pressure and resuscitate the heart. For example, pure  $\alpha$ -adrenergic agonists can be used in place of epinephrine during CPR. Phenylephrine and methoxamine, two  $\alpha$ -adrenergic agonists, have been used in animal models of CPR with success equal to that of epinephrine. Their use results in a greater O<sub>2</sub> supply to demand ratio in the ischemic heart and at least a theoretical advantage over the combined  $\alpha$ - and  $\beta$ -adrenergic agonist effects of epinephrine. These agonists, as well as other classes of vasopressors such as vasopressin, have been used successfully for resuscitation.

The merits of using a pure  $\alpha$ -adrenergic agonist during CPR have been questioned by some investigators. Although the inotropic and chronotropic effects of  $\beta$ -adrenergic agonists may have deleterious hemodynamic effects during CPR for ventricular fibrillation, increases in both heart rate and contractility will increase cardiac output when spontaneous coordinated ventricular contractions are achieved.

## EPINEPHRINE

Epinephrine (adrenaline) is an endogenous catecholamine with potent  $\alpha$ - and  $\beta$ -adrenergic stimulating properties. The  $\alpha$ -adrenergic action increases systemic and pulmonary vascular resistance, increasing both systolic and diastolic blood pressure. The increase in diastolic blood pressure directly increases coronary perfusion pressure, thereby increasing coronary blood flow and increasing the likelihood of ROSC.<sup>52,53</sup> The  $\beta$ -adrenergic effect increases myocardial contractility and heart rate and relaxes smooth muscle in the skeletal muscle vascular bed and bronchi. Epinephrine also increases the vigor and intensity of ventricular fibrillation, increasing the likelihood of successful defibrillation.<sup>55</sup>

Larger than necessary doses of epinephrine may be deleterious. Epinephrine may worsen myocardial ischemic injury secondary to increased O<sub>2</sub> demand and may result in postresuscitative tachyarrhythmias, hypertension, and pulmonary edema. Epinephrine causes hypoxemia and an increase in alveolar dead space ventilation by redistributing pulmonary blood flow.<sup>39,56</sup> Prolonged peripheral vasoconstriction by excessive doses of epinephrine may delay or impair reperfusion of systemic organs, particularly the kidneys and gastrointestinal tract.

Routine use of large-dose epinephrine in in-hospital pediatric cardiac arrest should be *avoided*. A randomized, controlled trial in 2003 compared high-dose with standard-dose epinephrine for children with in-hospital cardiac arrest refractory to initial standard-dose epinephrine. Survival was reduced at 24 hours, with a trend toward decreased survival to hospital discharge in the children who received large doses of epinephrine.<sup>57</sup> Despite these data, large doses of epinephrine may be considered in special cases (e.g.,  $\beta$ -blocker overdose), particularly when diastolic blood pressure remains low despite excellent chest compression and several standard doses of epinephrine.

## VASOPRESSIN

Vasopressin is a long-acting endogenous hormone that causes vasoconstriction (V1 receptor) and reabsorption of water in the renal tubule (V2 receptor). In experimental models of cardiac arrest, vasopressin increases blood flow to the heart and brain and improves long-term survival compared with epinephrine.<sup>58,59</sup> In a randomized trial comparing the efficacy of epinephrine to vasopressin in shock-resistant out-of-hospital ventricular fibrillation in adults, vasopressin produced a greater rate of ROSC.<sup>60</sup> In a study of in-hospital adult cardiac arrest, vasopressin produced a rate of survival to hospital discharge similar to that of epinephrine.<sup>61</sup>

In a pediatric porcine model of prolonged ventricular fibrillation, the use of vasopressin and epinephrine in combination resulted in greater left ventricular blood flow than either vasopressor alone, and both vasopressin alone and vasopressin plus epinephrine resulted in superior cerebral blood flow than epinephrine alone.<sup>62</sup> By contrast, in a pediatric porcine model of *asphyxial* cardiac arrest, ROSC was more likely in piglets treated with epinephrine than in those treated with vasopressin.<sup>63</sup> Pediatric<sup>64-66</sup> case series and reports suggested that vasopressin<sup>64</sup> or its long-acting analog, terlipressin,<sup>65,66</sup> may be effective in refractory cardiac arrest. In a 2009 National Registry of Cardiopulmonary Resuscitation (NRCPR) review, vasopressin was associated with reduced ROSC and a trend toward reduced 24-hour and discharge survival. There is insufficient evidence to make a recommendation for its routine use during cardiac arrest.<sup>20</sup>

## ATROPINE

Atropine, a parasympatholytic agent, blocks cholinergic stimulation of the muscarinic receptors in the heart, increasing the sinus rate and shortening atrioventricular node conduction time. Atropine may activate latent ectopic pacemakers. Atropine has little effect on systemic vascular resistance, myocardial perfusion pressure, or contractility.<sup>67</sup>

Atropine is indicated for the treatment of asystole, pulseless electrical activity, bradycardia associated with hypotension, second- and third-degree heart block, and slow idioventricular rhythms. Atropine is particularly effective in clinical conditions associated with excessive parasympathetic tone. *However, for children with asystole or symptomatic bradycardia associated with severe hypotension, epinephrine is the medication of choice and atropine should be regarded as a second-line drug.*

The recommended pediatric dose of atropine is 0.02 mg/kg, with a maximum dose of 2 mg. The increase in heart rate after intravenous atropine (20  $\mu$ g/kg) in infants and children may be attenuated compared with that in adults.<sup>68</sup> Although a minimum dose of 0.1 mg has been entrenched in the literature, it is not evidence-based.<sup>68,69</sup> Atropine may be given by any route, including intravenous, intraosseous, endotracheal, intramuscular, and subcutaneous. After intravenous administration, its onset of action is within 30 seconds and its peak effect occurs in 1 to 2 minutes. The recommended adult dose is 0.5 mg every 3 to 5 minutes until the desired heart rate is obtained, up to a maximum of 3 mg.

## SODIUM BICARBONATE

The routine use of sodium bicarbonate during CPR remains controversial, and it remains American Heart Association Class Indeterminate. Acidosis may depress myocardial function, prolong diastolic depolarization, depress spontaneous cardiac activity, decrease the electrical threshold for ventricular fibrillation, and

reduce the cardiac response to catecholamines.<sup>70-72</sup> Acidosis also vasodilates systemic vessels and attenuates the vasoconstrictive response of peripheral vessels to catecholamines,<sup>73</sup> which is the opposite of the desired vascular effect during CPR. In children with a reactive pulmonary vascular bed, acidosis causes pulmonary hypertension. Therefore correction of even mild acidosis may be helpful in resuscitating children with increased pulmonary vascular resistance. Additionally, the presence of severe acidosis may increase the threshold for myocardial stimulation in a child with an artificial cardiac pacemaker.<sup>74</sup> Other situations in which administration of bicarbonate is indicated include tricyclic antidepressant overdose, hyperkalemia, hypermagnesemia, or sodium channel blocker poisoning.

Potentially deleterious effects of bicarbonate administration include metabolic alkalosis, hypercapnia, hypernatremia, and hyperosmolality. In a 2004 multicenter cohort study of in-hospital pediatric cardiac arrest, the use of sodium bicarbonate was associated with increased mortality.<sup>15</sup> Alkalosis causes a leftward shift of the oxyhemoglobin dissociation curve and thus impairs release of O<sub>2</sub> from hemoglobin to tissues at a time when O<sub>2</sub> delivery may already be reduced.<sup>75</sup> Alkalosis also can result in hypokalemia by enhancing potassium influx into cells and in ionic hypocalcemia by increasing protein binding of ionized calcium. The marked hypercapnic acidosis that occurs during CPR in the venous circulation, including the coronary sinus, may be exacerbated by the administration of bicarbonate.<sup>76</sup> Myocardial acidosis during cardiac arrest is associated with decreased myocardial contractility.<sup>72</sup> Hypernatremia and hyperosmolality may decrease tissue perfusion by increasing interstitial edema in microvascular beds.

Paradoxical intracellular acidosis after bicarbonate administration can occur with the rapid entry of CO<sub>2</sub> into cells with a slow egress of hydrogen ions out of cells; however, in neonatal rabbits recovering from hypoxic acidosis, bicarbonate administration increased both arterial pH and intracellular brain pH as measured by nuclear magnetic resonance spectroscopy.<sup>77,78</sup> Likewise, in rats, intracellular brain adenosine triphosphate concentration did not change during severe intracellular acidosis in the brain produced by extreme hypercapnia.<sup>78</sup> In a separate animal study, bicarbonate slowed the rate of decrease of both arterial and cerebral pH during prolonged CPR, suggesting that the blood-brain pH gradient is maintained during CPR.<sup>79</sup> Given the potentially deleterious effects of bicarbonate administration, its use should be *limited to cases in which there is a specific indication*, as discussed earlier.

## CALCIUM

Calcium administration during CPR should be restricted to cases with a specific indication for calcium (e.g., hypocalcemia, hyperkalemia, hypermagnesemia, and calcium channel blocker overdose). These restrictions are based on the possibility that exogenously administered calcium may worsen ischemia-reperfusion injury. Intracellular calcium overload occurs during cerebral ischemia by the influx of calcium through voltage-dependent and agonist-dependent (e.g., *N*-methyl-D-aspartate [NMDA]) calcium channels. Calcium plays an important role in the process of cell death in many organs, possibly by activation of intracellular enzymes such as nitric oxide synthase, phospholipase A and C, and others.<sup>80</sup>

The calcium ion is essential in myocardial excitation-contraction coupling, in increasing ventricular contractility, and in enhancing ventricular automaticity during asystole. Ionized

hypocalcemia is associated with decreased ventricular performance and the peripheral blunting of the hemodynamic response to catecholamines.<sup>81,82</sup> Severe ionized hypocalcemia has been documented in adults suffering from out-of-hospital cardiac arrest<sup>82</sup> and in animals during prolonged CPR.<sup>83</sup> Thus children at risk for ionized hypocalcemia should be identified and treated as expeditiously as possible. Both total and ionized hypocalcemia may occur in children with either chronic or acute disease. Ionized hypocalcemia also occurs during massive or rapid transfusion of blood products (particularly whole blood and fresh frozen plasma) because citrate and other preservatives in stored blood products rapidly bind calcium. Because of this effect, ionized hypocalcemia is a known cause of cardiac arrest in the OR and should be treated immediately with calcium chloride or calcium gluconate (see Chapter 10). The magnitude of hypocalcemia in this setting depends on the rate and volume of blood products administered and the hepatic and renal function of the child. Administration of fresh frozen plasma at a rate in excess of 1 mL/kg/min significantly decreases the ionized calcium concentration in anesthetized children.<sup>84</sup>

The pediatric dose of calcium chloride for resuscitation is 20 mg/kg with a maximum dose of 2 g. Calcium gluconate is as effective as calcium chloride in increasing the ionized calcium concentration.<sup>85,86</sup> The dose of calcium gluconate should be three times that of calcium chloride (milligram per kilogram,) (i.e., 20 mg/kg calcium chloride is equivalent to 60 mg/kg calcium gluconate), with a maximum dose of 2 g in children. Calcium should be given slowly through a large-bore, free-flowing intravenous cannula, or preferably a central venous line. When administered too rapidly, calcium may cause bradycardia, heart block, or ventricular standstill. Severe tissue necrosis occurs when calcium infiltrates into subcutaneous tissue. Calcium administration is not recommended for pediatric cardiopulmonary arrest in the absence of documented hypocalcemia, calcium channel blocker overdose, hypermagnesemia, or hyperkalemia (Class III, level of evidence [LOE] B). Routine calcium administration in cardiac arrest provides no benefit and may be harmful.<sup>74,87</sup>

## GLUCOSE

The administration of glucose during CPR should be restricted to children with documented hypoglycemia because of the possible detrimental effects of hyperglycemia on the brain during or after ischemia. The mechanism by which hyperglycemia exacerbates ischemic neurologic injury may be due to an increased production of lactic acid in the brain by anaerobic metabolism. During ischemia under normoglycemic conditions, brain lactate concentration reaches a plateau. In a hyperglycemic milieu, however, brain lactate concentration continues to increase for the duration of the ischemic period.<sup>88</sup>

Clinical studies have shown a direct correlation between the initial post-cardiac arrest serum glucose concentration and poor neurologic outcome,<sup>89-92</sup> although the greater glucose concentration may be a marker rather than a cause of more severe brain injury.<sup>90</sup> However, given the likelihood of additional ischemic and hypoxic events in the postresuscitation period, it seems prudent to maintain serum glucose concentrations within the normal range. Additional studies are needed to determine if the benefit from tight control of serum glucose after cardiac arrest outweighs the risk of iatrogenic hypoglycemia. Some groups of children, including preterm infants and debilitated children with small endogenous glycogen stores, are more prone to

developing hypoglycemia during and after a physiologic stress such as surgery. Bedside monitoring of the serum glucose concentration is critical during and after a cardiac arrest and allows for the opportunity to administer glucose before the critical point of small substrate delivery has been reached. The dose of glucose generally needed to correct hypoglycemia is 0.5 g/kg given as 5 mL/kg of 10% dextrose in infants or 1 mL/kg of 50% dextrose in an older child. The osmolality of 50% dextrose is approximately 2700 mOsm/L and has been associated with intraventricular hemorrhage in neonates and infants; therefore the more dilute concentration is recommended in infants.

### AMIODARONE

Amiodarone has now supplanted lidocaine as the first drug of choice for medical management of shock-resistant ventricular tachycardia and fibrillation. The role of amiodarone was established for cardiac arrest after a series of studies showed it to be more effective than lidocaine in the management of refractory tachyarrhythmias in adults. Compared with lidocaine, amiodarone results in an increased rate of survival to hospital admission in patients with shock-resistant out-of-hospital ventricular fibrillation.<sup>93</sup>

Early reports on the use of oral amiodarone in children were favorable.<sup>94-96</sup> Recent data on amiodarone use in children are limited to case reports and descriptive case series. Nevertheless, it is now used widely for serious pediatric arrhythmias in the nonresuscitation environment and appears to be effective and have an acceptable short-term safety profile.

The pharmacology of amiodarone is complex and may explain the wide range of its usefulness. It is primarily classified as a Vaughn-Williams class III agent that blocks the adenosine triphosphate-sensitive outward potassium channels causing prolongation of the action potential and refractory period; however, this effect requires intracellular accumulation. On intravenous loading, the antiarrhythmic effects are primarily due to non-competitive  $\alpha$ - and  $\beta$ -adrenergic receptor blockade, calcium channel blockade, and effects on inward sodium current causing a decrease in anterograde conduction across the atrioventricular node and an increase in the effective atrioventricular refractory period. The  $\alpha$ -adrenergic blockade leads to vasodilation, which may increase coronary blood flow. It is poorly absorbed orally, requiring intravenous loading in urgent situations. The full antiarrhythmic impact requires a loading period of up to 1 to 3 weeks to achieve intracellular levels and full potassium channel-blocking effects.

Hypotension is commonly reported with intravenous administration and may limit the rate at which the drug can be given; however, the development of hypotension is less common with the newer, aqueous formulation.<sup>97</sup> The overall hemodynamic impact of intravenous administration will depend on the balance of its effect on rate control, myocardial performance, and vasodilation. Dosage recommendations for children are based on limited clinical studies. The dose is extrapolated from data on adults; 5 mg/kg intravenously for life-threatening arrhythmias. This dose can be repeated if necessary to control the arrhythmia. Intravenous loading doses are followed by a continuous infusion of 10 to 20 mg/kg/day if there is a risk of arrhythmia recurrence. The ideal rate of bolus administration is unclear; in adults, once diluted, it is given as an intravenous push. It is best administered over 20 to 60 minutes to avoid profound vasodilation. We recommend slow intravenous push (2 to 3 minutes) for pulseless

ventricular tachycardia or ventricular fibrillation until the arrhythmia is controlled and then a slower bolus (up to 10 minutes) for the remainder of the dose. An alternative dosing regimen for children is 1 mg/kg intravenous push every 5 minutes up to 5 mg/kg. The use of the small aliquot bolus technique may be particularly appropriate for infants younger than 12 months of age.

Amiodarone-induced torsades de pointes has been described.<sup>98</sup> The use of amiodarone should be avoided in combination with other drugs that prolong the QT interval, as well as in the setting of hypomagnesemia and other electrolyte abnormalities that predispose to torsades de pointes. Severe bradycardia and heart block have also been described, especially in the postoperative period, and ventricular pacing wires are recommended in this setting. Both amiodarone and inhalation anesthetic agents prolong the QT interval; however, no specific data exist to evaluate the use of amiodarone for ventricular arrhythmias in children receiving inhalation anesthetics. It would seem prudent to be especially vigilant for this adverse effect in this circumstance.

Noncardiac adverse effects are often seen, especially with chronic dosing.<sup>99</sup> The most serious of these has been the development of interstitial pneumonitis seen most commonly in patients with preexisting lung disease.<sup>100</sup> The incidence in children is unknown. Rarely, an acute illness similar to acute respiratory distress syndrome illness has been reported in both infants and adults at the initiation of treatment.<sup>101</sup> The lung disease may remit with early discontinuation of the drug. Hypothyroidism, hepatotoxicity, photosensitivity, and corneal opacities are also common side effects with chronic use.<sup>99</sup>

### LIDOCAINE

Lidocaine is a class IB antiarrhythmic that decreases automaticity of pacemaker tissue that prevents or terminates ventricular arrhythmias as a result of accelerated ectopic foci. Lidocaine abolishes reentrant ventricular arrhythmias by decreasing the action potential duration and the conduction time of Purkinje fibers and increases the effective refractory period of Purkinje fibers, reducing the nonuniformity of contraction. Lidocaine has no effect on atrioventricular nodal conduction time, so it is ineffective in the treatment of atrial or atrioventricular junctional arrhythmias. In healthy adults, no change in heart rate or blood pressure occurs with lidocaine administration. In patients with cardiac disease there may be a slight decrease in ventricular function when a lidocaine bolus is administered intravenously.

In children with normal cardiac and hepatic function, an initial intravenous bolus of 1 mg/kg of lidocaine is given, followed by a continuous intravenous infusion at a rate of 20 to 50  $\mu$ g/kg/min. If the arrhythmia recurs, a second intravenous bolus at the same dose can be given. In children with severely decreased cardiac output, a bolus of no greater than 0.75 mg/kg is administered, followed by an infusion at the rate of 10 to 20  $\mu$ g/kg/min. In children with hepatic disease, dosages should be decreased by 50%. Children with renal insufficiency have normal lidocaine pharmacokinetics; however, toxic metabolites may accumulate in children receiving infusions over a long period. In children with hypoproteinemia, the dose of lidocaine also should be lowered, because of the increase in free fraction of the drug.

Toxic effects of lidocaine occur when the serum concentration exceeds 7 to 8  $\mu$ g/mL and include seizures, psychosis, drowsiness, paresthesias, disorientation, agitation, tinnitus, muscle spasms,

and respiratory arrest. The treatment of choice for lidocaine-induced seizures is a benzodiazepine (midazolam or lorazepam) or a barbiturate (e.g., phenobarbital; chronic therapy also increases the hepatic metabolism of lidocaine).<sup>102</sup> Conversion of second-degree heart block to complete heart block has been described,<sup>103</sup> as has severe sinus bradycardia. Lidocaine is not as effective as amiodarone for improving ROSC or survival to hospital admission among adults with ventricular fibrillation refractory to ventricular fibrillation and shock.<sup>104</sup>

## Special Cardiac Arrest Situations

### PERIOPERATIVE CARDIAC ARREST

The incidence, causes, and risk factors associated with anesthesia- and operative-related cardiac arrest have been evaluated by the Pediatric Perioperative Cardiac Arrest registry.<sup>105,106</sup> Cardiovascular causes of cardiac arrest were the most common (41% of all arrests), with hypovolemia from blood loss and hyperkalemia from transfusion of stored blood the most common identifiable cardiovascular causes. Among respiratory causes of arrest (27%), airway obstruction from laryngospasm was the most common cause. Vascular injury incurred during placement of central venous catheters was the most common equipment-related cause of arrest. The cause of arrest varied by phase of anesthesia care.

Cardiac arrest in the OR should have the greatest potential for a successful outcome, because it is a witnessed arrest with virtually instantaneous availability of skilled personnel, monitoring equipment, resuscitative equipment, and drugs. Whenever a cardiac arrest occurs in the OR, the circumstances causing the arrest should be rapidly determined. The circumstances of the arrest may provide a clue as to the cause, such as hyperkalemia after succinylcholine administration or rapid blood transfusion, hypocalcemia during a rapid infusion of fresh frozen plasma or large blood transfusion, or a sudden fall in  $\text{ETCO}_2$  indicating air, blood clot, or tumor embolism. A bradyarrhythmia always must be assumed to be first resulting from hypoxemia; second, caused by anesthetic overdose (real or relative); and third, possibly related to a vagal reflex caused by surgical or airway manipulation. Administering 100%  $\text{O}_2$  and ensuring adequate ventilation is always the first maneuver, regardless of the cause of the bradycardia. In reflex-induced bradycardia, atropine may be the first drug of choice, but in extreme cases of bradycardia, whatever the mechanism, epinephrine should be used. Hypotension and a low cardiac output state must be rapidly corrected by appropriate administration of intravenous fluids, vasopressors, and adequate chest compressions to circulate drugs to have the needed clinical effect. Once chest compressions are required, the standard American Heart Association recommendations for CPR generally apply and this includes the frequent administration of epinephrine. Figure 39-5 presents an algorithm for the differential diagnosis and treatment of the more common causes of acute OR-associated cardiac dysfunction.

### HYPERKALEMIA

A child with a hyperkalemic cardiac arrest may be identified by history, by the progression of ECG changes leading up to the arrest, or by initial laboratory results. A high index of suspicion must be maintained for hyperkalemia as a cause of cardiac arrest because it requires specific therapy. Along with the usual resuscitation algorithms, immediate therapy to antagonize the effects of an increased serum potassium level is necessary. Calcium gluconate or calcium chloride will antagonize

the effects of hyperkalemia at the myocardial cell membrane, increasing the threshold for fibrillation. Sodium bicarbonate and hyperventilation will increase the serum pH and shift potassium from the extracellular to the intracellular compartment; insulin (with concomitant dextrose) will also cause potassium to shift intracellularly (0.1 unit/kg of insulin with 0.5 g/kg of dextrose; 2 mL/kg of dextrose 25%). The serum potassium concentration must be monitored frequently during this treatment, preferably by point-of-care testing modalities. Because these therapies shift potassium intracellularly, therapy to remove potassium from the body (furosemide, hemodialysis, sodium polystyrene sulfonate) also may be indicated.

### ANAPHYLAXIS

Anaphylaxis is an unusual, but usually reversible, cause of cardiac arrest. Manifestations of anaphylaxis include skin reaction (usually flushing, pallor, or urticaria), airway edema and possible obstruction, bronchospasm, and cardiovascular collapse. Anaphylaxis may be particularly severe in situations of decreased endogenous catecholamines, such as in a child taking  $\beta$ -blockers or in children receiving spinal or epidural anesthesia.

Resuscitation of the child with anaphylaxis rests on reversing airway obstruction and restoring intravascular volume and vascular tone. In the child with cardiac arrest, standard-dose epinephrine should be administered intravenously. In the child with impending cardiac arrest, 0.01 mL/kg of subcutaneous epinephrine (1:1000 concentration) may be preferred. Children with anaphylactic shock have profound intravascular depletion requiring rapidly administered, large-volume fluid resuscitation (20 mL/kg boluses). In addition to the usual resuscitation medications, treatment should include an antihistamine and corticosteroid, such as diphenhydramine (Benadryl), 1 mg/kg, and methylprednisolone (Solu-Medrol) 2 mg/kg. Inhaled bronchodilators such as albuterol may help reverse bronchospasm. If severe airway obstruction occurs, endotracheal intubation or even cricothyroidotomy may become difficult or impossible. Therefore the airway should be secured early on by a skilled practitioner.

### SUPRAVENTRICULAR TACHYCARDIA

Supraventricular tachycardia (SVT), a common arrhythmia in infants and children, may be associated with severe circulatory compromise or even cardiac arrest. Therapy for this arrhythmia should be based on the child's hemodynamic status. SVT associated with inadequate circulation should be treated immediately with synchronized cardioversion beginning at a dose of 0.5 J/kg. If intravenous access is available, adenosine can be administered while cardioversion is being prepared; however, cardioversion should not be delayed while intravenous access is being obtained.

Adenosine is the medical treatment of choice for SVT. The underlying mechanism in children is usually a reentry circuit involving the atrioventricular node. Adenosine causes a temporary block in the atrioventricular node and interrupts this reentry circuit. The initial dose is 0.1 mg/kg given as a rapid intravenous bolus. Central venous administration is preferable because the drug is rapidly metabolized by red blood cell adenosine deaminase and therefore has a half-life of only 10 seconds. When the drug is given peripherally, the intravenous line should be immediately and rapidly flushed with 10 mL of saline. If there is no interruption in the reentry circuit, successive doses of 0.2 and 0.4 mg/kg should be given. In neonates, a smaller initial dose of 0.05 mg/kg is given and increased by 0.05 mg/kg/dose until termination of the arrhythmia up to a maximum dose of

0.3 mg/kg.<sup>107</sup> When SVT appears without any circulatory compromise, conversion of the arrhythmia may first be attempted with a vagal maneuver such as ice to the face. If this is ineffective, then adenosine should be utilized.

Other medications used to treat SVT have a greater incidence of adverse effects than adenosine. Digoxin is often ineffective and causes frequent arrhythmias. Verapamil should be avoided in infants because of its association with congestive heart failure and cardiac arrest because of its negative inotropic effects.<sup>108</sup> Flecainide is effective in treating SVT but has many cardiac and noncardiac adverse effects<sup>109</sup>; its role for hemodynamically unstable SVT remains to be established. Other therapies include  $\beta$ -adrenergic blockers, edrophonium, and  $\alpha$ -agonists. If SVT persists despite medical therapy and the child progresses to circulatory instability, electrical cardioversion should proceed immediately.

### PULSELESS ELECTRICAL ACTIVITY

Pulseless electrical activity (PEA) is defined as organized ECG activity, excluding ventricular tachycardia and fibrillation, without clinical evidence of a palpable pulse or myocardial contractions. It may occur spontaneously after cardiac arrest or as an intervening rhythm associated with treatment for cardiac arrest. The causes of PEA is divided into primary (cardiac) and secondary (noncardiac) causes. Primary PEA, associated with cardiac arrest, is due to depletion of myocardial energy stores and thus responds poorly to therapy. Drugs used to treat primary PEA include epinephrine, atropine, calcium, and sodium bicarbonate.

The causes of secondary PEA are often remembered using the 4 Hs and 4 Ts mnemonic: *hypovolemia*, *hypoxia*, *hypothermia*, and *hypo- or hyper-electrolytemia* (hyperkalemia, hypocalcemia), *tension pneumothorax*, *pericardial tamponade*, *thromboembolism*, and *toxins* (anesthetic overdose). In secondary PEA, intervention is directed at the underlying disorder and usually results in a successful resuscitation. When the cause of PEA is unknown and the child does not respond to medications, giving a fluid bolus and inserting needles into the pleural space to rule out pneumothorax and into the pericardial space to rule out cardiac tamponade should be considered.

## Adjunctive Cardiopulmonary Resuscitation Techniques

### OPEN-CHEST CARDIOPULMONARY RESUSCITATION

The use of open-chest cardiac massage, although generally replaced by closed-chest CPR, still has an active role in the OR and ICU especially during and after thoracic surgery. Compared with closed-chest CPR, open-chest CPR generates greater cardiac output and vital organ blood flow. During open-chest CPR, less elevation occurs in intrathoracic, right atrial, and intracranial pressure, resulting in greater coronary and cerebral perfusion pressure and greater myocardial and cerebral blood flow.<sup>110-112</sup>

Typically, in the OR and ICU, open-chest CPR is preferable to closed-chest CPR in the child who has had a recent sternotomy. Open-chest CPR is also indicated for selected children when closed-chest CPR has failed, although exactly which children should receive this method of resuscitation under this condition is controversial. When initiated early after failure of closed-chest CPR, open-chest CPR may improve outcome.<sup>113-115</sup> When performed after 15 minutes of closed-chest CPR, open-chest CPR significantly improves coronary perfusion pressure and the rate of successful resuscitation.<sup>116</sup>

### EXTRACORPOREAL MEMBRANE OXYGENATION

In institutions with the ability to rapidly mobilize an extracorporeal circuit, extracorporeal cardiopulmonary bypass (CPB) should be considered for refractory pediatric cardiac arrest when the condition leading to arrest is reversible and when the period of no flow (cardiac arrest without CPR) was brief. Survival with a good neurologic outcome is possible after more than 50 minutes of CPR in selected children who were resuscitated via extracorporeal CPB.<sup>117,118</sup> CPB requires major technical support and sophistication but can be rapidly implemented in hospitals set up to do so. However, absence of a formal rapid deployment extracorporeal membrane oxygenation (ECMO) team does not preclude resuscitation ECMO in pediatric cardiac patients with good results.<sup>119</sup> Extracorporeal CPB should be reserved for children who have effective CPR initiated immediately after cardiac arrest.

### ACTIVE COMPRESSION-DECOMPRESSION

Active compression-decompression CPR uses a negative-pressure “pull” on the thorax during the release phase of chest compression using a handheld suction device. This technique has been shown to improve vascular pressures and minute ventilation during CPR in animals and humans.<sup>120-124</sup> The hemodynamic benefit of this technique is attributed to enhancement of venous return by the negative intrathoracic pressure generated during the decompression phase. Thus, when this technique was used with a device adding impedance to inspiration, vascular pressures and flow increased further.<sup>125</sup> Its effectiveness in adults shows promise, with increased survival and a trend toward neurologic improvement in prehospital victims.<sup>126-128</sup> However, two recent, larger trials did not demonstrate improved survival in in-hospital or prehospital victims of cardiac arrest, nor did any subgroup demonstrate benefit from active compression-decompression CPR.<sup>129-131</sup> The complication rate, including fatal rib and sternal fractures, may be greater with this technique.<sup>132</sup>

## Postresuscitation Stabilization (Post-Cardiac Arrest Care)

The goals of postresuscitation care are to prevent secondary organ injury, preserve neurologic function, diagnose and treat the cause of illness, and prevent recurrent arrest. Respiratory support should be tailored to minimize the risk of oxidative damage while maintaining adequate O<sub>2</sub> delivery. FiO<sub>2</sub> should be limited to the lowest necessary amount. Ventilation should be closely monitored, because both hypercarbia and hypocarbia have the potential for deleterious effects.

Mitigation of neurologic injury after cardiac arrest has been a goal of many investigator groups. In adult patients with out-of-hospital ventricular fibrillation and in asphyxiated newborns,<sup>47</sup> therapeutic hypothermia has been shown to be of benefit. In a retrospective study involving five hospitals, the effectiveness of hypothermia therapy was neither supported nor refuted.<sup>133</sup> Fink and colleagues<sup>134</sup> studied the feasibility of achieving mild hypothermia after pediatric cardiac arrest and found that they were reliably able to achieve a target temperature of 89.6° to 93.2° F (32° to 34° C) in less than 3 hours. A multicenter, randomized, controlled trial of systemic hypothermia for 48 hours after non-traumatic cardiac arrest (Therapeutic Hypothermia After Pediatric Cardiac Arrest [THAPCA]) is currently ongoing.

Nadkarni VM, Larkin GL, Peberdy MA, et al. First documented rhythm and clinical outcome from in-hospital cardiac arrest among children and adults. *JAMA* 2006;295:50-7.

*In this multicenter registry of in-hospital cardiac arrest, the first documented pulseless arrest rhythm was typically asystole or pulseless electrical activity in both children and adults. Because of improved survival after asystole and pulseless electrical activity, children had better outcomes than adults despite fewer cardiac arrests resulting from ventricular fibrillation or pulseless ventricular tachycardia.*

Perondi M, Reis A, Paiva E, et al. A comparison of high-dose and standard-dose epinephrine in children with cardiac arrest. *N Engl J Med* 2004;350:1722-30.

*This blinded, randomized controlled trial compared high-dose to standard-dose epinephrine as rescue therapy in children with in-hospital cardiac arrest. No benefit of high-dose epinephrine was detected. The data suggest that high-dose therapy may be more deleterious than standard-dose therapy.*

Postepisode Counseling	Myopathic Syndromes
Genetics	Malignant Hyperthermia Mimics
Physiology	Summary

**MALIGNANT HYPERTHERMIA (MH)** is a pharmacogenetic disease of skeletal muscle that may precipitate a potentially fatal sequence of metabolic responses in the presence of triggering anesthetics. The primary triggers for MH—inhalaional anesthetics and succinylcholine—induce an uncontrollable release of intramyoplasmic calcium ( $\text{Ca}^{2+}$ ) that results in sustained muscle contractures, which produce a hypermetabolic response. The hypermetabolic response manifests with hypercarbia, hyperpnea, tachycardia, and if not treated early, a mixed metabolic and respiratory acidosis. It is usually accompanied by some form of muscle rigidity: isolated muscle rigidity (e.g., masseter muscle tetany in the temporomandibular joint) or total body muscle rigidity (e.g., sustained contraction of major peripheral muscle groups).

MH was first described by Denborough and Lovell in 1960, who reported a 21-year-old man with compound fractures of his right tibia, who, with great trepidation, underwent general anesthesia with halothane.<sup>1</sup> After 10 minutes of anesthesia, he became hemodynamically unstable with hypotension, tachycardia, and mottled skin that was hot to the touch. The soda lime canister was found to be hot and was changed because it appeared to be exhausted. The anesthetic was discontinued, the patient was packed in ice, and he recovered without sequelae. Postprocedural examination did not reveal any known medical abnormalities. A careful family history disclosed that 10 blood relatives had previously died after ether anesthesia, suggesting an autosomal dominant pattern of inheritance for the disorder. This patient required a subsequent operation and was administered a spinal anesthetic without incident, demonstrating the effectiveness of nontriggering anesthetics.<sup>2</sup> Subsequent reports from around the world established this disorder as a familial entity that was potentially fatal.<sup>3,4</sup> The term *malignant hyperpyrexia* (later changed to *malignant hyperthermia*) was coined in 1967 at the first international meeting on this disorder.

The incidence of MH based on occurrences of MH reactions has been reported to be 1 case per 50,000 to 100,000 adults and 1 case per 3000 to 15,000 children.<sup>5,6</sup> Subsequent surveys of suspected MH reactions revealed even greater incidences; the

incidence of suspected MH was 1 case per 16,000 anesthetics in adults in Denmark, an incidence that increased to 1 case per 4200 adults when an inhaled anesthetic and succinylcholine were combined.<sup>7</sup> However, a survey of anesthesia in a pediatric hospital in the United States during the halothane era revealed an MH incidence of 1 case per 20,000 to 40,000 children, almost one half of that reported previously.<sup>8</sup> The incidence of fulminant MH (i.e., rapid increase in temperature accompanied by life-threatening metabolic changes, arrhythmias, and increased serum creatine kinase level) was 1 case per 250,000 general anesthetics in Denmark.<sup>7</sup> A similar incidence of 1 case of fulminant MH per 200,000 general anesthetics was reported from the United Kingdom.<sup>9</sup> The Danish survey found an incidence of 1 case of masseter muscle spasm per 12,000 anesthetics among children who received succinylcholine, whether in combination with inhalational or intravenous anesthetics.<sup>7</sup> Clinically, the demographic data suggested that the incidence or suspicion of MH was greater among children than adults and that the incidence was even greater among children in whom succinylcholine was used.

The frequency of MH reactions is greatest in childhood, with a peak age of 3 years, although recent data suggest that only about 18% of MH reactions occur in childhood.<sup>10,11</sup> Reactions have also been reported in neonates and infants, although they have been infrequent.<sup>12</sup> Many have perceived a decrease in the incidence of MH reactions in the past 2 decades, although some have challenged this perception.<sup>11</sup> Two reasons for the perception that the incidence of MH reactions have decreased are that many families with a genetic predisposition to MH have been identified and bring it to the attention of their surgical and anesthetic care providers preoperatively, and that the routine use of succinylcholine has decreased dramatically as a result of concerns regarding rare complications, such as hyperkalemic cardiac arrest. The latter has resulted in a black box warning admonishing against the routine use of succinylcholine in children, particularly male children younger than 8 years of age who may have unrecognized muscular dystrophy or other myopathy.<sup>13,14</sup>

**FIGURE 40-1** The trend in fatality rate in malignant hyperthermia is shown over time. The blue bars represent data from 361 patients, and the magenta bars represent data from 142 patients. Notice the marked decrease in mortality with dantrolene treatment. (Modified from Strazis KP, Fox AW. Malignant hyperthermia: a review of published cases. *Anesth Analg* 1993;77:297-304.)

It remains certain that all inhalational anesthetics and succinylcholine are potent triggers of MH reactions in susceptible patients,<sup>15-19</sup> with the possible exception of xenon based on evidence from MH-sensitive pigs<sup>20</sup> and caffeine-halothane contracture tests (CHCTs) from MH-susceptible and normal humans.<sup>21</sup> No other drugs used for intravenous or regional anesthesia trigger MH reactions. A comprehensive list of triggering and nontriggering drugs is available from the Malignant Hyperthermia Association of the United States (MHAUS) (<http://www.mhaus.org/> [accessed July 2012]).

The mortality rate for MH has decreased dramatically from more than 80% in the 1960s to 1.5% to 5% in recent years (Fig. 40-1).<sup>11,22-24</sup> For children, the MH mortality rate (0.7%) is 15-fold less than the rate (14%) for adults.<sup>11</sup> The overall decrease in mortality may be attributable to several factors: better identification of MH-susceptible individuals; the routine use of capnography and pulse oximetry, facilitating early identification of the signs and symptoms of an acute MH reaction<sup>25,26</sup>; a better understanding of the pathogenesis of MH; and the widespread availability of dantrolene.<sup>10</sup>

## Clinical Presentation

The most common presentation of MH is a hypermetabolic response to the inhalational anesthetics, with or without succinylcholine (Table 40-1). Among the earliest clinical signs is a marked increase in the end-tidal CO<sub>2</sub> that resists control by either mechanical ventilation or an increase in minute ventilation when the patient is breathing spontaneously.<sup>23,27</sup> Other nonspecific early signs include tachycardia and hemodynamic instability with a trend toward hypertension. Severe masseter muscle spasm (i.e., masseter tetany) refers to the inability to insert a laryngoscope blade into the mouth, the so-called “jaws of steel,” even with no

**FIGURE 40-2** The spectrum of masseter muscle responses to succinylcholine varies from a slight jaw stiffness that does not interfere with endotracheal intubation to the extreme “jaws of steel,” which is masseter muscle tetany that does not allow the mouth to be opened. The latter response is likely highly associated with malignant hyperthermia (MH). Even with the inability to open the mouth, the child’s lungs should still be able to be ventilated by bag and mask because all other muscles are relaxed. (From Kaplan RF. Malignant hyperthermia. Annual refresher course lectures. Washington, DC: American Society of Anesthesiologists; 1993.)

**TABLE 40-1** Clinical and Laboratory Findings Associated with Malignant Hyperthermia

Clinical Findings	Laboratory Findings
Tachycardia, tachypnea and hypertension	Increased PaCO <sub>2</sub>
Hypercarbia (ETCO <sub>2</sub> )	Acidosis (mixed respiratory and metabolic)
Greatly increased minute ventilation	Relative hypoxia, increased alveolar to arterial partial pressure gradient for oxygen
Generalized muscle rigidity (unresponsive to nondepolarizing muscle relaxants)	Hyperkalemia
Skin mottling	Elevated plasma lactate concentration
Hyperthermia (late sign)	Abnormal coagulation studies (late sign)
Cardiac arrhythmias (hyperkalemia-induced: PVC, VT, VF)	Myoglobinuria, myoglobinemia
Cola-colored urine (late sign)	Increased CPK level (usually a late sign)
Disseminated intravascular coagulation (late)	

Data from Malignant Hyperthermia Association of the United States. Available at <http://www.mhaus.org> (accessed July 2012).

CPK, Creatinine phosphokinase; ETCO<sub>2</sub>, end-tidal carbon dioxide; PaCO<sub>2</sub>, arterial partial pressure of carbon dioxide; PVC, premature ventricular contraction; VF, ventricular fibrillation; VT, ventricular tachycardia.

twitches evident on a blockade monitor after administration of succinylcholine, and it strongly indicates MH susceptibility (Fig. 40-2). In vitro live muscle biopsy testing revealed a 28% to 50% incidence of MH susceptibility among children with jaws of steel (Table 40-2).<sup>28-30</sup> Generalized muscle rigidity develops as a result of the excessive accumulation of myoplasmic Ca<sup>2+</sup> concentrations in MH-susceptible skeletal muscle, causing sustained muscle contractures.<sup>27</sup> This occurs even in the presence of

**TABLE 40-2** Limited Excursion of the Mandible: Differential Diagnosis

Temporomandibular joint dysfunction: congenital, inflammatory/infectious, trauma, neoplasm, collagen vascular disease (rheumatoid arthritis)
Muscle disease: malignant hyperthermia, Duchenne or Becker muscular dystrophy, myotonia congenita
Integumentary disease: inflammatory or infectious disease, neoplasm, radiation effects, collagen vascular disease (scleroderma)
Neurologic injury
Ultra-rapid metabolizer of succinylcholine (Nietlich or Cynthiana [C5 enzyme] variant of pseudocholinesterase) (see Chapter 6)
Ineffective succinylcholine

**TABLE 40-3** Arterial Blood Gas Data from a Child in Early Malignant Hyperthermia

Data	TIME AT MEASUREMENT			
	08:52	08:59	09:05	09:27
pH*	7.34	7.03	7.29	7.39
Pco <sub>2</sub> (mm Hg)	46.3	109.4	47.9	42.7
Po <sub>2</sub> (mm Hg)	236	159	589	635
Base excess	-1	-2	-3	1
HCO <sub>3</sub> <sup>-</sup> (mmol/L)	25.1	29	23.1	25.6

\*Notice the pure respiratory acidosis in this patient from Figure 41-3 and the rapid decrease in Pco<sub>2</sub> after dantrolene administration between 08:59 and 09:05.

neuromuscular blockade with nondepolarizing neuromuscular blocking drugs (NMBDs).

Hyperthermia, often a late sign, results from the greatly increased aerobic and anaerobic metabolic activity of triggered skeletal muscle; the overlying skin soon becomes hot to the touch. In many instances, the large muscle groups such as calf or thigh muscles feel tight or knotted. This is accompanied by exaggerated carbon dioxide (CO<sub>2</sub>) production, which usually is the first sign of an evolving MH reaction, and the accumulation of lactate fueled by markedly increased glycogenolysis and glycolysis (i.e., mixed respiratory and metabolic acidosis).<sup>31,32</sup> If an acute MH reaction is diagnosed and treated early in its evolution, before the body becomes unable to maintain this exaggerated aerobic metabolism, arterial blood gases may show an almost pure respiratory acidosis, which can make the diagnosis of MH difficult (Table 40-3). A mixed venous or peripheral venous blood gas analysis can be helpful in establishing the presence of hypermetabolism because it is more likely to demonstrate an increased CO<sub>2</sub> level, significant oxygen desaturation consistent with increased oxygen consumption ( $\dot{V}O_2$  less than 40 mm Hg, despite administering supplemental oxygen for which the expected  $\dot{V}O_2$  is greater than 60 mm Hg), and a possible increased lactate concentration.

In fulminant cases, untreated MH may increase the temperature as rapidly as 1° C every 10 minutes.<sup>27</sup> In one case, the temperature reached 43.8° C (110.8° F) within 18 minutes.<sup>33</sup> In addition to the profound hypercarbia and tachycardia, severe hypoxia, skin mottling, exuberant metabolic acidosis, rhabdomyolysis, coagulopathy, and hyperkalemia may follow. Unstable hemodynamics and ventricular arrhythmias inevitably follow. Intractable ventricular arrhythmias, pulmonary edema, disseminated intravascular coagulation, cerebral hypoxia or edema, and

**TABLE 40-4** Differential Diagnosis of Malignant Hyperthermia

Diagnosis	Distinguishing Traits
Hyperthyroidism	Patients often present with similar symptoms and physical findings; blood gas abnormalities gradually evolve; creatine phosphokinase value does not increase substantively.
Sepsis	Usually, blood gases are normal early, and metabolic acidosis occurs late; creatine phosphokinase remains normal.
Pheochromocytoma	Similar to MH, except for marked blood pressure swings
Metastatic carcinoid	Flushing, diarrhea, hypotension
Cocaine intoxication	Fever, rigidity, rhabdomyolysis similar to NMS
Heat stroke	Similar to MH, except that the patient is outside the operating room
Massefer muscle rigidity (MMR)	May progress to MH; total body spasm more likely than isolated MMR
Neuroleptic malignant syndrome (NMS)	Similar to MH but evolves over weeks; usually associated with the use of antipsychotics
Serotonergic toxicity	Similar to MH and NMS; associated with the administration of mood-elevating drugs (e.g., selective serotonin reuptake inhibitors)
Nonmalignant hyperthermia syndrome	Reported only once; severe hyperthermia seemingly associated with fentanyl

renal failure due to myoglobin deposition in the renal tubules are often associated with fatal outcomes.

In the early years of treating acute MH reactions, before dantrolene was identified as the specific antidote, symptomatic treatment was the mainstay of therapy. This included treatment of the acidosis and hyperkalemia with bicarbonate, and insulin with glucose, respectively; active cooling with iced saline gastric lavage; infusion of cold intravenous saline; and infusions of procainamide (a drug that was later shown to be ineffective). These interventions helped to reduce the mortality rate to about 50%, but with the availability of dantrolene, the mortality rate has decreased dramatically.

The presenting signs of MH vary (see Table 40-1). The syndrome may be fulminant or indolent, not all features of a classic MH reaction may be immediately evident, and it may occur intraoperatively or postoperatively, although the frequency of MH reactions occurring postoperatively is only 2%.<sup>27,34</sup> The latest that an MH reaction has reportedly occurred postoperatively is 11 hours, although a recent review of reports of postoperative MH in the North American Malignant Hyperthermia Registry has not found any case occurring beyond 40 minutes after the end of the anesthetic.<sup>34,35</sup> The likelihood that an MH-susceptible patient will develop MH in the presence of inhalational anesthetics is exasperatingly unpredictable. In one study, 50% of susceptible individuals reported two or more uneventful general anesthetics before an MH reaction was triggered.<sup>23,36</sup> Only 6.5% of probands in a retrospective review reported a family or personal history of MH.<sup>36</sup> A negative personal or family history is insufficient to conclude that a child is not susceptible to MH. Other disease states may be confused with MH (Table 40-4) and must be distinguished from it to provide correct therapy.

Given the variability of the clinical presentation of MH and the dearth of pathognomonic signs for this syndrome,

**TABLE 40-5** Clinical Indicators for Determining the Malignant Hyperthermia Raw Score

Process	Indicator	Points
Rigidity	Generalized muscular rigidity	15
	Masseter spasm	15
Muscle breakdown	Creatine kinase >20,000 IU after succinylcholine	15
	Creatine kinase >10,000 IU with no succinylcholine	15
	Cola-colored urine in perioperative period	10
	Myoglobin in urine >60 µg/L	5
	Myoglobin in serum >170 µg/L	5
	Blood, plasma, or serum K <sup>+</sup> >6 mEq/L, no renal illness	3
Respiratory acidosis	PETCO <sub>2</sub> >55 mm Hg with controlled ventilation	15
	Arterial Paco <sub>2</sub> >60 mm Hg with controlled ventilation	15
	PETCO <sub>2</sub> >60 mm Hg with spontaneous ventilation	15
	Arterial Paco <sub>2</sub> >65 mm Hg with spontaneous ventilation	15
	Inappropriate hypercarbia, anesthesiologist's call	15
	Inappropriate tachypnea	10
Temperature increase	Inappropriately rapid increase	15
	Inappropriately increased temperature >38.8° C (101.8° F)	10
Cardiac involvement	Inappropriate sinus tachycardia	3
	Ventricular tachycardia or fibrillation	3
Family history	Positive family history for first-degree relative	15
	Positive family history for more distant relative	5
Others	Arterial base excess more negative than -8 mEq/L	10
	Arterial pH <7.25	10
	Rapid reversal of malignant hyperthermia (MH) signs after intravenous administration of dantrolene	5
	Positive MH family history with another indicator from the patient's anesthesia experience other than increased creatine kinase level	10
	Elevated creatine kinase level and a family history of MH	10

From Larach MG, Localio AR, Allen GC, et al. A clinical grading scale to predict malignant hyperthermia susceptibility. *Anesthesiology* 1994;80:771-9.

establishing the diagnosis can be difficult. In response to the need for an objective measure to verify a clinical episode of MH, a retrospective, multivariable clinical grading scale was developed.<sup>37</sup> This grading scale was devised to clarify the cutoff value for a positive muscle CHCT result. It was not intended to be a clinical guide in the operating room. Despite recommendations not to use this scale to guide treatment and to be more conservative in its application, Tables 40-5 and 40-6 are provided to help clinicians identify true MH reactions. Although this clinical grading scale is somewhat cumbersome and has not been prospectively validated in clinical settings for use by nonexperts, it is a useful guide for the clinician.

**TABLE 40-6** Malignant Hyperthermia Clinical Grading Scale

Raw Score Range	Rank	Likelihood
0	1	Almost never
3-9	2	Unlikely
10-19	3	Somewhat less than likely
20-34	4	Somewhat greater than likely
35-49	5	Very likely
≥50	6	Almost certain

Modified from Larach MG, Localio AR, Allen GC, et al. A clinical grading scale to predict malignant hyperthermia susceptibility. *Anesthesiology* 1994;80:771-9.

## Patient Evaluation and Preparation

Optimal treatment begins with prevention and preparation. Obtaining an accurate family history of suspicious or unusual reactions to general anesthesia in blood relatives, unexpected admissions to intensive care after surgery, or unexplained sudden death during anesthesia should signal the surgeon and anesthesiologist to consider MH or another problem related to anesthesia. These questions assume the patient is part of a classic nuclear family, but with increasing levels of adoption, artificial insemination, surrogate motherhood, and egg donations, standard probing may not elicit clear family histories. The anesthesiologist must be sensitive but decisive in determining the true genetic relationship between the guardians and the child. Despite attempts to obtain an accurate history, misinterpretation of the questions may occur. In one case, an adopted child died of succinylcholine-induced hyperkalemic cardiac arrest, even though the parents denied that anyone in the family had anesthesia problems or muscle disease during the preoperative assessment. Only immediately after the event did the parent reveal that the child had been adopted and that the child's birth uncle had muscular dystrophy.

If the anesthesiologist is informed that the child has a blood relative who had an MH reaction or who has a myopathy with high concordance with MH, the most prudent course of action is to plan using a nontriggering anesthetic for total intravenous or regional anesthesia, or both. In the rare circumstance in which such prudence cannot be followed, extreme vigilance and preparation to treat MH are of the utmost importance.

Ambulatory surgery has rapidly expanded to include most pediatric surgery. Consequently, the safety of discharging children with a personal or family history of MH after an uneventful, trigger-free anesthesia on the day of surgery has raised concerns. Two retrospective studies concluded that the risk of a child developing an MH reaction after an uneventful, trigger-free anesthesia was exceedingly small.<sup>38</sup> Postoperative monitoring for an MH reaction while in the hospital was gradually reduced from 6 hours to 2 hours before discharge.<sup>39,40</sup> For MH-susceptible children, parents should be provided with a written description of the signs and symptoms of an MH reaction and a phone number for the on-call anesthesiologist for further advice. Families should contact an anesthesiologist rather than return to the emergency department, because the emergency physician may be unfamiliar with MH, particularly in children. Additional advice for the parents should include the use of an oral antipyretic drug (e.g., acetaminophen) to treat a mild fever. If the fever abates after a dose or two of acetaminophen, the fever was not caused by

MH. If the fever persists despite acetaminophen and sponge baths, and is accompanied by tachycardia and tachypnea, the parents should notify the on-call anesthesiologist and return the child to the hospital.

When a child with a known susceptibility to MH is scheduled for general anesthesia, the anesthesia machine (i.e., anesthetic workstation [AWS]) must be prepared to preclude the delivery of triggering agents. First, succinylcholine should be removed from the local vicinity to avoid inadvertent administration. Second, all vaporizers should be physically disengaged from the AWS, which is preferable because they can leak trace concentrations of inhalational anesthetics even in the off state, or if they cannot be removed from the AWS, tape should be placed across them in the off position to avoid accidentally turning them on.<sup>41</sup> Third, to accelerate the washout of anesthetics, the CO<sub>2</sub> absorbent should be replaced, a new anesthetic breathing circuit installed, and the ventilator bellows flushed and left operating.<sup>41-43</sup> Fourth, to eliminate inhalational anesthetics from the AWS, many clinicians follow a standardized protocol of flushing the workstation with 10 L/min of oxygen for 10 to 20 minutes, depending on the manufacturer and age of the machine.<sup>44</sup> However, the assumption that one protocol fits all to reduce the anesthetic concentration to less than 10 ppm, which is assumed to be the threshold below which an MH reaction cannot be triggered,<sup>45</sup> may not hold true for every AWS, particularly the newer ones, which are more complex in construction and more likely to contain internal working parts made of plastic, which act as sumps for inhalational anesthetics. To address the various types of AWS, the duration of flushing with large fresh gas flows (Table 40-7) and the need to exchange contaminated internal components with clean versions must be determined for each AWS. For some types of AWS, more than 60 minutes may be required to reach anesthetic concentrations less than 10 ppm.<sup>44,46,47</sup> To achieve an anesthetic concentration of 10 ppm or less in the Dräger Primus, Fabius, and Zeus machines in a timely manner, the ventilator diaphragm and integrated breathing system should be replaced with autoclaved components and then flushed for 20 minutes at a fresh gas flow of 10 L/min.<sup>46,47</sup> Table 40-7 lists the published times required to reach an anesthetic concentration of less than 10 ppm without replacing any AWS components.<sup>44,47,48</sup> These data support the notion that the previously held protocols

to wash out inhalational anesthetics from older AWSs do not hold true for the newer AWSs. The need for a single protocol or intervention that consistently achieves an anesthetic concentration of less than 10 ppm in all AWSs is of even greater importance because none of the available anesthetic agent analyzers is capable of measuring anesthetic concentrations in the 10 ppm range to confirm adequate removal of inhalational anesthetics.

After the AWS has been flushed with 10 L/min of an air and oxygen mixture, most anesthesiologists reduce the fresh gas flow during anesthesia. However, evidence has shown that the concentration of inhalational anesthetic surges ( $\geq 50$  ppm) when the fresh gas flow is reduced, and the magnitude of the rebound directly depends on the fresh gas flow rate.<sup>48,49</sup> Those who reduce the fresh gas flow after purging the AWS may be exposing their patients to concentrations of inhalational anesthetics that may trigger an MH reaction, although no MH reactions have been reported in patients in whom a reduced fresh gas flow was used in an AWS that had been purged using a large ( $>10$  lpm) fresh gas flow. To avoid confusion, a single, consistent, effective, and reliable intervention is required to prevent MH reactions in patients exposed to trace gases from a previously contaminated AWS.

A commercially available charcoal filter (Vapor-Clean, Dynasthetics, LLC, Salt Lake City) fitted to the expiratory and inspiratory limbs of the AWS reduces the concentration of inhalational anesthetics to less than 5 ppm within several minutes.<sup>50</sup> These filters are sold in pairs. The manufacturer recommends that a filter should be inserted into both limbs of the anesthesia breathing circuit just distal to the valves, which is reasonable during an acute MH reaction. However, when only the machine is contaminated with inhalational anesthetic (e.g., after flushing the AWS for elective MH cases), we apply a single filter in the inspiratory limb and keep the second of the pair to replace the first after 60 to 90 minutes, since it may become expended by that time.<sup>50</sup>

## Monitoring

Capnography and pulse oximetry, key monitors for early signs of an MH reaction, are required for all children who receive general anesthesia, irrespective of the duration of the procedure. Measurement of the body temperature is recommended for all children who undergo general anesthesia when fluctuations may be anticipated, according to the American Society of Anesthesiologists 2011 standards for basic anesthesia monitoring ([www.asahq.org/For-Members/Standards-Guidelines-and-Statements.aspx](http://www.asahq.org/For-Members/Standards-Guidelines-and-Statements.aspx)). Monitoring the axillary temperature site (opposite the extremity with the intravenous line) is recommended rather than a core site for early detection of an MH reaction because the axillary region is surrounded by large muscle bulk in the pectoral shoulder girdle. Although most consider an increasing temperature a late sign of an MH reaction, a retrospective review suggested that an increasing body temperature may occur early in an evolving MH reaction.<sup>36,51</sup> Evidence also suggests that crystalline skin temperature tapes may not reliably track temperature changes during MH reactions.<sup>36</sup>

## Diagnosis

Because the underlying disorder in MH is a hypermetabolic reaction (i.e., increased CO<sub>2</sub> production and oxygen consumption), massive volumes of CO<sub>2</sub> are released into the circulation, which rapidly increase the partial pressure of CO<sub>2</sub> (PCO<sub>2</sub>) and respiratory

Preparation of the Dräger Fabius CE and Dräger Zeus anaesthetic machines for patients susceptible to malignant hyperthermia. *Eur J Anaesthesiol* 2012;29:229-34.

rate in the unparalyzed child. The cardiovascular response is an increased cardiac output, heart rate, and in some cases, blood pressure (E-Fig. 40-1). The first clinical signs and symptoms of this hypermetabolic reaction in a spontaneously breathing patient are hypercapnia, tachypnea, and tachycardia (see Table 40-1).<sup>36</sup> A steady and relentless increase in the end-tidal CO<sub>2</sub> pressure (PETCO<sub>2</sub>) is the earliest sign of a reaction and is usually evident whether respirations are spontaneous or controlled. In some instances, the increase in PETCO<sub>2</sub> and heart rate occur contemporaneously, alerting the clinician to consider an evolving MH reaction (Fig. 40-3). Sudden unexpected cardiac arrest is a very rare presentation of MH and suggests a disease process other than MH, such as acute rhabdomyolysis and hyperkalemia after succinylcholine in a (male) child with an undiagnosed myopathy.

The presenting signs of an MH reaction are nonspecific and may suggest several possible disease states or equipment problems. The earliest sign of an MH reaction, an increase in end-tidal pCO<sub>2</sub>, may result from one or more of three factors from the CO<sub>2</sub> mass balance equation:

$$PCO_2 = (\dot{V}CO_2 / \dot{V}_A) + FICO_2$$

The circulating PCO<sub>2</sub> depends on the production of CO<sub>2</sub> ( $\dot{V}CO_2$ ), the elimination of CO<sub>2</sub> (i.e., alveolar ventilation ( $\dot{V}_A$ )), and the inspired concentration of CO<sub>2</sub> (FICO<sub>2</sub>). The differential diagnosis of an increased PCO<sub>2</sub> can be analyzed by considering the causes for each of these three factors. Causes of an increased  $\dot{V}CO_2$  include fever, MH, thyroid storm, and sepsis. Causes of a decreased  $\dot{V}_A$  include a deep level of anesthesia, endobronchial intubation, bronchospasm, and a kinked tracheal tube or airway breathing circuit. Causes of increased FICO<sub>2</sub> include an incompetent expiratory valve, exogenous source of CO<sub>2</sub>, low fresh gas flows with a partial or nonrebreathing circuit, and expired CO<sub>2</sub> absorbent. The initial evaluation should include a rapid assessment of the integrity of the breathing circuit, the presence of bilateral breath sounds and absence of wheezing, and examination of the CO<sub>2</sub> absorbent.

**FIGURE 40-3** Response of physiologic parameters to dantrolene during an apparent intraoperative episode of malignant hyperthermia. Notice the rapid fall in arterial and end-tidal carbon dioxide pressures after dantrolene (2.5 mg/kg) administration (arrow). (Courtesy Steven C. Hall, MD.)

During airway obstruction and hypermetabolic states such as thyrotoxicosis and sepsis, an increased PETCO<sub>2</sub> can be readily corrected with mild to moderate hyperventilation. During MH reactions, however, it is very difficult to restore the PETCO<sub>2</sub> to the normal range, even with vigorous mechanical hyperventilation.<sup>26</sup> The CO<sub>2</sub> production is sometimes so great that the in-circuit CO<sub>2</sub> absorbent rapidly becomes exhausted in an exothermic reaction, and the absorbent container becomes hot to touch.

A child's response to surgery during light anesthesia often includes tachycardia and may sometimes include bronchoconstriction. However, a dramatic and unexpected increase in heart rate from 120 to 180 beats/min in a healthy, 7-year-old child (or an increase from 70 to 120 beats/min in an adult) strongly suggests a pathologic process, and a differential diagnosis beyond light anesthesia should be seriously considered. Before intervening, it is important to quickly scan all of the monitors to determine whether the aggregate indices point to a specific diagnosis. If tachycardia is associated with an increase in body temperature, a differential diagnosis of fever and tachycardia under anesthesia should be considered. Fever related to sepsis or viral infection usually has a slow onset, whereas fever from an MH reaction typically has a rapid onset. The differential diagnoses include iatrogenic external overheating and an MH reaction (see Table 40-4). A rapid increase in the inspired concentration of desflurane and isoflurane, but not sevoflurane, may cause a sympathetic-based tachycardia that in isolation should not suggest a diagnosis of MH because the PETCO<sub>2</sub> remains unchanged.<sup>52,53</sup> Of the inhalational anesthetics, halothane appears to be the most likely to trigger an MH reaction and the best discriminator for the CHCT. Enflurane provides the smallest trigger, sevoflurane and isoflurane are intermediate, and preliminary data suggest that xenon does not trigger MH reactions.<sup>21,45,54-56</sup> If none of these factors appears to be causative and a deeper level of anesthesia (achieved with propofol with or without an opioid) fails to abate the signs, simultaneous venous and arterial blood gases should be analyzed to determine whether the patient has or is developing a hypermetabolic state.

A moderate but gradual increase in body temperature may occur in children excessively draped, those with forced-air warming devices, those with bilateral limb tourniquets, and those covered with plastic occlusive wrap. However, the sudden onset of a high fever must be more thoroughly investigated because it may result from several potentially fatal causes (see Table 40-4).<sup>57-60</sup>

## Management, Susceptibility Screening, and Counseling

### TREATMENT

If the anesthesiologist suspects that a child is experiencing an MH episode, the inhalational anesthetic should be immediately discontinued, 100% oxygen administered at a large fresh gas flow rate ( $\geq 10$  L/min), and the surgeon informed; if surgery cannot be aborted, it must be completed expeditiously. Charcoal filters should be inserted into both limbs of the breathing circuit until a clean breathing circuit is available (E-Fig. 40-2). They prevent the child from being contaminated by residual anesthetic in the AWS and to prevent the AWS from being contaminated by anesthetic in the patient.<sup>50</sup> The MH cart and additional personnel to assist in dissolving the dantrolene should be brought to the operating room immediately (Table 40-8). Minute ventilation should be increased to control the PaCO<sub>2</sub> and PETCO<sub>2</sub>.

AMERICAN ELECTRIC CO. 6455:

**E-FIGURE 40-2** Charcoal filters should be inserted into both the inspiratory and expiratory limbs of the anesthesia breathing circuit during an acute MH reaction to remove inhalational anesthetic from the anesthesia workstation and to prevent the patient from being exposed to additional inhalational anesthetic. They can also be used preoperatively to rapidly prepare an anesthesia workstation for use with an MH susceptible patient in the event a “clean machine” is not available, although only a filter on the inspiratory limb would be required in such a case. These filters are effective within a few minutes and reduce the anesthetic concentration to 2-3 ppm, well below the theoretical threshold to trigger an MH reaction.

**TABLE 40-8** Contents of a Pediatric Malignant Hyperthermia Emergency Cart

Fluids			
2000 mL of D <sub>5</sub> 0.2 NaCl, 500-mL IV bottles			
3000 mL of 0.9 NaCl, 500-mL IV bottles			
1 regular insulin, 100 units/mL, 10-mL vial			
4 ice packs			
Drug Number	Drug	Dose	Vessel
10	Dantrolene IV*	20 mg (dilute with 60 mL of sterile water)	
10	100 mL of sterile injectable water for dantrolene use only (red label)		
10	18- and 20-gauge needles		
4	Sodium bicarbonate	1 mEq/mL	50-mL vial
1	Sodium bicarbonate	1 mEq/mL	50-mL syringe
1	50% dextrose	500 mg/mL	50-mL vial
10	Sterile injection NaCl		10-mL vial
4	Mannitol 25%	12.5 g/50 mL	50-mL vial
10	Furosemide (Lasix)	10 mg/mL	4-mL ampule
10	20- and 22-gauge IV catheters		
8	Syringes, TB: 6, 12, 20, and 60 mL		

\*To rapidly mix dantrolene, use 18-gauge needles on 60-mL syringes to transfer sterile water to dantrolene vials. Have a colleague vigorously shake the vial while diluting the next dantrolene vial to ensure adequate dissolution and reduce the time of preparation. Final concentration is 0.33 mg/mL. Administer 2.5 mg/kg. For larger patients, several individuals may be needed to vigorously shake multiple dantrolene vials.

IV, Intravenous; TB, tuberculin.

The anesthesia should be converted to total intravenous anesthesia, and if charcoal filters are not available, hyperventilation should be continued using an external self-inflating or anesthesia-type bag with an exogenous source of oxygen that is uncontaminated by inhalational anesthetics. If the airway was not intubated, tracheal intubation should be performed and ventilation controlled mechanically to achieve a normal PETCO<sub>2</sub>.

Because native dantrolene is quite insoluble in water, several strategies have been developed to speed its solubility. The current formulation is packaged as a lyophilized yellow powder in 20-mg vials that contain 3 g of mannitol and enough base to maintain a pH of about 9.5 (E-Fig. 40-3). The lyophilized formulation, mannitol, and the alkaline pH all speed the dissolution of dantrolene in water. Sixty milliliters of sterile water should be added to each vial to dissolve the dantrolene, with a resultant dantrolene concentration of 0.33 mg/mL. Warming the sterile water speeds dissolution.<sup>61</sup> Most of the dantrolene in a vial dissolves within 60 seconds of adding the water. When the vial is vigorously shaken, any residual crystals dissolve, and the solution turns clear orange. The solution should be withdrawn immediately and administered intravenously as rapidly as possible. Occasionally, 1 or 2 additional minutes may be required to dissolve the last few crystals of dantrolene. Given the extreme alkaline pH of the

**FIGURE 40-4** Pharmacokinetics of dantrolene in children. (From Lerman J, McLeod ME, Strong HA. Pharmacokinetics of intravenous dantrolene in children. *Anesthesiology* 1989;70:625-9.)

dantrolene solution, it should be rapidly infused into a large vein to reduce the risk of phlebitis. Extravasation of dantrolene or prolonged continuous infusions of dantrolene may cause thrombophlebitis or thrombosis of large and small veins.<sup>62-64</sup> Some have recommended continuous infusions of dantrolene in adults after the initial bolus, although the risk/benefit ratio of this practice is unproved in adults and untested in children.<sup>65</sup> A new formulation of nanocrystalline dantrolene that rapidly dissolves and is available in a much greater concentration than the current formulation is undergoing federal review.<sup>66</sup>

The pharmacokinetics of intravenous dantrolene have been studied in MH-susceptible children 2 to 7 years of age.<sup>67</sup> A loading dose of 2.5 mg/kg produced predictable blood concentrations ( $\geq 3 \mu\text{g/mL}$ ) for about 6 hours after the loading dose (Fig. 40-4).<sup>67</sup> Based on these pharmacokinetic data, if half of the loading dose of dantrolene were repeated at 6 hours after the loading dose, therapeutic blood concentrations of dantrolene would be maintained for a total of 15 hours and possibly prevent a recrudescence.<sup>67</sup>

An initial bolus dose of 2.5 mg/kg can control most MH reactions if the dantrolene is administered as soon after the onset of the reaction as possible (see Fig. 40-3).<sup>68</sup> Delay in instituting dantrolene therapy increases the probability of failed therapy and death.<sup>36</sup> For a 70-kg patient, this corresponds to 8 vials of dantrolene. The response to dantrolene should be evident within minutes, with a marked reduction in PETCO<sub>2</sub>, heart rate, and respiratory rate (see Fig. 40-3). If there is no response within 3 to 5 minutes, the initial dose should be repeated until signs that the physiologic variables are abating. The clinical end points include resolution of the hypercapnia, tachypnea, and tachycardia; resolution of muscle rigidity; restoration of clear urine output; return of normal consciousness when sedation is discontinued; self-correction of blood gas abnormalities; and resolution of electrolyte disturbances. If these do not occur or are incomplete, additional doses of dantrolene should be administered until all signs and symptoms of the MH reaction have abated or the diagnosis reevaluated.<sup>68</sup> There is no upper limit to the amount of dantrolene that can or should be given acutely to stop an MH reaction. In rare instances of persistent MH or recrudescence, a cumulative dose of up to 40 mg/kg has been required.<sup>69</sup>

**E-FIGURE 40-3** Dantrolene for intravenous treatment of an acute MH reaction. This formulation is lyophilized for storage, stability, and reconstitution. Each bottle contains 20 mg of dantrolene. The dantrolene is reconstituted by injection of sterile water 60 mL per bottle, producing an orange-colored solution. Dissolution may be accelerated by shaking the bottle or by injecting warmed sterile water. An initial dose of 2.5 mg/kg IV dantrolene should be administered as quickly as possible. If the reaction does not abate, further dantrolene should be administered 1 mg/kg IV until the reaction stops.

Dantrolene is a fairly potent muscle relaxant, and a child with an intubated airway (particularly one with respiratory disorders) may become weak and require controlled respirations.

Although dantrolene is effective in terminating acute MH reactions, this effect may wane as the blood concentration of dantrolene decreases. In this case, the MH reaction may recrudescence. The prevalence of recrudescence has been reported to be as great as 20% and associated with several predictive factors, including muscular body type and a greater time interval between induction of anesthesia and the development of the initial reaction.<sup>70</sup> However, the first episode of recrudescence may occur any time after the initial reaction was successfully treated, up to and as late as 36 hours.<sup>71</sup> The possibility of recrudescence must always be considered during the first 2 to 3 days after an MH reaction has occurred. Because recrudescence cannot be predicted, all children who experience an MH reaction must be admitted to the pediatric intensive care unit or a monitored bed until the reaction resolves and the child's metabolic indices return to and remain normal for 2 to 3 days. MHAUS recommends that 1 mg/kg of dantrolene be administered intravenously every 6 hours for 24 to 48 hours after an MH reaction to prevent recrudescence. This recommendation remains empirical because there are no data to support the effectiveness of dantrolene in preventing recrudescence, although these dosages are consistent with pharmacokinetic data in children.<sup>67</sup> We recommend continued vigilance, frequent physical examinations for muscle tightness, and repeated laboratory tests (e.g., blood gas analyses), and monitoring of vital signs, particularly heart rate and expired CO<sub>2</sub> tension for evidence of a recrudescence during the first 48 hours after an MH episode. If recrudescence does occur, additional intravenous dantrolene should be administered until the reaction again abates.

Acute administration of dantrolene causes skeletal muscle weakness that can lead to respiratory embarrassment. Not surprisingly, neostigmine is ineffective in reversing the effects of dantrolene because the latter acts intracellularly, not at the neuromuscular junction (see the section on molecular mechanisms of dantrolene). It may be advisable to maintain control of the airway (combined with intravenous sedation) until there is no further need for dantrolene. Preoperative, orally administered dantrolene, initially recommended in MH-susceptible children 2 decades ago, caused skeletal muscle weakness, dysarthria, sialorrhea, and diplopia and was ineffective in preventing MH.<sup>72</sup> As a result, this practice has been discontinued.<sup>72</sup> There have been no reports of acute dantrolene toxicity, although reported adverse effects after intravenous administration include muscle weakness (about 22%), phlebitis (9%), gastrointestinal upset (about 4%), and respiratory failure (3.8%).<sup>63</sup> Long-term use in the treatment of chronic skeletal muscle spasticity has been reported to cause liver dysfunction and fatal hepatitis in about 1% and 0.1% of patients, respectively.<sup>73</sup> Given the risks of an MH reaction, there seems little downside to treating a child with dantrolene before the diagnosis is certain, provided all the necessary blood work and laboratory tests have been collected, because early treatment reduces mortality and morbidity (see Fig. 40-1).<sup>36</sup> The probability of developing a complication from an MH reaction increases almost threefold for every 2° C increase in body temperature and 1.6-fold for every 30-minute delay in administering intravenous dantrolene during a reaction.<sup>36</sup> Cardiac arrest and death during an MH reaction correlate with a muscular physique and greater time intervals between induction of anesthesia and the maximal value of PETCO<sub>2</sub>.<sup>24</sup> Other possible diagnoses should continue to be considered while the treatment for the suspected MH reaction

is organized (see Table 40-4). A positive response to dantrolene is not pathognomonic of an MH reaction, because other conditions may respond with resolution of their signs.

Moderate external cooling measures may be instituted to control a rapidly increasing temperature, although ice should never be applied directly to the skin because it may cause tissue injury and intense cutaneous vasoconstriction. The latter may decrease heat loss further by accelerating acidosis and pyrexia. It is important to avoid overshooting with cooling measures (i.e., stop aggressive cooling at a temperature of about 38.5° C), because hypothermia may ensue, particularly if dantrolene has been administered. A urinary catheter should always be inserted during an MH reaction to identify myoglobinuria and to facilitate bladder emptying because 0.375 g of mannitol/kg body weight is given as part of the initial (2.5 mg/kg) loading dose of dantrolene.

Initial laboratory assessments should be obtained before the initial bolus dose of dantrolene, and in addition to arterial and venous blood gases, determinations should include electrolyte, glucose, blood urea nitrogen, and creatinine levels; a complete blood cell count with platelets; prothrombin and partial thromboplastin times; creatine kinase concentrations; and serum and urine myoglobin levels. Because creatine kinase concentrations peak 12 to 24 hours after the onset of an MH reaction, it is prudent to obtain a baseline blood sample as soon as an MH reaction is suspected. The provider should be especially aware of the potential for hyperkalemia due to muscle breakdown and for acute renal failure as a late complication. An arterial catheter should be inserted to continuously monitor blood pressure and for serial determinations of arterial blood gas and serum levels of electrolytes and creatine kinase.

The potential for life-threatening acidosis—a pure respiratory acidosis early in the syndrome, followed later by a mixed metabolic/respiratory acidosis—always exists. Metabolic acidosis should be treated with sodium bicarbonate (1 to 2 mEq/kg IV initially), as would be done for any acutely acidotic child, and continue treatment guided by pH and base deficit, although if hypercapnia persists despite aggressive hyperventilation, administration of sodium bicarbonate should be reconsidered because the severity of the respiratory acidosis may increase. Because an acute MH episode is associated with catecholamine stress, hemodynamic instability, particularly due to dysrhythmias, may develop and should be treated according to advanced cardiac life support protocols. Calcium channel blockers should be avoided when treating MH reactions because they may cause cardiovascular collapse or acute hyperkalemia in the presence of dantrolene.<sup>74-76</sup> Acute hyperkalemia is common in patients with MH complicated by rhabdomyolysis and acidosis. Glucose and insulin should be immediately available and combined with the judicious use of exogenous calcium for treatment. There is no evidence that the use of calcium in this setting exacerbates an MH reaction.

After the acute crisis has been treated, late complications, particularly severe rhabdomyolysis, are possible. It is important to follow serial concentrations of creatine kinase; if they are greater than 10,000 IU or urinary myoglobin concentrations increase, the urine should be alkalinized, and forced diuresis (>2 mL/kg/hr) with mannitol should be induced to prevent myoglobin from precipitating in the renal tubules, causing acute myoglobinuric renal failure. The enormous fluid requirements and edema associated with rhabdomyolysis may produce a compartment syndrome, which requires immediate surgical treatment.

Other organ systems may be affected after an acute episode of MH. It is common for markers of liver function to increase 12 to 36 hours after the crisis; some liver enzymes, including lactate dehydrogenase, aspartate aminotransferase, and alanine aminotransferase, can also originate from muscle. A concomitant increase in creatine kinase to more than 10,000 IU strongly suggests a severe and acute muscle disorder. Accompanying increases in  $\gamma$ -glutamyltransferase and bilirubin suggest liver involvement. Disseminated intravascular coagulation as part of multisystem organ failure is a common and ominous late complication.<sup>77</sup> Coagulation profiles should be followed frequently to guide treatment appropriate to the case.

When necessary, the MH treatment algorithm should be accessed, available on the MHAUS web site (<http://www.mhaus.org/>). We think that an updated MH treatment algorithm should be attached to every MH cart and anesthesia machine and that operating room personnel should hold practice drills for the treatment of an MH crisis (see “Emergency Therapy for Malignant Hyperthermia” on the inside back cover of this text and at ExpertConsult.com). If the patient experiences what is thought to be an MH reaction, the care provider should call the MH emergency response line (1-800-644-9737 or 001-1-315-464-7079 if calling from outside the United States) for consultation with experienced anesthesiologists who are available 24 hours every day. We strongly encourage completion of an adverse metabolic reaction to anesthesia (AMRA) report by members of the team who provided anesthesia and postoperative care to the child. These forms can be downloaded ([www.mhreg.org](http://www.mhreg.org)), sent by the hotline consultant, or obtained from the MHAUS office through regular mail. The data contained in the completed AMRA forms allow the North American Malignant Hyperthermia Registry (NAMHR) and MHAUS to produce better data regarding the variability of MH crises and the effectiveness of treatment. Because anesthesiologists should take a leading role in managing these patients, the families should be strongly encouraged to register the proband before leaving the hospital for MedicAlert identification ([www.medicalert.org](http://www.medicalert.org)) that provides critical health information, such as “malignant hyperthermia susceptible, avoid inhaled anesthetics and succinylcholine.”

### STRESS-TRIGGERED MALIGNANT HYPERTHERMIA

In 1974, Wingard described an MH-susceptible family with a history of exercise- and emotion-induced fevers and sudden death not associated with anesthesia or surgery; he considered the possibility that MH was part of a spectrum of human stress syndromes.<sup>78</sup> Likewise, the porcine model of MH, also known as porcine stress syndrome, was first described as an awake, stress-induced syndrome brought about by tightly packing pigs in a train, car, or truck for shipment.<sup>79</sup> Dantrolene-responsive cases of awake and heat stroke-induced MH have been reported.<sup>80,81</sup> Heat stress-induced MH also seems to be characteristic of susceptible animal models.<sup>82-84</sup> A fatal case of exercise-induced MH in a 12-year-old boy who had previously survived a suspected episode of MH during general anesthesia to set a fractured humerus has been reported.<sup>85</sup> Eight months after surgery, while playing a game of football, the child became hyperthermic, collapsed, and died. Postmortem DNA testing revealed an MH-associated *RYR1* mutation in the child and his surviving father.<sup>85</sup> More cases of stress-induced MH have been reported, substantiated by genetic testing and in vitro contracture testing (IVCT).<sup>86,87</sup>

Screening for MH susceptibility in heat stroke patients and those suffering postexercise cramps or rhabdomyolysis using the

in vitro CHCT has led to the laboratory diagnosis of MH susceptibility in some patients.<sup>88-92</sup> Although there is laboratory evidence of similarities in skeletal muscle metabolism in exertional heat stroke and MH,<sup>93</sup> and one of the mouse MH knock-in models exhibits environmental heat triggering,<sup>51</sup> there is as yet little evidence that these are anything more than clinically similar presentations.<sup>92</sup> For this reason, dantrolene has rarely been an effective treatment for heat stroke.<sup>94</sup> Nonetheless, it seems reasonable to suggest that subsets of MH susceptible patients may be more sensitive to heat stroke. Therefore it may be helpful to test children with exertional heat illness for MH susceptibility.<sup>95</sup>

MH reactions have been reported infrequently in susceptible patients who received a nontriggering anesthetic.<sup>96-98</sup> Of 2214 patients who presented for muscle biopsy for MH susceptibility, 5 (0.46%) of 1082 who had MH-positive biopsy results developed MH reactions in the recovery room. None of the patients with negative biopsy results developed MH reactions. There is a small incidence of MH reactions among susceptible individuals that may occur despite a safe anesthetic regimen. Whether this is caused by stress or trace anesthetic concentrations that were inhaled is unclear. Massive rhabdomyolysis has been reported on rewarming from cardiopulmonary bypass despite the patient having received a nontriggering anesthetic.<sup>96,97</sup> The mechanism of these responses may be stress, but evidence is lacking.

### POSTEPISODE COUNSELING

Ideally, after treating a child for MH, the anesthesiologist should arrange for referral of the child and first-degree relatives to an MH diagnostic biopsy center. It is only at such centers that the CHCT can be performed in adults. The CHCT is the only test that can produce a true negative diagnosis (i.e., not MH susceptible),<sup>99</sup> but the sensitivity and specificity of this test are less than 100%. False-negative test results may occur, albeit rarely.<sup>100</sup> When the anesthetic management of a small number of MH biopsy-negative patients was reviewed, more than one half were given inhalational anesthetics, although the biopsy results for the remainder may not have been known at the time of anesthesia because they were given trigger-free anesthetics.<sup>101</sup>

Because there are no control muscle biopsy data for prepubescent children, contracture testing is not performed in this age group. Instead, children are more often fitted with MedicAlert bracelets, and the parents are counseled regarding their own need for biopsies. The children may be reconsidered for muscle biopsy upon reaching puberty.

Many persons suspected of having MH have normal muscle responses on the CHCT. In the event that an adult who experienced an MH reaction has a normal CHCT result, he or she should be referred to a neurologist with an interest in muscle diseases to determine whether an occult myopathy is responsible for the clinical events. Alternatively, the diagnosis may be incorrect, and other diagnoses should be considered (see Table 40-4). Individuals suspected of being MH susceptible should undergo CHCT; the family should also be evaluated and counseled.

Patients with strongly positive CHCT results should undergo screening for the ryanodine receptor 1 gene (*RYR1*), because mutations in this gene have been found in about 60% of family members who had an MH episode. If an MH-associated mutation (discussed later) is found in *RYR1*, first-degree relatives have a 50% probability of having a similar defect. Diagnostic testing for *RYR1* is performed on DNA obtained from a blood specimen, obviating the need to travel to an MH diagnostic biopsy center or undergo muscle biopsy for the genetic test. Genetic testing of

relatives can be undertaken through the office of the primary care physician or by the anesthesiologist, a process that will simplify evaluation of the family. Failure to identify an MH-causative *RYR1* mutation (E-Fig. 40-4) does not confirm a negative diagnosis (i.e., not MH susceptible) because more than one gene is associated with MH susceptibility, and not all are known.

Genetic testing and counseling can be arranged by the anesthesiologist or primary care physician by scheduling an appointment; one such center is located at the Center for Medical Genetics at the University of Pittsburgh. The genetic counselors have extensive experience in counseling patients on the utility of the ryanodine receptor gene test for evaluation of MH susceptibility. The center currently screens 12 exons of genomic *RYR1* that commonly contain MH mutations (exons 6, 9, 11, 14, 17, 39, 40, 44, 45, 46, 101, 102). A private commercial laboratory that also offers *RYR1* testing is Prevention Genetics ([www.preventiongenetics.com](http://www.preventiongenetics.com)), which screens for MH mutations. It has adopted a two-tiered approach: Tier 1 involves bidirectional sequencing of exons 2, 6, 8, 9, 11, 12, 14, 15, 17, 39, 40-41, 44-47, 95, and 100-104. These 22 exons contain most of the conclusively documented MH and central core disease causative mutations in the *RYR1* gene (<http://www.emhg.org/genetics/>). If the first tier is uninformative, their second-tier screen covers the remaining 84 exons of the 106 making up the human *RYR1* gene. The Prevention Genetics company corresponds only with physicians and does not provide patient or family counseling.

As DNA sequencing has become more automated and the cost has drastically declined, many private companies have arisen that purport to diagnose the entire panoply of human genetic diseases and resultant predispositions, including MH. We have no information about the reliability of their screening or the recommendations based on their findings. If no causative *RYR1* mutations are found, nothing more can be determined from genetic testing about susceptibility, because more than one mutated gene is linked to MH.

## Genetics

MH in humans follows an autosomal dominant inheritance pattern with incomplete penetrance and variable expressivity.<sup>27,102,103</sup> In the context of MH, incomplete penetrance means that there are fewer patients with MH susceptibility than would be predicted by simple autosomal dominant inheritance. Variable expressivity means that the presence of a genetic mutation defining susceptibility is documented, but it does not mean that a patient will have an MH reaction when first exposed to triggering agents. One patient in the NAMHR received 30 anesthetics before an MH reaction was triggered.<sup>36</sup> Another was discovered to be MH susceptible by IVCT during screening of a proband's family and later was inadvertently anesthetized with succinylcholine and isoflurane, but they did not trigger a reaction.<sup>104</sup> However, it seems that once an MH reaction has been triggered, the reaction will always be triggered when the patient is exposed to the offending agents.

The molecular and cellular bases of these phenomena remain unknown. Naturally occurring susceptibility to MH seems to follow autosomal dominant inheritance patterns in dogs<sup>105</sup> and horses<sup>106</sup> but follows a recessive inheritance pattern in pigs.<sup>107</sup> This suggests that other genetic and epigenetic factors may play a role in determining the degree and timing of MH susceptibility.

The first breakthrough in finding a gene that predisposed to MH was the serendipitous finding of a similar syndrome in

pigs.<sup>108,109</sup> When anesthetized with halothane and succinylcholine or with halothane alone, the pigs developed full-blown MH reactions (E-Fig. 40-5). The pig model has been a primary pathophysiologic, genetic, and pharmacologic model for the study of MH over the past 5 decades. A second, serendipitous event introduced a South African anesthesiologist, GG Harrison, to dantrolene, and he successfully tested it in his pig model of MH.<sup>110,111</sup> This observation was quickly followed by the successful treatment of a patient with dantrolene.<sup>112</sup> An interview about Harrison's discovery of dantrolene is available from the Wood Library-Museum of the American Society of Anesthesiologists (<http://www.woodlibrarymuseum.org/library/media>).

One of the most surprising findings was that six separate breeds of pigs at different locations worldwide shared this MH susceptibility to inhalational anesthetics and succinylcholine. All reactions were treated successfully with dantrolene, and all were determined to have an autosomal recessive inheritance pattern. It was established that MH was associated with an uncontrolled increase in intramyoplasmic  $Ca^{2+}$ , presumably the result of an exaggerated release of  $Ca^{2+}$  from the sarcoplasmic reticulum (SR).<sup>113,114</sup> Much effort has been expended in understanding the physiologic basis of excitation- $Ca^{2+}$ -release coupling (ECRC) as part of the general mechanism of skeletal muscle excitation-contraction coupling.

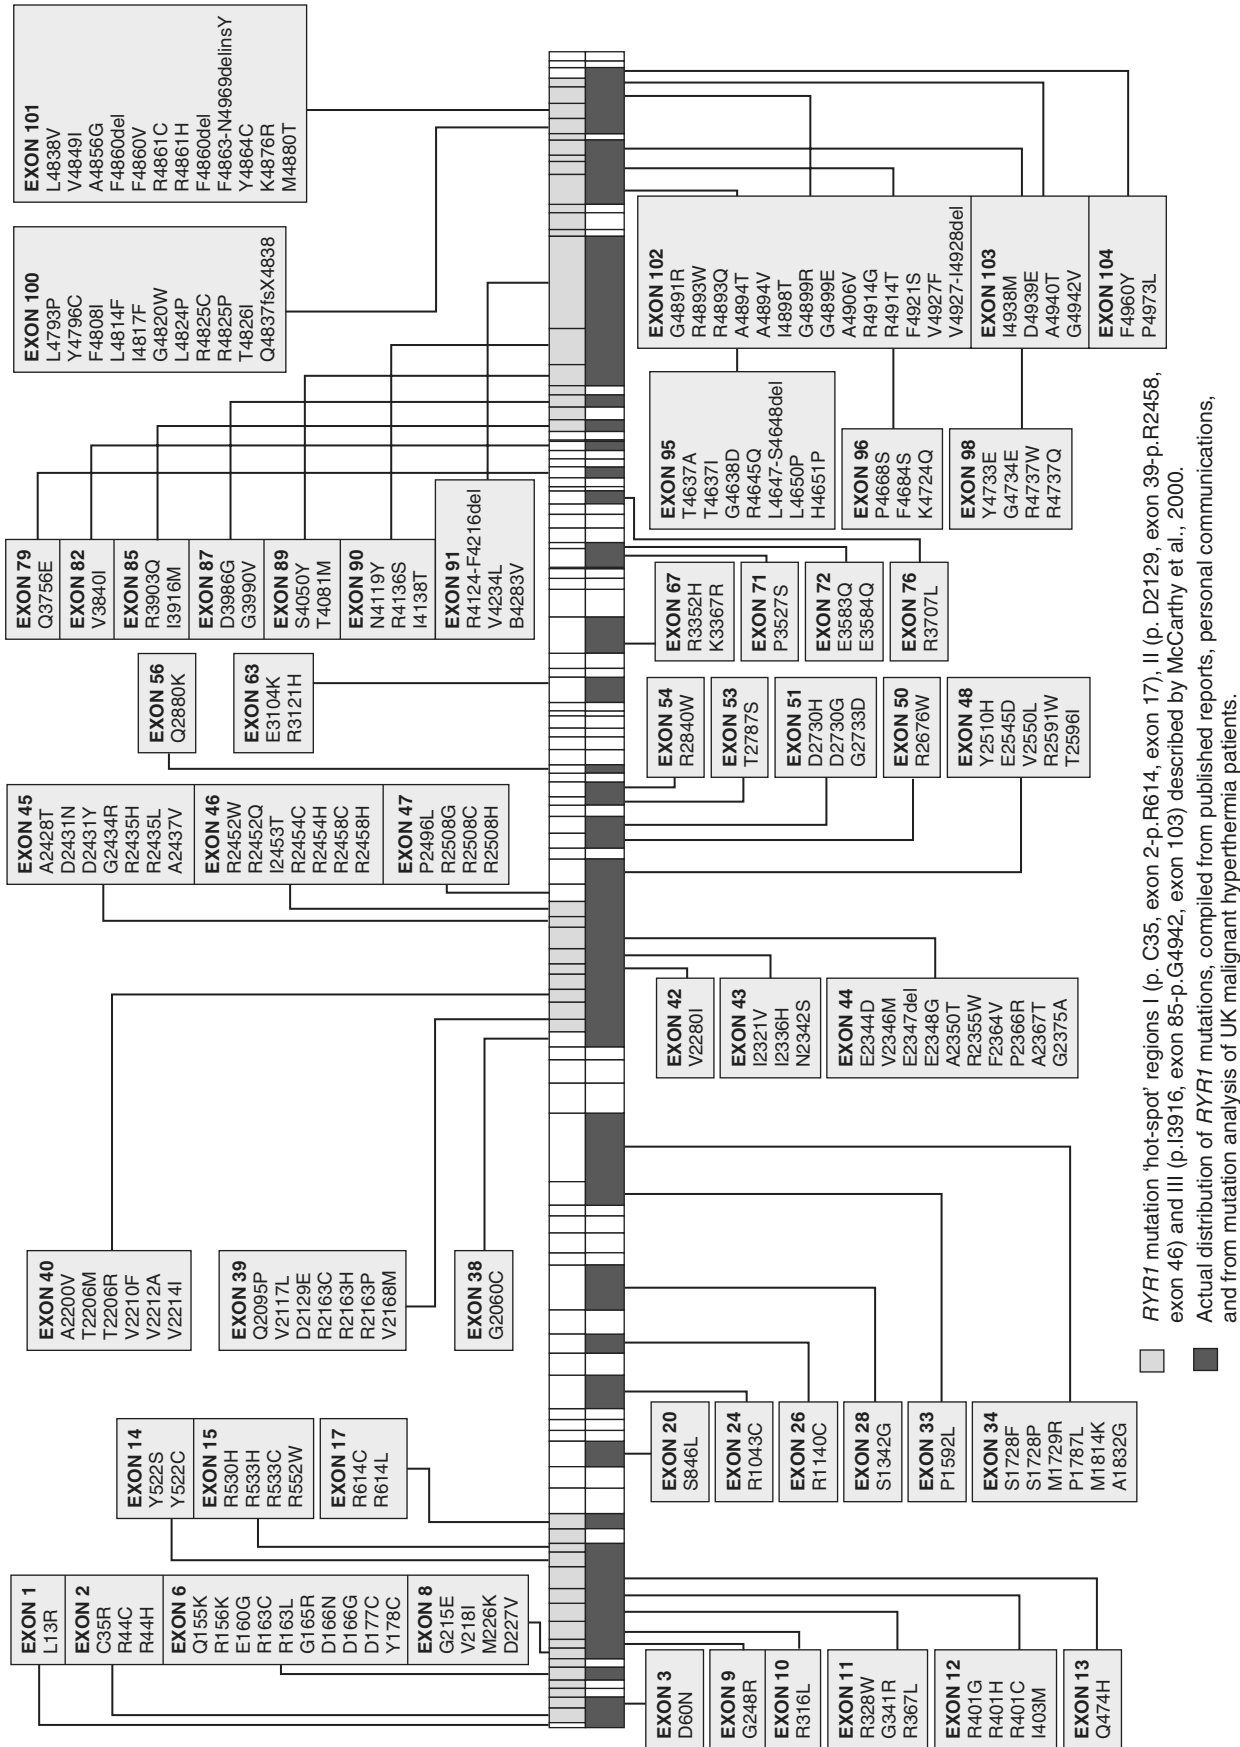

By the mid-1980s, a large channel in the SR membrane, now known as the ryanodine receptor (RyR1), was identified by its ability to bind a plant toxin, ryanodine. It was discovered to have properties consistent with being a  $Ca^{2+}$  channel.<sup>115-117</sup> In 1988, this presumed primary  $Ca^{2+}$ -release channel of the SR was found to have gap junction-like channel properties.<sup>118</sup> It was hypothesized that the ryanodine receptor might be the site of mutations that caused MH. Within a year, the cDNA for the skeletal muscle ryanodine receptor was cloned.<sup>119</sup> Two years after the initial cloning of RyR1 the identical single amino acid mutation (Arg-615Cys) was discovered in this channel in all six breeds of MH susceptible pigs.<sup>120</sup> *RYR1* was immediately acknowledged as a potential target gene in MH susceptibility studies.

Detailed genetic evaluations have linked MH susceptibility to chromosome 19q12-13.2, the location of the human *RYR1* gene (19q13.1), in most MH-susceptible families. This is the locus for malignant hyperthermia susceptibility type 1, symbolized by *RYR1* (formerly designated MHS1) (Table 40-9).<sup>102,121,122</sup> More than 300 variants have been identified in *RYR1*,<sup>123</sup> only about 30 of which have been documented as causing MH ([www.emhg.org](http://www.emhg.org))

TABLE 40-9 Malignant Hyperthermia Loci

Designation	Chromosome Locus	Gene
Ryanodine receptor 1 (skeletal) (formerly malignant hyperthermia susceptibility 1 [MHS1])	19q13.1	<i>RYR1</i>
Malignant hyperthermia susceptibility 2	17q11.2-q24	<i>MHS2</i>
Malignant hyperthermia susceptibility 4	3q13.2	<i>MHS4</i>
Calcium channel, voltage-dependent, L type, alpha 1S subunit (formerly malignant hyperthermia susceptibility 5 [MHS5])	1q32	<i>CACNA1S</i>
Malignant hyperthermia susceptibility 6	5p	<i>MHS6</i>

**E-FIGURE 40-5** **A**, A mask induction with halothane in a Landrace pig that is susceptible to malignant hyperthermia (MH). **B**, The anesthetized pig before the MH reaction. **C**, The pig's limbs become rigid during the MH reaction.

provides a comprehensive list of known causative mutations in *RYR1*). Not all MH-susceptible families have disorders linked to this chromosome (see Table 40-9), indicating that this syndrome is genetically heterogeneous.

The next gene identified, *MHS2*, was found on chromosome 17q11.2-q24 in North Americans. The previously designated *MHS3* locus, a voltage-dependent calcium channel (*CACNA2D1*), is no longer thought to be linked to MH susceptibility.<sup>123</sup> Although the data identify single genes that seem to affect individuals with MH susceptibility, there is discordance between a genetic marker and the likelihood of being MH susceptible.<sup>124-126</sup> Linkage analyses of six loci for MH susceptibility and other candidate loci suggest that multiple interacting genes may modify the primary genetic defect and subsequent clinical susceptibility to developing MH.<sup>127,128</sup>

Complicating the potential of genetic testing for MH even further is the phenomenon of gene silencing. This phenomenon mimics a recessive mutation in heterozygous individuals by allowing expression of only the affected allele while silencing the other, normal, allele.<sup>129</sup> Because MH is an autosomal dominant susceptibility, it is conceivable that a mechanism underlying the variability in MH triggering seen in patients with identical, monoallelic *RYR1* mutations results from skeletal muscle-specific silencing of the affected gene. It follows that inhalational anesthetics or succinylcholine, after multiple exposures, may release a gene from the silenced state, allowing triggering to occur. This may be an explanation for discordance between genetics, linkage analysis, and trait expressivity.

Although the inheritance of human MH is described as autosomal dominant, there are a few individuals who are allelically homozygous for an *RYR1* mutation,<sup>130,131</sup> intraallelically heterozygous for two different *RYR1* mutations, or compound heterozygotes containing one mutation in *RYR1* and a second mutation at another locus for MH susceptibility.<sup>132</sup> Surprisingly, no overt myopathies have been reported in these affected individuals.

## Physiology

### NORMAL SKELETAL MUSCLE: EXCITATION-CONTRACTION COUPLING

The neurochemical signal that triggers excitation-contraction coupling begins with the release of acetylcholine from the motor nerve terminal at the skeletal muscle nicotinic synapse, resulting in depolarization of the surface membrane, the sarcolemma. Sarcolemmal membrane depolarization is transmitted into the interior of the muscle cell by specialized invaginations of the surface membrane known as transverse tubules (TTs), which occur at regular intervals along the muscle cell (Fig. 40-5). The TT membrane is studded with the skeletal muscle isoform of the voltage-dependent  $\text{Ca}^{2+}$  channel known as the dihydropyridine receptor (DHPR). In skeletal muscle, this channel does not transmit  $\text{Ca}^{2+}$  in response to sarcolemmal depolarization. Rather, it functions as a sarcolemmal voltage sensor.

In response to depolarization, intrachannel charge movement across the TT membrane results in a conformational change of the DHPR. The TT is surrounded by specialized portions of the cellular organelle (i.e., SR) that are responsible for maintaining the cellular  $\text{Ca}^{2+}$  store, and the SR contains a high-capacity  $\text{Ca}^{2+}$  storage protein called calsequestrin, which regulates the ability of the RyR1 channel to open.<sup>133</sup> The face of the SR junctional membrane apposing the TT contains a packed, regular array of RyR1 proteins in close apposition to the DHPR. Physically, the

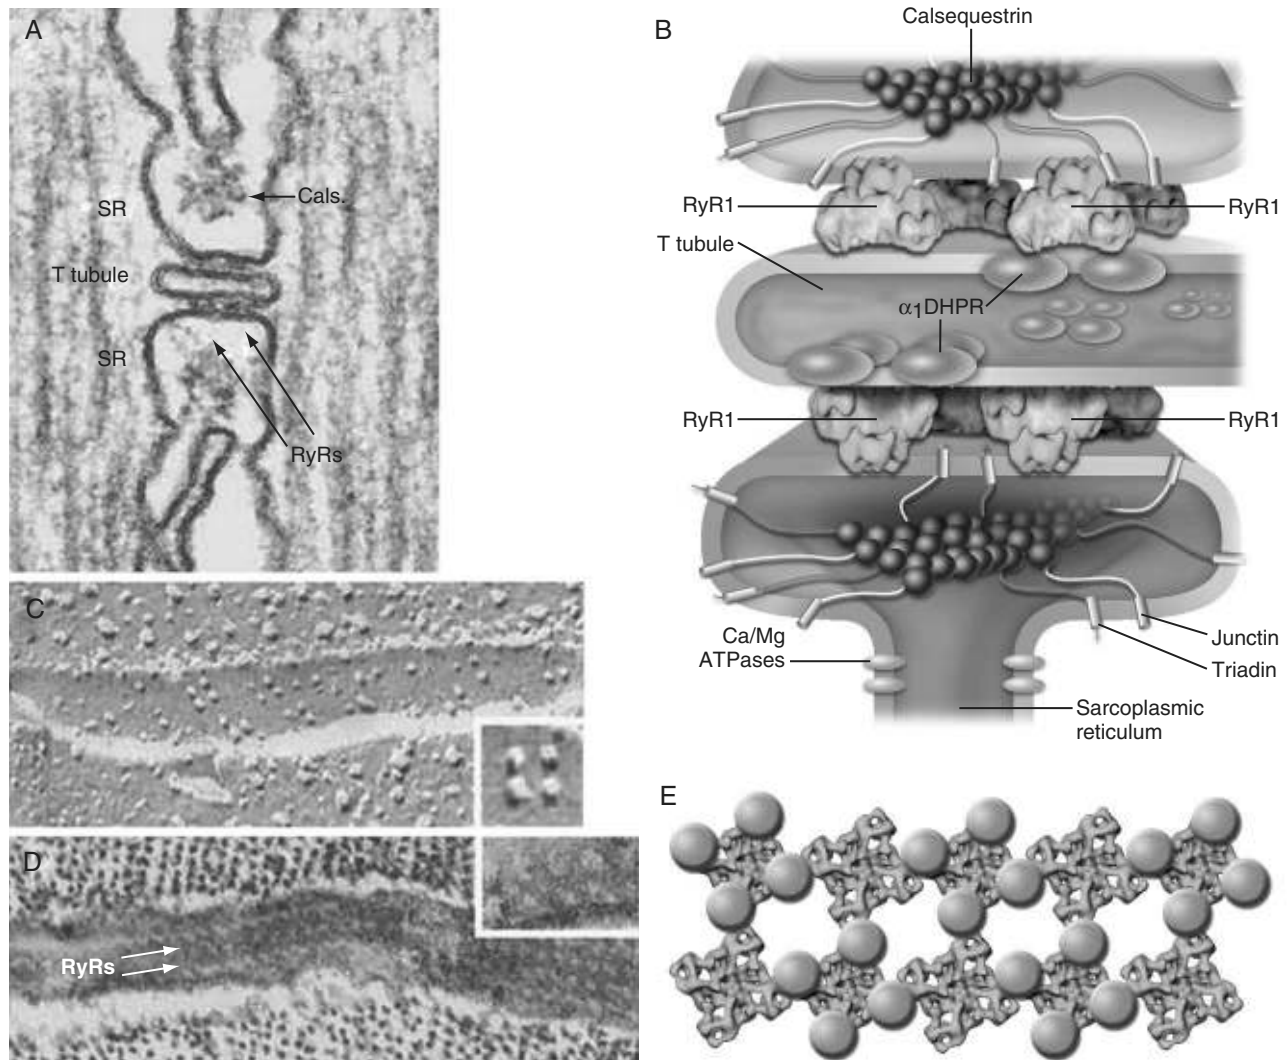

DHPR and RyR1 receptor proteins overlie each other in a unique arrangement of four DHPRs (tetrad) per one RyR1, with every other RyR1 lacking a tetrad (Fig. 40-6).<sup>134</sup> Physical interaction of the DHPR with RyR1 after depolarization causes the RyR1 channel to open, and SR-stored  $\text{Ca}^{2+}$  is released into the myoplasm. Orthograde and anterograde communication between the DHPR and RyR1 results in reciprocal regulation of both entities.<sup>135,136</sup>

In the myoplasm, the troponin C subunit of the troponin complex is bound to tropomyosin, which in the resting state inhibits myosin interaction with actin and maintains a relaxed muscle.  $\text{Ca}^{2+}$  binding to troponin C causes a conformational change in troponin and allows the complex to move away from tropomyosin, which rotates along the actin filament in a way that permits myosin head interaction with this fibrous protein. Fiber shortening and muscle contraction then occur in a myosin-ATPase-driven ratcheting reaction. The muscle relaxes when the SR membrane-bound  $\text{Ca}^{2+}$ -ATPase transports free myoplasmic  $\text{Ca}^{2+}$  back into the SR against its concentration gradient in an energy-dependent reaction, thereby driving myoplasmic  $\text{Ca}^{2+}$  concentrations down to resting levels. Troponin I, with its bound  $\text{Ca}^{2+}$  removed, moves back to block the myosin interaction with actin, thereby preventing muscle contraction and inducing its relaxation. Although a detailed description of the complexity of this process is beyond the scope of this chapter, reviews of excitation-contraction coupling are available.<sup>137,138</sup>

### PATHOPHYSIOLOGY OF MALIGNANT HYPERTHERMIA

Advances in the pathophysiology of MH have been reviewed in great detail elsewhere.<sup>139-142</sup> In brief, at the cellular level, MH is characterized by an inhalational anesthetic-induced, uncontrolled increase in intramyoplasmic  $\text{Ca}^{2+}$  levels,<sup>143,144</sup> which precedes the metabolic and clinical signs of this syndrome<sup>145</sup> (see Fig. 40-6). Increased intramyoplasmic  $\text{Ca}^{2+}$  has been demonstrated by directly measuring intracellular  $\text{Ca}^{2+}$  in anesthetic-triggered pigs<sup>143</sup> and by substantiating the sensitivity of stored  $\text{Ca}^{2+}$  release by isolated SR from MH-susceptible pigs.<sup>113,114,146,147</sup> There is also a significant loss in the ability of magnesium ( $\text{Mg}^{2+}$ ), the natural inhibitory divalent cation that competes with  $\text{Ca}^{2+}$  for binding sites on RyR1, to inhibit  $\text{Ca}^{2+}$  release in MH-susceptible skeletal muscle.<sup>148-150</sup> RyR1 isolated from MH-susceptible pigs demonstrate greater open probabilities, greater sensitivity to  $\text{Ca}^{2+}$  activation, less sensitivity to  $\text{Ca}^{2+}$  inactivation, and reduced inhibition by  $\text{Mg}^{2+}$ . As a result, the affected RyR1 channels spend more time in the open state and less time in the closed state than normal channels.<sup>151-155</sup> Although not formally confirmed, this mechanism presumably underlies the sensitivity of RyR1 channels to volatile anesthetics and to the increase in intramyoplasmic  $\text{Ca}^{2+}$  seen in MH-susceptible skeletal muscle.

Similar single-channel studies of the  $\text{Ca}^{2+}$  responsiveness of human MH-susceptible RyR1 channels have yielded more equivocal results,<sup>156</sup> presumably because of the genetic heterogeneity of the human MH-susceptible population. Even within a single individual, heterozygosity for an MH mutation permits a given RyR1 channel that is supposed to be made up of four identical subunits to contain any combination of zero to four MH susceptibility subunits in combination with wild-type, normal RyR1 subunits. When examining single channels from a population of channels isolated from a heterozygous, MH-susceptible patient, the clinician can expect a wider range of channel responses than in the homozygous, inbred, porcine population used for MH models.

**FIGURE 40-5** Structure of calcium release units in adult skeletal muscle fibers. In adult skeletal muscle, junctions are mostly triads: two sarcoplasmic reticulum (SR) elements coupled to a central transverse tubule (*T tubule*). **A**, A triad from the toadfish swimbladder muscle in thin-section electron microscopy shows the cytoplasmic domains of the SR  $\text{Ca}^{2+}$  release channel (RyR), or feet, and calsequestrin (*Cals.*), the SR  $\text{Ca}^{2+}$  storage protein. **B**, A tridimensional reconstruction of a skeletal muscle triad shows the ultrastructural localization of ryanodine receptors (RyRs), dihydropyridine receptors (DHPRs), calsequestrin, triadin, junctin, and  $\text{Ca}^{2+}/\text{Mg}^{2+}$ -ATPases. Notice the localization of DHPRs in the T-tubule membrane; DHPRs are intramembrane proteins that are not visible in thin-section electron microscopy but can be visualized by freeze-fracture replicas of T tubules (in **C**). **C**, DHPRs in skeletal muscle form tetrads, a group of four receptors (*inset*), that are linked to subunit of alternate RyRs (in **B** and **E**). **D**, In sections parallel to the junctional plane, RyR feet arrays are clearly visible in toadfish swimbladder muscle; the feet touch each other close to the corner of the molecule (*inset*). **E**, The model summarizes the findings of **C** and **D**: RyRs (green) form two (rarely three) rows, and DHPRs (orange) form tetrads that are associated with alternate RyRs. The T tubule is shown in blue in **B**, and sandwiched between two portions of the SR in **A**. (**A**, Courtesy Clara Franzini-Armstrong; **B**, courtesy T. Wagenknecht; from Protasi F. Structural interaction between RYRs and DHPRs in calcium release units of cardiac and skeletal muscle cells. *Front Biosci* 2002;7:d650-8.)

Several laboratories have reported the creation of knock-in mice containing one of two known MH-related RyR1 mutations: Tyr522Ser and Arg163Cys.<sup>83,84</sup> In contradistinction to the pig model, and like their MH-susceptible human counterparts, the knock-in MH mice are heterozygous. Their homozygous littermates die in utero on day 17. These heterozygous mice become rigid, hyperthermic, and hypermetabolic; die after exposure to inhalational anesthetics or heat stress; and respond therapeutically to dantrolene. They display exaggerated responses to the RyR1 agonists caffeine and 4-chloro-*m*-cresol and to potassium depolarization. As with MH-susceptible humans and pigs, their

muscle is less sensitive to inhibitory  $\text{Mg}^{2+}$  and possesses higher resting  $\text{Ca}^{2+}$  concentrations than wild-type animals. These experimental animals display a physiologic MH phenotype remarkably similar, if not identical, to the human syndrome and should prove extraordinarily useful in working out the details of MH pathophysiology.

Development of MH seems to require some form of neural input to muscle, because epidural anesthesia in the porcine MH model completely inhibits expression of MH.<sup>157</sup> However, complete inhibition of neural input into skeletal muscle in this model by the use of competitive, nondepolarizing, nicotinic cholinergic

**FIGURE 40-6** Schematic of the known pathophysiology of malignant hyperthermia (MH). Exposure of an individual who has a genetic susceptibility because of a ryanodine receptor (*RyR1*) or dihydropyridine (*DHP*) receptor mutation to an anesthetic triggering agent may result in MH. Normally, muscle cell depolarization (1) is sensed by the DHP receptor (2), which signals *RyR1* opening by a direct physical connection (3). The conventional view of the genesis of MH is that *RyR1* opening is easier and more sustained in the presence of volatile anesthetics (4), allowing a sustained rise in the  $\text{Ca}^{2+}$  concentration in the myoplasm (5) that surpasses the sarcoplasmic reticulum  $\text{Ca}^{2+}$  reuptake activity of the  $\text{Ca}^{2+}/\text{Mg}^{2+}$ -ATPase. This results in unrelenting muscle contraction and uncontrolled anaerobic and aerobic metabolism, which translate into the clinical manifestations of respiratory and metabolic acidosis, muscle rigidity, and hyperthermia. If the process continues unabated, adenosine triphosphate (ATP) depletion eventually causes widespread muscle fiber hypoxia with resultant cell death and rhabdomyolysis. Rhabdomyolysis manifests clinically as hyperkalemia and myoglobinuria and an increase in the serum creatine kinase level. Dantrolene sodium binds to *RyR1*, presumably causing it to favor the closed state and stemming the uninhibited flow of calcium into the myoplasm. The contributions of store-operated  $\text{Ca}^{2+}$  entry (SOCE) to myoplasmic  $\text{Ca}^{2+}$  fluxes and its inhibition by dantrolene suggest that MH may have a significant component from SOCE or excitation-coupled  $\text{Ca}^{2+}$  entry (ECCE), or both, and dantrolene may inhibit the *RyR1*-dependent activation of SOCE or ECCE. TRPC1, ORAI1, and STIM1 are proteins involved in calcium transport. SR, Sarcoplasmic reticulum. (Modified from Litman RS, Rosenberg H. Malignant hyperthermia: update on susceptibility testing. JAMA 2005;293:2918-24.)

receptor antagonists such as D-tubocurarine, pancuronium, and vecuronium before a halothane challenge does not inhibit development of MH.<sup>158,159</sup> Together, these results suggest that a neurologically significant contribution to MH arises from the central nervous system by means of sympathetic outflow or the neuroendocrine axis, rather than direct skeletal muscle stimulation. This theory is consistent with the awake or stress-related episodes of MH described earlier.

#### MOLECULAR MECHANISMS AND PHYSIOLOGIC EFFECTS OF DANTROLENE

Dantrolene (Fig. 40-7) is a hydantoin derivative originally synthesized as part of an effort to examine the muscle relaxant

properties of a series of substituted furan derivatives.<sup>160</sup> Thinking that they might have an NMBD, scientists investigated its mechanism of action but found that it was different from the known skeletal muscle relaxants. It affected the intrinsic properties of skeletal muscle without affecting the central nervous system, neuromuscular transmission, electrical properties of the sarcolemma or the T tubule, electromyogram, or train-of-four method for testing neuromuscular blockade. Its action was intracellular (Fig. 40-8).<sup>161</sup> Indirect evidence pointed to dantrolene affecting the  $\text{Ca}^{2+}$  fluxes that were intrinsic to skeletal muscle contraction.<sup>162-164</sup> Direct observations<sup>165,166</sup> demonstrated that dantrolene suppressed the rate and amount of  $\text{Ca}^{2+}$  released from the SR without completely abolishing it. Subsequently, it was

**FIGURE 40-7** Dantrolene and its congeners. Dantrolene and azumolene are equipotent drugs, but azumolene is far more water soluble. Only dantrolene is approved by the U.S. Food and Drug Administration for treatment of malignant hyperthermia. Aminodantrolene is a poorly active congener, demonstrating how small changes in drug structure can result in large changes in activity. (Modified from Parness J, Palnitkar SS. Identification of dantrolene binding sites in porcine skeletal muscle sarcoplasmic reticulum. *J Biol Chem* 1995;270:18465-72.)

demonstrated that dantrolene inhibited halothane-induced  $\text{Ca}^{2+}$  release from the isolated SR of MH-susceptible pigs,<sup>146,167,168</sup> while the drug had no effect on calcium reuptake into the SR.<sup>169,170</sup>

After SR  $\text{Ca}^{2+}$  release was identified as the likely target of dantrolene activity, several unsuccessful attempts were made at identifying a dantrolene binding partner in the SR, mainly because of the difficulties of doing detailed pharmacologic receptor analyses with a drug as hydrophobic as dantrolene.<sup>171,172</sup> In 1995, an assay for radioactively labeled dantrolene helped to elucidate specific binding sites in porcine skeletal muscle SR.<sup>173</sup> Dantrolene inhibits RyR1-dependent cellular  $\text{Ca}^{2+}$  fluxes in skeletal muscle, albeit incompletely, but it does not seem to affect RyR1 channel activity or its ability to transport  $\text{Ca}^{2+}$ .<sup>174</sup> With what does dantrolene interact, and how does this interaction relate to reduced  $\text{Ca}^{2+}$  fluxes in skeletal muscle and MH?

A second physiologic process, called store-operated  $\text{Ca}^{2+}$  entry (SOCE), contributes to the increase in intracellular  $\text{Ca}^{2+}$  as a result of the RyR1 channel opening in skeletal muscle.<sup>175-177</sup> SOCE is a process by which the SR store of  $\text{Ca}^{2+}$  is replenished from the extracellular milieu after significant loss of  $\text{Ca}^{2+}$  from the SR.<sup>178</sup> Experiments with azumolene, a more water-soluble congener of dantrolene, have demonstrated inhibition of skeletal muscle RyR1-dependent SOCE, not SR  $\text{Ca}^{2+}$  release.<sup>179</sup> These results raise profound questions. Do the induced  $\text{Ca}^{2+}$  fluxes during excitation-contraction coupling, experimental manipulation, and MH that result in an increase in intracellular  $\text{Ca}^{2+}$  all result from RyR1-dependent  $\text{Ca}^{2+}$  release or RyR1-dependent  $\text{Ca}^{2+}$  entry, or both?

Evidence of a dantrolene-sensitive, excitation-coupled  $\text{Ca}^{2+}$  entry mechanism of skeletal muscle (ECCE) that is more easily

**FIGURE 40-8** Intraoperative electromyogram of a child given intravenous dantrolene (2.4 mg/kg). The twitch tension decreased about 75% after dantrolene but was not reversed by administration of neostigmine, demonstrating the lack of involvement of the neuromuscular junction in the action of dantrolene.

activated in MH skeletal muscle has been described, as well.<sup>180-183</sup> ECCE is different from SOCE in that it does not require depletion of the SR  $\text{Ca}^{2+}$  store and is activated by high-frequency electrical stimulation of the skeletal muscle membrane. ECCE and SOCE present new physiologic targets of investigation in to the pathophysiology of MH that involve  $\text{Ca}^{2+}$  entry rather than  $\text{Ca}^{2+}$  release (see Fig. 40-6).

Elucidation of the pathophysiology of MH and the mechanism of action of dantrolene has radically transformed our understanding of muscle physiology and pathophysiology. As our understanding continues to evolve, the future for advances in therapy and testing capabilities hold great promise.

## Laboratory Diagnosis

### CONTRACTURE TESTING

The standard for testing susceptibility to MH in the human population is an in vitro contracture test that assesses live human

**FIGURE 40-9** Caffeine-halothane contracture test. **A**, Abnormal (positive) response to 3% halothane. Each small box represents 0.1 g of tension. The contracture response in this case is 1.6 g. A normal response to 3% halothane is a contracture up to 0.7 g. After exposure to halothane, 32 mmol/L of caffeine is added to the bath to determine maximal response. **B**, Abnormal (positive) response to caffeine. Caffeine exposure is increased to 0.5, 1.0, 2.0, 4.0, 8.0, and 32 mmol/L for 4 minutes. A contracture of greater than 0.3 g to 2 mmol/L of caffeine or less indicates susceptibility. (Modified from Rosenberg H, Antognini JF, Muldoon S. Testing for malignant hyperthermia. *Anesthesiology* 2002;96:232-7.)

muscle fibers from the vastus lateralis in a physiologic bath. With one end of the muscle tissue attached to a strain gauge, the degree of tension developed at baseline and on electrical stimulation is measured as a function of the concentrations of halothane or caffeine. The test is based on the observation that fresh muscle isolated from MH-susceptible patients behaved abnormally when exposed to halothane or caffeine in vitro (Fig. 40-9).<sup>184-187</sup> Two variations of this test have been developed and adopted: the CHCT by the North American Malignant Hyperthermia Group (NAMHG) and the IVCT by the European Malignant Hyperthermia Group (EMHG). The NAMHG test measures the response in separate muscle fascicles to a bolus of 3% halothane or incremental increases in the caffeine concentration,<sup>22,188,189</sup> and it requires a positive response to one of the challenges for a diagnosis of MH susceptibility. Those not responding are considered normal. The EMHG test measures the response to graded increases in the halothane concentration up to 2% and incremental increases in the caffeine concentration in different fascicles. The diagnosis of MH susceptibility by the IVCT requires a positive response to both challenges, whereas a positive response to one of the challenging agents results in equivocal diagnostic categorization (i.e., malignant hyperthermia equivocal [MHE]).<sup>190-192</sup>

Even though the EMHG protocol may prevent excess false-positive and false-negative results compared to the NAMHG protocol, overall results are comparable.<sup>193</sup> The EMHG reports that the sensitivity and specificity of its protocol are 99% and

94%, respectively,<sup>191</sup> whereas the NAMHG reports that its sensitivity and specificity are 97% and 78%, respectively.<sup>194</sup> Because the North American protocol is less specific and tends to over-diagnose MH susceptibility, it has a very small likelihood of failing to diagnose an MH-susceptible individual. The fact that there are some false-positive findings in the contracture testing demonstrates that other myopathic conditions that are not necessarily concordant with MH have muscle tissue that is also capable of giving an abnormal response to halothane and caffeine exposures. Discordance between the results of an IVCT and the presence of MH mutations in *RYR1* can occur in MH families such that 3.1% to 19.4% of family members who do not carry an MH mutation respond positively to an IVCT challenge.<sup>75,191</sup> This presumably indicates that there are other factors (e.g., a second MH susceptibility mutation in *RYR1*, another MH sensitivity locus, a sensitivity to caffeine and halothane that does not reflect MH susceptibility) in these individuals that give a positive IVCT result, but it does not necessarily mean that they are MH susceptible.

#### GENETIC TESTING

Limited examination of the *RYR1* gene is available for the purpose of diagnosing MH susceptibility at two Clinical Laboratory Improvement Amendments (CLIA)-approved laboratories in North America as discussed earlier. Any physician can write a prescription for the ryanodine receptor gene test for MH susceptibility or fill out the requisition form and send blood for genetic

testing. However, the probability of a positive outcome with genetic testing depends in part on the results of the *in vitro* CHCT because the clinical signs of MH are nonspecific. Current genetic testing indicates that about 60% of those who are positive with the CHCT also have positive genetic test results, whereas only 20% of those without a positive CHCT result yield positive genetic results.<sup>75</sup>

## Other Disorders and Malignant Hyperthermia

### MYOPATHIC SYNDROMES

An incriminatory association between various myopathies and malignant hyperthermia susceptibility, now known to be far more restricted than originally thought, was described in the 1970s and 1980s with much debate over the biochemical and pathophysiologic character of the clinical episodes that resulted from exposure to MH-triggering agents.<sup>195,196</sup> Did the clinical episodes represent true MH, did the episodes relate to the instability of myopathic muscle membrane with attendant destruction of muscle cells and release of intracellular proteins, and was there sometimes an associated hyperthermic reaction with these exposures? Although both types of episodes may result in increased creatine kinase levels, hyperkalemia, myoglobinemia, and myoglobinuria, one results from exaggerated ramping of cellular energy and heat production, and the other results from cellular destruction that does not involve abnormal cellular metabolism as a primary cause. Of the congenital myopathies, central core disease, the related multi-minicore disease, and the myopathy of King-Denborough syndrome are the only myopathies known to have a definite relationship with true MH (see Chapter 22).<sup>197</sup>

### MALIGNANT HYPERTHERMIA MIMICS

#### Malignant Hyperthermia-like Syndrome in Pediatric Diabetes Mellitus

Diabetes mellitus has two well-characterized, life-threatening childhood presentations: diabetic ketoacidosis (DKA) and hyperglycemic hyperosmotic nonketotic syndrome (HHNS).<sup>198-201</sup> DKA, which is associated with type 1 diabetes, usually manifests as nausea, vomiting, dehydration, and weakness, but shock and coma are uncommon (1% to 2%) in the absence of cerebral edema. Fever is rarely a symptom and usually spurs a search for an underlying infection. HHNS is usually associated with type 2 diabetes and classically manifests with symptoms of increasing polyuria, polydipsia, and lethargy that develop over a few days. The estimated mortality rate is between 12% and 46%, somewhat more dramatic than that seen for DKA (2% to 10%), presumably because most cases of HHNS occur in adults with many other medical problems. The greatest rates of mortality with HHNS occur in adults older than 75 years of age or those with osmolality values greater than 350 mOsm/L. The incidence of HHNS among U.S. children has been increasing rapidly and appears to be associated with the increase in childhood obesity. Despite this increase, pediatric HHNS is rare, and the presence of fever, as in DKA, usually prompts the search for an underlying infection.

A novel malignant hyperthermia-like syndrome (MHLS) against the background of pediatric diabetes mellitus was described in six adolescent boys between 14 and 18 years of age; the cases were culled from three tertiary care facilities in the United States.<sup>202</sup> The features of the syndrome included HHNS

with coma, fever, rhabdomyolysis, and severe cardiovascular instability. Among the six adolescents with MHLS, five were obese, five had acanthosis nigricans, four were African American, and four died. Two more cases were later described; one patient died 14 hours after admission due to too rapid a correction of serum osmolality and resultant cerebral edema and cardiovascular collapse, and a second patient was treated with dantrolene and completely recovered despite developing compartment syndrome in her left upper extremity due to rhabdomyolysis.<sup>203</sup> The survivor was tested for metabolic abnormalities, and a deficiency in short-chain acyl-coenzyme A (acyl-CoA) dehydrogenase was found.

Investigators recommend that anyone presenting with symptoms of HHNS and MHLS should be treated with dantrolene as soon as the syndrome is recognized and that fluid and insulin therapy be used for an appropriate rate of correction of serum osmolality. A search of the literature reveals a similar case described 10 years earlier as fulminant MH associated with DKA in a patient who survived with the addition of dantrolene to his treatment regimen.<sup>204</sup> Although it is difficult to ascertain the efficacy of dantrolene in abrogating the deleterious effects on skeletal muscle and in saving critically ill patients with MHLS during HHNS with such a small number of successfully treated patients, it seems prudent to initiate immediate treatment with dantrolene in these cases until the data can inform us about the true efficacy of this drug in MHLS.

### Disorders of Fatty Acid Metabolism

Growing numbers of reports have documented cases of rhabdomyolysis in patients with disorders of fatty acid metabolism that in some ways mimic awake MH. These disorders arise from mutations in the enzymes responsible for the metabolism of various fatty acids and for ensuring adequate energy substrate for the mitochondria during periods of reduced glucose availability, such as during stress. Although these disorders have profound effects on energy metabolism, they should not be confused with mitochondrial myopathies, which result from completely different molecular defects and have mutations in the proteins of the mitochondrial respiratory chain (see Chapter 22). In neither case has a real association with MH been established, but there have been case reports of rhabdomyolysis and cardiac arrest in patients with carnitine palmitoyltransferase II deficiency.<sup>205-207</sup>

Various forms of acyl-CoA dehydrogenase deficiencies (i.e., very-long-chain, long-chain, medium-chain, and short-chain forms) lead to different types of myopathy that can have severe clinical consequences, including hypoglycemia and rhabdomyolysis with attendant multiple-organ dysfunction, which in some deficiencies are brought about by stress, particularly heat and severe exercise.<sup>208,209</sup> These diseases can manifest early in childhood or late in adolescence or young adulthood, and they can be a particular problem for individuals in the military or those who participate in intense sports.<sup>209</sup> Patients with the very-long-chain acyl-CoA dehydrogenase deficiency can present with acute hypercapnic respiratory failure.<sup>210</sup> Dantrolene has been used successfully to treat one case of recurrent rhabdomyolysis in a patient with very-long-chain acyl-CoA dehydrogenase deficiency,<sup>211</sup> and it may be useful to treat acute intraoperative rhabdomyolysis in these patients, although there is a dearth of evidence in this regard.

Children may present for surgery without a diagnosis of an inborn error of fatty acid metabolism and develop intraoperative rhabdomyolysis, mimicking aspects of a fulminant MH reaction.

This may be the first manifestation of the child's fatty acid metabolism disorder. Preoperative increases in serum creatine kinase and uric acid levels, presumably due to subclinical rhabdomyolysis, suggest an inborn error of metabolism or myopathy,<sup>212</sup> but these tests are not part of the usual preoperative panel of blood tests in normal pediatric anesthesia practice. Perioperative stress that may result from fasting, fear, disease states, and other causes can induce metabolic decompensation and hypoglycemia. As a consequence, an intravenous glucose-electrolyte solution is recommended for affected children.<sup>213</sup> Because of a few reports of rhabdomyolysis when these children are anesthetized with inhalational anesthetics, there has been some reluctance to use inhalational anesthetics in them.<sup>213,214</sup> It is, however, likely that the number of patients with inborn errors of fatty acid metabolism who undergo surgery is far greater than the paucity of reports of adverse outcomes with inhalational anesthetics. Because these patients vary considerably in their responses to stress, it is not surprising that most do well with any well-managed anesthetic. The available evidence suggests that the perioperative risk is no greater with any particular anesthetic in these children.

If the clinician elects to avoid inhalational anesthetics, two alternatives remain: regional anesthesia and total intravenous anesthesia (TIVA). In children, peripheral limb surgery often allows for the use of intravenous sedation and regional anesthesia that may be suitable depending on the age of the child,<sup>191</sup> but most children do not tolerate this technique. However, TIVA often is used in children, most commonly with propofol.<sup>215</sup>

Propofol infusion syndrome, a rare, usually lethal complication of prolonged infusions of propofol, is diagnosed by cardiovascular collapse associated with lipemic plasma, enlarged fatty liver, severe metabolic acidosis, and rhabdomyolysis or myoglobinuria.<sup>216-218</sup> In this syndrome, a large increase in particular fatty acids (i.e., malonylcarnitine and C5-acylcarnitine) that points to impaired entry of long-chain fatty acids into mitochondria and to resultant failure of mitochondrial respiration at complex II has been identified.<sup>219</sup> Others suggest that propofol infusion syndrome may uncover medium-chain acyl-CoA dehydrogenase deficiencies, although this remains unproved.<sup>216</sup> The notion that propofol can impair fatty acid uptake and subsequent oxidation raises the possibility that the acute administration of propofol to a patient with a defect in fatty acid metabolism can precipitate a metabolic crisis, although this has never been reported. It has also been suggested that the lipid load from a propofol infusion in the absence of adequate carbohydrate intake can expose a carnitine deficiency as a model for propofol infusion syndrome.<sup>220</sup> Moreover, propofol itself has been shown to inhibit mitochondrial respiration, possibly compounding the effects of fatty acid oxidation deficiencies.<sup>216</sup> In these children, the use of propofol may be associated with an unclear risk of inducing a metabolic crisis. If their metabolic abnormalities are subclinical, there is no easy, inexpensive preoperative screening tool to establish a diagnosis for a rare abnormality. Even if the child is diagnosed with one of the subsets of fatty acid oxidation deficiencies, it is impossible to predict preoperatively which children will be sensitive to propofol and, if they are, how sensitive they are.

Other TIVA regimens that may be considered include ketamine, dexmedetomidine, benzodiazepines, and opioids. In these instances, the preoperative discussion with the parents, children, and surgeons must address the perioperative risks, including the lack of evidence that any particular anesthetic is

more likely to precipitate rhabdomyolysis and a MH-like reaction than another.

### Neuroleptic Malignant Syndrome

Neuroleptic malignant syndrome (NMS) is a rare, potentially lethal reaction to neuroleptics (0.1% to 2.5% of patients), which is characterized clinically by the slow onset of fever, muscle rigidity, altered consciousness, and autonomic instability over a protracted period of time.<sup>221</sup> Laboratory findings include increased creatine kinase levels, leukocytosis, increased liver enzyme values, and reduced serum iron or potassium concentrations.<sup>221</sup> NMS is similar to MH, and the distinction between the two is often difficult to make, except by medication history; neuroleptics are associated with NMS, and inhalational anesthetics and succinylcholine are associated with MH.

NMS has developed in children taking neuroleptics that block all dopamine D<sub>2</sub> receptors (i.e., high-potency neuroleptics, such as haloperidol; atypical neuroleptics, such as thiothixene; low-potency D<sub>2</sub>-receptor antagonists, such as metoclopramide; and tricyclic antidepressants) and in those with the withdrawal of antiparkinsonian medications. It is suggested that the syndrome results from a deficiency of central dopamine, but other pathophysiologic mechanisms have been proposed to explain the many clinical findings that cannot be explained by lack of dopamine.

Successful therapy for NMS requires early recognition, cessation of offending medications, and intensive medical and nursing care geared toward hydration and restoration of electrolyte balance.<sup>221</sup> Specific pharmacologic therapy with dopamine agonists such as bromocriptine or with dantrolene has been advocated, although use of dantrolene is controversial. Despite the fact that textbooks of psychiatry list dantrolene as the first-line pharmacologic treatment for NMS, there are no good data that it has a therapeutic effect in NMS, except for the occasional case report declaring that dantrolene is effective.<sup>221-223</sup>

Children with psychiatric diagnoses requiring treatment with neuroleptics make up a significant percentage of these pediatric patients. NMS in this pediatric population continues to be a problem, even with the newest of drugs. The perioperative period for the pediatric patient on neuroleptics is one fraught with potential diagnostic dilemmas. For example, one report described postoperative NMS in a child with severe cerebral palsy and seizure disorder who was not taking any neuroleptics and who was successfully treated three times with dantrolene.<sup>224</sup> Was this NMS or a mild form of MH? The answer is unclear.

## Summary

Many clinical scenarios in pediatric anesthesia can mimic MH and challenge our diagnostic acumen and our ability to deliver anesthesia safely. Not all metabolic syndromes that reveal themselves under inhalational anesthesia are MH, and not all metabolic syndromes that respond to dantrolene are MH. The examples given here underscore the need for expert advice during a case of suspected MH, and providers are urged to make use of the Malignant Hyperthermia Hotline when the need arises.

## Pharmacology and Pharmacokinetics of Local Anesthetics

Amides

Esters

Toxicity of Local Anesthetics

Prevention of Toxicity

Treatment of Toxic Reactions

Hypersensitivity to Local Anesthetics

## Equipment

Use of Ultrasound

Use of a Nerve Stimulator

## Specific Procedures

Central Neuraxial Blockade

Peripheral Nerve Blocks

## Summary

**THE USE OF REGIONAL** anesthesia techniques in children has increased dramatically in the past two decades.<sup>1-9</sup> Regional anesthesia is most commonly used in conjunction with general anesthesia, although in certain circumstances regional anesthesia may be the sole technique. In addition to central neuraxial blocks, peripheral nerve blocks are now employed with increasing frequency, in part because of the introduction of high-resolution portable ultrasound imaging. Ultrasound-guided visualization of anatomic structures permits both greater precision of needle or catheter placement and confirmation that the drug has been deposited at the site of choice (see Chapter 42). The advent of ultrasound guidance has also facilitated the performance of several blocks, including truncal blocks, which could not be otherwise performed safely using landmark techniques, especially in children. Evidence from recent large-scale collaborative studies of regional blockade in children supports the contention that peripheral nerve blockade is assuming greater prominence in pediatric anesthesia, and data from the Pediatric Regional Anesthesia Network (PRAN) suggests that increased use of ultrasound guidance may be, at least in part, driving this trend.<sup>10</sup> Supplementing a general anesthetic with a nerve block can result in a pain-free awakening and postoperative analgesia without the potentially deleterious side effects associated with parenteral opioids (see Chapter 43).<sup>11</sup> This benefit may be of particular importance to neonates, former preterm infants, and in children with cystic fibrosis and other conditions.<sup>4</sup> There is also evidence that suggests that regional anesthesia may improve pulmonary function in children who have undergone thoracic or upper abdominal surgery.<sup>12-15</sup> Lastly, the greatly increased number of “same day surgery” cases in recent years has made the advantages of regional anesthesia, such as the rapid awakening, enhanced postoperative analgesia

with no sedation or altered sensorium, and lack of opioid-induced nausea or vomiting, even more apparent. The safe and effective use of these techniques in children, however, requires an understanding of both the developmental anatomy of the region in which the block is placed and the developmental pharmacology of local anesthetics. This chapter will focus on landmark-guided techniques for those who do not have the advantage of ultrasound imaging; ultrasound techniques are described in Chapter 42.

## Pharmacology and Pharmacokinetics of Local Anesthetics

There are two classes of clinically useful local anesthetics, the amino amides (amides) and the amino esters (esters) (Table 41-1). The amides are degraded in the liver by cytochrome P450 enzymes, whereas the esters are hydrolyzed primarily by plasma cholinesterases.<sup>16-20</sup> These degradation pathways account for some of the differences in distribution and metabolism of local anesthetics, particularly in neonates when compared with adults.

### AMIDES

Amide local anesthetics commonly used in children include lidocaine, bupivacaine (and its isomer levobupivacaine), and ropivacaine. The choice of agent most often depends on the desired speed of onset and duration of action of the block, but in small infants and children issues related to potential toxicity are also important. Compared with an adult, the neonatal liver has limited enzymatic activity to metabolize and biotransform drugs (E-Fig. 41-1; see also Chapter 6). The ability to oxidize and to

**E-FIGURE 41-1** A semi-logarithmic plot of individual predicted levobupivacaine time to peak concentration ( $T_{max}$ ), after a 2 mg/kg dose, against postnatal age. The solid line represents the nonlinear relation between  $T_{max}$  and postnatal age. See original publication for citations for the three  $T_{max}$  studies. (Adapted from Chalkiadis GA, Anderson BJ. Age and size are the major covariates for prediction of levobupivacaine clearance in children. *Paediatr Anaesth* 2006;16:275-82, with permission.)

reduce drugs, in particular, is immature.<sup>19-25</sup> Clearance is immature in preterm neonates and matures rapidly through infancy. Neonates do not metabolize mepivacaine, with most of it excreted unchanged in the urine.<sup>26-32</sup> Conjugation reactions are limited at birth and do not reach adult rates until approximately 3 to 6 months of age.<sup>21-24,28</sup>

Older children also differ from adults with respect to the pharmacokinetics of local anesthetics. Children achieve peak plasma concentrations of amide local anesthetics more rapidly than adults after intercostal nerve blocks, but at similar times (approximately 30 minutes with lidocaine and bupivacaine) after caudal epidural administration.<sup>33-35</sup> Ilioinguinal nerve blocks in children weighing less than 15 kg may produce plasma concentrations of bupivacaine in the toxic range if more than 1.25 mg/kg is administered.<sup>36</sup>

The nature of the epidural space in infants differs from that in the adult with increased vascularity, less fat, and a smaller absorptive surface for local anesthetics. Anatomical studies have shown that the epidural fat is spongy and gelatinous in appearance, with distinct spaces between individual fat globules.<sup>37</sup> With increasing age, fat becomes more tightly packed and fibrous. The absorption half-time of epidural levobupivacaine decreases from 0.36 hours at 1 month postnatal age (PNA) to 0.14 hours at 6 months PNA. This, combined with reduced clearance (by the cytochrome P450, CYP3A4), causes a time to maximum plasma concentration (T<sub>max</sub>) to decrease from 2.2 hours at 1 month PNA to reach 80% of the mature value (0.75 hours) by 6 months PNA.<sup>38</sup> The steady-state volume of distribution (V<sub>dss</sub>) for amides in children is greater than that in adults, whereas their clearances (Cl) are similar.<sup>35,39,40</sup> Because the elimination half-life (t<sub>1/2</sub>) is related to the volume of distribution and clearance,

$$t_{1/2} = (0.693 \quad V_{dss})/Cl,$$

a larger steady-state volume of distribution directly prolongs the elimination half-life. However it is clearance that determines steady-state concentrations with continuous amide infusion; reduced clearance in neonates implies that repeated doses and continuous infusions will cause an accumulation of local anesthetic (see E-Fig. 41-1).<sup>41-43</sup> Thus infusion rates and local anesthetic concentrations must be reduced in this vulnerable age group when prolonged administration of amides are employed for postoperative analgesia.

### Bupivacaine

Bupivacaine may still be the most commonly used amide local anesthetic agent for regional blockade in infants and children, although ropivacaine (and in Canada and Europe, levobupivacaine) is being increasingly used. After a single administration, analgesia may be expected for up to 4 hours, although its duration of action is somewhat less in small infants. The

concentration used depends on the site of injection, the desired density of blockade, consideration of the toxic threshold of the drug, and the dosage limitations imposed by the concomitant administration of other local anesthetics, such as local infiltration by the surgeon or intravenous (IV) or topical laryngotracheal administration of lidocaine. The most commonly used concentration for peripheral nerve blocks is 0.25%, with reduced concentrations of 0.0625% to 0.1% used for continuous epidural administration. The 0.5% concentration is less commonly used in children, although it may be employed for peripheral nerve blocks where subsequent doses and drug accumulation are not of concern and where the volume of administered drug is sufficiently low to permit that concentration to be used without toxicity. Greater concentrations also increase the density of the motor block, an effect that may be desirable depending on the clinical situation.

Bupivacaine is highly bound to plasma proteins, particularly to  $\alpha$ 1-acid glycoprotein. It is a racemic mixture of the levorotary and dextrorotary enantiomers; the *l*-isoform is the bioactive one with regard to clinical effect, and the *d*-isoform contributes more to toxicity. Levobupivacaine, the *l*-enantiomer of bupivacaine, retains similar efficacy and duration of blockade as the racemic formulation (demonstrated in both an ovine model and in adult volunteers), yet carries up to a 30% reduced risk of cardiac and central nervous system (CNS) toxicities.<sup>44,45</sup> Although levobupivacaine's beneficial toxicity profile has resulted in its widespread use, it is currently unavailable in the United States.<sup>46</sup>

Several new experimental preparations of bupivacaine (for example, the recently approved liposome extended-release formulation) have the prospect to dramatically prolong analgesia with a reduced potential for toxicity.<sup>47-49</sup> Bioerodible encapsulated microspheres of bupivacaine administered for peripheral neural blockade<sup>50</sup> release local anesthetic over many hours to several days, depending on the formulation of the microsphere, thus producing very prolonged analgesia.<sup>51</sup> The addition of dexamethasone to the microspheres prolongs the block up to 13-fold, and plasma bupivacaine concentrations in animal studies were far below the toxic threshold.<sup>52</sup> No adverse local reactions were noted. Several different preparations have been developed and studied, including synthetic bioerodible microspheres, protein-lipid-sugar spheres, or lipospheres.<sup>53-55</sup> The first such preparation (Exparel, Pacira Pharmaceutical, Inc., Parsippany, N.J.) has recently been approved for use in patients 18 years of age or older by the FDA for surgical incision pain; toxicology studies suggest a low risk because of the slow rate of drug release.<sup>47,56-58</sup> If this and other formulations become available for use in children, they may be particularly useful for those who cannot have an indwelling catheter for a regional anesthetic, but still require prolonged neural blockade for analgesia. Potential applications include intercostal blockade for children with rib fractures, postoperative analgesia for ambulatory surgery, and children in whom an indwelling epidural catheter poses an excessive risk of infection.<sup>59</sup>

### Ropivacaine

Like levobupivacaine, ropivacaine is an *l*-enantiomer that has reduced risks of cardiac and neurologic toxicities compared with bupivacaine.<sup>60</sup> The lethal dose in 50% of animals (LD<sub>50</sub>) appears to be greater than that of bupivacaine. Rats of different maturity exhibit a threefold greater tolerance to equipotent doses of ropivacaine than of bupivacaine, when administered for a femoral nerve block.<sup>61</sup> Ropivacaine is also reputed to produce a less dense motor block at equianalgesic potency to other local anesthetics,

although the data are conflicting in this regard. Some studies report a greater sparing of motor function compared with bupivacaine, whereas others have report no difference in motor and sensory block. Ropivacaine produces a denser blockade of the A $\delta$  and C fibers than bupivacaine when low concentrations are used, lending mechanistic credence to the idea of differential blockade.<sup>62</sup> Much of the infant animal data, however, do not support the existence of a greater sensorimotor differential block than that after bupivacaine. The few clinical studies in infants and children currently available do not report a detectable motor-sensory differential, in contrast to the data in adults.<sup>61,63</sup> Several clinical studies in infants and children report a prolonged duration of analgesia with ropivacaine, despite using a solution of reduced potency.<sup>63-65</sup> Although there are still only limited data available in children, the decreased potential for toxicity makes ropivacaine an attractive agent in this age group. Most clinical studies have used a 0.2% solution (2 mg/mL) with a volume of drug that was similar to that of bupivacaine but that depended on the type of block and size of the child. We use concentrations of 0.1% for infusions with opioid for continuous postoperative analgesia.

### Lidocaine

Because lidocaine has a relatively short duration of action compared with bupivacaine and ropivacaine, it is not commonly used for single injection blocks in pediatric regional anesthesia, where a prolonged effect for postoperative analgesia is usually a priority. However, it can be used effectively in continuous blocks where the drug is continuously infused via a catheter, although here too, ropivacaine, levobupivacaine and bupivacaine are far more commonly employed. In vitro laboratory experiments have suggested that lidocaine might have greater potential for neurotoxicity in the developing nervous system than other local anesthetics, although the clinical implications of these findings remain unclear and unproved.<sup>66</sup>

### ESTERS

The pharmacokinetics of the ester local anesthetics are also affected by the quantitative and qualitative difference in plasma proteins. Plasma pseudocholinesterase activity in neonatal umbilical blood is decreased compared with adults.<sup>67</sup> The impact of this reduced activity on clearance is less certain. Other drugs that depend on plasma cholinesterase have mature clearance at birth (e.g., remifentanyl). Limited data suggest that 2,3-chloroprocaine may be safe for neonatal regional techniques, and that potentially toxic accumulation does not occur after several hours of use with a 1.5% concentration.<sup>68,69</sup>

Another enzymatic system with decreased activity in neonates is methemoglobin reductase, which is responsible for maintaining hemoglobin in a reduced valence state where it is capable of binding and transporting oxygen. Hepatic metabolism of prilocaine yields *o*-toluidine, which can produce methemoglobinemia, thereby rendering red blood cells less capable of carrying oxygen.<sup>70</sup> The decreased activity of methemoglobin reductase and the increased susceptibility of fetal hemoglobin to oxidation make prilocaine an unsuitable local anesthetic for use in neonates. Although prilocaine is no longer available for use in the United States as an injected local anesthetic, it is one of the components of EMLA cream (Eutectic Mixture of Local Anesthetics, AstraZeneca, Wilmington, Del.), a commonly employed transdermal local anesthetic. The total dose and surface area for EMLA application is therefore limited in neonates because methemoglobinemia has been reported; however,

the dose must be carefully chosen even in infants and toddlers.<sup>71</sup> Other local anesthetics, particularly topical agents, such as benzocaine, are potentially dangerous in infants because of the risk of methemoglobinemia by this same mechanism.<sup>72</sup> EMLA should only be applied to normal intact skin in appropriate doses<sup>73</sup> (less than 5 kg, 1 g applied to a maximum of approximately 10 cm<sup>2</sup> surface area; 10 to 20 kg, 10 g applied to a maximum of approximately 100 cm<sup>2</sup> surface area; greater than 20 kg, 20 g applied to a maximum of approximately 200 cm<sup>2</sup> surface area). The dose must be reduced if EMLA is applied to mucosal surfaces (such as the glans of the penis) compared with intact skin. The duration of action is 1 to 2 hours after the cream is removed. Adverse reactions include skin blanching, erythema, itching, rash, and methemoglobinemia. EMLA should be used with caution and with strict attention to the amount of cream and surface area of application in children younger than 1 month of age. Infants receiving drugs that may induce methemoglobinemia, such as phenytoin, phenobarbital, and sulfonamides may be at increased risk, and caution is warranted. It is contraindicated in children with congenital or idiopathic methemoglobinemia. Topical amethocaine (Ametop) has a more rapid onset of analgesia and increased depth of penetration through the skin and produces minimal vasoconstriction of the skin compared with EMLA.<sup>74</sup> Iontophoresis of lidocaine can also produce excellent transdermal skin analgesia with much faster onset of action (10 minutes) and greater depth of skin penetration than EMLA.<sup>74</sup>

### TOXICITY OF LOCAL ANESTHETICS

With the exception of uncommon effects, such as producing methemoglobinemia, the major toxic effects of local anesthetics are on the cardiovascular system and the CNS. Local anesthetics readily cross the blood-brain barrier to cause alterations in CNS function. A consistent sequence of symptoms can be observed as plasma local-anesthetic concentrations progressively increase, although this may not be readily apparent in infants and small children. Because of the smaller threshold for cardiac toxicity with bupivacaine, cardiac and CNS toxicity may occur virtually simultaneously in infants and children, or cardiac toxicity may even precede CNS toxicity. During the intraoperative use of bupivacaine, the risk of cardiac toxicity may be increased by the concomitant use of inhalational anesthetics and the CNS effects of the general anesthetic may obscure the signs of CNS toxicity until devastating cardiovascular effects are apparent.<sup>75</sup>

In awake adults, the earliest symptom of local-anesthetic toxicity is circumoral paresthesia, which is because of the high tissue concentrations of local anesthetic rather than CNS effects. The development of circumoral paresthesia is followed by the prodromal CNS symptoms of lightheadedness and dizziness, which progress to both visual and auditory disturbances, such as difficulty in focusing and tinnitus. Objective signs of CNS toxicity during this time are shivering, slurred speech, and muscle twitching. As the plasma concentration of local anesthetic continues to increase, CNS excitation occurs, resulting in generalized seizures. Further increases in the local anesthetic concentration depresses the CNS, with respiratory depression leading to a respiratory arrest. In adults, cardiovascular toxicity usually follows CNS toxicity. In this case, the systemic blood pressure decreases because the peripheral vasculature dilates, and because of direct myocardial depression, leading to a progressive bradycardia. These effects culminate in a cardiac arrest. In large doses, bupivacaine produces ventricular dysrhythmias, including ventricular tachycardia, peaked T waves, and ST segment changes

**FIGURE 41-1** Electrocardiographic changes associated with the intravenous injection of bupivacaine and epinephrine 1:200,000. Note the marked increase in the height of the T waves at 10 seconds. BP, Blood pressure; HR, heart rate. (From Freid EB, Bailey AG, Valley RD. Electrocardiographic and hemodynamic changes associated with unintentional intravascular injection of bupivacaine with epinephrine in children. *Anesthesiology* 1993;79:394-8.)

suggestive of myocardial ischemia, especially when epinephrine-containing solutions are used. Bupivacaine has a particularly strong affinity for the fast sodium channels, as well as the calcium and slow potassium channels in the myocardium. These effects explain why it is so difficult to resuscitate children from a toxic dose of bupivacaine.<sup>76-78</sup> Stereoselectivity of the sodium channel in the open state, however, has not been demonstrated. There is also evidence that the slow or “flicker” potassium channels may play a significant role in bupivacaine toxicity.<sup>79</sup>

With an intravascular injection of bupivacaine with epinephrine, characteristic changes on the electrocardiogram (ECG) may be seen without any observable symptoms of CNS toxicity. Figure 41-1 shows an ECG tracing obtained during an IV injection of bupivacaine with and without epinephrine. Even a small IV dose of 1 to 2  $\mu\text{g}/\text{kg}$  of epinephrine in a 1:200,000 solution with 0.25% bupivacaine produces peaked T waves with elevated ST segments, particularly in the lateral chest leads.<sup>80-82</sup> As opposed to the serious risk of ischemia and dysrhythmias with larger unintended doses of bupivacaine with epinephrine, small test doses result in only brief, transient changes in the ECG and may therefore be useful in the detection of an intravascular catheter or needle placement. Tachycardia is not a reliable indicator of an intravascular injection of bupivacaine, occurring in only 73% of intravascular injections during general anesthesia. When the ECG effects of bupivacaine, with and without epinephrine, and epinephrine alone were compared in children, the most reliable ECG changes (peaked T waves at 1 minute), and an increase in arterial pressure and heart rate, required the presence of epinephrine.<sup>83</sup> It should be noted, however, that these changes in the T waves depended on age, diminishing in responsiveness beyond 8 years of age. These data suggest that careful observation of the ECG during test-dose administration may be a sensitive indicator of unintended intravascular injection of bupivacaine in the child anesthetized with an inhalational anesthetic.<sup>84</sup>

Plasma protein binding is the most important pharmacologic factor that determines the toxicity of local anesthetics, particularly for amides, because it is the free (unbound) fraction of the drug that produces toxicity. Reduced plasma protein concentrations cause more drug to remain in the unbound active form with greater potential for toxicity (see Chapter 6). Plasma concentrations of  $\alpha$ 1-acid glycoprotein are less in neonates than in older children, and adults, producing a clinically crucial greater

free fraction of amide local anesthetics.<sup>41,85-89</sup> Current data suggest that the plasma concentration of free drug may be 30% greater in infants younger than 6 months of age and even greater in preterm infants than in adolescents<sup>90</sup> as a result of reduced clearance and reduced  $\alpha$ 1-acid glycoprotein concentrations.  $\alpha$ 1-Acid glycoprotein is an acute phase reactant whose concentration increases after surgery. Concentrations of  $\alpha$ 1-acid glycoprotein in infants are less in those undergoing elective rather than emergency surgery.<sup>91</sup> This increased concentration of  $\alpha$ 1-acid glycoprotein increases the total plasma concentrations for low to intermediate extraction drugs, such as bupivacaine. The unbound concentration, however, will not change because the clearance of the unbound drug is affected only by the intrinsic metabolizing capacity of the liver (i.e., clearance).<sup>92,93</sup>

Plasma concentrations of lidocaine that depress the cardiovascular and respiratory systems in human neonates are about half those that cause similar toxicity in adults.<sup>94</sup> In contrast, 2-day-old guinea pigs were less susceptible to the toxic effects of bupivacaine than 2-week or 2-month-old guinea pigs, even though the blood concentrations in the 2-day-olds were greater.<sup>75</sup> Data regarding toxicity in infant versus adolescent versus adult rats for both bupivacaine and ropivacaine are similar.<sup>61</sup> Young dogs, however, have a decreased threshold to both seizure and cardiac toxicity caused by excessive doses of bupivacaine.<sup>95</sup> Because the responses to toxic concentrations of local anesthetics vary among species, it is difficult to know which animal model and thus which study results are most applicable to human neonates.<sup>96</sup> No data exist in humans regarding age-dependent differences in the toxic threshold of bupivacaine at a given blood concentration. Seizures and cardiovascular collapse have been reported in human infants at the same blood concentrations of bupivacaine as in adults. Whereas data from some animal studies suggest that the greater volume of distribution of amides in younger children may protect against bupivacaine toxicity, retrospective analyses of large databases of infants who have received epidural infusions indicate that these findings may not be applicable to the human infant, particularly during continuous infusions or with repeated dosing. Current data on the pharmacokinetic and pharmacodynamic differences associated with early infancy suggest that caution should be exercised when using local anesthetics in infants. Several reports document that infants and children may develop systemic toxicity, including dysrhythmias, seizures, and cardiovascular depression

from the accumulation of bupivacaine administered via epidural infusions.<sup>41,97-100</sup> Meticulous attention must be paid to the total dose of local anesthetic administered, the rate of administration, the site of injection, and the use of vasoconstrictors to diminish the rate of uptake of the local anesthetic. This is particularly important when a continuous regional anesthetic technique is used postoperatively or when repeated doses of local anesthetic are administered during prolonged surgery.

We recommend that both the bolus and infusion doses of bupivacaine and lidocaine be reduced by approximately 30% for infants younger than 6 months of age to decrease the risk for toxicity. This would mean that the maximum rate of bupivacaine administration should not exceed 0.2 to 0.3 mg/kg/hr.<sup>42</sup> Whereas these recommendations are particularly applicable to continuous infusions of bupivacaine for postoperative analgesia, the same caveats apply to large single injections, repeated injections, and continuous infusions of local anesthetics during prolonged surgeries.

The *l*-stereoisomer (or enantiomer) of racemic mixtures of local anesthetics is associated with less cardiac and CNS toxicity compared with the *d*-enantiomer in the mixture.<sup>78</sup> Both ropivacaine and levobupivacaine, which are *l*-enantiomers, the latter the *l*-enantiomer of bupivacaine, induce less cardiac toxicity than the racemic mixture of bupivacaine in adults and experimental animals.<sup>79</sup> This may be due in part, to the reduced affinity of the *l*-enantiomers for cardiac and CNS binding sites.<sup>60</sup> The inclusion of levobupivacaine and ropivacaine into the clinical armamentarium may decrease the toxicity of local anesthetics.

## PREVENTION OF TOXICITY

There are few data that correlate the anesthetic block, blood concentration of local anesthetic, and dose in infants and children. Most dosing guidelines have been extrapolated from studies in adults. Table 41-2 lists the maximum recommended doses of local anesthetics, as well as their approximate durations of action. To avoid overdose and the possibility of toxic effects, it is prudent to remain within these guidelines until studies in children clarify the pharmacokinetics and pharmacodynamics of local anesthetics for specific nerve blocks. As discussed earlier, all of these doses should be reduced by approximately 30% in infants younger than 6 months of age.

**TABLE 41-2** Maximum Recommended Doses and Duration of Action of Commonly Used Local Anesthetics

Local Anesthetic	Maximum Dose (mg/kg)*	Duration of Action (minutes) <sup>†</sup>
Procaine	10	60-90
2-Chloroprocaine	20	30-60
Tetracaine	1.5	180-600
Lidocaine	7	90-200
Mepivacaine	7	120-240
Bupivacaine	2.5	180-600
Ropivacaine	3	120-240

\*These are maximum doses of local anesthetics. Doses of amides should be decreased by 30% in infants younger than 6 months of age. When lidocaine is being administered intravascularly (e.g., during intravenous regional anesthesia), the dose should be decreased to 3 to 5 mg/kg; there is no need to administer long-acting local anesthetic agents for intravenous regional anesthesia, and such a practice is potentially dangerous.

<sup>†</sup>Duration of action is dependent on concentration, total dose, site of administration, and the child's age.

Toxic reactions from local anesthetics are a function of (1) the total dose administered, (2) the site of administration, (3) the rate of uptake, (4) pharmacologic alterations in toxic threshold, (5) the technique of administration, (6) the rate of degradation, metabolism, and excretion of local anesthetic, and (7) the acid-base status of the child.<sup>101-106</sup> Thus recommendations (including those of the authors) of a specific dose limit for a given drug are both overly simplistic and potentially misleading.<sup>107</sup> Because of the multiplicity of factors that drive the final concentration of unbound local anesthetic, and in the absence of definitive and comprehensive data, conservative dosing remains the most prudent course.

## Total Drug Dose

The dose of local anesthetic should be determined by a child's age, physical status, the area to be anesthetized, and *weight according to lean body mass*. A severely ill child who is in congestive heart failure, for example, has a reduced capacity to metabolize amide local anesthetics because of a reduced cardiac output and hepatic blood flow. Similarly, a markedly obese child must not be given a larger dose simply on the basis of increased weight. If a large volume of local anesthetic is required for a particular procedure, a dilute concentration should be used to avoid exceeding maximal safe dosage recommendations. Doses are calculated based on the lean body weight of the child (e.g., a 20-kg child could receive up to 50 mg of bupivacaine). An easy approximation for bupivacaine is 1 mL/kg of 0.25% bupivacaine, reduced by approximately one-third for infants younger than 6 months of age.

## Site of Injection

Injection of local anesthetics into very vascular areas leads to greater blood concentrations than the same dose injected into less vascular areas. The order of uptake (i.e., maximum blood concentration) of local anesthetics (in order from greatest to least) with regional blocks in adults is (1) intercostal nerve blocks, (2) caudal blocks, (3) epidural blocks, and (4) brachial plexus and femoral-sciatic nerve blocks.<sup>108</sup> An easy way to remember this is by the mnemonic ICE Block:

I = intercostal

C = caudal

E = epidural

Block = peripheral nerve blocks

Studies are required to determine whether this order holds true for children. Blood concentrations of bupivacaine twice those measured in older children have been reported in children weighing less than 15 kg after ilioinguinal nerve block for herniorrhaphy using only 1.25 mg/kg of 0.5% bupivacaine without epinephrine, which is half the usual recommended maximal dose.<sup>36</sup> However, the fascia iliaca block in older children produced blood concentrations of bupivacaine that were within the acceptable safe range.<sup>109</sup> Local infiltration of the wound in herniorrhaphy has not been associated with increased blood concentrations of local anesthetics,<sup>110</sup> but scalp infiltration during neurosurgery may produce relatively greater blood concentrations.<sup>111</sup> As would be expected, spinal anesthesia results in very small blood concentrations, even in neonates.<sup>89</sup>

## Rate of Uptake

The rate of uptake of a local anesthetic depends on the vascularity of the site of injection. Increased perfusion increases uptake, whereas decreased perfusion decreases uptake.<sup>112</sup> The rate of uptake in children is usually more rapid than in adults. In general,

the addition of a vasoconstrictor to the local anesthetic reduces the rate of uptake and prolongs the duration of the block. In adults, the dose of epinephrine is usually limited when used in conjunction with potent anesthetic agents because of the risk of inducing cardiac arrhythmias. If epinephrine is combined with the ester anesthetics, there is no increased risk of arrhythmias. For example, in adults anesthetized with halothane, the maximum recommended dose of epinephrine is 1.0 to 1.5  $\mu\text{g}/\text{kg}$ . In children, however, larger doses of epinephrine may be safe.<sup>113-115</sup> We have used as much as 10  $\mu\text{g}/\text{kg}$  of epinephrine in children, with a maximum dose of 250  $\mu\text{g}$ , during halothane anesthesia without evidence of ventricular irritability, and these doses are likely to be even more safe with currently used inhalational anesthetics, which do not sensitize the myocardium to the arrhythmogenic effects of epinephrine. An epinephrine concentration of 1:100,000 should not be exceeded, and 1:200,000 or less is generally used. A quick reference for converting local anesthetic concentrations and the amount of epinephrine in various dilutions is presented in Tables 41-3 and 41-4. *Epinephrine is contraindicated in blocks in which vasoconstriction of an end-artery could lead to tissue necrosis, such as for digital and penile blocks, although this historical practice has recently been challenged, setting the stage for prospective studies.*<sup>116-118</sup>

#### Alteration in Toxic Threshold

Medications, such as diazepam or midazolam, that increase the seizure threshold (i.e., the threshold for CNS toxicity) can be valuable adjuncts to regional anesthesia. Premedication with diazepam (0.15 to 0.3 mg/kg) decreases a child's anxiety but also offers some protection from the toxic CNS effects of a local anesthetic overdose.<sup>119</sup> Although diazepam is no longer in common clinical use in children in the perioperative period, evidence in animal models and considerable clinical experience in humans suggests that midazolam is also effective in terminating seizure activity.<sup>120</sup> Animal data, however, suggest that the concomitant use of diazepam and bupivacaine decreases the elimination of bupivacaine from serum and cardiac tissue in mice.<sup>121</sup> This effect is not a result of changes in protein binding.<sup>122</sup> It is not known if this is true for all benzodiazepines or if this is also the case in humans. Although premedication with a benzodiazepine prevents manifestations

of CNS toxicity, the threshold for cardiovascular toxicity is unchanged.<sup>123</sup> Thus after premedication with a benzodiazepine, cardiovascular collapse can occur without warning because the symptoms of CNS toxicity may be blunted. Because most regional anesthesia administrations that are performed in children are placed after induction of general anesthesia (with the exception of some blocks in former preterm infants), this may be a moot point in most circumstances.

#### Technique of Administration

Whenever regional anesthesia is performed, the operator must be prepared for an adverse reaction and resuscitation supplies, including drugs, suction, and airway equipment, must be immediately available. The needle or catheter must always be inspected for blood as soon as it is positioned, but before injecting the local anesthetic, to determine if the tip is within an artery or vein. It is preferable to observe the needle or catheter for passive blood flow rather than to actively aspirate for blood because the blood vessels, such as the epidural venous plexus, are thin walled and collapse readily when negative pressure is applied. As a result, the inability to aspirate blood is not absolute proof that the needle or catheter is not in a blood vessel. For this reason, a small volume of local anesthetic with a marker for intravascular injection, such as epinephrine in a concentration of 1:200,000, is administered first, while the ECG is observed for 30 to 60 seconds. Data from awake adults indicate that the heart rate will increase within 1 minute of intravascular administration.<sup>124</sup> When the drugs are administered during general anesthesia, however, the efficacy of the test dose to detect an intravascular injection may be greatly reduced. Heart rate increases in only 73% of children after an IV injection of 0.5  $\mu\text{g}/\text{kg}$  of epinephrine during halothane anesthesia, suggesting that this marker of an intravascular injection is not completely reliable.<sup>125</sup> Administration of atropine several minutes before the test dose increased the rate of positive responders to 92%, suggesting that vagal tone and the anesthetic's blunting of the sympathetic reflexes are responsible for the reduced sensitivity to the test dose. Test doses during isoflurane anesthesia appear to have the same limitations.<sup>126</sup> With sevoflurane, positive results were obtained in 100% of children, if the threshold for a positive response was an increase in heart rate of 10 beats per minute and a dose in excess of 0.5  $\mu\text{g}/\text{kg}$  of epinephrine was used; positive results were obtained in 85% if 0.25  $\mu\text{g}/\text{kg}$  of epinephrine was used.<sup>127</sup> In all children, a change in the T-wave amplitude was a reliable indicator of intravascular injection with both doses of epinephrine (see Fig. 41-1). All children in that study were pretreated with atropine. It is not known if increasing the dose of epinephrine to 1.0  $\mu\text{g}/\text{kg}$  or increasing the concentration of epinephrine in the test dose solution to 1:100,000 during general anesthesia would increase the sensitivity of the heart rate response test without atropine. Systolic blood pressure increased by more than 10% within 60 seconds of the test dose injection, suggesting that an increase in blood pressure may be a more sensitive indicator of intravascular injection than heart rate during inhalation anesthesia. ST-segment and T-wave changes also appear to be sensitive indicators of intravascular injection of local anesthetic. Observation of the ECG yields a highly sensitive indicator of an intravascular injection of bupivacaine with epinephrine. These ECG changes were present in 97% of infants and children who received an IV dose of bupivacaine and epinephrine.<sup>81</sup> These investigators did not confirm the efficacy of pretreatment with atropine on the heart rate. Isoproterenol (added to the local anesthetic rather than

epinephrine), 0.075 to 0.1  $\mu\text{g}/\text{kg}$ , increases the heart rate in 90% to 100% of children during halothane anesthesia.<sup>128,129</sup> It also increases the heart rate in adults during isoflurane and sevoflurane anesthesia, but this has not been extensively studied in children.<sup>130-132</sup> During total intravenous anesthesia (TIVA) with propofol and remifentanyl, however, quite different results have been reported. A prospective study of children who received an IV injection of bupivacaine with epinephrine as a simulated positive test dose during TIVA, found that T-wave alterations were inconsistent and could not be relied on as an indicator of intravascular injection.<sup>107</sup> Only blood pressure (particularly diastolic) was a consistent and reliable marker of intravascular injection, increasing more than 10% in all subjects during TIVA.

Even though no test dose regimen is completely infallible, it appears most prudent to use an epinephrine-containing test dose before administering the therapeutic dose of local anesthetic, particularly if the block is administered in an anatomic location near a blood vessel.<sup>127</sup> The test dose should be repeated before subsequent bolus injections through a catheter. If the drug injection is visualized in real time using ultrasound, test dosing may be less critical, as the actual drug deposition can be visualized during the injection, although this, too, may not be infallible. If the child is receiving a general inhalation anesthetic, blood pressure and the ST-segment configuration, in addition to the heart rate, should be carefully and frequently observed after injection of the test dose.<sup>84</sup> Pretreatment with atropine may increase the rate of detecting an unintended intravascular injection. In addition, the rate of injection may also be a factor in the development of toxicity. If injection is partially or completely intravascular, a slow injection may not exceed the toxic threshold, whereas a rapid injection could. Thus slow, incremental injection of the therapeutic blocking dose of local anesthetic (over several minutes), even though repeated injections within a brief period might also result in toxic reactions, may further increase the safety of regional blockade.

### TREATMENT OF TOXIC REACTIONS

Treatment of toxic reactions to local anesthetic overdose requires knowledge of the signs and symptoms previously described. The signs of local-anesthetic toxicity, with the exception of the catastrophic cardiovascular events, are all masked by general anesthesia. Indeed, inhaled anesthetics may actually raise the threshold for seizures and thereby delay the detection of toxicity until cardiovascular collapse occurs. Even in the nonanesthetized child, the progression from prodromal signs to cardiovascular collapse may be very rapid and the initial resuscitative therapy in some cases may need to be directed at reestablishing circulation and normal cardiac rhythm, including the timely institution of chest compressions, while definitive treatments are being readied. As always, initial management should consist of establishing and maintaining a patent airway and providing supplemental oxygen. The timely administration of a CNS depressant that alters the seizure threshold may prevent seizures. Midazolam (0.05 to 0.2  $\text{mg}/\text{kg}$  IV), thiopental (2 to 3  $\text{mg}/\text{kg}$  IV), or propofol (1 to 3  $\text{mg}/\text{kg}$  IV) effectively prevent or terminate seizure activity, however the latter two agents are also potent myocardial depressants and should be used with caution. If seizure activity is present and the airway is not secured, the use of succinylcholine or other relaxant may facilitate tracheal intubation but does not prevent seizure activity. It should be remembered, however, that the acute morbidity from seizures is the result of airway complications (hypoxia and aspiration) and that securing the airway

takes precedence over the actual control of the electrical activity of the seizure. CNS excitability is exacerbated in the presence of hypercarbia; it is, therefore, important to mildly hyperventilate children who have seizures. None of these interventions should in any way supplant or delay the administration of lipid emulsion to directly treat the toxic levels of local anesthetic, and help should be sought to carry out these treatments simultaneously. Indeed, two case reports suggest that lipid emulsion may reverse the CNS symptoms of local-anesthetic toxicity in the absence of cardiovascular collapse, and might be a preferable first line therapy.<sup>133,134</sup>

Advances in the treatment of local-anesthetic toxicity have dramatically altered the therapeutic interventions that should be initiated in the event of cardiovascular collapse after a large intravascular injection of an amide local anesthetic. IV lipid emulsion has been shown to be effective for resuscitation of cardiac arrest caused by both bupivacaine and ropivacaine toxicity. In dogs, successful resuscitation after cardiac arrest and 10 minutes of external cardiac massage was demonstrated after lipid administration.<sup>135</sup> Although 100% of the dogs that received an infusion of 20% lipid emulsion were successfully resuscitated, none of the controls that received a saline infusion survived. A clear relationship between the tissue concentration and the response has also been established.<sup>136</sup> These animal studies have been corroborated by several anecdotal reports of rescue from cardiac arrest in humans that followed intravascular injections of all of the amide local anesthetics in common use.<sup>137-140</sup> The mechanism of action of lipid emulsions in bupivacaine toxicity is not entirely understood, but studies in isolated rat heart preparations concluded that lipid treatment promotes the elution of bupivacaine from the myocardium and accelerates the recovery from bupivacaine-induced asystole.<sup>141</sup> This "lipid sink" hypothesis suggests a novel mechanism of action as compared with more conventional antidysrhythmic drugs, and the treatment appears to be more effective as well. An inverse relationship between the concentration of lipid emulsion and the myocardial bupivacaine concentration (greater lipid concentrations were more effective at decreasing the bupivacaine concentration in the myocardium) suggests that this lipid sink hypothesis is correct.<sup>136</sup> In support of this theory, *in vitro* evidence indicates that the lipid solubility of the local anesthetic determines, in part, its responsiveness to lipid resuscitation.<sup>142</sup> Although long-chain lipids are recommended for resuscitation after the pH is normalized, recent evidence suggests that a lipid formulation that contains a mixture of medium- and long-chain lipids is superior to long-chain lipid to extract local anesthetic, and that the binding efficiency of the former is independent of blood pH.<sup>143</sup>

In a rat study of cardiac arrest, excessive epinephrine during the initial arrest phase may actually impair resuscitation with lipid emulsion and prevent a sustained response to treatment, and whereas the initial return to cardiac function may be quicker after epinephrine, sustained recovery was better after the lipid emulsion when compared with the high-dose (greater than 10  $\mu\text{g}/\text{kg}$ ) epinephrine group. This contrasts with a pig model of severe bupivacaine toxicity (50% reduction in arterial pressure) in which initial treatment with epinephrine more rapidly restored vital signs than did Intralipid (lipid emulsion) administration.<sup>144</sup> The same investigators also demonstrated that during bupivacaine-induced cardiac arrest in a pig model, survival after epinephrine alone or the combination of epinephrine and Intralipid was greater than after Intralipid alone or in combination with vasopressin.<sup>144</sup>

The anecdotal human reports and experimental literature suggests that 1.5 mL/kg of 20% lipid emulsion should be administered over 1 minute and repeated every 3 to 5 minutes, up to a maximum of 3 mL/kg, followed by a maintenance infusion rate of 0.25 mL/kg/min until the circulation is restored.<sup>145</sup> Several pediatric events report success with this intervention, with a range of doses similar to those reported in adults.<sup>138,146,147</sup> Therefore, although the dose of lipids in children remains speculative and has not been subject to controlled investigation, the adult guidelines appear to be effective in children. There is a growing consensus that 20% lipid emulsions should be immediately available in any location where regional anesthesia is performed, to permit rapid treatment of cardiac toxicity. Although propofol is compounded in a lipid emulsion, it is *not* recommended as a substitute for Intralipid for resuscitation from local-anesthetic toxicity.

Because the initial stage of cardiovascular toxicity consists of peripheral vasodilation, supportive treatment should include IV fluid loading (10 to 20 mL/kg of isotonic crystalloid) and, if necessary, titration of a peripheral vasoconstrictor, such as phenylephrine (initial rate of 0.1 µg/kg/min), to maintain vascular tone and systemic blood pressure at acceptable limits. As toxicity progresses to cardiovascular collapse, profound decreases in myocardial contractility occur, followed by dysrhythmias. In dogs, echocardiography showed that decreased systolic function always preceded the development of dysrhythmias. Before lipid emulsion treatment was described, norepinephrine was shown to be more effective than epinephrine, dopamine, isoproterenol, or amrinone to treat bupivacaine cardiac toxicity in rats.<sup>148,149</sup> In infants, a report suggested that phenytoin (5 mg/kg administered by a slow IV infusion) treated bupivacaine cardiac toxicity.<sup>150</sup> Many toxic reactions are self-limited because the local anesthetic redistributes throughout the body and plasma concentrations rapidly decrease. Excretion of local anesthetic is hastened by hydration and alkalization of the urine by IV administration of sodium bicarbonate.<sup>151,152</sup> Cardiopulmonary bypass has also been used to successfully resuscitate an adult with bupivacaine-induced cardiac toxicity.<sup>153</sup> All current data, however, strongly suggest that, in addition to the standard CPR algorithm, lipid infusion is the most successful treatment, and immediate administration of this agent should be the next first line of therapy.

### HYPERSENSITIVITY TO LOCAL ANESTHETICS

Hypersensitivity reactions to local anesthetics are rare.<sup>154-156</sup> Ester local anesthetics are metabolized to *p*-aminobenzoic acid, which is usually responsible for allergic reactions in this group. However, these agents may cause allergic phenomena in children who are sensitive to sulfonamides, sulfites, or thiazide diuretics.<sup>157,158</sup> Among the amide local anesthetics, only one case of a true allergic reaction has been documented. These drugs may contain the preservative, methylparaben, which can produce allergic reactions in those sensitive to *p*-aminobenzoic acid.<sup>158,159</sup> When in doubt, local anesthetic allergy must be ruled out. Detailed protocols are described elsewhere.<sup>160</sup>

## Equipment

### USE OF ULTRASOUND

Recently there has been great interest in the use of ultrasound-guided peripheral nerve blocks in children.<sup>161</sup> The availability of high-resolution portable ultrasound machines has become increasingly commonplace and ultrasound-guided treatment will

likely soon become the new standard of care for many peripheral nerve blocks. Although this requires sophisticated expensive equipment and the acquisition of new skills, it is likely to have a larger role in pediatric regional blockade because most blocks are performed while the child is anesthetized. Several manufacturers make ultrasound machines that are about the size of a laptop computer and have been designed for ease of use by the anesthesiologist. The cost-effectiveness of acquiring these devices is justified because they serve a dual purpose for placing invasive central lines. Direct visualization of the nerve may facilitate correct placement of the local anesthetic and may also help reduce the total dose of local anesthetic needed for successful blockade. It is imperative to use an ultrasound machine that is capable of scanning superficially because most of the nerves in children are usually less than a few millimeters from the skin. A more in-depth discussion of ultrasound guidance for peripheral nerve blocks can be found in Chapter 42. Because ultrasound might still not be available to every practitioner, a complete discussion of landmark and nerve-stimulator guided peripheral blockade is included in this chapter.

### USE OF A NERVE STIMULATOR

The use of a peripheral nerve stimulator is an alternative safe and effective method to locate the nerve to be blocked. Despite the increasing use of ultrasound guidance for placement of peripheral nerve blocks, some anesthesiologists still use nerve stimulation to verify the position of the tip of the needle when ultrasound is not available, or in combination with ultrasound, particularly when imaging is suboptimal. A nerve stimulator is not a substitute for anatomic knowledge, but is a useful adjunct that allows the performance of the block in an unconscious or uncooperative heavily sedated child. It avoids the need to seek sensory paresthesias or to rely purely on anatomic landmarks. The tiny amount of current flowing from the uninsulated needle tip stimulates the nerve and produces a motor response when the needle is in close proximity to the nerve. The nerve stimulator is attached to the child as shown in E-Figure 41-2. The cathode (negative pole) cable is attached to the low output terminal of the nerve stimulator at one end and to the proximal (uninsulated) shaft of a Teflon-insulated needle via a sterile alligator clip, or to the plug-in lead of a specially designed block needle at the other end (the child). The anode (positive lead) cable is attached to the high-output terminal of the stimulator at the one end and to the child, distant to the block site, via an ECG electrode at the other end.<sup>162,163</sup> The needle is advanced in the appropriate anatomic direction, and when it appears to be in the correct position, the nerve stimulator is adjusted to approximately 0.5 mA with repetitive single pulse output at 1-second intervals. Local muscle contraction should be minimal at this setting, although direct muscle stimulation can occur and must be distinguished from neural stimulation. The area innervated by the nerves to be blocked is observed for the appropriate muscle contractions. As the uninsulated needle tip approaches the nerve, the muscle contractions will increase in intensity and become less strong as the needle tip moves away from the nerve. One should be able to decrease the current to approximately 0.2 mA with continued elicitation of easily perceptible muscle contraction to be sure that the needle tip is correctly positioned. It should be noted that the injection of even a very small volume of local anesthetic will ablate or dramatically attenuate responses produced by the low current of the nerve stimulator, so the needle position should be

**E-FIGURE 41-2** A nerve stimulator should be used to locate a nerve in a child who is anesthetized, and in the awake, sedated child, to avoid the need to seek a sensory paresthesia. In this example, the brachial plexus is sought in the axilla. Note that the appropriate muscle response to nerve stimulation is elicited at 0.5 mA of current and should continue to respond with 0.2 mA of current.

**FIGURE 41-2** Characteristic movements of the fingers, wrist, and elbow in response to nerve stimulation of four specific nerves. (Modified from Cousins MJ, Bridenbaugh PO, editors. *Neural blockade in clinical anesthesia and management of pain*. 2nd ed. Philadelphia: JB Lippincott; 1988, p. 406.)

optimized before injection (Video: Popliteal Fossa Block of Sciatic Nerve with Nerve Stimulator). The responses to stimulation of the radial, median, ulnar, and musculocutaneous nerves are shown in Figure 41-2.

Nerve stimulation has been used to verify the dermatomal level to which the tip of an insulated epidural catheter has been threaded. A low-dose current applied to a fine wire within the lumen of the epidural catheter stimulates motor paresthesias in the muscles of the abdomen and thorax and the most cephalad responses represent the dermatomal level corresponding to the tip of the catheter.<sup>164,165</sup>

## Specific Procedures

### CENTRAL NEURAXIAL BLOCKADE

#### Anatomic and Physiologic Considerations

Several anatomic and physiologic differences between adults and children affect the performance of regional anesthetic techniques. The conus medullaris (the terminus of the spinal cord) in neonates and infants is located at the L3 vertebral level, which is more caudal than in adults. It does not reach the adult level at L1 until approximately 1 year of age (E-Fig. 41-3) owing to the difference in the rates of growth between the spinal cord and the bony vertebral column. Thus lumbar puncture for subarachnoid block in neonates and infants should be performed at the L4-5 or L5-S1 interspace to avoid needle injury to the spinal cord. The vertebral laminae are poorly calcified at this age, so a midline approach is preferable to a paramedian one in which the needle is “walked off” the laminae. Another anatomic difference is noted in the sacrum. In neonates, the sacrum is narrower and flatter than in adults (see E-Fig. 41-3). The approach to the subarachnoid space from the caudal canal is much more direct in neonates than in adults, making dural puncture more likely, so the needle must not be advanced deeply in neonates.<sup>166</sup> The presence of a deep sacral dimple may be associated with spina bifida

occulta, greatly increasing the probability of dural puncture. Thus a caudal block may be contraindicated in these children.

The distance from the skin to the subarachnoid space, which is very small in neonates (approximately 1.4 cm) and increases progressively with age (Fig. 41-3).<sup>167</sup> The ligamenta flava are much thinner and less dense in infants and children than in adults, which makes the engagement of the epidural needle more difficult to detect and unintended dural puncture during epidural catheter placement a greater risk for the infrequent operator. Cerebrospinal fluid (CSF) volume as a percentage of body weight is greater in infants and young children than in adults (E-Fig. 41-4), although these studies are limited.<sup>168-172</sup> This finding may account in part for the comparatively larger doses of local anesthetics required for surgical anesthesia with subarachnoid block in infants and young children. The CSF turnover rate is also greater in infants and children, accounting in part for the much briefer duration of subarachnoid block with any given agent compared with adults. These anatomic differences necessitate meticulous attention to detail to achieve successful and uncomplicated spinal or epidural anesthesia.

In contrast to older children and adults, subarachnoid and epidural blockade in infants and small children is characterized by hemodynamic stability, even when the level of the block reaches the upper thoracic dermatomes.<sup>173,174</sup> Although heart rate variability, as determined by spectral analysis, is less, the heart rate is preserved, because the parasympathetic activity modulating heart rate appears to be attenuated in infants who receive spinal anesthesia.<sup>175</sup> This attenuated vagal tone allows the heart rate to compensate for any changes in peripheral vascular tone, an effect that may be the most important factor in preserving hemodynamic stability compared with any other factor, such as the relatively small venous capacitance in the lower extremities in infants, and the relative lack of resting sympathetic peripheral vascular tone.<sup>176</sup> Very high levels of spinal anesthesia can cause significant bradycardia that may require an anticholinergic.<sup>177</sup>

**E-FIGURE 41-3** Anatomic differences between adults and children that affect the performance of spinal and epidural anesthesia; an infant's sacrum (*left*) is flatter and narrower than an adult's (*right*). Note that the tip of the spinal cord in a neonate ends at L3 and does not achieve the normal adult position (L1-2) until approximately 1 year of age. The relative location of the spinal cord with growth to adulthood is illustrated on the *right* as different shades of yellow, the darkest being neonates and the lightest being the final adult configuration.

**E-FIGURE 41-4** Approximate volume of cerebrospinal fluid (CSF) relative to weight and age. Note that preterm and full-term infants have a much greater CSF volume relative to weight than a child or adult; this may account in part for the increased dose (mg/kg) of local anesthetic required in infants to produce a successful subarachnoid block. (Data from Lups S, Haan AMFH, Bailey P. The cerebrospinal fluid. Amsterdam: Elsevier; 1954; Cutler RWP, Spertell RB. Formation and absorption of cerebrospinal fluid in man. *Brain* 1968;91:707-20; Otila E. Studies on the cerebrospinal fluid in premature infants. *Acta Paediatr* 1948;35:3-100; Kruse F. Cerebrale krankheiten des kindesalters in typischen encephalogrammen. *Ergeb Inn Med Kinderheilkd* 1930;37:333-464; Samson K. Der normale Liquor cerebrospinalis im ersten Lebenstrimenon. *Gesamte Neurol Psychiat* 1930;128:494-503.)

**FIGURE 41-3** Distance from the skin to the subarachnoid space as a function of age. (Data from Bonadio WA, Smith DS, Metrou M, et al. Estimating lumbar puncture depth in children. *N Engl J Med* 1988;319:952-3; Kosaka Y, Sato K, Kawaguchi R. [Distance from the skin to the epidural space in children.] *Masui* 1974;23:874-5; Lau HP. [The distance from the skin to the epidural space in a Chinese patient population.] *Ma Tsui Hsueh Tsa Chi* 1989;27:261-4.)

Nonetheless, data suggest that alterations in vascular resistance and blood flow to some vascular beds may occur, at least under certain conditions, in infants. In former preterm infants who received isobaric bupivacaine for subarachnoid block, cerebral blood flow decreased concomitant with changes in systemic blood pressure, although the conditions under which the baseline pressures were measured were not clear.<sup>178</sup> In a study in which changes in regional temperature were used as a surrogate sign of sympathetic activity, extremity but not truncal temperature increased during subarachnoid block, together with small insignificant changes in blood pressure.<sup>179</sup> In our clinical experience, and that of others, including the University of Vermont neonatal spinal anesthesia database, clinically significant systemic blood pressure changes do not occur in young infants after a subarachnoid block.<sup>177</sup>

Central neuraxial blockade can affect the respiratory mechanics of the chest wall and diaphragm by diminution in intercostal muscle activity. This may be particularly relevant in infants and young children, whose chest walls are very compliant because of limited ossification of the ribs.<sup>180</sup> Infants rely on the diaphragm for the maintenance of tidal volume to a greater extent than older children and adults. One may also observe some chest wall paradox, that is, inward displacement of the rostral edge of the rib cage in infants during deep sleep, even in the absence of airway obstruction. Studies of infants during sleep have demonstrated that during rapid eye movement (REM) and deep sleep, paradoxical chest wall motion occurs commonly and increases as the force of diaphragmatic excursion increases.<sup>181</sup> In a similar fashion, suppression of intercostal muscle activity, leading to decreased rib cage contribution to ventilation, has also been measured during spontaneous breathing in infants undergoing halothane anesthesia.<sup>182</sup> When respiratory inductance plethysmography was used to study rib cage and diaphragmatic contributions to breathing in seven former preterm infants who underwent spinal anesthesia for herniorrhaphy,<sup>180</sup> high thoracic (T2-4) levels of motor blockade were achieved, outward motion of the lower rib cage decreased, and paradoxical motion of the lower rib cage was noted in more than half of the infants. The diaphragmatic contribution to respiration, as estimated by abdominal displacement, was increased in all infants. This suggests a shift of respiratory workload from rib cage to diaphragm in compensation for the loss of the intercostal muscle

contribution to breathing. Other factors, such as the alteration of the conformation of the diaphragm relative to the chest wall, with concomitant changes in the size of the zone of apposition (the portion of the anterior diaphragm that lies against the lower rib cage), may also contribute. These measurements were compared with each infant's measurements before administration of the spinal anesthetic, but it is not known if these findings would be different if measured in unanesthetized infants during deep sleep. It is likely that these effects are well tolerated and that the ability of the diaphragm to compensate for loss of the contribution of the rib cage to breathing is adequate in the vast majority of infants.

Upper abdominal and thoracic surgery causes changes in respiration in the postoperative period by neurally inhibiting diaphragmatic function.<sup>183-185</sup> The afferent pathways that induce this inhibition are presumed to arise from the chest and abdominal walls and perhaps the diaphragm itself, although they have not been conclusively identified.<sup>186</sup> Contrary to popular belief, pain itself is not a major contributor to postoperative respiratory dysfunction. Numerous studies have demonstrated that opioids administered either parenterally or in the central neuraxis exert little effect on postoperative respiratory function.<sup>187-189</sup> Regional blockade, on the other hand, has been shown to improve several measures of postoperative respiratory function.<sup>15,184,190</sup> These data suggest that regional anesthesia has an important role to play in the attenuation of postoperative diaphragmatic dysfunction. Although the mechanism for this improvement has been attributed to blockade of the putative inhibitory neural pathways, other data suggest that alterations in respiratory mechanics, in particular an increase in the resting length of the diaphragm to its control value and the shift of the workload from rib cage to diaphragm, may play a greater role.<sup>14</sup> These data also suggest that the beneficial effects of regional anesthesia on postoperative respiratory function may, in part, be related to the degree of motor blockade. It is not known if the preoperative administration of regional blockade enhances respiratory function compared with postoperative application of the blockade, as has been postulated in "preemptive analgesia."

### Spinal Anesthesia

Spinal anesthesia has been successfully performed in children since the first published reports in 1900 to 1910.<sup>191-194</sup> The

observation of postanesthetic apnea in former preterm infants led to a resurgence in the use of spinal anesthesia in infants, particularly for herniorrhaphy in the latter 20th century.<sup>195,196</sup> Spinal anesthesia has even been administered for myelomeningocele repair<sup>197</sup> by direct injection of tetracaine into the sac and supplemented as needed by direct application of tetracaine by the surgeon. It has also been used with success for a variety of other surgical procedures performed on infants.<sup>197-200</sup> It has been recognized since the early 1980s that preterm and former preterm infants are at significant risk for developing perioperative apnea after undergoing general anesthesia.<sup>201-203</sup> The reason for these postanesthetic apneas is not well understood. Spinal anesthesia has been proposed as an alternative to general anesthesia to reduce the incidence of perioperative apnea. However, when the spinal anesthetic was supplemented with ketamine, the incidence of postoperative apnea was even greater than with general anesthesia.<sup>204</sup> Both retrospective and prospective studies of infants undergoing spinal anesthesia demonstrated fewer or no episodes of postanesthetic apnea compared with those undergoing general anesthesia.<sup>196,204</sup> Although most of these studies were confounded by the absence of preoperative and postoperative pneumograms to control for baseline apnea and bradycardia, a prospective investigation confirmed that neonates who received a subarachnoid block exhibited no changes in heart rate and oxygen saturation when preoperative and postoperative pneumograms were compared.<sup>205</sup> The infants in the general anesthesia group, however, exhibited both reduced oxygen saturation and slower heart rates in the postoperative period and these episodes were more severe than those seen preoperatively. However, these events were not consistently associated with central apnea, which was defined as a cessation of respirations lasting more than 10 seconds with no demonstrable chest wall movement. These data suggest that the several case reports of apnea after subarachnoid block may have occurred even in the absence of the anesthesia and surgery; however, one cannot entirely discount that they may have indeed been caused by the anesthetic or, perhaps, by the stress of surgery itself. Although the data from this study are persuasive, we remain cautious and have not modified the use of routine postoperative monitoring in these infants. Until studies with greater numbers of infants can distinguish which criteria would define a group with low apnea risk, all former preterm infants less than approximately 60 weeks postconceptional age should be treated similarly, regardless of the anesthetic technique.<sup>206-208</sup> However, the best data available at this time suggest that for surgeries amenable to neuraxial blocks, spinal anesthesia (or caudal epidural analgesia) is preferable to general anesthesia for former preterm infants. It should be noted that the use of epidural anesthesia has also been reported for lower extremity and abdominal surgery in former preterm infants. Continuous spinal and epidural anesthesia for surgical procedures that outlast the duration of a "single shot" subarachnoid block have also been reported and are alternative strategies that can achieve the same goals as single injection subarachnoid block. The risk of local-anesthetic toxicity with a continuous caudal epidural blockade must be recognized; some have suggested that 2,3-chloroprocaine may be the prudent choice for local anesthetic in this situation.<sup>209</sup> For cardiac surgery, high spinal anesthesia with tetracaine (2.4 mg/kg) has been used for ligation of the patent ductus arteriosus. Total spinal anesthesia has been used in conjunction with isoflurane general anesthesia for cardiac surgery in infants and children.<sup>210,211</sup> Those infants whose tracheas were not intubated before surgery were successfully extubated

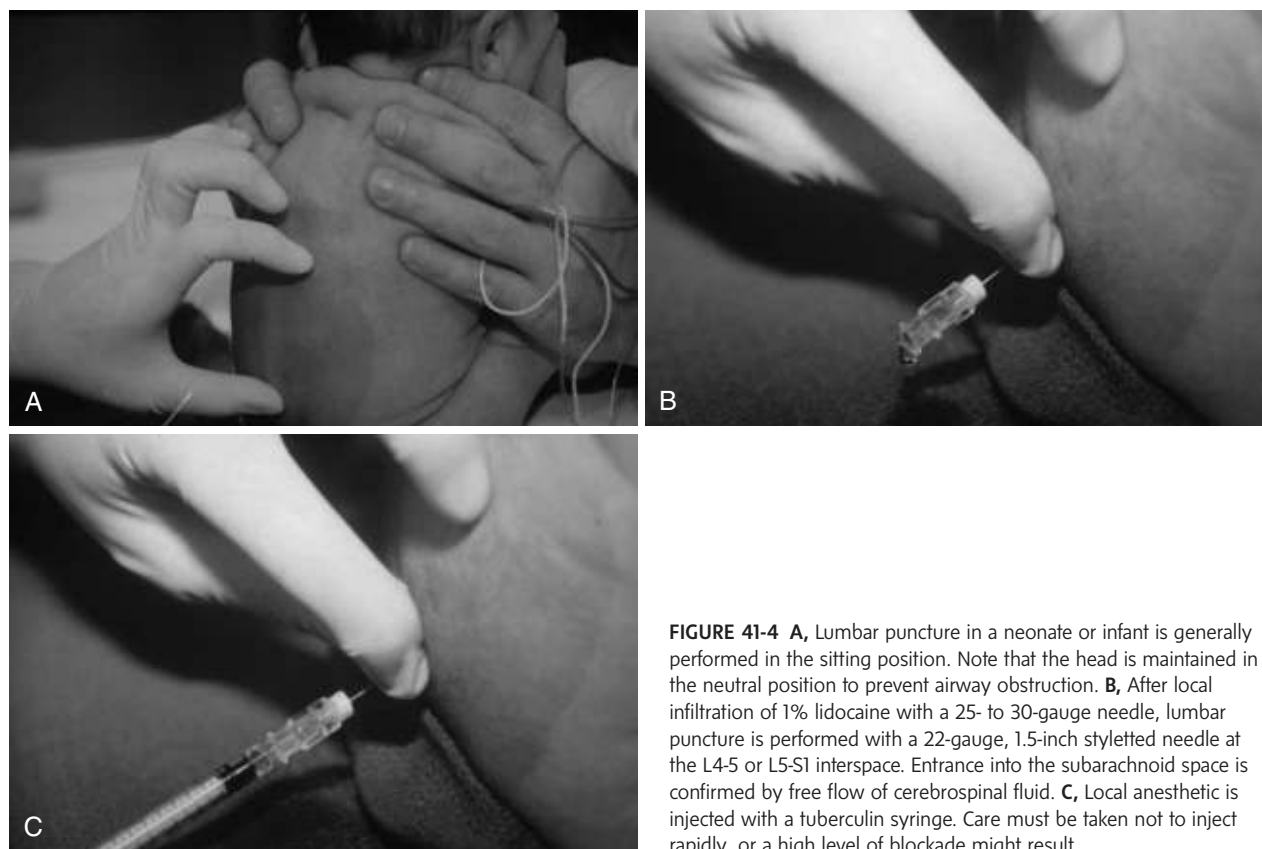

immediately after the operation. Hemodynamic stability was maintained without the use of inotropic agents in most children. A series of infants with gastroschisis closures, as well as open pyloromyotomies, have been reported using subarachnoid block.<sup>200,211</sup> Because spinal anesthesia in infants is associated with hemodynamic stability, it has been advocated as an ideal anesthetic for cardiac catheterization in infants with congenital heart defects and has been used, in conjunction with a light general anesthetic, for cardiac surgery.<sup>212-214</sup>

Recent concerns regarding the potential for adverse neurodevelopmental sequelae of general anesthetics administered to infants has led to additional interest in spinal anesthesia even in term infants. Although animal and retrospective human data are worrisome, a recent neonatal rat study demonstrated that memory was not impaired after sevoflurane anesthesia if the rats were exercised after the anesthetic.<sup>215</sup> There are no prospective data yet from which to make definitive conclusions, and several longitudinal prospective studies that will evaluate long-term neurocognitive development are in progress, including one in which infants undergoing herniorrhaphy are randomized to receive general or spinal anesthesia (see Chapter 23).<sup>216-219</sup>

When a solid block<sup>37,208,220-223</sup> is achieved, the majority of neonates fall asleep. This has been attributed to *deafferentation*, that is, a reduced level of consciousness because of diminished sensory input to the reticular activating system from the periphery, a mechanism confirmed in an animal model using spectral edge frequency analysis.<sup>224</sup> Sedation levels have been measured using bispectral index and spectral edge frequency analysis in infants undergoing spinal anesthesia without the use of adjunctive agents.<sup>225</sup> The investigators found a significant decrease in bispectral index, from 97 to 66.5 after 30 minutes, and in spectral edge frequency, from 26.1 to 9.9. These data indicate that sedation with dense regional blockade is a real physiologic phenomenon and can be used to the anesthesiologist's advantage during spinal anesthesia in infants. They also suggest that if sedation is administered to these infants, smaller doses than usual should be considered to avoid oversedation.

### Technique

After routine monitors (ECG, blood pressure cuff, pulse oximeter, and precordial stethoscope) are affixed, the child is placed in a sitting or lateral decubitus position. For neonates and infants, care must be taken to avoid excessive flexion of the neck (as in adults) because this position may obstruct the airway (Fig. 41-4, *A*).<sup>226,227</sup> The sitting position may aid in recognizing successful dural puncture by the increased CSF hydrostatic pressure and greater flow through the spinal needle. The skin is infiltrated with a minute quantity of 1% lidocaine (less than 0.25 mL should be sufficient; the authors use a 30-gauge needle on an insulin syringe), or a small amount of EMLA or other transcutaneous local anesthetic cream is applied to the infant's lumbar area at least 1 hour before spinal placement. The lumbar puncture is performed using a midline approach with a 22-gauge or smaller, 1.5-inch stylet spinal needle (see Fig. 41-4, *B* and *C*). We do not routinely use a 25-gauge spinal needle because of the time delay between entering the subarachnoid space and the appearance of CSF in the needle hub. This delay may make it difficult to recognize that the subarachnoid space has been entered. Whitaker, Sprotte, Marx, and other "pencil point" needles are available in pediatric sizes.<sup>228,229</sup> Lumbar puncture is performed only at the L4-5 or L5-S1 interspaces, for reasons previously described. The subarachnoid space in infants less than 60

**FIGURE 41-4** **A**, Lumbar puncture in a neonate or infant is generally performed in the sitting position. Note that the head is maintained in the neutral position to prevent airway obstruction. **B**, After local infiltration of 1% lidocaine with a 25- to 30-gauge needle, lumbar puncture is performed with a 22-gauge, 1.5-inch stylet needle at the L4-5 or L5-S1 interspace. Entrance into the subarachnoid space is confirmed by free flow of cerebrospinal fluid. **C**, Local anesthetic is injected with a tuberculin syringe. Care must be taken not to inject rapidly, or a high level of blockade might result.

**FIGURE 41-5** **A**, The proper method of applying an electrocautery pad; the infant's entire body is elevated while maintaining the horizontal position or the infant is log-rolled along its long axis to avoid excessively high spread of subarachnoid blockade. **B**, Improper method of applying an electrocautery pad in a neonate after subarachnoid administration of local anesthetic; the legs should never be elevated as this may lead to a total spinal.

weeks postconceptional age is approximately 1.5 cm from the skin (see Fig. 41-3); care must be taken not to pass the needle too deeply, passing beyond the subarachnoid space.<sup>167</sup> When the subarachnoid space is located, the local anesthetic is slowly administered and the child is immediately placed in the supine position. After subarachnoid administration of local anesthetic, the child's body should remain completely horizontal to preclude cephalad spread of the local anesthetic. If the legs are raised, a "total" spinal anesthetic results (Fig. 41-5, *A* and *B*).<sup>230</sup> The grounding pad can be safely placed by lifting the entire infant, while maintaining the body in the horizontal plane or log-rolling

the infant, or the pad can be affixed to the anterior thigh if sufficient space and muscle mass are available. *The legs should never be raised above the torso as this may produce a high spinal block.*

Spinal anesthesia maintains remarkable hemodynamic stability in infants, even when a high spinal block occurs. Some pediatric anesthesiologists advocate starting the IV line after the onset of the block to avoid pain associated with inserting an IV, although if the airway had to be instrumented or resuscitation drugs administered, not having IV access would be very problematic. In addition, should IV access prove difficult, valuable operating time and spinal block time would be lost while

searching for a suitable vein. We apply the pulse oximeter to a toe of one leg and the blood pressure cuff to the thigh of the other which avoid disturbing the neonate during the surgical procedure (e.g., inguinal herniorrhaphy) (E-Fig. 41-5).

Because the addition of sedatives has been associated with postanesthetic apnea with an incidence at least as great as that of general anesthesia, we try to avoid all sedatives, especially ketamine.<sup>204</sup> Most neonates will fall asleep once the block has set. A pacifier dipped in 50% dextrose will also help the infant to remain quiet and still. Gentle restraint is necessary in many cases, particularly during the most stimulating phase of the operation, when there is traction on the hernia sac, and thus on the peritoneum. It is particularly important for the infant to be still and not bear down when the hernia sac is dissected to avoid both tearing of the sac and of the extrusion of abdominal contents through the open hernia.

### Selection of Drug

**NEONATES AND INFANTS.** The proportional dose of local anesthetic required for subarachnoid block in neonates is much greater than that required for adults. When calculated on a per kilogram basis, there is a 5- to 10-fold greater drug requirement in neonates as for adults to reach a similar dermatomal distribution. In addition, the duration of the relatively larger dose lasts only about one-third to one-half as long as in the adult. As discussed previously, this appears to be due in part to the greater volume of CSF per kilogram and to the more rapid turnover of CSF in this age group. The drugs that have commonly been used for spinal anesthesia in neonates and infants include tetracaine, bupivacaine, and lidocaine.<sup>168,231-235</sup> Reported doses of tetracaine range from 0.22 to 1.0 mg/kg, with larger doses used more commonly to achieve an adequate height and duration of blockade. We use hyperbaric tetracaine (0.75 to 1.0 mg/kg [equal volumes of tetracaine 1.0% and 10% dextrose]) with 0.01 mL/kg of epinephrine (1:100,000) or hyperbaric bupivacaine (0.75 mg/kg of 0.75% bupivacaine in 8.25% dextrose). Epinephrine prolongs the duration of tetracaine blockade by more than 30%.<sup>236</sup> We draw a 1:1,000 epinephrine solution into a tuberculin or glass syringe and expel the contents in the manner of heparinizing a blood gas syringe. This leaves only a residual amount of epinephrine "wash" in the hub of the needle. The tetracaine dose and dextrose, if they are packaged separately, are combined. This dose usually provides adequate analgesia for inguinal hernia repair with a duration of motor block of 90 to 120 minutes and a dermatome height in the mid to upper thoracic region. For surgeries of limited duration that involve a lower extremity, smaller doses (0.5 to 0.6 mg/kg) may be used. The duration of bupivacaine is similar. Both isobaric and hyperbaric bupivacaine (0.5 to 1.0 mg/kg of a 0.5% solution) have been used in neonates and infants, with a reported duration similar to that of tetracaine, although the duration of action of the isobaric solution is slightly greater than for the hyperbaric solution.<sup>234,235,237</sup> A dose-ranging study reported that the addition of clonidine (1 µg/kg) prolonged the duration of blockade from a mean of 67 minutes (plain bupivacaine) to 111 minutes.<sup>238</sup> The use of larger doses of clonidine (2 µg/kg), however, caused transient hypotension and apnea, which required treatment with caffeine. Although lidocaine (2 mg/kg) is useful for a block of brief duration, such as for a muscle biopsy of the lower extremity, the duration of useful block is only approximately 30 minutes. In light of concerns regarding lidocaine in the subarachnoid space, we no longer recommend it in infants.<sup>239-241</sup> A summary of doses for commonly

**TABLE 41-5** Local Anesthetics for Spinal Anesthesia in Neonates and Infants

Anesthetic Drug	Usual Dose (mg/kg)	Range (mg/kg)
1% Tetracaine in 5% dextrose	0.75	0.6-1
0.5% Bupivacaine (isobaric)	0.8	0.5-1
0.75% Bupivacaine in 8.25% dextrose	0.75	0.5-1

used local anesthetics for subarachnoid block in neonates and infants is provided in Table 41-5.

**CHILDREN.** There is little information on the doses of local anesthetics for spinal anesthesia in children, as subarachnoid block is much less commonly used beyond infancy. When a regional technique is desirable in children, an epidural or caudal block together with a "light" general anesthetic is often preferable. For spinal anesthesia, 0.3 to 0.5 mg/kg of bupivacaine (5 mg/mL concentration) may be used in children 2 months to 12 years of age.<sup>229</sup> Doses of 0.3 to 0.4 mg/kg hyperbaric tetracaine have been used for subarachnoid block in children between 12 weeks and 2 years of age, and 0.2 to 0.3 mg/kg in children older than 2 years of age.<sup>242-244</sup> Based on these limited data, the dose requirement for spinal anesthesia decreases with increasing age. Because there are few data available on drug doses and the height of anesthetic block produced in this age-group, it is prudent to use these values as an appropriate reference point and to revise the dose as determined by clinical experience.

### Complications

Complications after spinal anesthesia include total spinal anesthesia, post-dural puncture headache, backache, neurologic sequelae, and the risk of lumbar epidermoid tumors if nonstyletted needles are used for subarachnoid puncture.<sup>228-230,245-251</sup>

Total spinal anesthesia has been reported in neonates. It is most commonly manifested by apnea with no change in systemic blood pressure or heart rate, although should pronounced bradycardia occur, a reduction in cardiac output is likely and should be treated aggressively.<sup>177,230,252</sup> It can occur after a dose of as little as 0.6 mg/kg of tetracaine.<sup>230</sup> Alteration in position, particularly by raising the lower body above the level of the head or thorax, may be the most common cause of a high spinal block. Although the rate of administration of the local anesthetic does not appear to affect the level of spinal anesthesia in adults, similar studies have not been conducted in neonates or infants.<sup>253</sup> It is possible that factors, such as the use of a relatively large-bore needle (22 gauge) and a tuberculin syringe providing the means for injecting with high pressure, along with the small distance between vertebrae, combine to make the rate of injection an important consideration in neonates and infants by producing unintended barbotage. We have also observed this complication with rapid drug administration. Management consists of assisted or controlled ventilation until the return of spontaneous respiratory function.

The incidence of post-dural puncture headache appears to be infrequent in infants and children, although the incidence in preverbal children is unknown. An early study reported an incidence of spinal headache of approximately 2% using 20- to 22-gauge needles in children 2 to 17 years of age.<sup>244</sup> However, no

**E-FIGURE 41-5** During spinal anesthesia, the intravenous catheter and oximeter probe are placed on one leg and the blood pressure cuff is applied to the other. The infant is thus allowed to remain undisturbed.

details were provided about the distribution of headache with respect to age. Other studies reported a 5% incidence of headaches in children ranging from 2 months to nearly 10 years of age, but, again, no age distribution was cited.<sup>228,229</sup> A prospective study of pediatric oncology patients undergoing diagnostic or therapeutic lumbar puncture with a 20-gauge needle reported that post-dural puncture headache was relatively rare in children younger than 13 years of age.<sup>246</sup> In most instances, the headaches were mild and resolved spontaneously. It is not entirely clear why young children should have a very low incidence of post-dural puncture headache. Several possible reasons include reduced CSF pressure,<sup>247</sup> the increased rate of CSF production, and hormonal changes with age.<sup>246</sup> As more pediatric regional anesthesia equipment becomes readily available, we expect that the use of "pencil point" (e.g., Whitaker, Marx, or Sprotte) needles will become more commonplace and will further reduce this already low incidence of headache.

Backache is a frequent postoperative complaint after both general and regional anesthesia in adults. It is thought to occur because of flattening of the normal lordotic lumbar curve secondary to muscle and ligament relaxation that occurs with spinal anesthesia. The incidence in children is unknown. Neurologic sequelae after spinal anesthesia are exceedingly rare. There are no reports in the literature of permanent neurologic injury caused by subarachnoid block, but good data in children are lacking. There have been no cases detected in over 1700 consecutive spinal anesthetics at the University of Vermont Medical Center, in another large series from Schneider Children's Medical Center (Petah Tiqva, Israel), or in the PRAN database.<sup>10,177,252</sup>

### Epidural Anesthesia

Epidural anesthesia administered by the caudal, lumbar, or thoracic route can be used for the same types of surgical procedures and indications as spinal anesthesia. Our most common indication, however, is for augmentation of general anesthesia and for postoperative pain management.

#### Caudal Epidural Anesthesia

Caudal epidural anesthesia is the regional technique that is used with the greatest frequency in children, although this may decline as familiarity with lumbar and thoracic epidural techniques and peripheral nerve blocks grows. Although its use was first described in 1933,<sup>254</sup> it was not until the early 1960s that caudal anesthesia gained any degree of popularity.<sup>255-270</sup> Improvements in catheter material and the availability of pediatric-sized needles and catheters, and the growing recognition of the benefits of regional analgesia in general, have increased the interest in this technique for children.

**TECHNIQUE.** The child is placed either in the lateral decubitus or prone position with a small roll beneath the anterior iliac crests. The cornua of the sacral hiatus are most easily palpated as two bony ridges, about 0.5 to 1.0 cm apart, when the examiner moves his or her finger in a medial to lateral direction (Fig. 41-6, *A*). When the sacral cornua are not prominent or easily appreciated, it may prove easier to locate the space by palpating the L4-5 intervertebral space in the midline and then palpate in a caudal direction until the sacral hiatus is reached. Because the space between the sacrum and coccyx may be mistaken for the sacral hiatus, the latter technique may make identification of the landmarks easier. The proper location is often, but not always, located just at the beginning of the crease of the buttocks. A short-bevel stylet needle, 22-gauge, should

be used because a long-bevel needle may increase the risk of intravascular injection.<sup>271</sup> Some practitioners think that a stylet needle avoids the possibility of introducing a dermal plug into the caudal space whereas others think that if the skin and subcutaneous tissues are punctured with an 18-gauge needle, an IV catheter can be inserted without entraining a dermal plug and transferring it to the subarachnoid space. Still others suggest that if using an IV catheter, it should be inserted with the bevel facing down because once in place, easy advancement of the IV catheter off the needle suggests that the caudal canal has been entered and may reduce the risk of intravascular placement. Although smooth and easy advancement of the cannula off the stylet is not a completely reliable sign that placement is correct, difficulty in doing so is virtually always a sign that the needle has penetrated bone or another extra-spinal structure. The needle is initially directed cephalad at a 45- to 75-degree angle to the skin until it "pops" through the sacrococcygeal ligament (see Fig. 41-6, *B*) into the caudal canal, which is contiguous with the epidural space. If bone is encountered before the sacrococcygeal ligament, the needle should be withdrawn 1 to 2 mm, the angle with the skin decreased to approximately 30 degrees, and the needle again should be advanced in a cephalad direction until the sacrococcygeal ligament is pierced (see Fig. 41-6, *C*). As the needle is advanced slightly farther, bone (the anterior table of the sacrum) is encountered, and the needle should be leveled in orientation before further advancement, so that it is nearly parallel to the child's back. Once the caudal-epidural space has been entered, the needle should be advanced only a few millimeters. If an IV catheter was used, the catheter should be advanced off the needle several millimeters in distance, while transfixing the latter. Advancing the needle any further should not be attempted because the dural sac lies relatively caudad in infants and may be entered a very short distance from the ligament (Video: Single Shot Caudal Epidural).<sup>166,272</sup>

Assessing whether the tip of the needle is outside the caudal epidural space may be difficult. Some clinicians aspirate the needle with a syringe, concluding that the absence of blood rules out an intravascular injection. Unfortunately, most unsupported veins collapse when negative pressure is applied (not yielding blood), and bone marrow does not yield much marrow through such small diameter needles. Another approach to rule out a vascular cannulation is to simply observe the needle and/or catheter for a passive return of blood. An effective means to identify an intraosseous cannulation is that attempts to slide the catheter off the needle are met with resistance; the catheter actually accords or buckles. A subarachnoid puncture will yield a "gush" of CSF (without the need for negative pressure aspiration) immediately through the needle once the space has been breached.

After the caudal epidural location has been confirmed, a test dose of local anesthetic is administered. If neither ECG changes during inhalational anesthesia nor blood pressure changes during TIVA are evident after the test dose, the remainder of the dose of local anesthetic should be slowly injected in an incremental fashion over at least 1 to 2 minutes. Some view the entire volume of local anesthetic as simply an aggregate of multiple (1 to 2 mL) test doses and administer the entire in increments while observing the ECG for peaked T waves and changes in heart rate and/or blood pressure. Data from the PRAN showed that positive test doses occurred in 20 of 5,958 single injection neuraxial blocks, a rate of 0.34%, when there was no aspiration of blood [unpublished data, PRAN].<sup>273</sup> We strongly recommend the use of a test dose, even with "single shot" caudal anesthesia.

**FIGURE 41-6** Performing a caudal block. The child is placed in a lateral decubitus position (A). The posterior superior iliac spines are located and the sacral cornu is palpated; either an intravenous needle, an intravenous catheter, or a Crawford needle of appropriate size is advanced at an angle of approximately 45 degrees until a distinct “pop” is felt as the needle pierces the sacrococcygeal ligament (B). The angle of the needle with the skin is reduced parallel to the sacrum, and the needle or intravenous catheter is advanced into the caudal canal (C). If a continuous technique is used, the caudal catheter is advanced to the mid level of the surgical incision (it usually readily passes in children younger than 5 years of age), and the introducing needle or catheter is withdrawn. The catheter is secured with benzoin and an occlusive dressing (D).

Intraosseous injection of drugs results in very rapid uptake, similar to direct IV injection. The authors are aware of at least one case of circulatory collapse that occurred from this complication when a test dose was not employed.

The block may be placed before the onset of surgery without a significant decrement in duration of postoperative analgesia for short surgical procedures.<sup>274</sup> This has the advantage of reducing the amount of general anesthesia needed, resulting in a more rapid recovery. In addition, there is adequate time for the block to “set up,” improving the chances of a pain-free awakening.

Inserting a catheter for a continuous caudal block follows a similar procedure (Video: Caudal Catheter Placement). First, one should determine the length of catheter that should be inserted into the caudal space by measuring the distance from the sacral hiatus to the desired site where the catheter tip will be positioned. Instead of a small-gauge needle or catheter, an 18-gauge IV catheter<sup>275</sup> or an 18-gauge Crawford needle is used to enter the epidural space (see Fig. 41-6, D). Because the internal diameters of

different IV cannulae vary, it is advisable to test that the epidural catheter easily passes through the IV cannula before puncturing the sacrococcygeal membrane. Once the epidural space has been accessed, the IV catheter and needle are advanced several millimeters. The catheter is then advanced off the needle several millimeters. Localization of the IV catheter tip in the epidural space is confirmed by lack of resistance to the injection of a small volume of saline and the absence of CSF or blood. If the needle had perforated the sacrum, the cannula will not easily advance off the needle. During injection, the area of the back overlying the IV catheter tip should be palpated; swelling or a fullness on injection of local anesthetic indicates a subcutaneous (SC) rather than an epidural catheter placement. The epidural catheter is advanced through the IV catheter and the IV catheter is withdrawn. After confirming the presence of neither blood nor CSF, a test dose of local anesthetic containing 1 : 200,000 epinephrine may be administered (see earlier). Test doses should be repeated each time a catheter is reinjected with a bolus dose of local anesthetic.

**FIGURE 41-7** Epidurogram, performed with 0.5 to 2 mL (max) of iopamidol nonionic contrast agent, demonstrating the “bubbly” appearance of contrast in the epidural space (arrow). Note the central localization of contrast within the borders bounded by the vertebral bodies. On occasion, contrast may be seen only on one side of the epidural space, with a sharp line of demarcation in the midline. This usually results in unilateral blockade, and is theorized to result from septation or some other impediment to bilateral spread of anesthetic within the epidural space.

For those younger than 5 years of age, the catheter can often be advanced to any level desired without exiting a dural sleeve or becoming tangled or knotted, although one study found a surprisingly high rate of catheter misplacements as detected using epidurograms, that were not suspected clinically.<sup>37,276</sup> Epidurograms are easily performed in the operating room when the catheter is placed. A small (0.5 to 2 mL max) volume of iopamidol is injected and imaged using fluoroscopy. A characteristic “bubbly” pattern in the midline is diagnostic of proper placement (Fig. 41-7). In addition to confirming placement in the epidural space and the location of the catheter tip, spread of the contrast may give a sense of how much volume is needed to cover the desired dermatomes. Besides epidurography, there are two other useful localizing techniques. The Tsui stimulating catheter, described earlier, produces motor twitches in the myotome at the catheter’s tip. One can mark the catheter’s advance by watching the motor paresthesias move up the legs, abdomen and thorax. Ultrasound has also been used to visualize the catheter in the epidural space, although this technique becomes more difficult with increasing age because of ossification of the posterior spinal column, and is frequently not possible in children older than 6 months of age.<sup>277,278</sup> For infants less than 5 kg, successful catheter advancement may be less reliable than in older children, and an epidurogram, ultrasound, or use of a stimulating catheter may be

needed to confirm proper placement of the catheter tip if the catheter is not radiopaque.<sup>279</sup> An epidurogram can be useful in any situation in which the catheter is threaded or when there is concern for proper catheter position, although the routine use of an epidurogram is not standard practice. We usually strive to place the catheter tip at a level near or at the midpoint of the dermatomes encompassing the surgical incision. This position allows a more specific site of administration for both intraoperative anesthesia and continuous infusions for postoperative pain management, with the attendant advantage of being able to use reduced doses of medication. If the catheter does not pass easily to the desired level, it should be withdrawn several millimeters and a localizing technique employed to ascertain its location. The catheter should never be forced or advanced against resistance. It is thus prudent to use some method of localization when a catheter is threaded cephalad more than several centimeters.

Because caudal catheters are at increased risk of contamination from fecal soiling in children who are not yet continent of stool, meticulous attention to the dressing is necessary. Our practice is to use Mastisol (Ferndale Labs, Ferndale, Mich.) or tincture of benzoin to secure the catheter with several layers of an adherent clear dressing, such as Tegaderm (3M, St Paul, Minn.) or OpSite (Smith & Nephew, Andover, Mass.), to affix the dressing in the crease of the buttocks (Video: Tegaderm Application). This transparent dressing permits the observation of the insertion site, which is the most likely source of infection (see later). A piece of single adhesive-edged plastic drape (e.g., Steri-Drape 1010; 3M, St Paul, Minn.) can be affixed just caudad to the lower edge of the dressing in a similar manner; this prevents direct soiling of the dressing. If there is any question of contamination, the catheter should be promptly removed.

### *Lumbar and Thoracic Epidural Anesthesia*

It may be preferable to place epidural catheters at a lumbar or thoracic interspace when the area of operation is innervated by higher dermatomes. Advantages include less risk of contamination by stool and urine, closer proximity to the desired tip location and smaller volume of drug required for a more cephalad dermatomal level (if the caudal catheter is not threaded cephalad). Both lumbar and thoracic epidural catheters may be safely placed in anesthetized infants and children by experienced anesthesiologists.<sup>280</sup> Although the adult literature has raised concerns about the risks of neural injury in the unconscious patient, no longitudinal studies have shown this to be the case in practice. An expert panel has recommended that, although caution must be used in all cases, there are few contraindications to the performance of regional blocks in anesthetized or heavily sedated children, and little evidence to support the notion that blocks placed while the patients are awake have fewer complications.<sup>281,282</sup> All large-scale prospective studies of regional anesthetics in children have found that the risk of permanent neural injury related to regional anesthetics in children, the vast majority of which are performed under general anesthesia, is exceedingly small when performed by experienced pediatric anesthesiologists.<sup>11,66,283,284</sup> Indeed, many of the arguments against regional anesthesia in the unconscious child are speculative, especially when one considers as the alternative a moving and uncooperative child.<sup>280</sup>

The technique for both lumbar and thoracic epidural catheter placement is similar to that in adults, with certain important exceptions (see Chapter 42 for ultrasound techniques). The midline approach is most commonly used, for the same reasons

cited earlier regarding subarachnoid block. The ligamenta flava are considerably thinner and less dense in infants than in older children and adults. This makes recognition of engagement in a ligament more difficult and requires both extra care and slower, more deliberate passage of the needle to avoid subarachnoid puncture. It takes experience to perceive the more subtle differences in “feel” that are characteristic of the tissue planes in small children. The angle of approach to the epidural space is slightly more perpendicular to the plane of the back than in older children and adults, owing to the orientation of the spinous processes in infants and small children. The loss of resistance technique should be used with saline, not air. There are several reports of venous air embolism in infants and children when air was used to test for loss of resistance.<sup>285-287</sup> Another method used to identify the epidural space is to attach an IV infusion chamber with a mini-drip or other free-flowing fluid delivery device to the epidural needle. When the epidural space is entered, the IV set begins to drip (Video: Hanging Drop Technique).<sup>288-290</sup> We use a short (5 cm) 18-gauge Tuohy needle and a 20- or 21-gauge catheter in infants and children. The shorter length offers much better control than an adult-length (9 to 10 cm) needle. These catheters have fewer problems than the 24-gauge catheters, which in our experience are prone to kinking under the skin and have very high resistance to flow. Epidural kits specifically for infants and children are available, but aside from the substitution of a shorter needle they are identical to the adult sets.

**SELECTION OF DRUG.** The drug dose required to place an epidural block at a given dermatomal level depends on the volume (not concentration) of the local anesthetic and the volume and capacitance of the epidural space, which changes with age. There is a general impression that it takes greater volume on a per kilogram basis to achieve equal block heights in smaller children as compared with their older counterparts, but this has not been confirmed. Numerous studies have discussed the doses of local anesthetic drugs used for caudal anesthesia in children.<sup>255,257-259,261,262,264-270</sup> The volumes of local anesthetic that block from a T4 to a T10 dermatome level span a fivefold range. In our experience, the formula of Takasaki and colleagues<sup>262</sup> has best approximated good clinical results: Volume (mL) = 0.05 mL/kg/dermatome to be blocked.

Thus, in a 10-kg child in whom we wish to produce a T10 dermatome level, we would use a volume of (0.05 mL/kg/dermatome)  $\times$  (10 kg)  $\times$  (12 dermatomes) = 6 mL.

Another simple method is to administer 1 mL/kg (up to 20 mL) of local anesthetic (usually 0.125% bupivacaine with 1:200,000 epinephrine). This generally provides a sensory block with minimal motor block up to the T4-6 level; this volume limits the potential for toxicity for children over 6 months of age and is on the border for younger infants. If repeated doses are anticipated, or in infants less than 6 months of age, it is prudent to reduce the concentration or volume to avoid the risk of accumulation.

A third simple regimen for a caudal block used in UK and Australasia is that of Armitage<sup>269</sup>: 0.5 mL/kg for lumbosacral, 1 mL/kg thoracolumbar, and 1.25 mL/kg mid thoracic. If the total volume is less than 20 mL then use bupivacaine 0.25%. If the volume exceeds 20 mL then use bupivacaine 0.19%.

Because the level of the block depends on the volume of drug administered, the concentration of the local anesthetic should be based on the desired density of the block (less dense for postoperative analgesia, more dense for intraoperative anesthesia) and on the risk of toxicity.

### Continuous Epidural Infusions

Although intermittent doses of local anesthetic are often used to maintain epidural anesthesia during a prolonged surgical procedure, it is also common practice to initiate continuous infusions of local anesthetics during surgery. Continuous infusions maintain the block at a constant level, assuming that the infusion rate is appropriate. This obviates the need for repetitive test dosing. Theoretically, fewer entries into the epidural catheter may reduce the risk of infection and the risk of accidental administration of the wrong drug. Strict attention to the total drug administered per hour (i.e., the drug concentration and infusion rate) is required to preclude potentially toxic drug doses. We recommend that the same dosing guidelines for postoperative infusion rates be followed intraoperatively: *a maximum of 0.4 mg/kg/hr of bupivacaine after the initial block is established, with this dose reduced by approximately 30% for infants younger than 6 months of age.*<sup>42</sup> The concentration of local anesthetic solution depends on the age of the child, the surgical procedure, and the extent of area that needs to be blocked. When a more dense block is required in a small infant, it may be beneficial to use 2,3-chloroprocaine because its action is terminated by ester hydrolysis and has a minimal risk of accumulation compared with amide local anesthetics. A denser block with a more concentrated solution may then be achieved. The amides ropivacaine and levobupivacaine, because they are levorotary enantiomers and carry reduced risks of toxicity, may also successfully address these issues and allow the administration of more concentrated agents to produce denser blockade with less potential for adverse effects (see Chapters 42 and 43). In a study of children 1 to 9 years of age, infusion rates of up to 0.4 mg/kg/hr of ropivacaine that followed a 2 mg/kg bolus were found to result in stable levels of unbound ropivacaine in plasma, all well below the toxic threshold; clearance did not differ with age.<sup>291</sup>

### Epidural Opioids

Epidural opioids can be safely used to augment intraoperative anesthesia in children, as well as to provide postoperative analgesia. Their use is discussed in detail in Chapter 43. If extubation of the trachea is expected at the end of the surgical procedure, one must take into account both the systemic and the central neuraxial opioid doses to avoid excessive respiratory depression.

### Adjunctive Drugs

Numerous agents have been injected into the epidural space in attempts to prolong analgesia, to improve the quality of analgesia while reducing the dose of opioid and local anesthetic, or to replace the local anesthetic or opioid with a drug thought to possibly have fewer side effects. It is concerning, however, that several of these agents have not undergone exhaustive neurotoxicity testing and are not prepared or labeled for neuraxial use.<sup>292</sup> In the United States, the only adjunctive drug accepted for epidural administration is clonidine, an  $\alpha_2$ -adrenoceptor agonist. There is some controversy in the literature regarding the beneficial effect of clonidine on the duration of epidural analgesia. Several studies, including a meta-analysis, found a significant prolongation of analgesia (2 hours), as measured by the time to first supplemental analgesic requirement.<sup>292-296</sup> Other investigators found no significant increase in the duration of analgesia, including one double blind, randomized trial.<sup>297,298</sup> In neonates, neuraxial clonidine, particularly at doses of 2  $\mu$ g/kg or greater, has been associated with apnea. Increased sedation is often reported in older infants and children at those doses as well.

### Complications

Complications after epidural anesthesia or analgesia include cardiac arrest from an intravascular or intraosseous injection, hematoma, neural injury, and infection. E-Figure 41-6 illustrates sites of unintended needle placement during the performance of a caudal epidural block. Injection of local anesthetic into an epidural blood vessel or intraosseous injection into the marrow cavity may result in a rapid increase in the blood concentration of the local anesthetic and a toxic reaction as discussed previously. It is also possible to pass the needle through the sacrum and perforate bowel or the pelvic organs, particularly in infants in whom ossification of the sacrum is incomplete.

There are now several large-scale prospective audits that have examined both the incidence and the nature of complications in regional anesthetics in children. The prospective audit from the UK and Ireland is the largest and most carefully described study on complications of epidural anesthesia in pediatrics to date. 10,633 cases were accrued over a period of 5 years, and all complications were reviewed and categorized by severity and type. Only five complications were graded as serious, and of these only one, the result of a drug error, had lasting sequelae. The French-Language Society of Pediatric Anesthesiologists (ADARPEF) published a follow-up prospective study on regional anesthetics in children in which they reported on 10,098 epidural blocks.<sup>66</sup> There were no permanent sequelae seen in any child. The PRAN consortium in the United States, reported data from their first prospective cohort in which 9087 epidural and caudal blocks were accrued, 6210 single injection (mostly caudal) and 2946 continuous caudal or epidural anesthetics.<sup>10</sup> In this study there were no complications of any kind lasting more than 3 months. The most common complication was catheter displacement or malfunction in the postoperative period in continuous blocks.

**Infection** is of grave concern when it occurs in either the subarachnoid or the epidural space.<sup>299</sup> A study of 1620 children over a 6-year period found no incidence of epidural abscess.<sup>300</sup> Catheters remained in situ for a mean of 2 days (maximum 8 days). The adult literature also suggests that infection is an uncommon complication.<sup>301,302</sup> However, both superficial and deep abscesses may rarely occur, particularly in those children with immunodeficiency syndromes and cancer who are receiving long-term infusions.<sup>303</sup> Epidural abscess and meningitis are the most potentially serious complications.<sup>299,304</sup> The development of an epidural abscess is a surgical emergency, because failure to treat it can lead to a permanent neurologic injury. The signs and symptoms (Table 41-6) are the same as for epidural hematomas, although fever, increased erythrocyte sedimentation rate, and increased leukocyte count with a leftward shift are also often present. Surgical drainage may be necessary. In the British audit, three serious infections (two epidural abscesses and one case of meningitis) were noted. These infections were all related to insertion site infections. All cultures grew *Staphylococcus aureus*. Twenty-five local infections were reported, mostly *S. aureus*, and 80% were associated with catheters left in place more than 48 hours. Of note is that some localized infections that developed at the catheter insertion site only became apparent several days after the catheter had been removed (see Fig. 43-11). Similar findings were reported in the PRAN data. In the British study one case progressed to an epidural abscess. Whether these infections developed while the catheter was in place leaving bacteria to track through the open site in the skin after the catheter was removed, or by hematologic spread is unknown, although the former etiology is most frequently cited. Infants and toddlers who are in

diapers require meticulous management of these catheters and their insertion site. A mild erythema occasionally occurs at the site of catheter insertion when children have indwelling catheters in place for several days, and this must be distinguished from a cellulitis (see Fig. 43-11). In most cases these superficial infections resolve with removal of the catheter and local care. On occasion these superficial infections may require treatment with a systemic antibiotic. If there is any question that the site is infected, the catheter should be removed. Although no serious systemic infection occurred in a prospective study of 210 children with 170 caudal catheters (age  $3 \pm 1$  years) and 40 lumbar epidural catheters (age  $11 \pm 3$  years) that were in place for  $3 \pm 1$  days, 35% were colonized with bacteria.<sup>305</sup> This rate of colonization was similar with both caudal (25%) and lumbar epidural (23%) approaches. These results suggest that colonization is not synonymous with infection and that caudal catheters are not necessarily associated with greater infectious risk than lumbar epidural catheters. The factors that transform colonization into infection remain unknown.

It is common to have epidural fluid leak from the insertion site in caudal epidural catheters, especially in the presence of presacral edema. If an indwelling caudal epidural catheter is in place when a child develops a fever of unknown origin, the catheter should be removed because it may be causing the infection or become seeded by the infection (see Chapter 43).

**Epidural hematoma** is also a rare complication after epidural blockade. Optimal outcome depends on rapid diagnosis and prompt treatment and decompression. Signs and symptoms are presented in Table 41-6. The presence of clinically important coagulopathy or thrombocytopenia is an unacceptable risk for developing an epidural hematoma and is a contraindication to central neuraxial blockade. Guidelines for the conduct of neural blockade in the anticoagulated patient have been published by the American Society for Regional Anesthesia.<sup>306</sup> Of particular note is that there is a difference in the management of the patient who is receiving conventional (unfractionated) heparin and low molecular weight heparins, such as enoxaparin. Guidelines for the management of patients who are anticoagulated are shown

**E-FIGURE 41-6** Sites of misplacement of the needle tip and the local anesthetic for caudal block anesthesia. Note that injection may be made into bone marrow (A), into subperiosteum (B), into posterior sacral ligaments (C), into a false "decoy" hiatus (D), into the anterior sacral wall and possibly out into the pelvis (E), or into a lateral foramen (F), producing a limited block. (Reproduced from Cousins MJ, Bridenbaugh PO, editors. *Neural blockade in clinical anesthesia and management of pain*. 2nd ed. Philadelphia: JB Lippincott; 1988, p. 378.)

**TABLE 41-7** Guidelines for the Use of Regional Anesthesia in the Anticoagulated Patient

Drug (Generic)	Common Trade Names	Interval for Catheter Placement after Last Dose	Interval for Catheter Removal after Most Recent Dose	Time Interval to Restart Med after Catheter is Removed
Enoxaparin* (therapeutic)	Lovenox (>60 mg daily or 1 mg/kg bid or 1.5 mg/kg daily)	24 hours	Catheter should be removed before first dose. If med given, wait >24 hours	2-4 hours after catheter removed
Enoxaparin* (prophylactic)	Lovenox (≤60 mg per day)	12 hours	12 hours	2-4 hours
Heparin SC bid	Heparin	No significant risk at dose of 5000 units bid		
Heparin SC tid	Heparin	Unknown risk at 5000 units tid: suggest check PTT. 10,000 units tid: check PTT		
Heparin IV	Heparin	2-4 hours, PTT < 35	2-4 hours, PTT < 35	2 hours
NSAID, ASA	Celebrex, Motrin, Naprosyn, etc.	No significant risk		
Streptokinase	Streptase	10 days	10 days	Uncertain; at least 24 hours
Warfarin	Coumadin	3-5 days, INR ≤ 1.5	If >24 hours, check INR ≤ 1.5	Same day

Modified from the guidelines of the Massachusetts General Hospital Department of Anesthesia, Critical Care and Pain Medicine, 2011.

ASA, Acetylsalicylic acid; INR, international normalized ratio; IV, intravenous; NSAID, nonsteroidal antiinflammatory drug; PTT, partial thromboplastin time; SC, subcutaneous.

\*Note for low molecular weight heparin: Prophylactic dosing may be started 6 to 8 hours postoperatively. Therapeutic dosing or bid dosing should be started at least 24 hours postoperatively. Epidural catheters should be removed before initiation of therapy.

in Table 41-7; however, each case must be decided on an individual basis.<sup>306</sup> Postoperatively, *urinary retention* has been associated with the presence of both epidural and spinal anesthesia. In this regard, it is important to distinguish between the effects of local anesthetics and central neuraxial opioids in the blocks. There is no evidence to support the notion that regional anesthesia with local anesthesia causes urinary retention, and, indeed, there are data to the contrary. In a prospective study of infants and children undergoing inguinal herniorrhaphy or orchiopexy, caudal blockade, ilioinguinal-iliohypogastric nerve block by the surgeon, or a control consisting of caudal injection of 1 : 200,000 epinephrine (no local anesthetic) yielded similar times to voiding postoperatively.<sup>307</sup> In a retrospective study of 326 children undergoing inguinal herniorrhaphy and urologic surgery, 237 received a caudal block and 66 received local anesthesia by the surgeon. The incidence of urinary retention was similar for the two groups, with the type of surgery being the primary determinant of urinary retention.<sup>308</sup>

The epidural and subarachnoid use of opioids, however, is associated with an increased incidence of urinary retention. Epidural morphine in a dose of 70 µg/kg (a dose that would now be considered excessive) was associated with a 50% incidence of urinary retention<sup>309</sup>; 70% of those with urinary retention required treatment. Another study reported an incidence of urinary retention of 27% after caudally administered morphine, 33 to 100 µg/kg, although most of the children had urinary catheters.<sup>310</sup> Finally, 50 µg/kg diacetylmorphine was associated with an 11% incidence of urinary retention.<sup>311</sup> A dose of 33 µg/kg epidural morphine is the most common recommended in current practice.

Data from the large prospective databases indicate that the incidence of *neural injury* after epidural blockade is very small and that long-term neurologic sequelae of neuraxial blockade is rare. One must slightly temper these conclusions, however, based on the limited follow up of children in these studies who did not have problems reported within the immediate time frame of the block. A prospective study of more than 2,500 infants and children who received epidural blocks demonstrated no evidence of neurologic complications, although a retrospective review of the first ADARPEF data determined that 1 in 5000 infants younger than

3 months of age had neurologic complications with MRI evidence of spinal cord ischemia.<sup>99,312</sup> In four of the five cases reported in that study the epidural space was located using loss of resistance to air (in the fifth the technique was not specified) and the authors thought that air embolus was the etiology of the neurologic injury. Based on these data, the use of air for loss of resistance in infants and children has been strongly discouraged, and saline should be used instead. In the follow up ADARPEF study there were no cases of neurologic injury.<sup>66</sup> The British epidural audit found six cases of neural injury in 10,633 children in this prospective study. Of particular note was the delay in recognition of the injury, as no cases were discovered before 2 days had elapsed from the time the block was placed, and some diagnoses were not made for 10 days after the block. All children had complete resolution of their symptoms within 1 year. Two children were referred to a chronic pain service and treated with gabapentin, and one child developed a common peroneal nerve injury that was attributed to malpositioning of the leg during surgery. We have had one child who developed symptoms of complex regional pain syndrome after common peroneal nerve injury from positioning in the postoperative period. This child had persistent motor block, which emphasizes (1) the importance of early recognition of motor blockade as a potential for injury after surgery and (2) the critical importance of positioning and nursing care in preventing pressure injuries. There were no cases of persistent neurologic injury in the initial PRAN data cohort. An in vivo study in young rabbits, using colored microspheres to assess spinal cord and organ blood flow, found that a decrease in blood pressure, when accompanied by epidural anesthesia with lidocaine, decreased spinal cord blood flow.<sup>313</sup> The addition of epinephrine to the local anesthetic solution did not increase the incidence of ischemia. These studies suggest that it may be particularly important to maintain adequate systemic blood flow during “combined technique” anesthesia in infants and children, and to treat hypotension promptly. Because blood pressure changes caused by neuraxial blockade are uncommon in infants and small children, hypotension in these patients is likely to be due to other causes and should prompt an assessment of intravascular filling pressures, inotropic state, and the depth of general anesthesia.

## PERIPHERAL NERVE BLOCKS

Peripheral nerve blocks are useful adjuvants to general anesthesia. These blocks are also useful as a means for providing postoperative pain relief. Peripheral nerve blocks differ from central neuraxial blocks in several respects:

- A targeted area is anesthetized.
- Side effects, such as weakness of extremities, are minimal.
- The dose of local anesthetic is reduced.
- There is no risk of an unintended spinal anesthetic.
- There is no risk of urinary retention.
- They can be used in areas where a central neuraxial block is not possible (e.g., face and scalp).

There are many peripheral nerve blocks that can be used in the practice of pediatric anesthesia and each is described below (Table 41-8; see also Chapter 42).

### Selection of a Local Anesthetic

Local anesthetics commonly used for peripheral blocks in children include lidocaine, mepivacaine, bupivacaine, and, more recently, levobupivacaine and ropivacaine.<sup>63,65,314</sup> Longer-acting agents have a greater role in peripheral blocks than shorter-acting agents because of the increased duration of postoperative analgesia. Lidocaine can be combined with bupivacaine to provide both a rapid onset and a long duration of action, a practice that we advocate if the child is having the procedure performed with a local block under sedation. If this is done, one must be careful to calculate the doses of the two drugs properly to avoid toxicity. Alternatively, the addition of sodium bicarbonate (1 mEq of bicarbonate/10 mL of local anesthetic [lidocaine]) can speed the onset and reduce the pain of injection of the block by increasing the pH of the solution.<sup>315-318</sup> This alters the  $pK_a$  of the solution,

increasing the active cationic form of the local anesthetic in the solution.<sup>319</sup> Bicarbonate should be added to the local anesthetic solution immediately before administration because precipitation of the local anesthetic and therefore loss of bioavailability increases over time (it should be administered within 10 minutes after alkalinization).<sup>320,321</sup> This is particularly a problem with mepivacaine, bupivacaine, and ropivacaine in which the addition of 0.1 mL of 8.4% bicarbonate results in precipitation within 10 minutes.<sup>319,320</sup> The total drug dose administered should not exceed the maximum milligram per kilogram dose permitted for the local anesthetic (see Table 41-2). The addition of epinephrine (1:200,000) may decrease both the vascular absorption and the potential for toxicity; for some local anesthetics the addition of epinephrine will also extend the duration of the block. The exact dose of local anesthetic in terms of volume or concentration needed for most peripheral blocks in children has not been adequately studied. Most blocks performed in children are based on adult experience. Suggested dosing for common peripheral blocks based on volume per kilogram and our experience is presented in Table 41-9.

### Head and Neck Blocks

Peripheral nerve blocks for postoperative pain relief for the head and neck can be performed with the child under general anesthesia.<sup>322</sup> These blocks can also be used for the provision of pain relief in children with chronic painful problems, such as headaches. Anatomically, two major nerves, the ophthalmic division ( $V_1$ ) of the trigeminal nerve and the branches of the cervical root C2, supply the sensory innervations of the face and scalp (Fig. 41-8).

#### Supraorbital and Supratrochlear Nerve Block

**ANATOMY.** The supraorbital and supratrochlear are the end branches of the ophthalmic division ( $V_1$ ) of the trigeminal nerve. The supraorbital nerve, the terminal branch of  $V_1$ , exits the supraorbital foramen to supply the scalp anterior to the coronal suture. The supratrochlear nerve leaves the orbit between the trochlea and the supraorbital foramen and innervates the lower part of the forehead (Fig. 41-9, A). We use this combined block to provide pain relief in children undergoing frontal craniotomies and in children undergoing frontal ventriculoperitoneal shunt revisions. The technique can be used as the sole anesthetic in very sick neonates,<sup>323</sup> and also to control postoperative pain in children undergoing excision of scalp lesions.<sup>324</sup> The major advantage is the avoidance of opioids, thereby facilitating an early hospital discharge.

**TECHNIQUE.** With the child supine and the head in the neutral position, the supraorbital notch is palpated by running

**FIGURE 41-8** Dermatomeal innervation of head and neck. Sensory and dermatomeal innervation of greater and lesser occipital nerves and the innervation of the anterior head by the first division of the trigeminal nerve. Note the sensory innervation anterior to the coronal suture is from the first division of the trigeminal nerve (supraorbital and supratrochlear nerves) and posterior to the coronal suture is from branches of C2 (greater and lesser occipital nerves). These nerves can be blocked individually and in combination to provide postoperative analgesia for a wide variety of procedures; see text for details. **A**, Posterior view. **B**, Anterolateral view. **C**, Axial view. a, Artery; C2, C3, C4, cervical sensory branches of the nerve roots; n, nerve; SCM, sternocleidomastoid muscle; V1, V2, V3, branches of the trigeminal nerve. (Modified from Brown DL, Wong GY. Occipital nerve block. In: Waldman S, Winnie AP, editors. *Interventional pain management*. Philadelphia: WB Saunders; 1996, p. 227.)

a finger from the midline laterally along the eyebrow (the supraorbital notch is usually located in line with the pupil with the eye in midline position). The skin is prepared with povidone-iodine or chlorhexidine and care is taken to avoid spilling the solution into the eye. A 27-gauge needle is inserted in the proximity of the supraorbital notch; 0.5 to 1.0 mL of bupivacaine (0.25% with epinephrine 1:200,000) is injected into the space after careful aspiration to prevent intravascular placement (see Fig. 41-9, B). To block the supratrochlear nerve, the needle is withdrawn to the skin level and then directed and advanced several millimeters medially toward the apex of the nose; 0.5 to 1.0 mL of bupivacaine (0.25% with epinephrine 1:200,000) is injected (Video: Supraorbital Nerve Block).

**COMPLICATIONS.** Because of the loose adventitious tissue of the eyelid, gentle pressure should be applied to the supraorbital area; this prevents the dissection of the local anesthetic into the eyelid and supraorbital tissue, and may reduce the potential for ecchymosis and/or hematoma.

#### Greater Occipital Nerve Block

The greater occipital nerve block is used to diagnose and treat occipital pain. If this technique is used for the diagnosis of occipital neuralgia, a careful history and physical examination is performed to rule out other pathologic causes of headaches, including posterior fossa tumors and Arnold-Chiari malformation.<sup>325</sup> It can also be used to treat postoperative pain in the posterior fossa after posterior fossa surgery, and in children undergoing posterior ventriculoperitoneal shunt revisions.<sup>326</sup>

**ANATOMY.** The cervical spinal nerves innervate the posterior head and neck. The dorsal rami of C2 end in the greater occipital nerve, which provides the cutaneous innervation to the major portion of the posterior scalp (Fig. 41-10, A). The nerve becomes subcutaneous slightly inferior to the superior nuchal line by passing above the aponeurotic sling; here it is in close proximity and medial to the occipital artery.

**TECHNIQUE.** With the child supine and the head laterally rotated or with the child prone, the occipital artery is palpated at the level of the superior nuchal line. The occipital artery is usually located at approximately one-third of the distance from the external occipital protuberance to the mastoid process on the superior nuchal line (see Fig. 41-10, B). A total volume of 2 mL of bupivacaine (0.25% with 1:200,000 epinephrine) is injected SC (Video: Greater Occipital Nerve Block). A recent technique using ultrasound guidance has been used in children for performing occipital nerve blocks.<sup>327</sup>

**COMPLICATIONS.** It is rare to see complications with this block because of the superficial location of the nerve. One has to bear in mind the close proximity to the spinal canal, particularly in children who have had surgery in the area. Thus the needle must remain just beneath the skin during injection of local anesthetic. It is more difficult to perform this block at the C2 nerve root without the aid of either ultrasonography or fluoroscopy and hence it cannot cover the entire distribution of the greater occipital nerve. Intravascular injection may be avoided with incremental injection and frequent aspiration.

#### Infraorbital Nerve Block

**ANATOMY.** The infraorbital nerve is the termination of the second division of the trigeminal nerve, the maxillary nerve (Fig. 41-11, A). This nerve is entirely sensory in function. It leaves the skull through the foramen rotundum and enters into the pterygopalatine fossa. It then enters the infraorbital groove and passes through the infraorbital canal. The nerve emerges in front of the maxilla through the infraorbital foramen and then divides into four branches: the inferior palpebral, the external nasal, the internal nasal, and the superior labial. The anatomic location of the infraorbital foramen has been studied using CT scans: the average distance from the midline (in millimeters) is  $21.3 + 0.5 \times \text{age (years)}$ .<sup>328,329</sup> The branches of the infraorbital nerve innervate the lower eyelid, the lateral inferior portion of the nose and

A

B

**FIGURE 41-9 A**, Supraorbital and supratrochlear nerve block. The supraorbital notch is palpated by running a finger from the midline laterally along the eyebrow. A 27-gauge needle is inserted into the supraorbital notch perpendicularly; bupivacaine (1 mL, 0.25% with 1:200,000 epinephrine) is injected into the space after careful aspiration (**B**). To block the supratrochlear nerve, the needle is withdrawn to skin level and then directed medially several millimeters toward the apex of the nose; bupivacaine (1 mL, 0.25% with 1:200,000 epinephrine) is injected. This block provides postoperative pain relief for children undergoing frontal craniotomies or frontal ventriculoperitoneal shunt insertion.

its vestibule, the upper lip, the mucosa along the upper lip, and the vermilion. This block is effective for surgery of the upper lip and the vermilion after a cleft lip repair,<sup>330</sup> for reconstructive procedures on the nose (including septal reconstruction and rhinoplasty),<sup>331</sup> and for endoscopic sinus surgery.<sup>332</sup> There are two approaches to the infraorbital nerve: intraoral and extraoral.

**INTRAORAL APPROACH.** This is our preferred method for this block. The infraorbital foramen is located by palpation of the infraorbital notch. After folding back the upper lip, a 27-gauge needle is inserted through the buccal mucosa approximately parallel to the maxillary second molar and passed SC with the tip of the needle directed toward the infraorbital foramen. It is important to place a finger over the infraorbital foramen so as to palpate the progress of the needle beneath the skin and prevent unintended passage of the needle into the orbit. With the tip of

A

B

**FIGURE 41-10 A**, Greater occipital nerve block. With the patient supine and with the head turned to one side or with the patient prone, the occipital artery is palpated at the level of the superior nuchal line. The occipital artery is located about one-third of the distance from the external occipital protuberance (*dashed line*) to the mastoid process on the superior nuchal line. A total volume of 2 mL of bupivacaine (0.25% with 1:200,000 epinephrine) is injected subcutaneously to form a skin wheal (**B**). Frequent aspiration and incremental injection may avoid intravascular injection. This block is used to diagnose occipital neuralgia and as a means for providing postoperative pain relief for children undergoing posterior fossa tumor resection or posterior ventriculoperitoneal shunt insertion. a, Artery; n, nerve. (Modified from Brown DL, Wong GY. Occipital nerve block. In: Waldman S, Winnie AP, editors. *Interventional pain management*. Philadelphia: WB Saunders; 1996, p. 228.)

the needle at the level of the infraorbital foramen and after careful aspiration, 0.5 to 1.0 mL of local anesthetic is injected (see Fig. 41-11, B, and Video: Infraorbital Nerve Block). Bupivacaine (0.25% with epinephrine 1:200,000) provides prolonged postoperative analgesia with this block.

**EXTRAORAL APPROACH.** The infraorbital ridge of the maxillary bone should be identified and the infraorbital foramen palpated. A 27-gauge needle is advanced toward the foramen at a 45-degree angle to the maxilla (see Fig. 41-11, C). After careful aspiration, 0.5 to 1.0 mL of bupivacaine (0.25% with epinephrine 1:200,000) is injected.

A

B

C

**FIGURE 41-11** **A**, Infraorbital block (intraoral approach): The infraorbital foramen is located by palpation of the infraorbital notch (right-sided block). **B**, The lip is folded back and a 27-gauge needle is inserted through the buccal mucosa approximately parallel to the maxillary second molar. The tip of the needle is directed toward the infraorbital foramen. A finger is placed over the infraorbital foramen to avoid accidental placement of the needle into the orbit. After careful aspiration to avoid intravascular injection, 0.5 to 1.0 mL of bupivacaine (0.25% with 1:200,000 epinephrine) is injected (left-sided block). **C**, For the extraoral approach (left-sided block) the infraorbital ridge of the maxillary bone should be identified and the infraorbital foramen is palpated. A 27-gauge needle is advanced toward the foramen at a 45-degree angle to the maxilla (midpupillary point). After careful aspiration, 0.5 to 1.0 mL of bupivacaine (0.25% with epinephrine 1:200,000) is injected. This block is used to provide postoperative pain relief for children undergoing upper lip or cleft lip repair, reconstructive procedures of the nose (e.g., rhinoplasty), and endoscopic sinus surgery.

**COMPLICATIONS.** Because of the loose adventitious tissue, children can develop ecchymosis and swelling. Pressure should be applied to the infraorbital area to retain the solution within the infraorbital foramen, prevent dissection of the local anesthetic into the periorbital area, and reduce the potential for the formation of a hematoma or ecchymosis. Care should be taken to avoid direct injection into the orbit or eye. Intravascular injection may be avoided with incremental injection and frequent aspiration. This block can be achieved with low volumes in infants and toddlers and hence every attempt should be made to decrease the volume of the local anesthetic solution. Using other additives, including clonidine, may be helpful, although there are no randomized controlled trials to demonstrate the improved efficacy of this block using additives.

#### **Great Auricular Nerve Block**

The great auricular nerve supplies the sensory innervation to the mastoid area and the external ear. It is a branch of the superficial cervical plexus. Cervical plexus blocks were first performed by

Halstead in 1884. This block has been used to provide postoperative analgesia in children undergoing otoplasty repair,<sup>333</sup> as well as in tympanomastoid surgery.<sup>334</sup> We found that the great auricular nerve block decreases the incidence of nausea and vomiting, which is a major morbidity associated with tympanomastoid surgery.<sup>334</sup> It provides surface analgesia but not muscle relaxation and hence can be used for intraoperative analgesia despite the need for facial nerve monitoring in children undergoing tympanomastoid procedures.

**ANATOMY.** The cervical plexus is formed by the anterior primary division of the anterior and posterior roots of cervical nerves C2-4. The great auricular nerve is derived from C3, which was described by McKinney. The anatomic location of the nerve for blockade has been described as the McKinney point.<sup>335</sup> The great auricular nerve wraps around the belly of the sternocleidomastoid muscle at the level of the cricoid cartilage and emerges to supply the area of the mastoid and external ear (Fig. 41-12, *A*).

**TECHNIQUE.** With the child under general anesthesia, the cricoid cartilage is identified. A line is drawn from the superior

**FIGURE 41-12 A**, Great auricular nerve block. The cricoid cartilage is identified. A broken line drawn from the superior border of the cricoid cartilage laterally to the posterior border of the sternocleidomastoid (SCM) (McKinney point) is identified; bupivacaine (2.0 to 3.0 mL, 0.25% with 1:200,000 epinephrine) is injected subcutaneously at this point (**B**). Gentle massage after the injection allows spread of the local anesthetic in the injected site. This block is used to provide postoperative analgesia for children undergoing tympanomastoid surgery or otoplasty. *n*, Nerve. (Modified from Brown DL, editor. *Atlas of regional anesthesia*. Philadelphia: WB Saunders; 1999, p. 185.)

margin of the cricoid cartilage laterally to the posterior border of the sternocleidomastoid muscle (McKinney point). Bupivacaine (2 to 3 mL, 0.25% with epinephrine 1:200,000) is injected superficially at this point (see Fig. 41-12, *B*, and Video: Great Auricular Nerve Block).

**COMPLICATIONS.** Deep rather than superficial injection can result in a deep cervical plexus block and the risk of Horner syndrome, phrenic nerve block, or unintended central neuraxial blockade. A small erythematous area may be seen at the site of the needle injection. Intravascular injection may be avoided by incremental injection of the solution and frequent aspiration.

### *Nerve of Arnold (Auricular Branch of Vagus)*

The auricular branch of the vagus supplies the sensory nerve that supplies the innervation to the auditory canal, as well as the inferior portion of the tympanic membrane. This is useful for providing analgesia to the tympanic membrane following myringotomy and tube placement, as well as for tympanoplasty surgery. In a randomized controlled trial, intranasal fentanyl and blockade of the auricular branch of the vagus provided equivalent analgesia without adverse effects.<sup>336</sup>

**INDICATIONS.** This block is used to provide analgesia for myringotomy and tube placement, and for tympanoplasty.

**TECHNIQUE.** After induction of anesthesia, and with the child turned to one side, the tragus is cleaned and reflected laterally, a 30-gauge needle is inserted into the tragus to pierce the cartilage, after aspiration, 0.2 mL of local anesthetic solution is injected (Video: Nerve of Arnold Block). Mild pressure is applied to prevent any bleeding following the procedure.

**COMPLICATIONS.** It is rare to see complications, although occasionally there can be some brisk bleeding from the needle entry site, which can be offset by applying pressure.

### **Truncal Blocks**

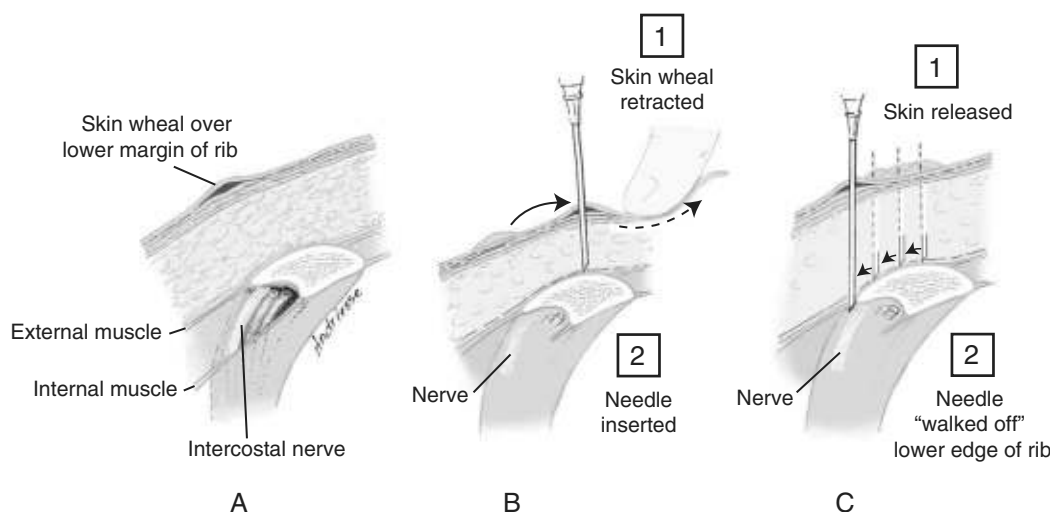

Truncal blocks are performed in children for a variety of different surgical procedures. The most common blocks include intercostal blocks,<sup>33</sup> ilioinguinal blocks, penile blocks, rectus sheath blocks, and paravertebral blocks.

#### *Intercostal Nerve Block*

Intercostal blocks after thoracotomy are useful in reducing opioid requirements, optimizing respiratory mechanics, and encouraging early ambulation.<sup>33,337,338</sup> Their major disadvantage is the limited duration of analgesia. Currently, we more commonly employ epidural blockade for this purpose. The development of degradable bupivacaine microspheres and the recent approval of liposomal encapsulated bupivacaine, which produce analgesia of dramatically greater duration, may change this practice in the future.<sup>47,56-59,61</sup> There are, however, still situations in which intercostal blocks are useful, particularly in children who cannot have a neuraxial catheter placed.

The uptake of local anesthetic after intercostal blocks is the most rapid of all sites of regional anesthesia, yielding the greatest plasma concentrations of local anesthetics following any other regional block. Furthermore, plasma concentrations in children increase more rapidly than after identical blocks in adults.<sup>339</sup> For this reason, epinephrine (1:200,000) should be added to reduce the absorption of local anesthetic. We commonly use 0.25% bupivacaine with epinephrine in a dose of 1 to 5 mL for each nerve being blocked, depending on the size of the child and the number of ribs to be blocked. A maximum of 2 mg/kg of bupivacaine is used, although this amount should be reduced by about 30% for infants younger than 6 months of age. The concentration of bupivacaine should be decreased to provide adequate volume for the desired number of intercostal blocks while avoiding the risk of systemic toxicity.

**ANATOMY.** The intercostal nerves are derived from the ventral rami of the first through twelfth thoracic nerves. There are four branches: the first is the gray rami communicans, which goes to the sympathetic ganglion; the second branch arises as the posterior cutaneous branch, which supplies the skin in the paravertebral area; the third branch, the lateral cutaneous branch, arises anterior to the midaxillary line and sends subcutaneous branches both anteriorly and posteriorly; and the final branch

**FIGURE 41-13** Intercostal block. A skin wheal is inserted on the lower rib margin (**A**). The skin wheal is retracted over the body of the rib, and a needle is inserted until contact is made with the rib (**B**). The skin is released, and the needle is carefully “walked” off the edge of the rib margin (**C**). After negative aspiration for blood, the appropriate volume of drug is injected. This block is used for postoperative analgesia for thoracotomy or chest tube insertion (see also E-Fig 41-7).

provides cutaneous innervation to the midline of the chest and abdomen. The dura mater and the arachnoid membrane fuse with the epineurium as they exit the vertebral foramen. This could lead to subarachnoid block if the posterior paravertebral approach is used.

**TECHNIQUE.** The site of injection may be either paravertebral or in the midaxillary line. The lower rib margin is located, and the skin is retracted cephalad (Fig. 41-13, *A*). The needle is inserted perpendicular to the skin over the rib and advanced until the rib is encountered (see Fig. 41-13, *B*). The skin through which the needle is passed is allowed to retract caudally, and the needle is then walked off the lower edge of the rib a distance of 2 to 3 mm (see Fig. 41-13, *C*). This method may reduce the potential for pneumothorax, because the needle strikes the rib and is not advanced more than half of the thickness of the rib. A distinct pop may be felt as the needle enters the neurovascular sheath. After negative aspiration for blood, an appropriate volume of anesthetic is injected. Recently, with the use of ultrasound guidance, we can visualize the pleura, thereby avoiding puncturing the pleura because it can be adequately visualized while performing the block (E-Fig. 41-7; see also Fig. 42-11).

**COMPLICATIONS.** Pneumothorax has been reported after intercostal blockade, with an incidence of approximately 0.07% in adults.<sup>340</sup> However, the majority of the blocks in that study were performed by residents in training. If a small pneumothorax occurs, reabsorption is facilitated with the use of oxygen. Placement of a chest tube is only indicated if respirations are compromised. A more significant complication is the toxic effect of absorbed local anesthetic drugs. Using smaller volumes of more dilute local anesthetic may reduce the risk of achieving toxic plasma concentrations. The risk of intravascular injection may be reduced with incremental injection and frequent aspiration. A third complication is a high subarachnoid block, usually associated with the posterior paravertebral approach.

#### **Inguinal Block (Ilioinguinal and Iliohypogastric Nerves)**

Inguinal block, supplemented by wound infiltration, is sometimes used in adult patients undergoing inguinal hernia repair. However,

in children, it is used almost exclusively as an adjunct to general anesthesia and for postoperative pain management. This block is as effective as caudal anesthesia for inguinal repairs.<sup>341,342</sup> Blockade of the ilioinguinal and iliohypogastric nerves is very successful for this purpose and has few associated complications, although injection into the femoral vessels and potential femoral nerve block is a possibility.<sup>343,344</sup> The risks of toxicity from excessive drug doses may be greater than previously recognized, as discussed earlier, but ultrasound guidance has demonstrated adequate analgesia with reduced doses of local anesthetic solution because of the optimal drug placement.<sup>345</sup> This block may be (and commonly is) performed in conjunction with infiltration of the wound. The use of ultrasound may also avoid the risk of bowel perforation (see also Chapter 42, and Figs. 42-35 and 42-36).<sup>346</sup>

**ANATOMY.** The inguinal area is innervated by the subcostal nerve (T12), iliohypogastric and ilioinguinal nerves (derived from L1). These nerves lie in close proximity to each other medial and superior to the anterior superior iliac spine (Fig. 41-14, *A*). After piercing the internal oblique 2 to 3 cm medial to the anterior superior iliac spine, the nerve then lies between the internal oblique and the external oblique aponeurosis. Here it accompanies the spermatic cord (in males) to the genital area.

**TECHNIQUE.** The block may be performed either at the beginning of surgery or before the end of general anesthesia. If bupivacaine is used, a minimum of 15 minutes is usually required from the completion of the block until maximal analgesia is obtained. Thus blocks placed at the beginning of the surgical procedure (our preference) are usually more effective than those performed at the end of surgery. Blocks performed before skin incision may also provide “preemptive analgesia,” although the evidence for this is still under debate and somewhat confusing.<sup>347-350</sup> The duration of postoperative analgesia is unaffected by the timing of placing the block: at the beginning of the procedure, assuming that the surgical procedure is not of more than 1.5 hours in duration or at the end. A short-bevel 27-gauge needle is inserted at a 45-degree angle at a point one-fourth of the way toward the midline along a line drawn from the anterior superior iliac spine to the umbilicus (1.0 to 1.5 cm cephalad and toward

**E-FIGURE 41-7** **A**, A linear ultrasound probe is placed overriding the ribs. **B**, The innermost intercostal muscle is identified, a needle is placed using an off-plane approach, and, after negative aspiration, 2 mL of local anesthetic is injected. Spread of the local anesthetic solution in the innermost intercostal signifies blockade of the intercostal nerves.

**FIGURE 41-14** Ilioinguinal and iliohypogastric nerve blocks. **A** and **B**, The anterior superior iliac spine (ASIS) is palpated, and a point 1.0 to 1.5 cm cephalad and toward the midline is located (dashed line). A 22-gauge needle is passed through the external and internal oblique muscles, and 1.0 to 5.0 mL of local anesthetic is deposited in a fan-like fashion cephalad toward the umbilicus, medially, and caudad toward the groin (solid arrows). Just before removal from the skin, another 0.5 to 1.0 mL of local anesthetic is injected subcutaneously to block the iliohypogastric nerve. Blockade of these nerves provide postoperative analgesia for inguinal hernia and orchiopexy procedures (see also E-Fig. 41-8).

the midline from the anterior superior iliac spine in a 10- to 15-kg child). As the needle is advanced through the external and internal oblique muscles (see Fig. 41-14, B), two pops are elicited and provide useful guides of proper needle placement. Negative aspiration should be confirmed several times during the incremental injection of local anesthetic. A volume of 0.3 mL/kg of local anesthetic solution is injected in a fan-like fashion, cephalad toward the umbilicus, caudad toward the groin, and medially. Before removal of the needle from the skin, an additional 0.5 to 1.0 mL of local anesthetic is injected SC to block the iliohypogastric nerve (Video: Ilioinguinal Nerve Block with Ultrasound). Care must be taken to avoid entering the peritoneum, which has been reported after the blind injection approach.<sup>346</sup> For inguinal herniorrhaphy, orchiopexy, or other inguinal procedures, local anesthetic deposited directly into the wound before it is closed has also proved effective for postoperative analgesia.<sup>342</sup> The volume of drug used by this approach, like the volume of drug used for wound infiltration, must be accounted for when calculating the maximal dose of local anesthetic that can be used. It is important to note that this block will not provide pain relief for scrotal procedures because this is supplied by the genitofemoral nerve and hence it is important to have the surgeon infiltrate the scrotum for complete pain relief following orchiopexy or any other scrotal procedures. As mentioned earlier, an ultrasound-guided technique may be easier and leads to fewer complications while performing the block (E-Fig. 41-8).<sup>345</sup>

**COMPLICATIONS.** Complications are rare. Care should be taken not to enter the peritoneal cavity. Intravascular injection may be avoided by incremental injection with frequent aspiration.

#### Penile Block

A penile block is used for anesthesia and postoperative analgesia for circumcision, urethral dilatation, and hypospadias repair.

Caudal anesthesia is superior for proximal shaft or penoscrotal hypospadias repair because a penile block provides analgesia only for the distal two-thirds of the penis.<sup>266,351,352</sup> The block is easily performed and has a high success rate. Bupivacaine, levobupivacaine, and ropivacaine are the most useful agents because of their prolonged duration of action. *Epinephrine must never be used for this block because the dorsal artery of the penis is an end artery and vasospasm caused by epinephrine could cause necrosis.*

**ANATOMY.** The nerve supply of the penis is from the pudendal nerve and the pelvic plexus (Fig. 41-15, A). Along the dorsal artery to the penis are two dorsal nerves that separate at the level of the symphysis pubis; they supply the sensory innervation to the penis.

**TECHNIQUE.** There are two commonly used techniques for penile block: (1) a ring block and (2) blockade of the dorsal nerve. One investigation compared the efficacy of these techniques and concluded that the ring block provided analgesia of prolonged duration, although both techniques provided analgesia superior to EMLA cream.<sup>353</sup> The ring block is performed by inserting a 27-gauge needle at the base of the penis and, after negative aspiration, injecting the local anesthetic without epinephrine in a ring-shaped pattern around the base of the penile shaft. The needle may be inserted once in the midline and then redirected to each side (see Fig. 41-15, B). The alternate dorsal nerve block is performed with a 27-gauge needle inserted 1 cm above the symphysis pubis, in the midline, at a 30-degree angle and directed caudad (see Fig. 41-15, C). The needle is advanced 1 cm after it pierces the penile fascia. After negative aspiration for blood, 1 to 4 mL of local anesthetic *without epinephrine* is injected slowly. There is a small risk of injury to the adjacent neurovascular structures.

**COMPLICATIONS.** The major complication is compromise of organ blood flow. *Vasoconstrictors, such as epinephrine, must never be used for this block.* Applying pressure after the injection may

**E-FIGURE 41-8** **A**, Ultrasound-guided ilioinguinal nerve block: a linear ultrasound probe is placed along the superior margin of the iliac crest. (Orientation: thorax at the bottom of figure, legs at the top of the figure.) **B**, The internal oblique and the transversus abdominis are visualized. The ilioinguinal nerve and the iliohypogastric nerves are located between the two muscle layers. Using an in-plane approach, the nerves are accessed and 0.1 mL/kg of local anesthetic solution is injected.

**FIGURE 41-15** Penile block. **A**, Dorsal nerve block: a 27- or 25-gauge needle is inserted in the midline, 1 cm above the symphysis pubis at an angle of 30 degrees from the plane of the abdominal wall and directed caudad. **B**, After piercing the penile fascia (0.5 to 1.0 cm) and negative aspiration for blood, 1.0 to 4.0 mL of local anesthetic without epinephrine is injected. **C**, Ring block: a 25-gauge needle is inserted at the base of the penis at a 45-degree angle, and a ring of local anesthetic is deposited (curved arrows). This may be done through a single needle placement by redirecting the needle. This block may be used in children in whom a caudal block is contraindicated.

minimize hematoma formation. Intravascular injection may be avoided with incremental injection and frequent aspiration.

#### **Rectus Sheath Block**

Although reported almost 20 years ago,<sup>354</sup> this block has recently become popular for children undergoing repair of an umbilical hernia.<sup>355-357</sup> The rectus sheath contains the thoracic intercostal nerves (T-10) that can be blocked at the paraumbilical area using a small volume of local anesthetic solution.

**TECHNIQUE.** On either side of the umbilicus, about 1 cm from midline a needle is inserted into the rectus sheath (Fig. 41-16, *A*). A pop can be felt as the needle advances beyond the anterior rectus sheath, through the rectus abdominis muscle and then just anterior to the posterior rectus sheath. After aspiration, a volume of 0.1 mL/kg of local anesthetic solution is injected (Video: Rectus Sheath Block with Ultrasound). This provides excellent analgesia for most umbilical area surgery, including laparoscopic surgery. Use of ultrasound may facilitate performing this block<sup>358</sup> (see Fig. 41-16, *A* and *B*; see also Chapter 42, and E-Figs. 42-2 and 42-3).

#### **Paravertebral Block**

This block is also gaining some popularity for use in children. The main advantage is that deposition of local anesthetics in the

paravertebral space will lead to strict unilateral anesthesia of one or more adjacent dermatomes (Fig. 41-17); the main indications for a paravertebral nerve block are unilateral thoracic or abdominal surgical procedures.

**ANATOMY.** The paravertebral space is a triangular wedge-shaped area situated in the angle between the lateral border of the vertebral body and the anterior surface of the transverse process (Fig. 41-18). The paravertebral space exists only between T1 and T12. Below T12 the space is sealed off by the origin of the psoas muscle from the vertebral body and the transverse process.<sup>359</sup> Cranially the space appears to communicate with fascial planes in the neck, because an upper thoracic paravertebral block may cause Horner syndrome. The communication of different thoracic levels of the paravertebral space is the foundation for spread of local anesthetic to multiple segments (see Fig. 41-17). The medial boundary of the paravertebral space is the lateral part of the vertebral body and disc, the dorsal limitation is the transverse process and costotransverse ligament, and the anterolateral boundary is the parietal pleura. Structures that pass through the paravertebral space include the spinal nerve root–intercostal nerve, the sympathetic chain, and the intercostal vessels. The paravertebral space is not like the epidural space, because the pleura are very adhesive to the other structures but should instead be viewed as a “potential space.” This accounts

**FIGURE 41-16** Rectus sheath block. The rectus sheath is encompassed between the rectus abdominis muscle anteriorly and the posterior rectus sheath. **A**, A linear ultrasound probe is placed lateral to the umbilicus, and the anterior rectus sheath, the rectus abdominis muscle, and the posterior rectus sheath are identified. **B**, With the use of an in-plane approach, a 27-gauge needle is inserted through the rectus abdominis muscle anterior to the posterior rectus sheath and 0.1 mL/kg of local anesthetic solution is injected (arrow).

**FIGURE 41-17** Distribution of somatic and sympathetic blockade after thoracic paravertebral blocks. Blue shading indicates the approximate spread of somatic blockade and pink shading indicates the approximate extent of sympathetic blockade. (See text for details.) (From Lönnqvist PA, Richardson J. Use of paravertebral blockade in children. *Tech Region Anesth Pain Manage* 1999;3:184-8.)

**FIGURE 41-18** Anatomic relationship of the paravertebral block and correct position of Tuohy needle and catheter. (From Lönnqvist PA, Richardson J. Use of paravertebral blockade in children. *Tech Region Anesth Pain Manage* 1999;3:184-8.)

for the slight difficulty in introducing a percutaneous catheter into the paravertebral space. In the lumbar region a paravertebral block is still possible but each individual space must be blocked separately because there are no communications between adjacent lumbar levels.

**TECHNIQUE.** Three approaches to perform a paravertebral block in children have been described:

*Loss-of-Resistance Technique*<sup>359</sup>: The skin is punctured laterally to the spinous process and the needle is advanced in a perpendicular manner until contact is made with the transverse process. A Tuohy needle (19 to 20 gauge if younger than 1 year of age, 18 gauge if older than 1 year of age) is then “walked” below (underneath) the transverse process and by means of a loss-of-resistance technique the costotransverse ligament is pierced and the paravertebral space located. Alternatively the needle can be “walked” above (over the top of) the transverse process, but by using this approach there is the risk of striking the neck of the rib before entering the paravertebral space. Occasionally this will redirect the needle, making it virtually impossible to obtain access to the paravertebral space. The approach from below the transverse process is clearly advantageous.

Once in the paravertebral space, the bolus dose of local anesthetic can be injected after careful aspiration to exclude the presence of blood or air. If a continuous technique is preferred, a catheter can be introduced 1 to 2 cm into the paravertebral space through the Tuohy needle. The insertion of the catheter frequently needs manipulation of the Tuohy needle to be successful, and occasionally one will have to make the injection of the bolus dose to “open up” or “create” a space to allow catheter insertion. One should not insert more than 1 to 2 cm of the catheter into the paravertebral space because further advancement may cause the catheter to migrate into the spinal canal through the intervertebral foramen (causing an epidural distribution of the block) or to go laterally, following the path of the intercostal nerve (giving a dense block of only one dermatome).

An estimate of the distance from the spinous process to the skin puncture site (spinous process to paravertebral space distance) and the distance from the skin to the paravertebral space can be approximated by the following equations<sup>360,361</sup>:

$$\begin{aligned} \text{Spinous process to paravertebral space distance (mm)} \\ = 0.12 \text{ kg} + 10.2 \end{aligned}$$

$$\text{Skin to paravertebral space distance (mm)} = 0.53 \text{ kg} + 21.2.$$

The level of the puncture depends on the surgical intervention, but for a thoracotomy the puncture is best performed at T5-6 and for renal surgery at T9-10.

*Nerve-Stimulator-Guided Technique*<sup>362</sup>: The intervertebral lines corresponding to the specific dermatomes are determined by manual palpation. The site of injection is marked 1 to 2 cm laterally from the midline on the intervertebral line according to the child's weight. A 21-gauge insulated needle of appropriate length, attached to a nerve stimulator (initial stimulating current: 2.5 to 5 mA, 1 Hz), is introduced perpendicularly to the skin in all planes. A contraction of the paraspinal muscles is initially observed, and the needle is advanced until the costotransverse ligament is reached. At this point the contraction of the paraspinal muscles will disappear. After piercing the costotransverse ligament, muscle contractions of the corresponding level are sought and the needle tip is manipulated into a position allowing continued muscular contractions while reducing the stimulating

current to 0.4 to 0.6 mA; the desired local anesthetic dose and volume is injected. Manipulation of the needle tip within the paravertebral space is not an “in and out” movement but is rather an angular manipulation and circumferential rotation around the axis of the needle to reach an optimal position of the needle tip with regard to the nerve within the paravertebral space.

*Ultrasound-Aided Approach.* With the aid of ultrasound the position of the transverse processes and the depth to the paravertebral space can be determined; ultrasound is very helpful regardless of whether a loss-of-resistance or nerve-stimulator-guided technique is used.

**SELECTION OF DRUG.** After a negative aspiration test and administration of a test dose, 0.5 mL/kg of the local anesthetic (levobupivacaine 0.25% with epinephrine 1:200,000, bupivacaine 0.25% with epinephrine 1:200,000, or lidocaine 1% with epinephrine 1:200,000) is injected in toddlers and older children. This dose will usually spread to cover at least five dermatomes. A typical distribution of the block will be unilateral analgesia of the trunk ranging from T4 to T12 (see Fig. 41-17). In neonates and infants, slightly modified dosage regimens are recommended<sup>363-365</sup>; these dosages have been found to be both effective and associated with acceptable plasma concentrations of bupivacaine.<sup>363</sup>

**COMPLICATIONS.** The use of a percutaneous loss-of-resistance technique in a mixed adult and pediatric population was found to be associated with an overall failure rate of approximately 10% and the complications experienced were hypotension (5%; only adults), vascular puncture (4%), pleural puncture (1%), and pneumothorax (0.5%).<sup>366</sup> The risk for block failure is reduced to less than 5% when a nerve-stimulator-guided technique is used, and this technique also appears to be associated with a reduced risk for complications.<sup>362,367</sup> Use of ultrasound may further improve success while reducing complications.

## Upper Extremity Blocks

### Brachial Plexus Block

Of the four techniques used to block the brachial plexus (axillary, infraclavicular, supraclavicular, and interscalene), the axillary approach is most commonly used in children when using nerve stimulation or landmark techniques.<sup>368</sup> Advantages include ease of insertion, a high rate of success in experienced hands, and low morbidity. The block is also well suited for orthopedic or plastic surgical repairs on the hand or forearm in a child with a full stomach.<sup>369,370</sup> In this situation, deeper levels of sedation, intravascular injection, or drug overdose places the child at risk for aspiration of gastric contents. Because it is unnecessary to elicit a sensory paresthesia, the block can also be performed in an anesthetized child for postoperative pain management. Toxicity is avoided if the dose of bupivacaine is less than 2.5 mg/kg.

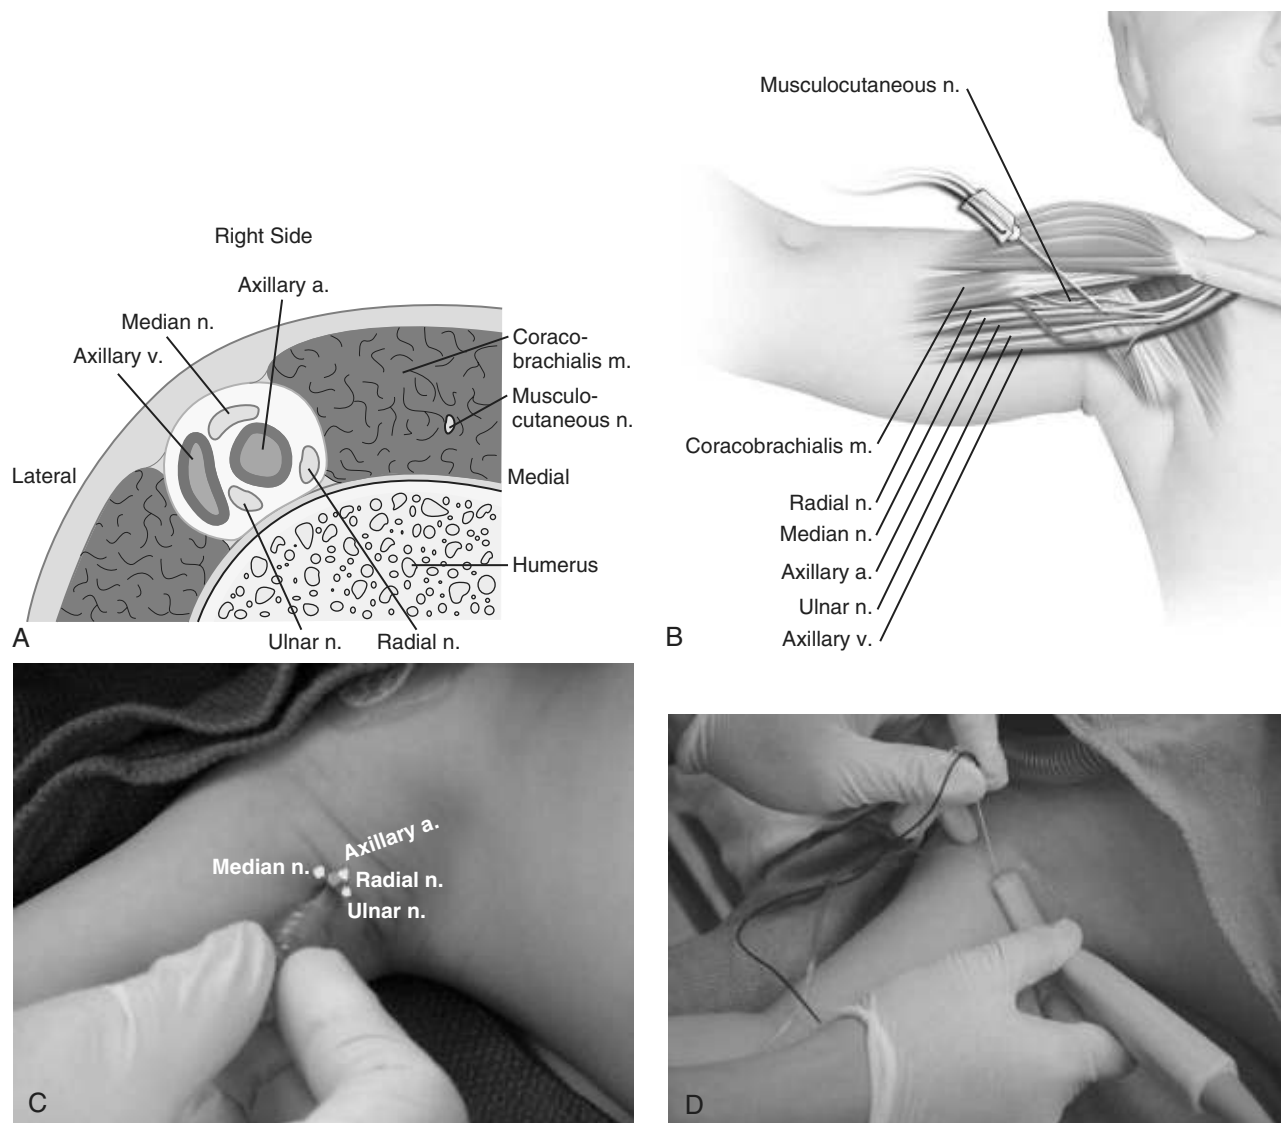

Infraclavicular, supraclavicular, and interscalene blocks are not as frequently used as the axillary block in children. The infraclavicular block is our preferred technique for the placement of a continuous catheter in the postoperative period. Unintentional block of the phrenic and recurrent laryngeal nerves is much more common in young children because these nerves are close to the site of injection, especially with an interscalene block. Data suggest that some degree of phrenic nerve blockade is present in all children receiving interscalene blocks.<sup>371,372</sup> Phrenic nerve blockade may cause respiratory failure in very young children whose breathing is almost totally dependent on the diaphragm, whereas block of the recurrent laryngeal nerve may cause increased

airway resistance because of vocal cord paralysis. The risk of pneumothorax is greater because the apex of the lung is situated more rostral in infants and small children. Total spinal anesthesia is also more likely with the interscalene approach to axillary plexus blockade.<sup>373</sup>

**ANATOMY.** The brachial plexus arises in the neck from spinal nerves C5, C6, C7, C8, and T1, passes between the clavicle and first rib, and extends into the axilla. At that point, the axillary

artery is surrounded by a narrow fascial sheath that contains the median nerve anteriorly, the ulnar nerve posteriorly, and the radial nerve on the posterolateral aspect (Fig. 41-19, *A*). In children, the axillary artery and, at times, the axillary sheath itself may be palpable.

**TECHNIQUE.** Several techniques can be used to establish that the needle is within the axillary sheath. The first is by eliciting a sensory paresthesia with the needle, but this has little application

**FIGURE 41-19** **A** and **B**, The anatomic relationships of the brachial plexus are presented. Note that the fascial sheath envelops the nerves and the axillary artery and vein; the musculocutaneous nerve lies within the body of the coracobrachialis muscle. Local anesthetic injected within the sheath (on either side of the axillary artery) produces a satisfactory block. There may be septation within the sheath in some individuals (not pictured). **C**, The axillary artery is palpated with the arm in abduction in the axilla. A needle is introduced superior to the pulsation to block the median nerve. If a nerve stimulator is used, opposition of the thumb can be elicited as the median nerve is stimulated. The needle is then gently positioned below the artery; the ulnar nerve can be blocked in this position. If a nerve stimulator is used, flexion of the fifth finger is elicited. For blocking the radial nerve that is situated posterior to the artery, it may be necessary to pass the needle posterior to the artery while constantly aspirating to avoid intravascular placement. If the needle does encounter the axillary artery, continue to advance the needle so that the aspirate is negative while the needle is situated posterior to the artery. If a nerve stimulator is used, biceps flexion may be observed. A total volume of 0.1 to 0.15 mL/kg in divided doses between all three nerves will provide an adequate blockade of the nerves. If the axillary artery is encountered while accessing the radial nerve, it is imperative to apply pressure after the block is placed to avoid hematoma formation. **D**, An ultrasound is particularly useful for successful placement of an axillary block. A linear ultrasound probe or a hockey stick probe is placed on the axilla. With the use of an in-plane approach, the median nerve (located anterior to the artery), then the radial nerve (located posterior to the axillary artery), and then the ulnar nerve (located below the artery) are blocked individually. Careful aspiration before injection may prevent intravascular injection. *a*, Artery; *m*, muscle; *n*, nerve; *v*, vein.

in pediatric practice, particularly in young children and in those who are anesthetized. The use of a nerve stimulator allows precise placement of the needle in the neurovascular sheath without either the cooperation of the child or the need for painful sensory paresthesias (see Fig. 41-2). In thin children, the sheath can often be palpated as a cord-like structure inferior to the coracobrachialis muscle, allowing the placement of the needle in the sheath by “feel.” A transarterial approach can also be used.<sup>374</sup> With all techniques, it is useful to attach a short piece of extension tubing between the needle and syringe to facilitate precise handling during needle placement, aspiration, and drug injection.

The use of a nerve stimulator for the axillary approach to the brachial plexus is best accomplished by abducting the arm to 90 degrees (see E-Fig. 41-2). Care should be taken not to hyperabduct the arm, obscuring the axillary pulse. The artery is palpated in the axilla, and a short beveled needle is advanced toward it (see Fig. 41-19, B). When using a nerve stimulator, a distal motor response is elicited in the distribution of the radial, ulnar, or median nerves at a threshold of less than 0.2 mA (see E-Fig. 41-2). If one is not using a nerve stimulator, the needle is advanced until a distinct pop is felt as the needle pierces the axillary sheath. The axillary sheath may be divided into fascial compartments for each nerve, and these may limit the spread of local anesthetic within the axillary sheath. Although distinct paresthesias to the distribution of all three nerves may be elicited with the nerve stimulator, and divided doses of anesthetic may be administered to each of those locations, in practice it becomes extremely difficult to find the second and third motor paresthesia after the administration of even a very small amount of local anesthetic with the first injection (Video: Axillary Block with Ultrasound

Guidance). Alternatively, the transarterial technique, which involves direct puncture of the axillary artery, allows deposition of local anesthetic in two sites within the sheath. The needle is aimed directly toward the axillary pulse. As soon as blood is aspirated, the needle is advanced through the posterior wall of the artery. When blood can no longer be aspirated, half of the dose of local anesthetic is deposited posterior to the artery. The needle is withdrawn through the anterior wall of the artery, and the remainder of the dose is deposited anterior to the artery after reconfirming a negative aspiration for blood. Regardless of technique, the local anesthetic is administered in incremental quantities with intermittent aspiration to confirm that the needle is still outside the blood vessel. Some practitioners advocate applying a tourniquet distal to the site where the block is to be performed. It is sometimes difficult to block the musculocutaneous nerve, which carries sensory fibers to the radial aspect of the forearm, because it exits the brachial plexus proximal in the axillary fossa. Applying a tourniquet may promote proximal spread of local anesthetic and enhance the chances of a successful block of this nerve. Alternatively, the musculocutaneous nerve may be blocked by infiltrating 1 to 3 mL (proportional to the size of the child) of local anesthetic into the body of the coracobrachialis muscle. Regardless of the technique chosen, an additional 1 to 3 mL of local anesthetic is deposited as a subcutaneous cuff to block the intercostobrachial nerve and its communications with the musculocutaneous nerve. These additional quantities of local anesthetic must be accounted for when calculating the total drug dose. An ultrasound may also be used in conjunction with a nerve stimulator to further improve the localization of each nerve bundle (see Figs. 42-16 and 42-21).<sup>370</sup>

**SELECTION OF DRUG.** Local anesthetics commonly used in our practice include lidocaine and bupivacaine (see Table 41-2).

As with other regional techniques that involve larger volumes of local anesthetic, the addition of both levobupivacaine and ropivacaine to the armamentarium is likely to prove beneficial in reducing the risk of toxicity from local anesthetics. Because it is desirable to have a prolonged duration of postoperative analgesia, longer-acting agents are usually used in place of lidocaine. To help ensure block of the musculocutaneous nerve, we use large volumes (0.5 mL/kg), diluting the concentration of local anesthetic with normal saline as needed to avoid toxicity. Care must always be taken not to exceed the maximal allowable doses of bupivacaine on a milligram per kilogram basis (2.5 mg/kg).<sup>375</sup> Adding epinephrine (1:200,000) may decrease vascular absorption and the potential for toxicity. Sodium bicarbonate (1 mEq/10 mL of local anesthetic) added to the local anesthetic will speed the onset of blockade by increasing the pH of the solution; this is particularly the case with the premixed anesthetic-epinephrine formulations that have a reduced pH.

**COMPLICATIONS.** All of the nerves of the brachial plexus occupy a neurovascular bundle and hence are prone to unintended injection into a blood vessel. A hematoma may form at the site of injection. If it is large enough, the hematoma may compress the neurovascular bundle, rendering the limb ischemic. Hence it is important to know the child's coagulation status before attempting the block. Intravascular injection may be avoided with incremental injection and frequent aspiration. Intraneural injection may be minimized by use of a nerve stimulator. Surgeons may feel the importance to check the viability of the radial, median, and ulnar nerves before injecting local anesthetic solution. This block can be carried out in the recovery room after the function of the nerves are determined. A simple rule of thumb is to check the radial nerve (extension of the thumb), median nerve (flexion of the proximal interphalangeal joint of the thumb), and ulnar nerve (scissoring of the fingers) (Video: Finger Examination). This can functionally check the nerves before injection of local anesthetic solution.<sup>376</sup>

**INFRACLAVICULAR APPROACH.** This approach to the brachial plexus is very helpful, particularly in children who may have fractures making it painful to abduct the arm. A vertical approach to the infraclavicular brachial plexus is performed using the coracoid process as a landmark to access the nerve.<sup>377</sup> We routinely use this technique in children who require continuous infusions of local anesthetic solution in the postoperative period.

**TECHNIQUE.** With the arm in abduction or adduction, the acromial process is palpated. A line drawn 2 cm below and medial to the coracoid process is usually where the needle is introduced (Fig. 41-20, A). At this level, the pleura is not usually affected. A sheathed needle with a nerve stimulator is introduced, and the nerve is stimulated at about 1 mA. Any stimulation other than forearm flexion is taken as a positive stimulation of the brachial plexus. Forearm flexion denotes stimulation of the musculocutaneous nerve. The needle should then be directed medial to provide a blockade of the cords of the brachial plexus (see Fig. 41-20, B). An ultrasound-guided technique may also be used (see also Chapter 42 and Figs. 42-17 to 42-19).

**COMPLICATIONS.** There is the potential for intrapleural injection and pneumothorax, especially if the needle is directed medially. Because of the proximity of the plexus to the subclavian vein and artery, it is imperative that the procedure not be attempted on children who have coagulation abnormalities.

**SUPRACLAVICULAR APPROACH.** This is an easy approach to the brachial plexus in children and can be readily performed, particularly with the aid of ultrasound guidance. The risk with

A

B

**FIGURE 41-20** **A**, Anatomic landmarks for the infraclavicular approach to the brachial plexus. Note that the arm is in an abducted position, which may be quite useful for children with fractures. **B**, The coracoid process is palpated. With the arm abducted, a needle is inserted 2 cm medial and inferior to the coracoid process. A nerve stimulator is used and stimulation is initiated at 1 mA and then decreased to 0.4 mA as the nerve is accessed. Elicitation of hand flexion or extension is used as an indicator of being close to the nerve. After aspiration, 0.2 mL/kg of local anesthetic solution is injected. Use of ultrasound may also improve the success of this block. *a*, Artery; *m*, muscle. (Modified from Wilson JL, Brown DL, Wong GY, et al. Infraclavicular brachial plexus block: parasagittal anatomy important to the coracoid technique. *Anesth Analg* 1998;87:870-3.)

performing this procedure without ultrasound guidance is the potential for injection into the vertebral artery. It can be used for most procedures performed on the upper arm and forearm. The cervical pleura is also located close to the supraclavicular plexus; thus caution should be exercised while performing this block. The entire brachial plexus, including the musculocutaneous and the axillary nerves, is located lateral to the artery. Occasionally, the suprascapular nerve may leave the upper trunk more cranially.

**INDICATIONS.** This block is used for analgesia or anesthesia for upper arm surgery and can be performed with either a single injection or catheter technique.

**TECHNIQUE.** The supraclavicular plexus is located above the clavicle and is located superficially approximately at the middle

of the sternocleidomastoid. A stimulating needle (1 mA) is passed above the clavicle lateral to the arterial pulsation and close to the inferior margin of the anterior scalene. The plexus is located superficially and can be easily stimulated as soon as the skin is pierced. Any movement of the child's fingers or arm is accepted as an adequate stimulation to the plexus. The energy is reduced to 0.4 mA and, if continued response to the stimulation is observed, 0.15 to 0.2 mL/kg of local anesthetic solution is injected in graduated doses after careful aspiration.

*The ultrasound-guided technique* is now our preferred method for blocking the supraclavicular plexus. We use a linear probe or a hockey stick probe and, using the in-plane technique, pass the needle close to the plexus. If a stimulating needle is used, the needle is advanced until we see movement of the hand. We have been able to decrease the dose of local anesthetic solution to 0.15 to 0.2 mL/kg (Fig. 41-21 and Video: Ultrasound-Guided Supraclavicular Block; see also Fig. 42-16).

**COMPLICATIONS.** Pleural puncture and intravascular injection can occur from misplacement of the needle.

**INTERSCALENE APPROACH.** This approach is not commonly used in children. The main indication for this technique is for children undergoing shoulder surgery; this approach is generally reserved for the older teenager or young adult.

**ANATOMY.** The interscalene groove is formed by the anterior and middle scalene muscles and is located in most children at the lateral border of the sternocleidomastoid muscle (see Fig. 41-21, *A*). The upper three nerve roots are superficial, whereas the lower two roots are in a deeper position. In children the lower nerve roots are close to the pleura, which may increase the potential for a pneumothorax. The phrenic nerve is also close to the nerve roots and may often be unintentionally blocked on the side of the intended nerve block. Therefore this block is clearly avoided in children who may have a compromised pulmonary system. The vertebral artery is located in close proximity to the lower nerve roots (C7) and hence it is important to aspirate and ensure that the needle is not in a vessel.

**INDICATIONS.** Shoulder and upper arm surgery and ensuing postoperative analgesia can be provided with this block.

*Conventional Techniques.* Dalens and associates reported a technique of parascapular brachial plexus blockade for pediatric shoulder surgery using an extended head position and placing the puncture between the lower and middle thirds of the line extending from the center of the clavicle to the C6 transverse process (Chassaignac; see Fig. 41-21, *A*).<sup>378</sup> The rationale for selecting this puncture site was to avoid the vertebral artery and pleura. With the use of a perpendicular needle orientation, the lower roots (C8 and T1) are not blocked at all or require very large amounts of local anesthetic to be successfully blocked. Ultrasound guidance is greatly advantageous in this situation because it paves the way for safe blockade of both roots (C8 and T1). With the use of a nerve stimulator, diaphragmatic stimulation may be observed as a result of ventromedial needle position (the phrenic nerve runs ventral to the body of the anterior scalene muscle).

*Ultrasound-Guided Technique* (see Chapter 42). To visualize the anatomic structures of a child's neck, a high-frequency linear ultrasound probe is used. The process is facilitated by slightly turning the child's head to the contralateral side. The probe should be oriented from the medial to the lateral aspect. Medially, the thyroid gland and the major vessels in the neck area (carotid artery and internal jugular vein) are easily identified. Then the probe is moved along the sternocleidomastoid muscle

C

**FIGURE 41-21** A right-sided supraclavicular block (landmark technique): The supraclavicular block is used frequently in children for most procedures on the hand and elbow. **A**, The divisions and cords are located around the carotid artery cephalad to the clavicle at the inferior margins of the scalene muscles. **B**, A stimulating needle, using 0.5 mA of energy, is introduced at the inferior border of the anterior scalene muscle. Any movement of the patient's fingers (including flexion or extension) suggests adequate positioning of the needle. After aspiration to avoid intravascular injection, 0.15 mL/kg of local anesthetic solution is injected. **C**, Supraclavicular block with ultrasound guidance. A linear ultrasound probe or a hockey stick probe is placed lateral to the suprasternal notch and above the clavicle. The carotid artery is identified. The supraclavicular plexus is located around the carotid artery at this location like a "bunch of grapes." A needle is placed in an in-plane approach (along the axis of the probe), and the plexus is penetrated. Injection of local anesthetic solution will be seen as a hypoechoic spread around the plexus.

until its lateral border is reached. At the same time, the transducer is moved in a caudal direction such that the posterior scalene gap and the upper anterior roots (C5-7) of the brachial plexus become visible between the anterior and medial scalene muscles. In very small children, all roots of the brachial plexus (C5-T1) can be simultaneously visualized. The puncture is performed in a tangential direction relative to the neck above the transducer. The C5 nerve root will be encountered superficially, within a few millimeters. As a rule, the needle should be oriented lateral to the C7 root, which will ensure that the neck vessels remain at an adequate distance from the needle insertion site. As soon as the local anesthetic has been injected, it will spread toward the C5 root, which can be visualized in the ultrasound image. Depending on the blockade required, the needle can be advanced to a deeper level for injection after the deep roots (C8 and T1) have been visualized. If the local anesthetic fails to spread adequately in a medial direction, the needle is retracted toward the subcutaneous level and is then repositioned on the medial side of the posterior scalene gap in the area of the C7 root. In the majority of cases, however, the local anesthetic will spread in an adequate manner even when the needle is in a lateral position. The injected volume of local anesthetic should not exceed the amount necessary to fully cover the root surfaces. It is, therefore, inappropriate to recommend a specific volume. In general, however, complete blockade via the interscalene route can be expected with local anesthetic volumes of 0.15 to 0.25 mL/kg.

**COMPLICATIONS.** Pneumothorax, intravascular injection, and temporary phrenic nerve injury are risks of this block.

### ***Intravenous Regional Anesthesia***

IV regional anesthesia was first described in 1908 by August Bier and is frequently referred to as the Bier block.<sup>379</sup> This technique has been advocated for upper extremity procedures lasting 30 to 60 minutes in children because of its rapid onset of anesthesia and its ease of performance.<sup>380-382</sup> *Only dilute lidocaine (0.25% or 0.5%) can be used because of the risk of local-anesthetic toxicity.* This can be a useful block for upper extremity fracture reduction or suture of a large laceration in children with a full stomach. It is also helpful for chronic painful conditions, including complex regional pain syndrome type 1, in children and adolescents.<sup>383</sup> The exsanguination and manipulation of the limb before administering the local anesthetic may prove to be unduly painful for children with a fracture, and many children may not tolerate the discomfort of the tourniquet without significant sedation. Another disadvantage is the possibility of toxic reactions in the event of tourniquet failure. Strict attention to detail—elevation or exsanguination of the extremity to be blocked, proper application of a double pneumatic cuff, careful attention to anesthetic dose, and care not to deflate the tourniquet until 30 minutes after injection of the local anesthetic—is important to avoid serious complications and provide a successful block. This block is unsuitable for children younger than 1 year of age because of the risk of toxic reactions in infants. This technique may also be contraindicated for children in whom the prolonged use of a tourniquet is inadvisable.

**TECHNIQUE.** A small-gauge IV cannula is inserted in a vein on the dorsum of the hand. Exsanguination of the arm may be accomplished either by wrapping the limb with an Esmarch bandage, or by elevation of the limb if wrapping is too painful. The proximal compartment of a double tourniquet is inflated to a pressure of 200 to 250 mm Hg, although some have

recommended that it be inflated to 150 mm Hg above the child's systolic blood pressure. If tourniquet pain develops during the course of the procedure, the distal cuff may be inflated, followed by deflation of the proximal cuff. The tourniquet must remain inflated for a minimum of 30 minutes to prevent a rapid IV infusion of lidocaine. It is best to deflate the tourniquet incrementally. Because no residual blockade persists after the tourniquet is released, supplementary analgesia must be considered (e.g., IV opioids, local infiltration with a long-acting local anesthetic).

**SELECTION OF DRUG.** Only *preservative-free* 0.25 to 0.5% lidocaine without epinephrine (1 mL/kg) should be used for this block because the duration of the block is limited by tourniquet time and because of the potential for cardiac toxicity with longer-acting agents. A very low dose of a nondepolarizing neuromuscular blocking agent, such as rocuronium (0.03 mg/kg), may improve the quality of the motor blockade.<sup>384-386</sup>

**COMPLICATIONS.** Unintended deflation of the tourniquet results in release of drug into the intravascular compartment; hence, only a short-acting local anesthetic, such as lidocaine, should be used. *Bupivacaine should never be used for this block because of the risk of cardiotoxicity.*

### ***Peripheral Blocks at the Elbow***

There is usually no great advantage to blocking the peripheral nerves at the elbow compared with blocking them at the wrist for analgesia or anesthesia of the hand because the forearm is supplied by cutaneous branches that originate in the upper arm. However, on some occasions (e.g., to avoid injections into surgical fields or areas of infection), anesthesia of the hand may be achieved by blocking the appropriate nerves at the elbow because the cutaneous nerve supply to the hand arises at the elbow.

### ***Radial Nerve***

**ANATOMY.** The radial nerve supplies the radial side of the dorsum of the hand and the proximal parts of the radial three-and-a-half digits. Block at the elbow is useful for the provision of anesthesia for an arteriovenous fistula. It is also useful to supplement an inadequate brachial plexus block at the axillary level. The radial nerve passes over the anterior aspect of the lateral epicondyle (Fig. 41-22, A).

**TECHNIQUE.** The intercondylar line is marked. After identification of the biceps tendon, a 27-gauge needle is inserted directly toward the bone of the lateral epicondyle toward the lateral margin; 2.0 to 5.0 mL (depending on the child's weight) of bupivacaine (0.25% with epinephrine 1:200,000) is injected into the area (see Fig. 41-22, B). Ultrasound guidance can help with determination of exact location of the nerve in the forearm (see Chapter 42 and Fig. 42-25).

**COMPLICATIONS.** Intravascular injection and intraneural injections are potential complications. The use of a nerve stimulator or ultrasound can reduce unintended intraneural injection. Intravascular injection may be avoided with incremental injection and frequent aspiration.

### ***Median Nerve***

**ANATOMY.** This nerve supplies the radial side of the palm and the three-and-a-half digits of the palmar aspect (see Fig. 41-22, A). It accompanies the brachial artery in its course down the arm. It is initially lateral and then crosses the ventral side of the artery and eventually lies medial to the artery at the bend of the elbow.

**FIGURE 41-22** **A**, Anatomic relationship of the nerves around the elbow. **B**, Radial nerve block: the intercondylar line is marked. After identification of the biceps tendon, a 27-gauge needle is inserted directly toward the bone of the lateral epicondyle toward the lateral margin; 2.0 to 5.0 mL (depending on the patient's weight) of bupivacaine (0.25% with epinephrine 1:200,000) is injected into the area. To block the median nerve, the brachial artery is palpated at the elbow crease. The median nerve is located immediately medial to the brachial artery. A nerve stimulator is used, and flexion of the patient's fingers denotes adequate localization of the nerve.

It is deep to the bicipital fascia and superficial to the brachialis muscle.

**TECHNIQUE.** The arm is abducted and the forearm supinated. After marking the intercondylar line between the medial and the lateral epicondyle of the humerus, the brachial artery is palpated (see Fig. 41-22, *A*). A 27-gauge needle is inserted just medial to the artery and directed perpendicular to the skin; 2.0 to 5.0 mL (depending on the child's weight) of bupivacaine (0.25% with epinephrine 1:200,000) is injected to the site. Caution must be exercised to avoid the artery because it is in close proximity to the nerve. Surface mapping employing a nerve stimulator probe generating 5 mA or greater can be used to locate the nerve in the forearm if there is difficulty in palpating the artery (see Fig. 41-22, *A*).<sup>387</sup> An ultrasound-guided technique may also be used for this block (see Chapter 42 and Fig. 42-23).

**COMPLICATIONS.** Intravascular injection and intraneural injections are potential complications. The use of a nerve stimulator can prevent the unintended intraneural injection. Intravascular injection may be avoided with incremental injection and frequent aspiration.

### *Ulnar Nerve*

**ANATOMY.** The ulnar nerve is the superficial nerve to the arm and the ulnar side of the forearm and the hand. It is the terminal continuation of the medial cord of the brachial plexus. At the elbow, it pierces the medial intermuscular septum and follows along the medial head of the triceps to the groove between the olecranon and the medial epicondyle of the humerus. It is covered only by skin and fascia and can be easily palpated and blocked at this level (see Figs. 41-22, *A*, and 41-23; see also Fig. 42-24).

**TECHNIQUE.** With the child supine, the elbow is flexed. The medial epicondyle and the ulnar groove are palpated (see Fig. 41-23). A 27-gauge needle is advanced perpendicular to the skin along the line of the nerve; 2.0 to 3.0 mL (depending on

**FIGURE 41-23** Ulnar nerve block at the elbow. The olecranon process is palpated. The ulnar nerve is located in the olecranon groove; after aspiration, 1 to 3 mL of local anesthetic solution is injected. It is important not to deposit the local anesthetic deep into the olecranon groove because the nerve is superficial and can be easily blocked by a subcutaneous injection.

the child's weight) of bupivacaine (0.25% with epinephrine 1:200,000) is injected in the area. An ultrasound-guided technique may also be used for this block (see Chapter 42 and Fig. 42-24).

**COMPLICATIONS.** Intravascular injection and intraneural injections are potential complications. Because this is a very superficial nerve, injection just after the skin is pierced in the area of the ulnar nerve usually produces a good block. Intravascular injection may be avoided with incremental injection and frequent aspiration.

### Wrist Blocks

Blocking the median, radial, and ulnar nerves at the wrist can be easily achieved. These blocks provide very good analgesia and, because they are easy to perform, they generally have a predictable successful outcome.

### Radial Nerve

The cutaneous branches of the radial nerve supply the radial side of the dorsum of the hand and the proximal parts of the radial three-and-a-half digits.

**ANATOMY.** The superficial branch of the radial nerve runs along the lateral border of the forearm under the brachioradialis muscle. In the distal third of the forearm it angles dorsally under the tendon of the brachioradialis toward the dorsum of the wrist. It pierces the deep fascia and divides into two branches: (1) the lateral branch supplies the radial side and the tip of the thumb and (2) the medial branch communicates with the dorsal branch of the ulnar nerve. This then divides into the four digital nerves that supply the ulnar side of the thumb, the radial side of the index finger, and the space between the index finger and thumb. A communicating branch with the ulnar nerve supplies the adjacent sides of the middle and ring finger (Fig. 41-24, *A*).

**TECHNIQUE.** This is essentially a field block of the superficial terminal branches. An attempt to make the "anatomic snuffbox" prominent by extension of the thumb before anesthesia is desirable. The extensor pollicis and brevis tendons are marked. A 27-gauge needle is inserted close to the dorsal radial tubercle over the extensor longus tendon, and 2.0 mL of bupivacaine (0.25% with epinephrine 1:200,000) is injected SC. An attempt to fan the local anesthetic in the anatomic snuffbox helps to distribute the local anesthetic over the radial nerve (see Fig. 41-24, *B*).

**COMPLICATIONS.** Intravascular injection may be avoided with incremental injection and frequent aspiration. Post-nerve block dysesthesia may be occasionally experienced with a radial nerve block and is usually self-limited.

### Median Nerve

**ANATOMY.** In the palm of the hand, the median nerve is very superficial and is covered only by skin and the palmar aponeurosis and rests on the tendons of the flexor muscles. It emerges from under the retinaculum and splits into muscular and digital branches. The muscular division of the median nerve supplies the muscles of the thenar eminence. The palmar digital nerve supplies the thumb, index finger, middle finger, and ring finger. These nerves also supply the lumbricals (Fig. 41-25, *A*).

**TECHNIQUE.** The palmaris tendon is identified. This may be done before general anesthesia by asking the child to flex the wrist against resistance. The radial border of the tendon is identified. Cutaneous landmarks include both distal wrist skin creases. A 27-gauge needle is inserted at the level of the second skin crease

**A** Extensor pollicis brevis

**FIGURE 41-24** Wrist block: radial nerve. **A**, This is a superficial block of the terminal branches of the radial nerve. An attempt to make the "anatomic snuffbox" prominent by extension of the thumb before anesthesia is desirable. The extensor pollicis and brevis tendons are marked. **B**, A 27-gauge needle is inserted close to the dorsal radial tubercle over the extensor longus tendon; bupivacaine (2 mL, 0.25% with 1:200,000 epinephrine) is injected subcutaneously. Fanning the local anesthetic in the anatomic snuffbox helps to distribute the local anesthetic over the radial nerve. (Modified from Raj P, Pai U. Techniques of nerve blocking. In: Raj P, editor. Handbook of regional anesthesia. New York: Churchill Livingstone; 1985, p. 185.)

(1 to 1.5 cm proximal to the distal crease in teenagers) perpendicular to the skin. The nerve is at a depth of less than 1 cm in the teenager and less in younger children; 1.0 to 2.0 mL of bupivacaine (0.25% with epinephrine 1:200,000) is injected in the area (see Fig. 41-25, *B*). If the child is awake, it is better to elicit paresthesias because the needle may be anterior to the neurovascular bundle and the nerve could be missed altogether.

**COMPLICATIONS.** Intravascular placement should be avoided by repeated aspiration before injection.

### Ulnar Nerve

**ANATOMY.** The palmar cutaneous branch of the ulnar nerve arises near the middle of the forearm and accompanies the ulnar artery into the hand (see Fig. 41-25, *A*). It then perforates the flexor retinaculum and ends in the skin of the palm

**FIGURE 41-25** Wrist block: median and ulnar nerves. **A**, Median nerve: identify the palmaris tendon by asking the child to flex the wrist against resistance. Distal skin creases are identified. **B**, A 27-gauge needle is inserted at the level of the distal skin crease perpendicular to the skin. The nerve is at a depth of less than 1 cm in teenagers and less than that in younger children; 1.0 to 2.0 mL of bupivacaine (0.25% with 1:200,000 epinephrine) is injected in the area. If the child is awake, it is better to elicit paresthesias because the needle may be anterior to the neurovascular bundle, which can be missed altogether. Ulnar nerve: identify the flexor carpi ulnaris tendon, which lies proximal to the pisiform bone. A 27-gauge needle is inserted just proximal to the pisiform bone and directed radially a distance of approximately 0.5 cm. Bupivacaine (2 mL, 0.25% with epinephrine 1:200,000) is injected. (Modified from Raj P, Pai U. Techniques of nerve blocking. In: Raj P, editor. Handbook of regional anesthesia. New York: Churchill Livingstone; 1985, p. 185.)

communicating with the palmar branch of the median nerve. There are two dorsal digital nerves and a metacarpal communicating branch. The more medial digital nerve supplies the ulnar side of the little finger and the digital branch supplies the adjacent sides of the little and ring finger. The palmar or the terminal portion of the ulnar nerve crosses the ulnar border of the wrist in company with the ulnar artery.

**TECHNIQUE.** Blocking the ulnar nerve at the wrist is easier than at the elbow. The nerve is blocked at the wrist where it lies under cover of the flexor carpi ulnaris tendon just proximal to the pisiform bone. The best way to access the nerve is to approach it from the ulnar side of the tendon. A 27-gauge needle is inserted just proximal to the pisiform bone and directed radially a distance of approximately 0.5 cm; 2.0 to 3.0 mL of bupivacaine (0.25% with epinephrine 1:200,000) is injected (see Fig. 41-25, *A*).

**COMPLICATIONS.** The ulnar artery runs in close proximity to the ulnar nerve; every possible effort should be made to avoid intravascular placement. Intravascular injection may be avoided with incremental injection with frequent aspiration.

#### *Digital Nerve Blocks: Hand*

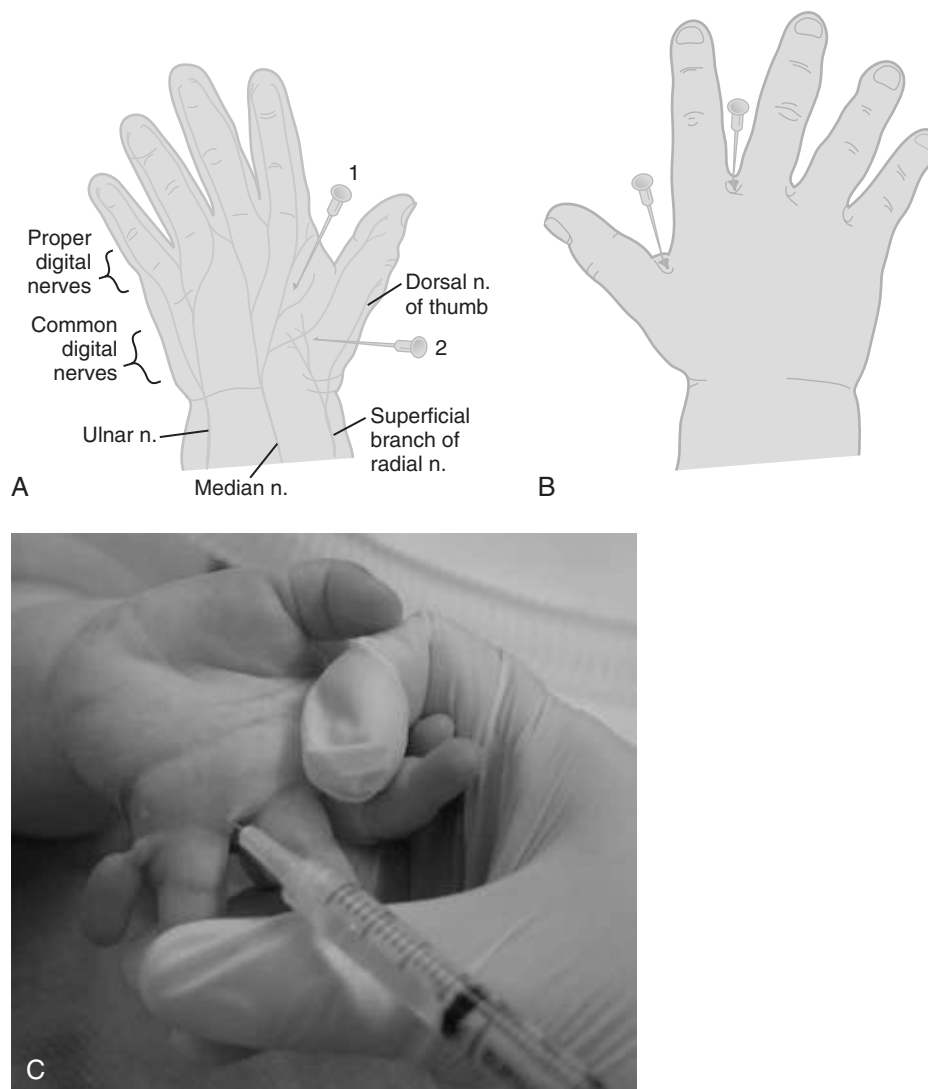

Digital nerve blocks are useful for providing pain relief to children who are undergoing procedures to individual fingers. These are useful for postoperative analgesia in procedures, such as trigger finger release, and also for the provision of pain relief in children undergoing laser therapy for warts on their fingers.<sup>388</sup>

**ANATOMY.** The common digital nerves are derived from the median and ulnar nerves and divide in the palm to volar digital nerves that supply the fingers. All digital nerves are usually accompanied by digital vessels. There are three digital nerves derived from the median nerve: the first divides into three palmar digital nerves that supply the sides of the thumb; the second common digital nerve supplies the web between the index and middle finger; and the third common palmar digital nerve communicates with a branch of the ulnar nerve and supplies the web space between the middle and ring fingers. These common digital nerves then become the proper digital nerves (digital collaterals) that supply the skin of the palmar surface and the dorsal side of the terminal phalanx of their respective digits. All digital nerves ultimately terminate in two branches: one ramifies in the skin of the fingertips and the other ends in the pulp under the nail. Smaller digital nerves are derived from the radial and ulnar nerves and supply the back of the fingers. These tend to lie on the dorsolateral aspect of the finger. There are four dorsal digital nerves: (1) ulnar side of the thumb; (2) radial side of the index finger; (3) adjacent sides of index and middle fingers; and (4) communication to the adjacent sides of middle and ring finger.

**TECHNIQUE.** There are two techniques for blockade of the digital nerves.

For blockade at the base of the thumb (Fig. 41-26, *A* and *B*), with the thumb extended, on the palmar surface of the hand, a 27-gauge needle is inserted into the web space between the index finger and thumb. The needle is advanced to the junction of the web space and the palmar skin of the hand, a distance of about 1 cm; 0.5 mL of bupivacaine *without epinephrine* is injected. A second needle is inserted into the thenar eminence on the radial aspect of the thumb; 1.0 mL of bupivacaine *without epinephrine* is injected. Caution has to be exercised if the child has collagen vascular disease, because this may precipitate acute vascular spasm that may not be relieved.

Blockade of the other fingers is accomplished at the bifurcation between the metacarpal heads (see Fig. 41-26, *B* and *C*). With the fingers extended, a 27-gauge needle is inserted into the web about 3 mm proximal to the junction between the web and the palmar skin; 1.0 to 2.0 mL of bupivacaine *without epinephrine* is injected. This can be performed either from a dorsal approach or a volar approach.

**FIGURE 41-26** Digital nerve blocks. **A**, Blockade of the thumb: with the thumb extended, on the palmar surface of the hand, a 27-gauge needle is inserted into the web space between the index finger and thumb (1). The needle is advanced to the junction of the web space and the palmar skin of the hand a distance of about 1 cm; bupivacaine (0.5 mL, *without epinephrine*) is injected. A second needle is inserted into the thenar eminence on the radial aspect of the thumb, and 1.0 mL of bupivacaine *without epinephrine* is injected (2). Caution has to be exercised if the patient has collagen vascular disease because this may precipitate acute vascular spasm that may not be relieved. **B**, Blockade of other digits: blockade of the other fingers is accomplished at the bifurcation between the metacarpal heads. With the fingers widely extended, a 27-gauge needle is inserted into the web about 3 mm proximal to the junction between the web and the palmar skin; bupivacaine (1.0 to 2.0 mL, *without epinephrine*) is injected. **C**, This can be performed either from a dorsal approach or a volar approach. The web on either side will have to be blocked to provide analgesia for each finger to be anesthetized. *n*, Nerve.

**Caution:** Vasoconstrictors are avoided when blocking digital nerves because these are end vessels and acute vasospasm caused by epinephrine can lead to permanent damage or necrosis of the digits.

**COMPLICATIONS.** Large volumes of local anesthetic are contraindicated because of the possibility of pressure and vascular compromise. Vasoconstrictors should be avoided because they may cause necrosis of the digit. Intravascular injection may be avoided with incremental injection and frequent aspiration.

### Lower Extremity Blocks

The major use of nerve blocks of the lower extremity in children is for managing postoperative pain and as an adjunct to general anesthesia. When considering the sensory and cutaneous innervation of the lower extremity (Fig. 41-27), it is not surprising that

few surgical procedures can be accomplished under single nerve blocks. However, combinations of sciatic, femoral, and lateral femoral cutaneous blockade can provide both excellent postoperative analgesia and surgical anesthesia for selected operations; the fascia iliaca block produces anesthesia of multiple nerves with a single injection.

### Sciatic Nerve Block

**ANATOMY.** The sciatic nerve arises from the L4 through S3 roots of the sacral plexus, passes through the pelvis, and becomes superficial at the lower margin of the gluteus maximus muscle. It then descends into the lower extremity in the posterior aspect of the thigh, supplying sensory innervation to the posterior thigh, as well as to the entire leg and foot below the level of the knee, except for the medial aspect, which is supplied by the femoral

**FIGURE 41-27** The sensory innervation of the lower extremity is presented. Note that anesthesia of the lower extremity requires block of the femoral nerve (**A**) (and its branches), as well as the sciatic nerve (**B**). *n*, Nerve.

nerve (see Fig. 41-27, *A*). Although a sciatic nerve block alone is useful for few surgical procedures, it can be combined with a femoral nerve block (see Fig. 41-32; cited early) for operations below the knee and for postoperative pain relief. There are multiple approaches to the sciatic nerve.<sup>389</sup> All blocks are performed with the aid of a nerve stimulator to elicit a motor paresthesia in the foot, and, if the block is performed in a lightly sedated trauma victim, the approach that places the child in a greater position of comfort should be chosen. Ultrasound guidance improves the performance of the nerve block (see Chapter 42). A newer approach to the sciatic nerve using a lateral approach to the popliteal fossa has been described. This offers the additional advantage of being able to provide the block in the supine position. An infragluteal-parabiceps approach is another easy method of providing a sciatic nerve block in children.<sup>390</sup>

**APPROACH OF LABAT (POSTERIOR APPROACH).** The child is placed in the lateral decubitus position lying on the nonoperative leg. The leg to be blocked is flexed and the lower leg is extended (Fig. 41-28, *A*). A line is drawn from the posterior superior iliac spine to the greater trochanter of the femur. Another line is drawn from the greater trochanter to the coccyx. The first line is bisected, and a perpendicular line is drawn from that point to the second line; the point at which it intersects the second line is the site of needle insertion (see Fig. 41-28, *B*). A 22-gauge insulated needle is advanced in the perpendicular plane until it strikes bone. It is possible for the needle to pass through the sciatic notch without either encountering bone or causing a paresthesia. In that case, the needle is redirected in a cephalad direction until bone is encountered. A motor paresthesia is then sought using an organized grid-like approach, fanning medially to laterally.

**ANTERIOR APPROACH.** As the sciatic nerve emerges from the lower border of the gluteus maximus to extend down the thigh, it passes medial and deep to the lesser trochanter of the femur (Fig. 41-29, *A*; see also Figs. 42-31 and 42-32).

With the child in the supine position, a line is drawn from the anterior superior iliac spine to the pubic tuberosity. The greater trochanter is then located, and another line is drawn

parallel to the first line (see Fig. 41-29, *B*); at the medial one-third of the first line, a perpendicular is dropped to the second line. The point of intersection with the line originating at the greater trochanter marks the point of needle entry. The needle is inserted in a perpendicular plane until bone is encountered. It is then partially withdrawn and redirected medially. When the needle is posterior to the medial margin of the femur, ease of injection is determined after negative aspiration for blood. This approach carries a greater risk of unintended puncture of the femoral vessels, and repeated negative aspirations must precede incremental injection. If the needle is in muscle or a fascial bundle, resistance to injection will be felt. In this case, the needle is advanced until minimal resistance to injection is felt. Motor paresthesia is a helpful indicator.

For the previous two techniques, a dose of 0.2 mL/kg of bupivacaine (0.25% with epinephrine 1:200,000) is the dose usually administered for children older than 6 months of age. If the sciatic nerve block is used in conjunction with a femoral nerve block, consideration should be given to diluting the local anesthetic concentration further to limit the injected dose to 2.5 mg/kg of bupivacaine.<sup>391</sup>

#### **Lateral Popliteal Sciatic Nerve Block**

This approach to the sciatic nerve can be performed with the child in the supine position.<sup>392</sup> This block provides postoperative analgesia in children undergoing surgery to the foot and knee, such as clubfoot repair or triple arthrodesis, and in children having knee surgery, particularly when combined with a femoral nerve block.<sup>393</sup> It has the advantage of preserving hamstring function and allows early ambulation with crutches.

**ANATOMY.** The popliteal fossa is a diamond-shaped area located behind the knee. It is bordered by the biceps femoris laterally, medially by the tendons of the semitendinosus and semimembranosus muscles, and inferiorly by the heads of the gastrocnemius muscle. The sciatic nerve, after its formation from L4 through S5, innervates all areas of the leg and foot below the knee except the anteromedial cutaneous areas of the leg and foot, which are supplied by the femoral nerve. The sciatic nerve divides

**FIGURE 41-28 A**, Sciatic nerve block (approach of Labat). The patient is placed in a lateral position with the lower leg extended and the upper leg, the one to be blocked, flexed; a line is drawn from the greater trochanter of the femur to the posterior superior iliac spine (*line 1*). A second line is drawn from the greater trochanter to the coccyx (*line 2*). Line 1 is bisected, and a perpendicular line is drawn from that point to line 2 (*black line 3*); the point at which the perpendicular broken line intersects line 2 (*circle with dot*) is the point of needle insertion. **B**, A 22-gauge needle is advanced perpendicular to the skin until it strikes bone or, if the child is awake, a paresthesia is elicited. Use of a nerve stimulator will produce either plantar flexion or dorsiflexion of the foot.

into two branches, the larger tibial nerve located medially and the common peroneal nerve located laterally. The nerves are together at the apex of the popliteal fossa where they are in close proximity to each other and are enclosed in a connective tissue sheath for a few more centimeters before dividing into the component nerves (Fig. 41-30, *A*).

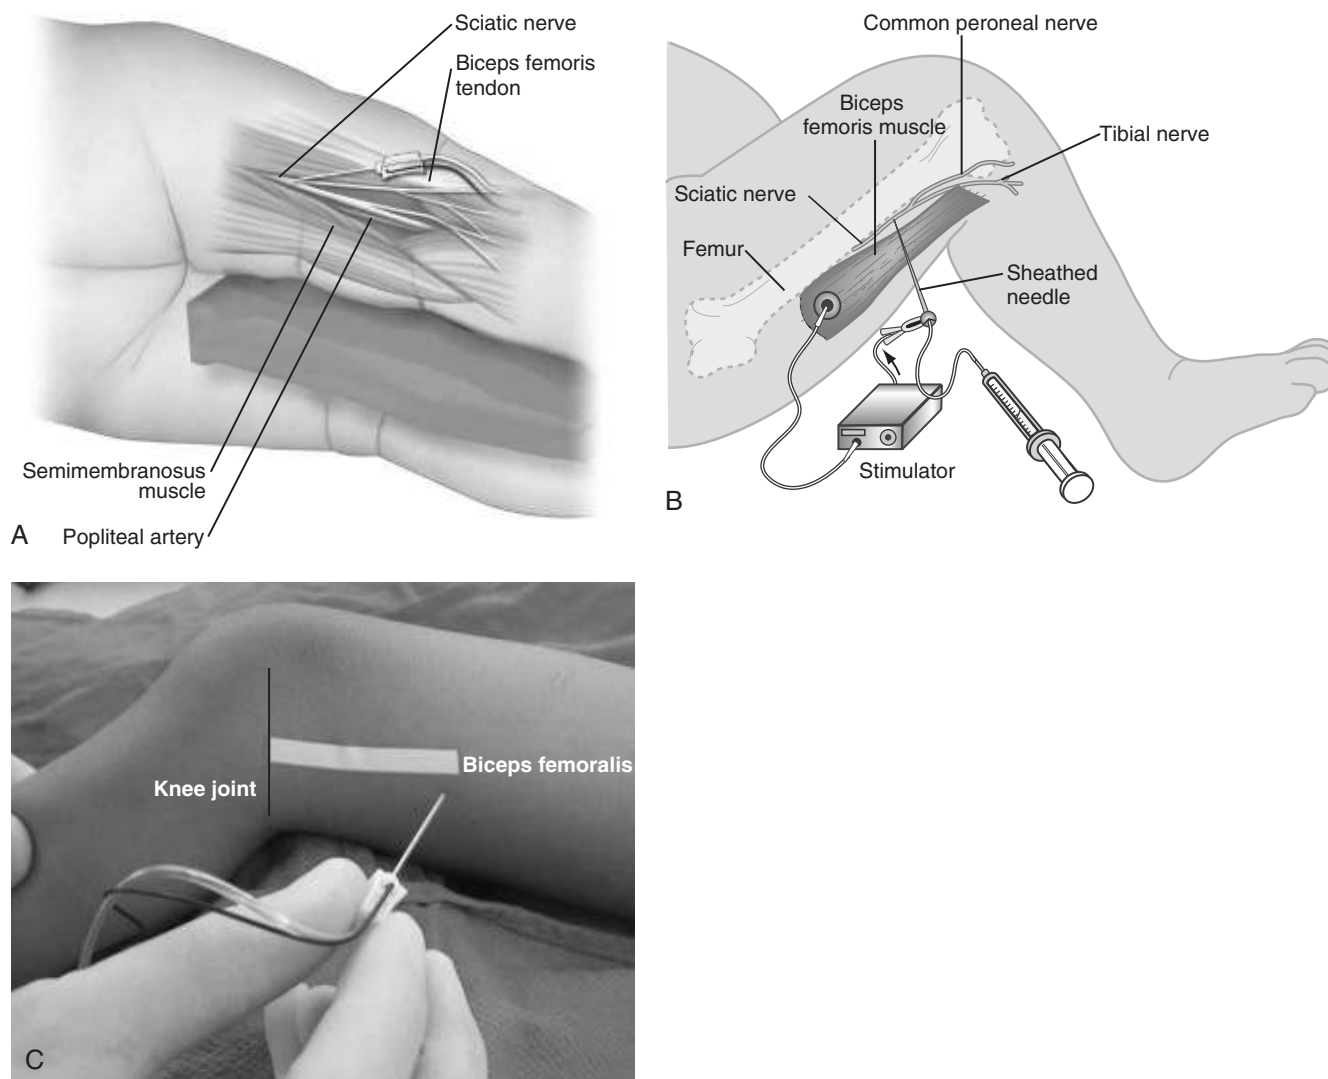

**TECHNIQUE.** After induction of general anesthesia, the lower leg is elevated on a pillow. The biceps femoris tendon is palpated. The tendon is then traced upward for 3 to 5 cm. A 22-gauge insulated needle is inserted anterior to the tendon in a horizontal plane with a cephalad angulation (see Fig. 41-30, *B*). A nerve stimulator is attached to the sheathed needle and with low voltage stimulation (0.2 to 0.5 mV), the foot is observed for

**FIGURE 41-29 A**, Sciatic nerve block (anterior approach). With the patient supine, a line is drawn from the anterior iliac spine to the pubic tuberosity (*line 1*). The greater trochanter is located, and another line is drawn parallel to the first (*line 2*). A perpendicular line is drawn from line 1 at a point one third the distance laterally from the pubic tuberosity to the anterior iliac spine (*solid line 3*). **B**, Left sciatic nerve block. A needle is inserted at the intersection of line 2 and the perpendicular line (in **A**, *solid dot*) until bone is encountered. The needle is redirected off the edge of the femur to the approximate posterior margin of the femur and, after negative aspiration for blood, ease of injection is ascertained. Resistance to injection indicates that the needle is within muscle or fascial bundle; the needle should be advanced until there is minimal resistance to injection or until a paresthesia is elicited.

plantar flexion or dorsiflexion. On injection of a test dose of 1 mL bupivacaine (0.25% with epinephrine 1:200,000), the twitching is abolished. This confirms the correct placement of the needle (see Fig. 41-30, *C*); 5 to 10 mL of additional local anesthetic is then injected (Video: Ultrasound-Guided Popliteal Nerve Block). In adult studies, it has been shown that the sciatic nerve block is longer lasting than an ankle block or subcutaneous infiltration, and it provides excellent postoperative analgesia.<sup>392</sup> Continuous catheter techniques can be used to provide effective analgesia in children in the postoperative period.<sup>394</sup> An ultrasound-guided technique may also be used (see Chapter 42 and Figs. 42-33 and 42-34).

**COMPLICATIONS.** Intraneural injection must be avoided. Using a low-voltage nerve stimulator ensures the proper placement of the needle. It is rare to see intravascular placement of

**FIGURE 41-30** Lateral popliteal sciatic nerve block. **A**, Anatomy for lateral popliteal approach to the sciatic nerve. The lower leg is elevated on a pillow and the biceps femoris tendon is palpated. The tendon is traced proximally for 3 to 5 cm. **B**, A 22-gauge insulated needle is inserted anterior to the tendon in a horizontal plane with a cephalad angulation. A nerve stimulator is attached to the needle and with low voltage stimulation (0.2 to 0.5 mV), the foot is observed for plantar flexion or dorsiflexion. With injection of the test dose of 1.0 mL of bupivacaine (0.25% with 1:200,000 epinephrine), the twitching is abolished. This confirms the correct placement of the needle. **C**, Then 5 to 10 mL of additional local anesthetic is injected.

the needle with this approach. Intravascular injection may be avoided with incremental injection and frequent aspiration.

#### *Infragluteal-Parabiceps Approach*

This approach is a simple way to access the sciatic nerve.<sup>390</sup> It offers an advantage over the popliteal fossa technique because the posterior cutaneous nerve supplying the posterior portion of the thigh can be blocked with this approach.

**TECHNIQUE.** The child is placed in the supine position or a lateral position to perform this block. The biceps femoris tendon is palpated and traced cephalad to the distal crease of the buttocks (Fig. 41-31, *A*). A stimulating needle is then inserted perpendicular to the femoral shaft, along the biceps femoris tendon (parabiceps) until a twitch is obtained (see Fig. 41-31, *B*). Either inversion or eversion of the foot is a reasonable response for localization of the nerve. Next, 0.2 mL/kg of local anesthetic solution is injected into the area (Video: Subgluteal Sciatic Ultrasound Nerve Block). An ultrasound-guided

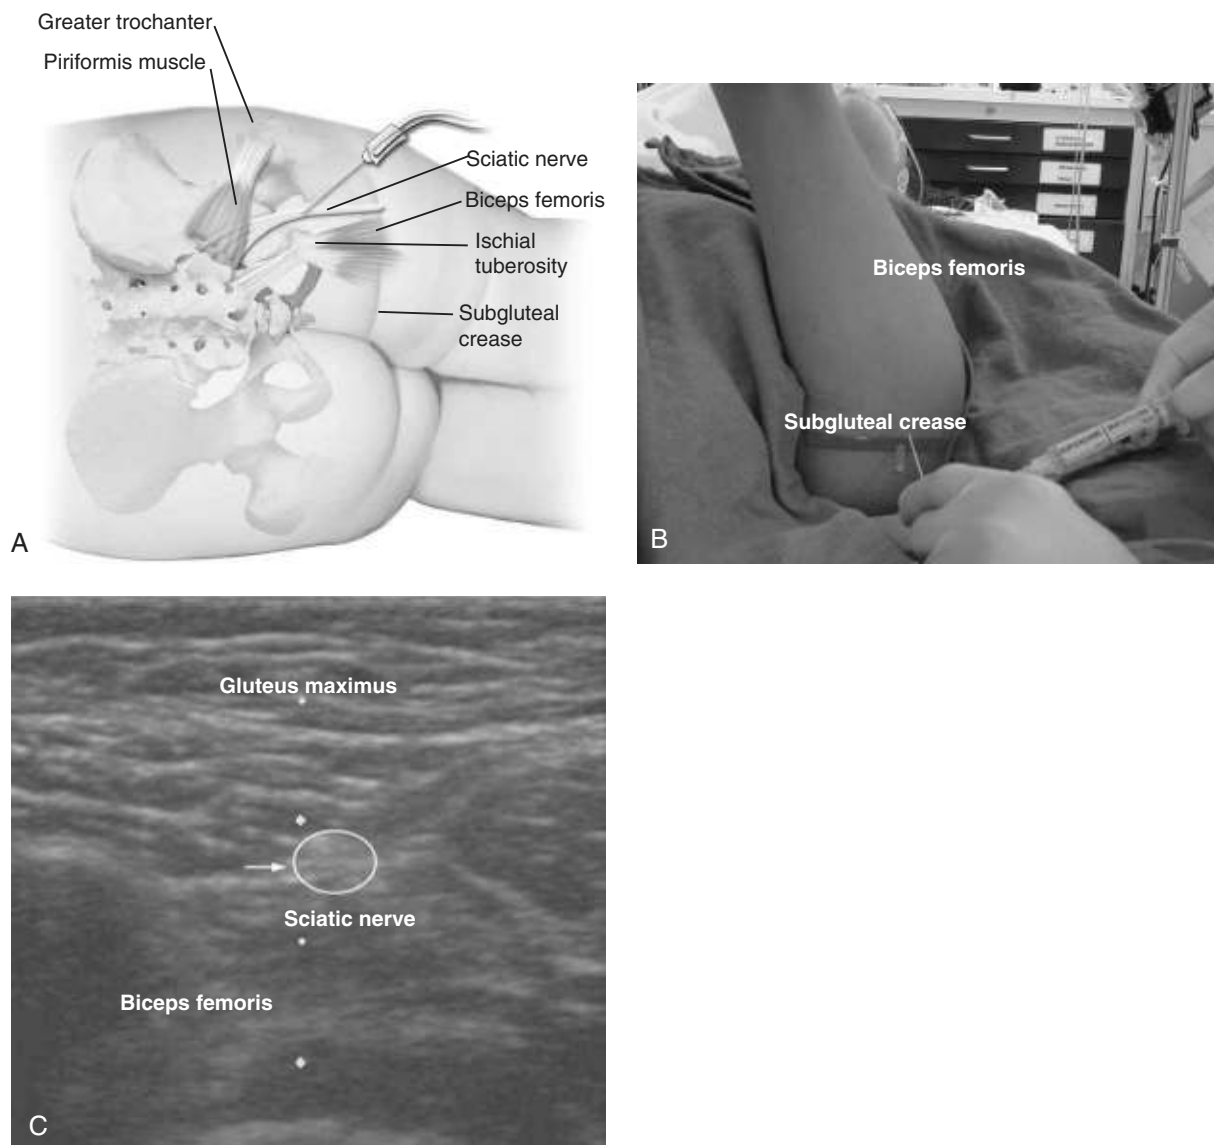

approach may facilitate this block (see also Chapter 42 and Figs. 42-31 to 42-33).<sup>395</sup>

**COMPLICATIONS.** Profound motor block can be seen in most children after a subgluteal (infragluteal) parabiceps sciatic nerve block. If the child is discharged home, caution should be exercised because of the motor weakness produced. More recently, we have used continuous catheters in hospitalized children having major lower extremity surgical procedures, with very good results.<sup>396</sup>

#### *Femoral Nerve Block*

A femoral nerve block is particularly useful in children with a fractured femoral shaft so that transport, radiographic, and other manipulations are not painful.<sup>397-399</sup> This block provides analgesia and relieves muscle spasms around the fracture site.

**ANATOMY.** The femoral nerve is located immediately lateral to the femoral artery and deep to both the fascia lata and fascia iliaca (Fig. 41-32, *A*).

**FIGURE 41-31** **A**, Artist's rendering of infragluteal-parabiceps block. **B**, The gluteal crease is identified (left leg) in the prone or supine position. The biceps femoris muscle is identified (distal portion not illustrated) and followed cephalad to the gluteal crease. A stimulating needle is inserted at the level of the gluteal crease along the medial border of the biceps femoris muscle; with stimulation at 0.5 mA, plantar flexion or extension or inversion or eversion denotes adequate positioning of the needle. After aspiration to rule out intravascular injection, 0.2 mL/kg of local anesthetic solution is injected to provide an adequate blockade of the sciatic nerve. **C**, An ultrasound technique may also be used. A linear ultrasound probe is placed along the inferior border of the gluteus maximus along the gluteal crease. The biceps femoris muscle and the semitendinosus muscle are identified. The sciatic nerve is seen as a hyperechoic shadow. In this location, the nerve may be isoechoic. This may require mild rotation or movement of the ultrasound probe to recognize the nerve completely. With the use of an in-plane approach, the needle is advanced close to the sciatic nerve. After aspiration, 0.2 mL/kg of local anesthetic solution is injected. A "donut sign" is seen as the nerve is surrounded by the local anesthetic solution.

**TECHNIQUE.** A 22-gauge blunt B-bevel needle is advanced lateral to the pulsation of the femoral artery. Two fascial planes can be located by the distinct pop that is felt as the needle traverses these fascial tissues. The nerve is blocked by depositing an appropriate volume (5 to 10 mL) of local anesthetic lateral to the femoral pulse and deep to the fascia iliaca. The needle is advanced in a perpendicular plane (see Fig. 41-32, *B*, and Video: Femoral Nerve Block). It is not necessary to elicit a motor paresthesia, provided that the two fascial planes are penetrated. Performance of this block may, on occasion, produce a fascia iliaca block. Repeated aspiration and incremental injection should be used to avoid injection into the femoral artery. With ultrasound guidance,

the femoral nerve can be easily visualized and can be blocked (see also Chapter 42 and Fig. 42-29).<sup>395</sup> A catheter can be placed to provide continuous analgesia in the postoperative period.<sup>397</sup>

**COMPLICATIONS.** It may be preferable to avoid this technique in children who are on anticoagulants or who may have blood dyscrasias, owing to the close proximity of the nerve to the femoral artery. Intravascular injection may be avoided with incremental injection and frequent aspiration.

#### *Lateral Femoral Cutaneous Nerve*

**ANATOMY.** The lateral femoral cutaneous nerve arises from the L2 and L3 roots of the lumbar plexus. It emerges from the lateral

**FIGURE 41-32** **A**, Right femoral nerve block and fascia iliaca compartment block. Note that the femoral nerve lies lateral to the femoral artery. The appropriate dose of local anesthetic is administered while maintaining pressure on the nerve sheath distal to the site of injection just below the inguinal ligament; local anesthetic is thus forced proximally. **B**, For a left femoral nerve block, the point of injection is lateral to the pulse, over the site of the nerve (V, vein; A, femoral artery; N, femoral nerve). **C**, The left lateral femoral cutaneous nerve is blocked by injecting 1.0 to 2.0 mL of local anesthetic 1 to 2 cm medial to the anterior superior iliac crest (ASIS). A caudal needle is used so as to better feel the “pop” through tissue planes. For the fascia iliaca block, the point of injection is just lateral to the site depicted for the femoral nerve block, 1 cm inferior to the lateral and middle thirds of the inguinal ligament. An injection at this location will bathe all three nerves in the compartment, resulting in blockade with a single injection.

border of the psoas muscle and passes obliquely under the fascia iliaca to enter the thigh 1 to 2 cm medial to the anterior superior iliac crest (Fig. 41-32, *A*). The nerve innervates the lateral aspect of the thigh. One of its anterior branches forms part of the patellar plexus; thus it must be blocked for regional anesthesia of the knee. Blockade is also indicated for supplementation of femoral and sciatic nerve blocks to provide relief of tourniquet pain. It is also suitable for anesthetizing the lateral aspect of the thigh as a donor site for small skin grafts, fascia iliaca grafts, or muscle biopsy for muscular disorders.<sup>400,401</sup> This block can also be used for both diagnostic and therapeutic purposes in treating meralgia paresthetica, a condition that leads to chronic pain along the lateral aspect of the thigh.<sup>402,403</sup> In most cases, a fascia iliaca block will block this nerve along with the femoral and obturator nerves, thus obviating the need for performing an isolated lateral femoral cutaneous block.

**TECHNIQUE.** A point approximately 2 cm caudal and 2 cm medial to the anterior superior iliac spine is located (see Fig. 41-32, *C*). A blunt needle is then advanced through the skin and then through the fascia lata. A distinct pop is felt at this point. The fascia lata and fascia iliaca compartments are entered as two

distinct pops can be felt as the needle advances into the fascia iliaca compartment. Two to 10 mL of local anesthetic, depending on the size of the child, is deposited in a fan-like fashion (Video: Lateral Femoral Cutaneous Nerve Block with Ultrasound). Recently we have used an ultrasound-guided technique that allows us to visualize the fascia iliaca compartment as it fills up with the local anesthetic solution on injection.

**COMPLICATIONS.** It is rare to see any complications associated with a lateral femoral cutaneous nerve block. However, care must be taken to avoid an intraneural placement of the local anesthetic solution. Intravascular injection may be avoided with incremental injection and frequent aspiration.

#### **Fascia Iliaca Block**

This block is particularly useful in children to provide unilateral anesthesia or analgesia of the lower extremity. The block has been reported to be less reliable in adults than in children.<sup>404</sup> It produces blockade of the femoral, lateral femoral cutaneous, and obturator nerves with a single injection of local anesthetic.

**ANATOMY.** The compartment is bounded superficially by the fascia iliaca and iliacus muscle, superiorly by the iliac crest, and

deeply by the psoas muscle (see Fig. 41-32, *A*). It has the advantage of producing blockade without requiring the needle to be in the close proximity to any major nerves or blood vessels. One study reported a greater than 90% success rate and found it far superior in children to the "3 in 1" block described by Winnie.<sup>404</sup>

**TECHNIQUE.** The injection is made approximately 1 cm inferior to the junction of the outer and middle thirds of the inguinal ligament (see Fig. 41-32, *A*). As the needle is inserted at a perpendicular angle of about 75 degrees to the skin, two characteristic pops are felt as the needle pierces the fascia lata and then the fascia iliaca. Slight pressure on a fluid-filled syringe attached to the needle may aid in placement of the block by producing a subtle loss of resistance when the fascia iliaca compartment is entered. The angle of needle insertion is decreased and directed cephalad, and the local anesthetic is incrementally injected. One should feel little resistance to injection. Digital pressure is exerted distally to the site during the injection and for a short time afterward, and the swelling produced in the groin by the volume of local anesthetic is massaged to promote proximal flow of the drug. A long-acting local anesthetic, such as bupivacaine, ropivacaine, or levobupivacaine, is usually chosen so that postoperative blockade can provide prolonged analgesia. A volume of 0.3 to 0.5 mL/kg is sufficient in most cases. An ultrasound-guided technique similar to that for the lateral femoral cutaneous block may also be used for this block.

**COMPLICATIONS.** Because of the larger volume that is required to provide an adequate block, care has to be taken to not exceed the maximum dosage of the local anesthetic. Intravascular injection may be avoided with incremental injection and frequent aspiration.

### Ankle Block

Block of the nerves of the foot at the ankle is a technique that is valuable to produce both surgical anesthesia and postoperative analgesia for procedures on the foot.

**ANATOMY.** Three nerves can be blocked from the dorsal aspect of the foot. The deep peroneal nerve (L4, L5, S1, and S2) innervates the web space between the great and second toes. This nerve extends down the anterior aspect of the leg medial to the extensor hallucis longus and lateral to both the anterior tibial

muscle and the anterior tibial artery. It is blocked at the level of the ankle crease in the lower part of the leg by inserting a 25-gauge needle through the skin until it contacts the tibia (Fig. 41-33, *A*). Several milliliters of local anesthetic are injected, and then an additional amount as the needle is being withdrawn. The superficial peroneal nerve (L4, L5, S1, and S2) innervates the medial and lateral aspects of the dorsum of the foot. Its anatomic course passes through the crural fascia on the anterior aspect of the distal two-thirds of the leg and subcutaneously along the lateral aspect of the foot. It is blocked immediately above the talocrural joint. It can be blocked by subcutaneous infiltration of local anesthetic from the anterior border of the tibia to the lateral malleolus. The last nerve that lies on the dorsal aspect of the foot is the saphenous nerve, which innervates the skin over the medial malleolus. It is blocked by subcutaneous infiltration around the great saphenous vein at the level of the medial malleolus. The tibial and the sural nerves are blocked using a posterior approach. The tibial nerve (L4, L5, S1, S2, and S3) lies posterior to the posterior tibial artery and divides into the medial and lateral plantar branches, which innervate their respective aspects of the sole of the foot. It is blocked at the level of the medial malleolus.

**TECHNIQUE.** It is not necessary to elicit paresthesias, and an ankle block can be satisfactorily performed in sedated children without the use of a nerve stimulator. Five principal nerves must be blocked to provide analgesia to the entire foot: (1) the deep peroneal, (2) superficial peroneal, (3) saphenous, (4) tibial, and (5) sural nerves (see Fig. 41-33). The technique is the same as in the adult. It should be noted that there might be some variation in the precise distribution of distal innervation from child to child. A 25-gauge needle is inserted at a 90-degree angle to the posterior aspect of the tibia and is directed lateral to the posterior tibial artery until the tibia is contacted. Several milliliters of local anesthetic are deposited at this level and several more are injected as the needle is withdrawn. The sural nerve innervates the heel. It is blocked by subcutaneous infiltration of local anesthetic from the Achilles tendon to the lateral malleolus (see Fig. 41-33, *B*). The deep peroneal nerve is located next to the extensor hallucis longus tendon. Usually it can be located by palpating the dorsalis pedis artery. The needle is inserted lateral to the extensor hallucis

**FIGURE 41-33** Ankle block. Block of the ankle generally requires five separate nerves to be blocked. Three nerves can be blocked from the dorsal aspect of the foot (**A**) and two on either side of the Achilles tendon (**B**). Sites of injection are indicated by the circles. *a.*, Artery; *n.*, nerve.

longus tendon and is advanced until it meets the periosteum of the metatarsal. It is then withdrawn a few millimeters. After careful aspiration, a volume of 2 to 3 mL of local anesthetic is injected. The superficial peroneal nerve is located under the dorsum of the foot. A superficial injection from the lateral malleolus to the extensor hallucis longus tendon area blocks all the branches of the superficial peroneal nerve.

COMPLICATIONS. It is very rare to see complications from an ankle block. However, the use of vasoconstrictors can cause necrosis of the toes. Care should be taken to avoid the use of an ankle block in children who may have compromised blood flow to the lower extremity.<sup>405</sup>

#### **Digital Nerve Blocks: Foot**

This is an easy block to perform and is useful for surgeries that include trauma to the nails and toes, ingrown toenail surgery, and laser treatment of warts.<sup>388</sup>

ANATOMY. The digital nerves of the foot are derived from the plantar cutaneous branches of the tibial nerve. The proper digital nerve of the great toe pierces the plantar aponeurosis posterior to the tarsal-medial joint and supplies the medial side of the great toe. The three common digital nerves pass between the divisions of the plantar aponeurosis and split into two proper digital nerves each. The first supplies the adjacent areas of the great and second toes; the second supplies the adjacent sides of the second and third toes; the third supplies the adjacent sides of the third and fourth toes. Each proper digital nerve gives off cutaneous and articular filaments that terminate in the tip of the toe. The superficial peroneal nerve gives off branches that supply the dorsum of the foot. They are derived from two nerves: (1) the dorsal cutaneous divides into two branches, a medial one that supplies the great toe and a lateral one that supplies the adjacent sides of the second and third toes; and (2) the intermediate dorsal cutaneous nerve, which passes along the lateral part of the foot supplying the lateral part of the dorsum of the foot and communicating with the sural nerve. This latter nerve terminates by dividing into two dorsal digital branches, one of which supplies the adjacent sides of the third and fourth toes and another one that supplies the adjacent sides of the fourth and little toes.

TECHNIQUE. Digital blocks of the foot can be difficult owing to the thickness of the overlying skin. We prefer using an approach in which we access the nerve from the web space or at the dorsolateral aspect of the toe. Bupivacaine *without epinephrine* is injected (1 to 2 mL) after aspiration to rule out intravascular

placement. These blocks should be avoided in children with already compromised blood flow to the toes.

COMPLICATIONS. Large volumes of local anesthetic are contraindicated because this may cause pressure and vascular compromise. *Vasoconstrictors should be avoided because this may cause necrosis of the digit.* Intravascular injection may be avoided with incremental injection with frequent aspiration.

## **Summary**

Most regional techniques that are suitable for adults can be used in children. Although in most children sedation or general anesthesia is necessary in addition to the regional anesthetic, in certain neonates, regional anesthesia is often used as the sole technique and may reduce the incidence of postanesthetic apnea in former preterm infants. In addition to the intraoperative benefits, regional anesthesia may improve postoperative analgesia and may offer some improvement to postoperative respiratory function in selected children. Regional anesthesia is particularly useful in outpatient surgery, providing postoperative analgesia with rapid emergence and a low incidence of side effects. It is important to realize, however, that anatomic, physiologic, and pharmacologic factors that are unique to children can affect the performance and safety of regional anesthetic techniques. The advent of ultrasound guidance for placement of peripheral, as well as central, neuraxial blockade may increase the use of these blocks. Continuous catheter techniques can also increase the postoperative pain control in these children, with fewer adverse effects related to opioid use.<sup>406</sup> Once these differences are understood, regional anesthesia can be safely and efficaciously used, either as the sole anesthetic or as a supplement to general anesthesia, to provide a smooth intraoperative course and pain-free awakening.

## **ACKNOWLEDGMENT**

The authors wish to thank Per-Arne Lönnqvist, MD, DEAA, FRCA, PhD, for his generous contribution to the paravertebral block section of this chapter.

## Education and Training

## Summary

**PERIPHERAL NERVE BLOCKS** ARE frequently performed in children to provide anesthesia or analgesia during the perioperative period.<sup>1-3</sup> Success depends on the ability to accurately place the needle and thereby the local anesthetic close to the target nerve without causing injury to the nerve or adjacent structures. Peripheral nerve blocks are not without risk and can pose a serious challenge even to the experienced anesthesiologist because they are usually performed after the child is anesthetized. In the past, clinicians relied on anatomic landmarks,<sup>1-3</sup> fascial clicks,<sup>4</sup> loss of resistance,<sup>5</sup> or nerve stimulation<sup>6</sup> to position the needle in the vicinity of the nerve (see Chapter 41). Anatomic landmarks provide valuable clues to the position of the nerve, but they are surrogate markers, lack precision,<sup>7</sup> vary among children of different ages, and may be difficult to locate in obese children. Even nerve stimulation, which has been recommended as the gold standard for nerve localization, may not always elicit a motor response<sup>8</sup> and its use does not guarantee success or preclude complications.<sup>9</sup> Moreover, the accuracy of needle placement cannot be predicted with any of these methods,<sup>8</sup> which may lead to multiple attempts to place the needle that may result in pain and possibly an incomplete or failed nerve block.

Various imaging modalities, such as fluoroscopy,<sup>10</sup> computed tomography (CT),<sup>11</sup> and magnetic resonance imaging (MRI),<sup>7</sup> improve the accuracy of block placement in adults. However, these adjuncts are rarely used in children<sup>1-3</sup> and are not practical in the operating room. Recently, increased interest has been

shown in the use of ultrasound (US) to guide peripheral and central neuraxial blocks in both adults and children.<sup>12-21</sup> In this chapter, the basic principles of US imaging and US-guided regional anesthesia (USGRA) in children are described. It is assumed that the reader has a basic understanding of common landmark-based nerve block techniques in children.

The use of US for regional anesthesia dates to 1978, when La Grange and associates<sup>22</sup> used a Doppler flow detector to locate the subclavian artery and guide supraclavicular brachial plexus blocks. In 1994, Kapral and colleagues<sup>23</sup> published the first report on direct sonographic visualization in regional anesthesia. They used US to directly visualize the brachial plexus and observe the spread of the local anesthetic in real time during supraclavicular brachial plexus block. Today, US is used to guide peripheral nerve blocks and central neuraxial blocks in both adults and children.<sup>12-21</sup> This has become possible owing to improvements in US technology and the availability of portable US machines with high-resolution imaging capabilities. The ability to directly visualize the peripheral nerves and central neuraxial structures in children is truly exciting and can be compared to removing a blindfold from the anesthesiologist performing regional anesthesia. Currently, outcome data that prove US increases the safety and efficacy of regional anesthesia in children are rapidly accumulating. For example, when compared with nerve stimulation, US speeds the onset time of infraclavicular block.<sup>20</sup> A greater success rate of pediatric truncal blocks is seen when US guidance is used.<sup>21</sup>

## Principles of Ultrasound

Sound is a form of mechanical energy that propagates through a medium as a wave of alternating pressure, causing local regions of compression and rarefaction (Fig. 42-1). The frequency ( $f$ ) of sound is the number of cycles of oscillation per second made by the sound source and the particles in the medium through which it moves. It is expressed in hertz (Hz, cycles per second). Sound waves propagate symmetrically away from the source at a constant velocity ( $v$ ), which is the speed of sound in the medium. Distance between the wavefronts is the wavelength ( $\lambda$ ) of the sound. The speed of sound through a medium can thus be represented as:

$$v = f \lambda$$

Amplitude is the strength of a sound wave, and the unit used to describe it is decibels (dB). The velocity of transmission of sound through a medium depends on its acoustic impedance and is determined by factors such as the stiffness, elasticity, and density of the medium. This accounts for the varying velocity of sound transmission through different tissues in the human body (Table 42-1). The average velocity of sound transmission through biologic tissue is 1540 m/sec. If the time taken by the US signal to return to the transducer is known, the distance of the target from the transducer (depth) can be computed.

FIGURE 42-1 Sound wave.

TABLE 42-1 Propagation Velocity of Sound in Body Tissues

Tissue	Propagation Velocity of Sound (m/sec)*
Bone	4080
Muscle	1580
Blood	1570
Kidney	1560
Liver	1550
Soft tissue (average)	1540
Water	1480
Fat	1450
Lung	600
Air	330

m/sec, Meters per second.

\*Medical ultrasound device measurements are based on an assumed average propagation velocity of 1540 m/sec.

The human ear can detect sound between 20 and 20,000 Hz. US is sound with a frequency beyond 20,000 Hz (20 KHz). For medical imaging, US typically uses a frequency between 1 million and 15 million Hz (megahertz [MHz]) and is produced by a piezoelectric crystal (element) within the transducer. Artificial ferroelectric materials, such as lead zirconate titanate or lead zirconium titanate (PZT), are commonly used as elements in transducers, and their thickness determines the resonant frequency. When an electrical field is applied to the surface of an element in a transducer, it undergoes dimensional changes that cause it to vibrate and produce sound. The element is typically driven by a pulsed alternating voltage. This results in the generation of short pulses of US that are emitted into body tissues. Between successive short pulses of US generation, the transducer does not transmit but rather functions as a receiver of the reflected US energy (i.e., the echoes). The percentage of time that a transducer is transmitting is termed the *duty factor* and is typically less than 1%. The US transducer thus has a dual function—it functions as both a transmitter and a receiver.

The emitted US signal travels through the tissue medium, and when it encounters a tissue interface it is reflected back. The degree of reflection of US from tissues is related to the changes in acoustic impedance ( $Z$ ) between two tissue interfaces. The reflected echoes are detected by the transducer and converted into electrical energy; they are then processed by the US machine according to their strength and displayed as dots on the monitor. The brightness of each dot corresponds to the strength of the echo signal. Strong echoes produce bright white dots, weak echoes produce gray dots, and anatomic structures that do not reflect US appear as black dots. The position of the dot on the monitor represents the depth from which the echo is received. When all of these dots are combined, they produce a complete image of the area scanned.<sup>24-26</sup>

### MODES OF ULTRASOUND

#### A-Mode (Amplitude)

In amplitude, or A-mode, the echoes from tissue interfaces are represented on the monitor as a spike, and the spike height represents the amplitude of the echo.<sup>27</sup> The distance of the interface from the transducer is calculated from the time taken for the signal to be sent and received, the “round-trip time.” A-mode US imaging is rarely used and is considered obsolete.

#### B-Mode (Brightness or Two-Dimension Mode)

Brightness, or B-mode, is the most commonly used US mode. In this mode, the spike is converted to a dot and the brightness of the dot represents the amplitude of the returning signal.<sup>24-26</sup> The position of the dot on the display represents the depth from which the signal is returning and depends on the round-trip time of the US signal. Multiple scan lines across a plane are combined to produce a single two-dimensional (2D) image. A series of frames are then displayed in rapid succession to give the impression of constant motion, the quality of which depends on the number of images displayed per second, that is, the frame rate.

#### M-Mode (Motion)

Motion, or M-mode, US is directed along a single scan line (sample line), and reflected signals along this scan line are converted to a brightness scale and displayed against a time axis. Because M-mode is produced from US signals along a single scan line, the 2D anatomy of the underlying body tissues should be studied first using the 2D mode (see later). M-mode is of

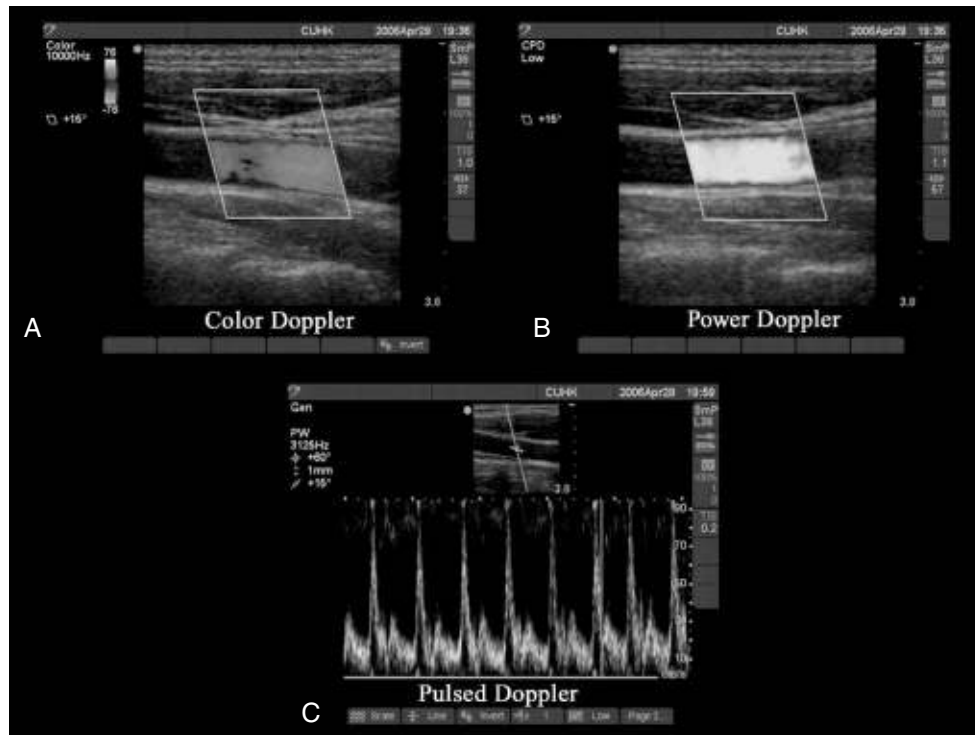

FIGURE 42-2 Doppler ultrasound. **A**, Color Doppler. **B**, Power Doppler. **C**, Pulsed Doppler.

particular interest when time resolution is necessary, such as when examining a target with rapid movement (e.g., the mitral valve during echocardiography).<sup>28</sup>

### Doppler Ultrasound

Doppler US (based on the Doppler principle) detects a shift in frequency between the emitted US waves and their echoes.<sup>29-32</sup> It is used to detect and measure blood flow, and the major reflector for this purpose is red blood cells. Several modes are available:

- *Color Doppler* measures and color codes the direction and magnitude of the mean Doppler frequency shifts that occur in moving red blood cell and superimposes a color depiction of these data on the gray-scale image (Fig. 42-2, *A*).
- *Power color Doppler* depicts the amplitude, or power, of the Doppler signals (see Fig. 42-2, *B*). This allows better sensitivity for visualization of small vessels, but at the expense of directional information.
- *Pulsed Doppler* allows a sampling volume (or gate) to be positioned in a vessel visualized on the gray-scale image and displays a spectrum of the full range of blood velocities within the gate plotted as a function of time (see Fig. 42-2, *C*).

### THE ULTRASOUND MACHINE

US machines are either cart-based or portable systems. Irrespective of their shape or size, US machines are made up of the following components: a *monitor* (where the clinical images are displayed), the *US unit* (where the signals are processed), the *control panel* (with the knobs and controls), one or more *transducers*, and a *data storage device*.<sup>33-35</sup> For an anesthesiologist, the first encounter with an US machine can be quite intimidating. The wide array of knobs and controls that are available may be

confusing. However, several controls are common in most US machines, and a clear understanding of their function (“knobology”) is essential for optimal imaging.

### Presets

Most US machines have a number of presets, which are factory set, to allow optimal US imaging of a specific area of the body or type of examination. Some of the categories of presets that are available include small part, vascular, breast, nerve, musculoskeletal, abdominal, and so on. For example, if a small part preset is chosen, the US machine assumes that the operator is scanning for small, relatively superficial structures and automatically adjusts the depth, power, focus, gain, and time-gain compensation (TGC) (see later) to allow optimal imaging of superficial structures. Some US machines also allow the operator to customize presets according to clinical requirements. Power output is the amount of energy transmitted from the US transducer. In most machines, the power cannot be adjusted by the operator but is automatically set when a particular preset is chosen.

### Frequency

This control is used to select the desired frequency, within certain limits, of a broadband transducer, that is, a transducer that serves a range of frequencies. In some US systems (M-Turbo, SonoSite Inc, Bothell, Wash.), this is available as an image optimization control. In the “Res” (resolution) setting the highest frequency of the broadband transducer is selected; in the “Pen” (penetration) setting the lowest frequency is selected; and in the “Gen” (general) setting an intermediate frequency is selected.

### Gain

The gain control adjusts the amplification of the returning acoustic signals and is used to optimize the US image (Fig. 42-3). Reduced gain produces a dark image (see Fig. 42-3, *A*) and detail

**FIGURE 42-3** Transverse sonogram of the forearm demonstrating reduced gain (A), excess gain (B), and optimal gain (C).

is masked. In contrast, too much gain produces a white image and detail is saturated (see Fig. 42-3, B). In some US machines there are separate controls for overall gain and gain for the near and far fields. “Auto-gain,” by which the US machine automatically adjusts the gain, is also available in some machines.

### Time-Gain Compensation

US energy is progressively attenuated as it travels through tissue. Therefore signals returning from reflectors at a depth are weaker in strength. By selectively amplifying the echoes from greater depths, using the TGC method or depth-gain compensation (DGC), equal reflectors at unequal depths are displayed as structures of equal brightness on the monitor. TGC is preset to a large degree, and the operator can make fine adjustments if necessary. The TGC control is presented as a series of sliders arranged in a vertical fashion on the control panel. Each of the sliders adjusts the amplification of the returning US signals at a specific image depth.

### Depth

Adjustment in the displayed depth may be necessary depending on the location of the target, the patient’s body size, or other anatomic factors. A depth greater than necessary should not be chosen because this reduces the frame rate and resolution of the image.

### Focus (Focal Zone)

The focus of the US signal occurs at a point at which the beam is at its narrowest width. It is also the region where lateral resolution is the best. The focus point should therefore be positioned at the depth at which the pertinent anatomic structures are located. In some US machines, the operator can select multiple focal zones, but this markedly reduces the frame rate and thus should not be routinely used.

### Freeze and Unfreeze

The “freeze” function allows the operator to lock a static image on the monitor. A number of frames (usually 20 or more) are also simultaneously stored in a memory bank. A trackball or an “arrow” key is then used to scroll back and forth through these frames. The selected still image can then be used for annotation, documentation, storage, review, or teaching. Pressing the freeze button once again will unfreeze the image.

### Ultrasound Transducers

The transducer functions both as a transmitter and a receiver of the ultrasound signal.<sup>33-35</sup> Three types of transducers are currently used (Fig. 42-4): (1) in a linear-array transducer, the piezoelectric crystals are arranged in a linear fashion and sequentially fired to produce parallel beams of ultrasound in sequence, creating a field of view that is rectangular and as wide as the footprint of the transducer (see Fig. 42-4, A); (2) a curved linear-array transducer has a curved surface, creating a field of view that is wider than the footprint of the probe (see Fig. 42-4, B), but at the cost of reduced lateral resolution in the far field as the scan lines diverge; (3) a phased-array transducer has a small footprint, but the ultrasound beam is steered electronically to produce a sufficiently wide far field of view. The ultrasound beam diverges from virtually the same point in the transducer (see Fig. 42-4, C). Phased-array transducers are routinely used for transthoracic echocardiography.<sup>34</sup> The footprints of these transducers are small enough to fit between the ribs and still produce a wide far field of view to image the heart. US transducers serve either a single frequency or a range of frequencies (broadband). For example, a transducer with the notation HFL38/13-6 indicates that it is a high-frequency broadband (13-6 MHz) linear transducer with a 38-mm footprint. Note that the nomenclature used for transducers varies among manufacturers of US devices.

**FIGURE 42-4** Schematic diagram illustrating the different types of ultrasound transducers. Note how the ultrasound beam is emitted from each of these transducers.

### Ultrasound Transducer Selection

*Resolution* is the ability to distinguish two objects that are close together. Axial resolution is the ability to distinguish two objects that are along the axis of the US beam, and lateral resolution is the ability to distinguish two objects that are side by side. High-frequency US (13-6 MHz) has a higher axial and lateral resolution compared with low-frequency US but cannot penetrate as deeply into body tissue. Therefore high-frequency US is used to image superficial structures such as the brachial plexus in the interscalene groove or supraclavicular fossa. A lower-frequency US transducer (10-5 MHz) is suited for slightly deeper structures, such as the brachial plexus in the infraclavicular fossa, whereas a low-frequency US transducer (5-2 MHz) is used to image deep structures, such as the lumbar plexus or the sciatic nerve. Broad-band transducers allow a single transducer to be used for scanning over a wide range of depths. Because regional blocks are performed at relatively shallow depths in neonates, infants, and young children, high-frequency linear transducers are perfectly adequate for most procedures in these age groups. High-frequency linear transducers with a small footprint (13-6 MHz, hockey stick, 25 to 26 mm) are particularly suited for young children.

## Essentials of Musculoskeletal Ultrasound Imaging

### AXIS OF SCAN

In diagnostic ultrasonography, scans are performed in the transverse, longitudinal (sagittal), oblique, or coronal axis. During a transverse (axial) scan the transducer is oriented at right angles to the target, producing a cross-sectional display of the structures (Fig. 42-5, *A*). During a longitudinal scan, the transducer is oriented parallel to and along the long axis of the target (e.g., a

blood vessel or nerve) (see Fig. 42-5, *B*). During USGRA procedures, US scans are most commonly performed in the transverse axis. In this axis, the nerves, the adjoining structures, and the circumferential spread of the local anesthetic are easily visualized.

### PROBE AND IMAGE ORIENTATION

The US image must be properly oriented to accurately identify the anatomic relations of the various structures on the monitor. To facilitate this, all US probes have an orientation marker, which is usually represented by a groove or a ridge on one side of the transducer and corresponds to a green dot (or a logo) on the monitor. By convention, the orientation marker on the transducer is directed cephalad when performing a longitudinal scan and directed toward the right side of the patient when performing a transverse scan. This way the orientation marker on the left upper corner of the monitor always represents the cephalad end during a longitudinal scan or the right side of the patient during a transverse scan. The top of the display monitor therefore represents superficial structures and the bottom of the monitor the deep structures.

### ECHOGENICITY

Certain terms are frequently used to describe the sonographic appearance of musculoskeletal structures (Fig. 42-6):

*Echogenic*: A bright white structure against a dark background

*Reflective*: Synonymous with an echogenic structure

*Isoechoic*: A shade of gray that is of the same brightness or echogenicity as the surrounding tissues

*Hyperechoic*: A shade of gray that is bright white or brighter than the surrounding tissues

*Hypoechoic*: A shade of gray that is dark or less bright than the surrounding tissues

*Anechoic*: An absence of echoes, hence blackness

**FIGURE 42-6** Schematic diagram to demonstrate the relative echogenicity of various tissues.

### AXIS OF INTERVENTION

The plane of US imaging is only 1 mm thick (Fig. 42-7); for a needle to be visible during US imaging it must lie within this narrow plane of imaging. During USGRA procedures, the block needle is inserted either outside of the plane (out-of-plane approach) (Fig. 42-8, *A*) or within the plane of the US beam (in-plane approach) (see Fig. 42-8, *B*). In the out-of-plane approach, the needle is inserted in the short axis and is initially outside the plane of imaging and therefore not visible. It becomes visible only when the needle crosses the plane of imaging and is seen as an echogenic dot on the monitor (see Fig. 42-8, *A*). It is important to note that this echogenic dot may be just the cross-sectional image of the shaft of the needle as it passes through the

plane of the US beam and thus may not represent the tip of the needle. In the in-plane approach, the needle is inserted along the long axis of the transducer in the plane of imaging and therefore both the shaft and tip of the needle are visible on the monitor.

Both approaches are commonly used, and no data have shown that one is better than the other. Proponents of the out-of-plane approach<sup>13,14,36</sup> have had great success with this method and claim that it causes less needle-related trauma and pain because the needle is advanced through a shorter distance to the target. However, critics of the short-axis approach express concerns that the inability to reliably visualize the needle and to use tissue movement as a surrogate marker to locate the needle tip during a procedure can lead to complications. The needle is better

visualized in the in-plane approach,<sup>37,38</sup> but this requires good hand and eye coordination and reverberation artifacts from the shaft of the needle can be problematic. Moreover, there are claims that the in-plane approach also causes more discomfort in awake patients because longer needle insertion paths are required.<sup>13,14,36</sup>

**FIGURE 42-7** The plane of ultrasound imaging. Note that the ultrasound beam is only 1 mm thick and for a needle to be visible during an ultrasound-guided intervention it must lie within this plane of imaging.

## NEEDLE VISIBILITY

The ability to visualize the needle during a US-guided procedure is critical for precision, safety, and success. However, this is often limited by the dispersion of the reflected US signals away from the transducer. Several factors have been identified that can influence needle visibility. The shaft of the needle is better visualized in the long axis than in the short axis, and its visibility decreases linearly with steep angles of insertion and smaller needle diameters. The needle tip is better visualized when it is inserted in the long axis for shallow angle of insertion (less than 30 degrees) and in the short axis when the angle of insertion is steep (greater than 60 degrees). This is also true when the needle is inserted with its bevel facing the US transducer. To overcome the effect of angle on needle visibility, some high-end US machines allow the operator to steer the US beam toward the needle during steep needle insertions. However, this requires experience and decreases in needle visibility can still occur. Needle visibility is also enhanced in the presence of a medium-sized guidewire. Priming a needle with saline or air, insulating it, or inserting a stylet before insertion does not improve visibility.<sup>39-41</sup>

We think that the anesthesiologist's skill in aligning the needle along the plane of imaging is by far the most important variable influencing needle visibility because minor deviations of even a few millimeters from this plane will result in inability to visualize the needle. Even with experience, needle tip visibility is a problem when performing blocks at a depth in areas that are rich in fatty tissue. Under such circumstances, gently jiggling (rapid in-and-out movement) the needle and observing tissue movement or performing a test injection of saline or 5% dextrose (1 to 2 mL) and observing tissue distention can help locate the position of the needle tip. Five percent dextrose is preferred for the latter when nerve stimulation is used because it does not increase the electric current required to elicit a motor response.<sup>42</sup>

**FIGURE 42-8** Axis of intervention. Out-of-plane (A) and in-plane (B) techniques.

**FIGURE 42-9** Anisotropy. Note how a small change in angle of the ultrasound beam from the neutral position (**A**) has affected the visibility of the median nerve (white arrow, **B**) in the forearm.

## ANISOTROPY

*Anisotropy*, or angular dependence, is a term used to describe the change in echogenicity of a structure with a change in the angle of insonation of the incident US beam (Fig. 42-9).<sup>43</sup> It is frequently observed during scanning of nerves, muscles, and tendons. This occurs because the amplitude of the echoes returning to the transducer varies with the angle of insonation. Nerves are best visualized when the incident beam is at right angles (see Fig. 42-9, *A*); small changes in the angle away from the perpendicular can significantly reduce their echogenicity (see Fig. 42-9, *B*). Therefore, during USGRA procedures, the transducer should be tilted, from side to side, to minimize anisotropy and optimize visualization of the nerve.<sup>44</sup> Although poorly understood, different nerves also exhibit differences in anisotropy, which may be related to the internal architecture of the nerve.

## Identification of Nerves, Tendons, Muscle, Fat, Bone, Fascia, Blood Vessels, and Pleura

### NERVES

On a transverse scan, nerves appear round, oval, triangular, lip shaped, or even flat.<sup>45,46</sup> Nerves also assume different shapes along their course depending on the surrounding structures. The echogenicity of nerves also varies and depends on the nerve and area scanned. They are generally hyperechoic and stand out in the background of the hypoechoic muscles (Fig. 42-10, *A*), but they can also appear hypoechoic with a hyperechoic rim (see Fig. 42-10, *B*). They also have been described to have a fascicular or honeycomb appearance (i.e., echogenic structures with internal punctate, echo-poor spaces) (see Fig. 42-10, *C*). On longitudinal scan, the appearance of peripheral nerves has been likened to a “tram track”; that is, parallel hyperechoic lines are seen against a

background of echo-poor space (see Fig. 42-10, *D*). Nerve motion also can be demonstrated on dynamic US imaging.

### TENDONS

Tendons appear to have numerous fine parallel hyperechoic lines separated by fine hypoechoic lines (*fibrillar* pattern) on long-axis scans.<sup>46</sup> Compared with nerves, tendons have more hyperechoic lines and move more than adjacent nerves when the corresponding muscle is contracted or passively stretched.

### MUSCLE

Muscle fibers are hypoechoic, but the connective tissue structure enveloping the entire muscle (*epimysium*) is hyperechoic.<sup>47,48</sup> The *perimysium* that envelops individual muscle fascicles is also hyperechoic. Muscle fibers converge to become tendons or aponeurosis.

### FAT

Fat lobules appear as round to oval hypoechoic nodules that are separated by fine hyperechoic septa. Fat tends to be superficially distributed (subcutaneous fat), slightly compressible, and similar on transverse and longitudinal scans.

### BONE

Bone reflects most of the US energy. Therefore it appears bright and has a hyperechoic edge on US imaging, with a large anechoic shadow (acoustic shadow) distal to it (Fig. 42-11).

### FASCIA

Fascia, peritoneum, and aponeurosis appear as thin hyperechoic layers on US imaging.

### BLOOD VESSELS

Arteries are identified by their intrinsic pulsatility, are not compressible, and have anechoic lumens. Veins are not pulsatile, are

**FIGURE 42-12** Tissue harmonic imaging (THI). Sagittal sonogram of the infraclavicular fossa. **A**, Conventional scan. **B**, Conventional scan with THI.

**FIGURE 42-13** Compound imaging. Transverse sonogram of the axilla. **A**, Conventional scan. **B**, Conventional scan with compound imaging.

composite image that has reduced noise or speckle and improved definition (Fig. 42-13).

### PANORAMIC IMAGING

B-mode (2D) ultrasonography has a limited field of view and allows visualization of only a small portion of any large structure. Panoramic imaging, as the name implies, is a technique used to extend the field of view so that larger structures and their surrounding tissues can be visualized together.<sup>56</sup> During a panoramic scan, the operator slowly slides the US transducer across an area of interest. During this motion, multiple images are acquired from many different transducer positions across the area of interest. The registered image data are accumulated in a large buffer and then combined to form the composite panoramic image (Fig. 42-14). Although useful for annotation, documentation, teaching, and research, it is rarely used in children during USGRA procedures.

### ARTIFACTS

US artifacts are structures that are visible in the US image that do not correlate with any anatomic structure.<sup>57</sup> The US machine makes the following assumptions when generating an image:

1. The US beam is considered to travel only in a straight line, with a constant rate of attenuation.
2. The average speed of sound through body tissue is considered to be 1540 m/sec.
3. The US beam is assumed to be infinitely thin, with all echoes originating from its central axis.
4. The depth of a reflector is calculated by determining the round-trip time of the US signal.

**FIGURE 42-14** Panoramic imaging. Transverse panoramic scan of the forearm. FCU, Flexor carpi ulnaris; FDP, flexor digitorum profundus; FDS, flexor digitorum superficialis; FPL, flexor pollicis longus.

When a deviation from any of these assumptions occurs, the US machine is unable to determine it. This results in the display of an echo that has no relation with the interface that actually produced the echo; that is, an artifact is produced. Some artifacts are undesirable and interfere with interpretation, whereas others help identify certain structures. It is essential to recognize them to avoid misinterpretation. Therefore, when a structure appears abnormal on ultrasonography, it must be examined in two planes to avoid making a wrong interpretation. Real anatomic structures are visible in both planes of imaging, whereas artifacts are visible in only one plane.

### Contact Artifact

The contact artifact is the most common artifact produced when loss of acoustic coupling occurs between the skin and the transducer. This could occur because the transducer is not touching the skin, but more frequently it is due to air bubbles that are trapped between the skin and the transducer. Therefore it is prudent to apply liberal amounts of gel to exclude air from the skin and transducer interface.

### Reverberation Artifact

Reverberation artifacts, also known as repetitive echoes, occur when repeated reflection of US occurs between two highly reflective surfaces.<sup>58</sup> Some of the US signals returning to the transducer are reflected back, then strike the original interface, and are reflected back toward the transducer a second time. As a result, the first reverberation artifact is twice as far from the skin surface as the original interface. A second or third reverberation artifact also may be seen. Because of attenuation, the intensity of the artifacts decreases with increasing distance from the transducer. Reverberation artifacts are frequently seen during US-guided axillary brachial plexus block, particularly when the needle is inserted in the long axis.

### Mirror Image Artifact

Mirror image artifact is a type of reverberation artifact that occurs at highly reflective interfaces.<sup>59</sup> The first image is displayed in the correct position, and a false image is produced on the other side of the reflector because of its mirrorlike effect.

### Propagation Speed Artifact

Propagation speed artifacts occur when the medium through which the US beam passes does not propagate at 1540 m/sec, resulting in echoes that appear at incorrect depths on the monitor. An example of propagation speed artifact is the “bayonet artifact,”<sup>60</sup> which has been reported during an US-guided axillary brachial plexus block. The shaft of the needle appeared bent when it accidentally traversed the axillary artery. This happens because of the difference in the velocity of sound between whole blood (1580 m/sec) and soft tissue (1540 m/sec).

### Acoustic Shadowing

Acoustic shadow is an echo-free area behind surfaces that are highly reflective or attenuating, such as bone (see Fig. 42-11) or metallic implants. The implication for regional anesthesia is that tissues in the area of the shadow cannot be imaged.

## SCANNING ROUTINE

Being able to consistently produce high-quality images of the area scanned is vital for safety and success during any USGRA procedure. Without optimal images, it is not possible to accurately identify musculoskeletal structures or perform interventions with precision. We have found that following a “scanning routine” or a set of simple steps, which is repeatable, is essential for optimal imaging; the routine that we follow is outlined in Table 42-2. Although the suggested routine may appear complicated at first, with repetition these steps are gradually internalized. Attaching a card with the scanning routine to the US machine facilitates easy recall.

### Scout Scan

The aim of the scout scan, or the preintervention scan, as the name implies, is to examine the area of interest before the

**TABLE 42-2 Scanning Routine**

1. Turn on the ultrasound machine.
2. Select a scanning mode.
3. Select an appropriate transducer.
4. Dim the lights in the room.
5. Assume a comfortable position.
6. Apply liberal amount of ultrasound gel.
7. Perform a scout scan.
8. Orient the transducer and image.
9. Select the appropriate ultrasound settings (preset, frequency—for broadband transducers, depth, gain, and focus point).
10. Mark the position of the transducer on the patient’s skin once an optimal image is obtained before the intervention.

intervention. This has also been referred to as a “mapping scan.” During the scout scan, steps 8 and 9 described in Table 42-2 are performed, the sonoanatomy of the area is visualized, and the image is optimized. Once an optimal view with the target structure is obtained and the best possible site for needle insertion is determined, it is advisable to mark the position<sup>44</sup> of the transducer on the patient’s skin so the transducer can be returned to the same position after sterile preparations have been completed. It is common to diagnose anatomic variations during the scout scan. The operator can then decide whether to continue with the block in the same location or to choose an alternative approach or technique that may be safer. This assessment of anatomic variation is one of the major benefits of using US for regional anesthesia.

## GENERAL CONSIDERATIONS IN CHILDREN

Preparations for an ultrasound-guided nerve block should begin during the preoperative visit by adequately explaining the technique, its benefits and risks, and, more importantly, the possibility of a failed block to the parents. In the event of failure, a contingency plan to quickly convert to general anesthesia or another form of postoperative analgesia must always be in place. In children, most regional anesthetic procedures are performed while the child is anesthetized. However, in a cooperative child or under special circumstances, such as in a child with difficult airway or a child predisposed to malignant hyperthermia, it is possible to perform the block after light sedation. We find that it is easy to explain the procedure to children who are older than 8 years of age. Some of them may even express a wish to stay awake and observe the US images during the block. Eutectic mixture of local anesthetic (EMLA) cream applied an hour before the procedure to the skin over the area where the block needle and the intravenous catheter are to be inserted helps reduce needle-related pain. Parental presence during the nerve block may also be helpful. In older children, allowing the child to listen to favorite music through a personal stereo or watch a video are useful distraction techniques that make the whole experience a more pleasant one for the child. We have connected a DVD player to our US machine, and this is used to play movies or cartoons through the monitor during the surgical procedure (E-Fig 42-1).

Before any USGRA procedure, intravenous access is established, standard monitoring is applied, and equipment and drugs appropriate for the child are prepared. Aseptic precautions are maintained, and the skin over the needle puncture site is

**E-FIGURE 42-1** The monitor of the ultrasound machine is being used to display a cartoon from a DVD player while a child is undergoing surgery under regional anesthesia.

prepared with antiseptic solution in the usual fashion. The US probe is prepared by covering the footprint with a sterile transparent dressing. It is important to avoid trapping any air between the transparent dressing and the footprint. This is done by gently stretching the transparent dressing before applying it on the footprint. The transducer and cable are then covered using a sterile plastic cover. We use the same plastic cover that our surgeons use to cover their laparoscopic camera.

### TIPS AND TRICKS FOR SUCCESS

Certain steps are common to all US-guided procedures, and, if followed, they may increase success. The lights in the room must be dimmed to avoid any glare or reflection from the US monitor. The operator must assume a comfortable position (Fig. 42-15). For upper extremity blocks, the operator sits at the ipsilateral head end of the child and the US machine is placed directly in front. For lower extremity blocks, such as femoral nerve block, the operator stands on the ipsilateral side of the child and the US machine is placed on the opposite side. For lower extremity or central neuraxial blocks in the lateral position, the operator sits behind the child and the US machine is placed in front, with the monitor in the line of view of the operator. Because of the small muscle bulk in young children the nerves are relatively superficial and can most frequently be easily visualized using high-frequency linear transducers. The exact choice of transducer depends on the area scanned, but a high-frequency linear transducer with a small footprint (13-6 MHz, 25-mm footprint) is particularly suited for young children. The 15-6-MHz broadband linear-array transducer, which has recently become available, is also useful for most blocks in young children. In older children, a 10-7-MHz broadband linear-array transducer, which allows greater flexibility with the depth of scan, is adequate for most procedures. Low-frequency (5-2 MHz) curved-array transducers are rarely used in children but are useful for imaging deeper structures such as the lumbar plexus and sciatic nerve in older children.

To improve dexterity, hold the transducer with the nondominant hand and perform interventions with the dominant hand.

Holding the transducer steady for even short periods can be quite testing. We have found that gently resting the hand that is holding the transducer on the child during a procedure helps to keep the transducer steady (see Fig. 42-15). It is important to maintain light contact between the transducer and the skin because excessive pressure in a child will cause the veins to collapse or distort the anatomy of the area of interest. Always apply liberal amounts of US gel to maintain adequate acoustic coupling between the skin and the transducer because even small amounts of air trapped between the two can result in artifacts. We use sterile US gel from single-use sachets for all US-guided peripheral nerve blocks. At any given time during an US-guided intervention either the transducer or the needle must be moved. It is impossible to maintain the needle within the plane of imaging if both are moving, a common error by novices. This results in an inability to visualize the needle. If the needle is not visible in the US image, a good strategy is to keep the needle steady and manipulate the transducer (slide, tilt, or rotate) until the needle becomes visible on the monitor. Thereafter the transducer should be held steady and the needle should be gently advanced to the target nerve, maintaining it in the imaging plane. When the angle of insertion of the needle is steep (greater than 60 degrees), it is preferable to introduce the needle in the short axis using the out-of-plane technique. However, if the in-plane approach is used for all US-guided interventions, as in our case, inserting the needle a few centimeters away from the edge of the transducer may improve needle visibility by decreasing the angle between the needle and the imaging plane.

Injecting air into the area of the intervention must be avoided at all cost because air bubbles in the field of imaging will degrade the US image. We routinely introduce the needle into the subcutaneous tissue and then purge it with saline or the local anesthetic to remove any air from the shaft of the needle, extension, and syringe system before proceeding with the block. An assistant aids with the injection. When the needle tip is close to the target nerve, the assistant gently aspirates to exclude unintended intravascular placement. The assistant must avoid generating excessive negative pressure because small blood vessels are prone to

**FIGURE 42-15** Position of the child, anesthesiologist, and ultrasound machine during a ultrasound-guided regional anesthesia procedure.

collapse. A short length of extension tubing attached between the needle and the local anesthetic syringe allows the operator to hold the needle steady while the assistant performs the injection.<sup>61</sup> We routinely perform a test injection with 1 to 2 mL of saline or 5% dextrose (when nerve stimulation is also used) and visualize the distribution of the injectate in real time before injecting the local anesthetic. Failure to visualize the injectate in the US image indicates that the needle is not in the plane of imaging or it is intravascular until proven otherwise. No further injection should be made until the needle is repositioned and the distribution of the injectate is confirmed.

### ANCILLARY EQUIPMENT

Other than the US machine, equipment required for US-guided nerve block procedures in children is relatively simple. We are not aware of any needle that has been specifically designed for US-guided interventions in children but do believe that such equipment will be available in the future. In our experience, most single-shot peripheral nerve blocks can be performed with a standard short-bevel needle designed for regional anesthesia. In older children, we have found the 22-gauge Tuohy needle (B. Braun Medical Inc., Bethlehem, Pa.) to be a very useful alternative. The tip of the needle is relatively blunt, and its design (when introduced with the bevel facing upward) also allows it to be easily identified on US imaging. Moreover, graduations on the shaft of the needle provide useful cues about the depth to which the needle has been inserted. Insulated needles used for peripheral nerve stimulation (Stimuplex A, 50 or 100 mm, B. Braun Melsungen AG, Melsungen, Germany) are also suited for US-guided peripheral nerve blocks in children. Indwelling catheters also can be placed under US guidance; however, compared with single-shot techniques, experience with US-guided catheter placement for continuous peripheral nerve blocks in children is still limited. A standard epidural kit or an insulated continuous peripheral nerve block kit of an appropriate size can be used for catheter placement.

## Specific Ultrasound-Guided Nerve Blocks

### UPPER EXTREMITY BLOCKS

#### Supraclavicular Brachial Plexus Block

Supraclavicular brachial plexus block has been described in children, although it is rarely used because of fear of pleural puncture and pneumothorax.<sup>62</sup> US-guided supraclavicular brachial plexus block has recently been successfully performed in a series of 17 children aged younger than 6 years for orthopedic upper limb surgeries.<sup>63</sup> Even though the brachial plexus and cervical pleura are clearly delineated using US in the supraclavicular fossa, this technique should be performed only by experienced operators because of the close proximity between the cervical pleura and the brachial plexus.

The child's head rests on a head ring and is slightly turned to the contralateral side, and a small roll is placed between the scapula. For a right-sided block, a right-handed operator stands or sits at the head end of the child and the US machine is placed directly in front on the ipsilateral side (see Fig. 42-15). The position of the operator and US machine is reversed for a left-sided block. In the supraclavicular fossa, the subclavian artery lies on top of the first rib. The trunks and divisions of the brachial plexus are superficial and lateral to the subclavian artery and sandwiched between the scalenus anterior and scalenus medius muscle (Fig. 42-16). A linear-array transducer (13-10 MHz) is used to perform

**FIGURE 42-16** Sonographic appearance of the brachial plexus (white arrows) in the supraclavicular fossa. SA, Scalenus anterior; SCA, subclavian artery; SM, scalenus medius.

the block; the hockey stick probe or a linear-array transducer with a small footprint (25 mm) is particularly suited for this block.

During the scout scan the transducer is positioned parallel to and against the clavicle and the subclavian artery is identified. The trunks and divisions of the brachial plexus often look like a bunch of grapes on the superficial and lateral aspect of the subclavian artery (see Fig. 42-16). The cervical pleura and lung are deep to the first rib. The operator should bear in mind that the acoustic shadow of the first rib can obscure the view of the pleura and lung (see also Fig. 41-21 and Chapter 41 for the landmark-guided techniques). The block needle is inserted in the long axis (in-plane) of the transducer in a lateral to medial direction, keeping the pleura in view. A test injection with saline is performed to ensure optimal needle position, after which the calculated dose of local anesthetic is injected in aliquots.

### INFRACLAVICULAR BRACHIAL PLEXUS BLOCK

US-guided infraclavicular brachial plexus block is performed with the child in the supine position. The block can be performed with the arms by the side, but it is preferable to abduct the arm (to 90 degrees) whenever possible because it elevates the lateral part of the clavicle, which makes more space available below the clavicle for transducer placement. The operator sits at the ipsilateral head end of the child, and the US machine is positioned directly in front. Because the cords of the brachial plexus are relatively superficial in the infraclavicular fossa in children, a linear-array transducer (13-10 MHz in young children and 10-7 MHz in the older child) is used to perform the block. The transducer is positioned in the sagittal plane over the deltopectoral region, medial and inferior to the coracoid process, with its orientation marker directed cephalad.

During the scout scan the second part of the axillary artery and the axillary vein are identified deep to the pectoral muscles (Fig. 42-17). The axillary artery is located superior to the vein, and the cords of the brachial plexus are closely related to the axillary artery at this level. The medial cord is situated caudal to the axillary artery, often between the axillary artery and vein, whereas the posterior and lateral cords are posterior and cephalad to the artery, respectively (see Fig. 42-17). Despite this relation, in most cases it is not easy to identify all three cords of the brachial plexus in a single plane of imaging. If the transducer is

**FIGURE 42-17** Sagittal sonogram of the left infraclavicular fossa. AA, Axillary artery; AV, axillary vein.

**FIGURE 42-19** Infraclavicular brachial plexus block. Sagittal sonogram of the infraclavicular fossa after local anesthetic injection demonstrating the circumferential spread of local anesthetic around the axillary artery—the “doughnut sign.” AA, Axillary artery; LA, local anesthetic; Pec, pectoralis.

**FIGURE 42-18** Sagittal sonogram of the infraclavicular fossa with the transducer positioned medially. Note the hyperechoic pleura in the lower right corner of the image. AA, Axillary artery; AV, axillary vein; Pec, pectoralis.

moved medially, the pleura usually comes into view (Fig. 42-18). In infants and young children, the margin of safety between the cords of the brachial plexus and the pleura is relatively small and pleural puncture is a risk if the block is performed in this medial position. Therefore we recommend that the infraclavicular brachial plexus block be performed laterally where the pleura is not visible in the US image.

We prefer to perform multiple injections targeting the areas where the three cords of the brachial plexus are located. The aim is to produce a circumferential spread of the local anesthetic around the axillary artery, the “doughnut sign” (Fig. 42-19), which correlates well with successful brachial plexus anesthesia.<sup>64-71</sup> This perivascular injection technique is best visualized by imagining the transverse image of the axillary artery as a clock face with its 12-o’clock position in its anterior aspect and the 6-o’clock position in the posterior aspect of the artery (Fig. 42-20). The block needle is inserted using in-plane technique from a cranial to caudal direction (see Fig. 42-20), and one third of the total dose of local anesthetic is injected close to each of the posterior (6-o’clock position), lateral (9-o’clock position), and medial (3-o’clock position) cords.<sup>38</sup> Because the angle of needle insertion

is fairly steep with this approach, the needle is rarely seen on the US image and the operator has to gently jiggle the needle to locate the needle tip. A subtle pop may be felt as the needle tip traverses the epimysium of the pectoralis minor muscle. A test injection with 1 to 2 mL of saline should be performed before the local anesthetic injection to ensure optimal needle position and distribution of the injectate (see also Fig. 41-20 and Chapter 41 for landmark-guided techniques).

### AXILLARY BRACHIAL PLEXUS BLOCK

US-guided axillary brachial plexus block is typically performed with the child in the supine position.<sup>72-74</sup> The arm is abducted (to 90 degrees) and externally rotated so that the palm of the hand is facing the ceiling. The operator sits at the ipsilateral head end of the child, and the US machine is positioned directly in front (see Fig. 42-15). Because the nerves of the brachial plexus are relatively superficial in the axilla a high-frequency linear-array transducer (13-6 MHz) is used. During the scout scan, the transducer is positioned just below the lateral border of the pectoralis major muscle, with its orientation marker directed laterally (Fig. 42-21). The resultant image in the monitor is a transverse scan of the axillary structures. The pulsatile vessel in the image is the axillary artery. The axillary vein is located medial to the artery. It is common to see more than one vein in the scan (see Fig. 42-21).

At this level, the three major nerves of the brachial plexus (the median, ulnar, and radial nerves) lie very close to the axillary artery. In adults, when the arm is abducted and externally rotated, the median nerve is located on the anterior or anterolateral side of the axillary artery (97.9%), the ulnar nerve is located on the anteromedial side of the artery (91.3%), and the radial nerve is located posterior to the axillary artery (89.9%) (Fig. 42-22).<sup>75</sup> No comparable data exist in children, but we find that the location of the median, ulnar, and radial nerves in children closely reflect those in adults. To accurately identify these three nerves it may be necessary to trace the nerve distally along its course. The musculocutaneous nerve is frequently seen between the coracobrachialis and the biceps muscle or within the substance of the coracobrachialis muscle (see Fig. 42-21).<sup>76,77</sup> Occasionally, the musculocutaneous nerve also may be located very close to the median nerve, and local anesthetic injected close to the median

**FIGURE 42-20** Infraclavicular brachial plexus block. Schematic diagram showing the positions of the cords of the brachial plexus and the sites at which the local anesthetic is injected: (1) posterior cord, (2) lateral cord, and (3) medial cord.

**FIGURE 42-21** Transverse sonogram of the left axilla. AA, Axillary artery; AV, axillary vein; CRB, coracobrachialis muscle; MCN, musculocutaneous nerve; MN, median nerve; Res, resolution; RN, radial nerve.

nerve may affect the musculocutaneous nerve. The shape of the musculocutaneous nerve varies along its course, and it may appear oval, round, elliptical, or even triangular.

We prefer the in-plane approach for needle insertion during axillary brachial plexus block in both sedated and anesthetized children. The block needle is inserted from the lateral to the medial side of the arm, keeping it within the plane of the US imaging. A subtle pop is often felt when the tip of the needle traverses the epimysium of the biceps muscle and enters the fascial plane containing the neurovascular bundle. Multiple injections are required to block the median, radial, and ulnar nerves. The objective is to produce a circumferential spread of local

**FIGURE 42-22** Schematic diagram showing the positions of the three main nerves (median, radial, and ulnar) of the brachial plexus in relation to the axillary artery, as identified on transverse ultrasonography, at the axilla.

anesthetic around the artery (i.e., “the doughnut sign” in the US image). To achieve this, local anesthetic is injected close to the anterior (12-o’clock position), posterior (6-o’clock position), and lateral (9-o’clock position) aspects of the axillary artery. The musculocutaneous nerve is then identified and selectively blocked using a few milliliters of local anesthetic.<sup>77</sup> We have found this approach to be technically simple, safe, and effective in producing brachial plexus blockade in children (see also Fig. 41-19 and Chapter 41 for landmark-guided techniques).

### SELECTIVE PERIPHERAL NERVE BLOCKS OF THE UPPER EXTREMITY

Selective blockade of the nerves of the upper extremity is very rarely performed in children. It can be used to rescue incomplete or partial axillary brachial plexus block or provide analgesia or anesthesia over a specific dermatome.<sup>78</sup> We have also found it to be useful for US-guided differential nerve blockade in adults undergoing ambulatory hand surgery, and the same also may be applicable in children. In this technique an axillary brachial plexus block is performed using a short-acting local anesthetic agent such as lidocaine and combined with a peripheral nerve block (e.g., a median or ulnar nerve block, depending on the dermatomes involved) in the forearm using a long-acting drug (bupivacaine or ropivacaine). Because of the shorter duration of action of lidocaine compared with bupivacaine or ropivacaine, the child

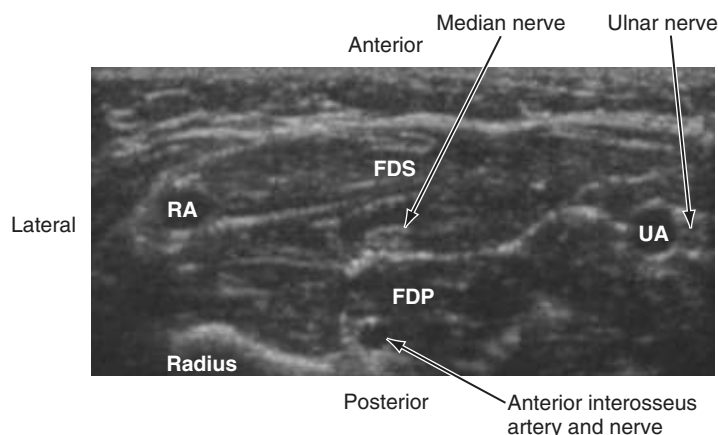

regains protective motor function of the elbow fairly quickly after surgery (2 to 4 hours) while still enjoying prolonged postoperative analgesia from distal nerve blockade. All of the major nerves of the upper extremity (median, ulnar, and radial) can be identified using high-frequency linear-array transducers (13-10 MHz), and it is possible to selectively block these nerves at various sites along their course with only 1 to 2 mL of local anesthetic. We prefer the in-plane needle insertion technique and use a short-beveled block needle for this purpose.

### Median Nerve

The median nerve is closely related to the brachial artery throughout its course in the arm. In the upper part, it is lateral to the artery; in the middle of the arm it crosses the artery from the lateral to medial side and continues on the medial side all the way up to the elbow. In the antecubital fossa, the median nerve lies medial to the brachial artery, behind the bicipital aponeurosis, and in front of the brachialis muscle (Fig. 42-23). In the forearm, the median nerve is deep to the flexor digitorum superficialis and on the surface of the flexor digitorum profundus (Fig. 42-24) and accompanied by the median artery that is a branch of the anterior interosseous artery. Pulsations of the latter can occasionally be observed on the US image. A few centimeters proximal to the wrist, the median nerve becomes superficial and lies between the tendon of the flexor carpi radialis (laterally) and the

**FIGURE 42-23** Transverse sonogram of the cubital fossa. BA, Brachial artery; BCR, brachioradialis.

**FIGURE 42-24** Transverse sonogram of the forearm. FDP, Flexor digitorum profundus; FDS, flexor digitorum superficialis; RA, radial artery; UA, ulnar artery.

flexor digitorum superficialis (medially) and may also be overlapped by the tendon of the palmaris longus. Because the nerve is superficial at this level and it can be difficult to differentiate the nerve from the tendons, we prefer to perform median nerve block at the midforearm, where it is clearly delineated (see also Fig. 41-22 and Chapter 41 for landmark-guided techniques).

### Ulnar Nerve

In the arm, the ulnar nerve runs on the medial side of the brachial artery up to about the midhumeral level or the insertion of the coracobrachialis muscle, where it pierces the medial intermuscular septum and enters the posterior compartment of the arm. At the elbow, it passes behind the medial epicondyle to enter the ulnar nerve sulcus. Although the nerve is palpable and superficial at the sulcus, it is often difficult to visualize using US because of bony and contact artifacts. The ulnar nerve then enters the proximal forearm and runs between the flexor digitorum profundus (posterior) and the flexor digitorum superficialis (laterally) muscles, and in the distal forearm it is accompanied by the ulnar artery (lateral) (see Fig. 42-24). Close to the wrist, the ulnar nerve is lateral to the flexor carpi ulnaris muscle. The ulnar artery may be used as a reference to locate the ulnar nerve. Once the artery is located, the nerve is traced backward and the local anesthetic injection is performed away from the artery (see Chapter 41 for landmark-guided techniques).<sup>79</sup>

### Radial Nerve

In the arm the radial nerve is posterior to the brachial artery. It then leaves the artery to enter the radial (spiral) groove on the back of the arm, where it is accompanied by the profunda brachii artery. In the distal arm the radial nerve pierces the lateral intermuscular septum and enters the anterior compartment. In the antecubital fossa it is lateral to the biceps tendon and lies in an intermuscular gap between the brachialis (medially), the brachioradialis, and the extensor carpi radialis longus (laterally) (Fig. 42-25). At the level of the lateral epicondyle the radial nerve gives off the posterior interosseous nerve (deep branch of the radial nerve), which leaves the fossa by piercing the supinator muscle. In the forearm, the radial nerve (superficial branch of the radial nerve) continues as a pure cutaneous nerve and supplies the radial half of the dorsum of the hand and the proximal parts of the dorsal

**FIGURE 42-25** Transverse sonogram of the arm, just above the elbow, showing the radial nerve. BCR, Brachioradialis; ECRL, extensor carpi radialis longus.

surfaces of the thumb and index finger. The radial nerve is best blocked before its division in the antecubital fossa (see also Figs. 41-2, 41-23, and Chapter 41 for landmark-guided techniques).<sup>78</sup>

## LOWER EXTREMITY BLOCKS

### Lumbar Plexus Block

The lumbar plexus results from the union of the ventral rami of the first four lumbar spinal nerves within the substance of the psoas major muscle.<sup>80</sup> The plexus may also receive contributions from the 12th thoracic nerve or the 5th lumbar nerve. In adults, the plexus is located between the fleshy anterior part of the psoas major muscle, which arises from the anterolateral part of the vertebral bodies and the intervertebral disc, and the accessory posterior part of the muscle that originates from the anterior surface of the transverse process.<sup>81</sup> Local anesthetic injected into this intramuscular plane, also referred to as the *psoas compartment*, produces ipsilateral lumbar plexus block.

An US scan for the lumbar plexus block can be performed in the transverse or sagittal axis at the L3-4 vertebral level. The child is positioned in the lateral position with the side to be blocked uppermost with the hip and knees flexed. A linear-array transducer (10-5 MHz) is adequate for imaging in young children, whereas in the older child (older than 6 to 8 years) a curved-array transducer (8-5 or 5-2 MHz) is required.

For a transverse scan,<sup>82</sup> the US transducer is positioned approximately 2 to 3 cm lateral to the lumbar spine at the L3-4 vertebral level, with its orientation marker directed laterally. We also prefer to align the transducer slightly medially so as to produce a paramedian oblique transverse scan (PMOTS) of the lumbar paravertebral region. Also during a PMOTS of the lumbar paravertebral region, the US beam can be insonated either at the level of the transverse process (PMOTS-TP, Fig. 42-26) or through the gap between the two adjacent transverse process (i.e., the intertransverse space [ITS]) producing a PMOTS-ITS scan (Fig. 42-27). In a typical PMOTS-ITS sonogram of the lumbar paravertebral region, the erector spinae muscle, the vertebral body, the psoas major muscle, quadratus lumborum muscle, and the

**FIGURE 42-26** Paramedian oblique transverse scan of the right lumbar paravertebral region at the level of the transverse process (PMOTS-TP) in a 11-month old infant. Note how the acoustic shadow of the transverse process (TP) obscures the posterior part of the psoas muscle (PM) and how parts of the spinal canal and neuraxial structures (dura, intrathecal space, and cauda equina) are seen through the interlaminar space. CSF, Cerebrospinal fluid; ESM, erector spinae muscle; IVC, inferior vena cava; QLM, quadratus lumborum muscle; SP, spinous process; VB, vertebral body.

**FIGURE 42-27** Paramedian oblique transverse scan of the right paravertebral region through the gap between two adjacent transverse processes (PMOTS-ITS) in a 14-month old child. Note the intervertebral foramen (IVF), articular process (AP), and the lumbar plexus in the posterior part of the psoas muscle (PM). ESM, Erector spinae muscle; IVC, inferior vena cava; PM, psoas muscle.

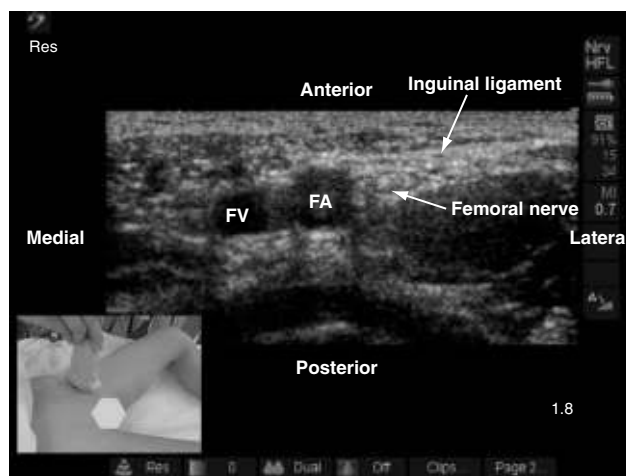

anterolateral surface of the vertebral body are clearly visualized (see Fig. 42-27). The inferior vena cava (on the right side) and the aorta (on the left side) are also identified anterior to the vertebral body. The lower pole of the kidney is closely related to the anterior surfaces of the quadratus lumborum and psoas muscle and is seen as an oval structure that moves with respiration in the retroperitoneal space. The lumbar plexus is not sonographically visualized in all patients, but when it is visualized, it appears as an oval hyperechoic structure in the posterior part of the psoas muscle (see Fig. 42-27) and close to the intervertebral foramen. In contrast, because the acoustic shadow of the transverse process obscures the posterior part of the psoas muscle and the area close to the intervertebral foramen during a PMOTS-TP, the lumbar plexus is rarely visualized in this US scan window (see Fig. 42-26). Therefore, if a transverse scan is performed during an ultrasound-guided lumbar plexus block, it is our recommendation to use the PMOTS-ITS.

For a sagittal scan of the lumbar paravertebral region, the US transducer is positioned approximately 2 to 3 cm lateral and parallel to the lumbar spine,<sup>83</sup> with its orientation marker directed cranially. In a typical sagittal sonogram of the lumbar paravertebral region, the L2, L3, and L4 transverse processes with their acoustic shadow produce what we refer to as the “trident sign” (Fig. 42-28) because of its similarity to the trident (*Limia tridens* or *tridentis*) that is often associated with Poseidon (the god of the sea in Greek mythology) and the trishula of the Hindu god Shiva. The hypoechoic psoas muscle is seen between the transverse processes, and the lumbar plexus is identified as hyperechoic longitudinal striations within the posterior aspect of the muscle. A laterally positioned transducer will produce a suboptimal scan without the trident, and the lower pole of the kidney, which can reach the L4-5 level in young children, will come into view.

Once an optimal image of lumbar paravertebral region is obtained, the insulated block needle is inserted in the plane of the US beam. The needle is inserted from the medial side of transducer when a PMOTS-ITS is used or from the caudal end of the transducer when a sagittal scan is used. The needle is slowly advanced under ultrasound guidance to the posterior part of the psoas muscle, and the correct position of the needle tip close to

**FIGURE 42-28** Longitudinal sonogram of the lumbar paravertebral region showing the lumbar plexus. ESM, Erector spinae muscle; PM, psoas muscle; TP, transverse process (“trident sign”).

the lumbar plexus is confirmed by observing ipsilateral quadriceps muscle contraction. After negative aspiration, an appropriate dose of local anesthetic is injected in aliquots over 2 to 3 minutes and the patient is closely monitored.

### Femoral Nerve Block

The femoral nerve is the largest branch of the lumbar plexus and is the major nerve of the anterior (extensor) compartment of the thigh. It is formed by the dorsal division of the anterior primary rami of spinal nerves L2, L3, and L4. It exits the pelvis and enters the femoral triangle in the thigh by passing under the inguinal ligament just lateral to the femoral artery. In the thigh it lies in the groove between the iliacus and the psoas major muscle, outside the femoral sheath, and lateral to the artery. A high-frequency (13-10 MHz) linear-array transducer is used to scan the femoral nerve.<sup>36,84</sup> On a transverse sonogram the femoral nerve is seen as an oval or triangular hyperechoic structure lateral to the femoral artery (Fig. 42-29). The femoral nerve exhibits marked anisotropy, and it may be necessary to tilt or rotate the transducer during the scan before it can be visualized. In young children

one must avoid exerting too much pressure during the scan because it is easy to collapse the femoral vein.

A femoral nerve block is used to provide postoperative analgesia after femoral fractures. It is performed with the child in the supine position. The ipsilateral lower limb is slightly abducted and externally rotated, and the knee is also slightly flexed. A right-handed operator stands on the right side of the child, and the US machine is positioned directly in front on the contralateral side. The sides of the operator and the US machine are reversed for a left-handed operator. The scout scan is performed with the transducer positioned parallel and just below the inguinal ligament. This ensures that the femoral nerve is scanned before its division. Once an optimal view of the femoral nerve is obtained, the block needle is inserted in the long axis (in-plane) of the US transducer from the lateral to medial side and directed to the lateral aspect of the femoral nerve. A test injection with saline (1 to 2 mL) is performed before the local anesthetic is injected to confirm that the needle is deep to the fascia iliaca and to observe the distribution of the injectate in relation to the femoral nerve (see also Fig. 41-32 and Chapter 41 for landmark-guided techniques).

### Subsartorial Saphenous Nerve Block

The saphenous nerve is a branch of the anterior division of the femoral nerve and supplies the skin on the medial aspect of the leg and foot up to the ball of the big toe. In the thigh, the saphenous nerve is located in the subsartorial canal and local anesthetic injected into this intramuscular space produces a saphenous nerve block.<sup>85-87</sup> The subsartorial canal is also referred to as the adductor canal or Hunter's canal and is situated on the medial side of the middle one third of the thigh and extends from the apex of the femoral triangle, above, to the tendinous opening in the adductor magnus muscle, below. The canal is triangular in cross section, and its anterior wall is formed by the vastus medialis muscle, the posterior wall or floor is formed by the adductor longus, and the medial wall or roof is formed by a strong fibrous membrane that is overlapped by the sartorius muscle (Fig. 42-30). The subsartorial canal contains the following structures: femoral artery and vein, saphenous nerve, nerve to vastus medialis, and the two divisions of the obturator nerve. The femoral vein lies posterior to the artery in the upper part and

lateral to the artery in the lower part of the canal. The saphenous nerve crosses the femoral artery anteriorly from the lateral to the medial side in the canal.

A high-frequency (13-6 MHz) linear-array probe is used to scan the saphenous nerve in the subsartorial canal with the child in the supine position. The ipsilateral lower limb is slightly abducted and externally rotated, and the knee is also slightly flexed. For a right-sided block, a right-handed operator stands on the right side of the patient and the US machine is positioned directly in front on the contralateral side. The transducer is positioned in the transverse axis over the middle one third of the thigh. The triangular subsartorial canal can be identified between the epimysium of the vastus medialis (closely related to the femur), the adductor longus, and the sartorius muscles. The pulsatile femoral artery lies anterior to the vein in the canal, and the saphenous nerve is seen as a round or oval hyperechoic structure anterior to the artery (12-o'clock position). Because the saphenous nerve is a small nerve, it may not always be visible on US imaging in children. However, owing to the close relation of the saphenous nerve to the femoral artery in the subsartorial canal, a perivascular (arterial) injection in the canal will produce saphenous nerve block. The block needle is inserted in the long-axis (in-plane) of the US transducer from the medial to lateral side and is directed to the anterior aspect of the femoral artery. A test injection of saline (1 to 2 mL) is performed to confirm that the tip of the needle is in the canal, after which the local anesthetic is injected.

### Sciatic Nerve Block

The sciatic nerve is the largest mixed nerve in the body and arises from the lumbosacral plexus (L4, L5, S1-3). It innervates the posterior aspect of the thigh and the entire lower limb below the knee except for a small patch of skin on the medial aspect of the leg and ankle, which is innervated by the saphenous nerve. Sciatic nerve block is frequently used to provide analgesia for foot (clubfoot) and leg surgery in children. Several different approaches to the sciatic nerve have been described in the literature. Most approaches described to date rely on surface anatomic landmarks (anterior, transgluteal, infragluteal, lateral, posterior subgluteal, proximal thigh, or at the popliteal fossa). Recently, US-guided sciatic nerve block also has been described.<sup>88,89</sup> A proximal approach to the sciatic nerve is selected when surgery involves the hip (rare in children) or block of the posterior cutaneous nerve of the thigh is warranted. Because sciatic nerve block is most frequently used for foot (clubfoot) surgery in children, a distal approach to the sciatic nerve at the popliteal fossa is usually preferred (see also Fig. 41-31 and Chapter 41 for landmark-guided techniques).

### Sciatic Nerve Block at the Subgluteal Space

The sciatic nerve exits the pelvis through the greater sciatic foramen, between the piriformis and the superior gemelli muscles, and enters the subgluteal space below the piriformis muscle. It then descends over the dorsum of the ischium, lying on the dorsal surface of the gemellus superior muscle, tendon of obturator internus, gemellus inferior muscle, and quadratus femoris muscle (in a cranial to caudal relation) before it enters the hollow between the greater trochanter and the ischial tuberosity and then goes on to the posterior compartment of the thigh. The anterior surface of the gluteus maximus covers the upper part of the sciatic nerve; and immediately distal to its lower border (infragluteal position), the sciatic nerve is fairly superficial. In between the greater trochanter and the ischial tuberosity, the sciatic nerve lies

**FIGURE 42-30** Transverse sonogram of the thigh showing the adductor canal. AL, Adductor longus; FA, femoral artery; FV, femoral vein; VM, vastus medialis.

**FIGURE 42-31** Transverse section through the gluteal region at the level of the quadratus femoris muscle showing the subgluteal space and its contents.

in the subgluteal space, which is a well-defined anatomic space between the anterior surface of the gluteus maximus and the posterior surface of the quadratus femoris muscle (Fig. 42-31).<sup>88,89</sup> Other structures that are present in the subgluteal space include the posterior cutaneous nerve of the thigh, inferior gluteal vessels and nerve, nerve to the short and long head of the biceps femoris, the comitans artery and vein of the sciatic nerve, and the ascending branch of the medial circumflex artery (see Fig. 42-31). Local anesthetic injected into the subgluteal space blocks not only the sciatic nerve but also the posterior cutaneous nerve of the thigh. The latter is useful when anesthesia over the posterior aspect of the thigh is needed.

US-guided sciatic nerve block at the subgluteal space is performed with the child in the lateral position. The side to be anesthetized is placed uppermost, and the hip and knees are flexed (Fig. 42-32). The operator sits or stands behind the child, and the US machine is positioned directly in front. In young children, a linear-array transducer (10-5 MHz) is adequate for imaging the sciatic nerve. In children older than 6 to 8 years, the sciatic nerve can also be imaged using a linear-array transducer (10-5 MHz). However, the increased depth of scan required (as a result of increased muscle bulk) limits the field of vision because as the depth of scan increases the field of vision becomes narrower when a linear transducer is used. Therefore a curved-array transducer (8-5 or 5-2 MHz) with a wide field of vision is preferable in older children.

The greater trochanter and the ischial tuberosity are identified, and a line is drawn between these two landmarks. The US transducer is placed parallel to this line, with its orientation marker directed toward the greater trochanter to obtain a transverse scan of the sciatic nerve and the subgluteal space. It may be necessary to slide the transducer slightly cephalad or caudad before an optimal image of the sciatic nerve in the subgluteal space can be obtained. On a sonogram, the subgluteal space is seen as a hypoechoic area between the hyperechoic epimysium of the gluteus maximus and quadratus femoris muscle (see Fig. 42-32) extending from the greater trochanter laterally to the ischial

**FIGURE 42-32** Transverse sonogram between the greater trochanter and the ischial tuberosity showing the hypoechoic subgluteal space between the hyperechoic perimysium of the gluteus maximus and the quadratus femoris muscle. The sciatic nerve is seen as a hyperechoic structure in the medial aspect of the subgluteal space. GM, Gluteus maximus; QF, quadratus femoris.

tuberosity medially.<sup>88,89</sup> The subgluteal space is not so well delineated in young children and is better visualized in older children. The sciatic nerve is seen as an oval or triangular hyperechoic structure within the subgluteal space (see Fig. 42-32). The medial limit of the space is obscured by the attachments of the semi-membranosus, semitendinosus, and biceps femoris muscles to the ischial tuberosity. Pulsations of the inferior gluteal artery often can be detected medial to the sciatic nerve on the sonogram.

The block needle is inserted using in-plane technique from the ischial tuberosity side and advanced slowly toward the sciatic nerve. Once the block needle is deemed to be in the subgluteal space, the position is confirmed by injecting 1 to 3 mL of saline through the needle and observing a distention of the subgluteal space (i.e., separation of the epimysium of the gluteus maximus

**FIGURE 42-33** Transverse sonogram of the sciatic nerve at the subgluteal space after local anesthetic injection. Note the distention of the subgluteal space caused by the local anesthetic and the distribution of local anesthetic around the sciatic nerve. GM, Gluteus maximus; LA, local anesthetic; QF, quadratus femoris.

and quadratus femoris muscle) on the US image (Fig. 42-33). However, if the test injection of saline is seen to spread posterior to the epimysium of the gluteus maximus muscle, it indicates that the tip of the needle is not in the subgluteal space. The needle should be reoriented and advanced a little farther until the typical distention of the subgluteal space to the saline test injection is seen. Occasionally, a subtle pop is felt when the needle tip traverses the epimysium of the gluteus maximus muscle and enters the subgluteal space. Local anesthetic is then injected in aliquots over 2 to 3 minutes while observing for the distention of the subgluteal space and the spread of local anesthetic in relation to the sciatic nerve. It is also easy to pass a catheter into the subgluteal space when a continuous sciatic nerve block is planned. Because the catheter is inserted into an anatomic space, the catheter is also more likely to stay in situ (see also Figs. 41-28, 41-29, and 41-31, and Chapter 41 for landmark-based techniques).

### Sciatic Nerve Block at the Popliteal Fossa

The sciatic nerve block at the popliteal fossa is also referred to as the *popliteal fossa block* and is the preferred approach for sciatic nerve block in children undergoing foot surgery. The popliteal fossa is a diamond-shaped space lying behind the knee joint, the lower part of the femur, and the upper part of the tibia. It is bound superolaterally by the tendon of biceps femoris, superomedially by the tendon of semitendinosus and the semimembranosus, inferolaterally by the lateral head of gastrocnemius, and inferomedially by the medial head of gastrocnemius. The sciatic nerve enters the posterior aspect of the thigh at the lower border of the gluteus maximus and runs vertically downward to the apex of the superior triangle of the popliteal fossa, where it terminates by dividing into the tibial and the common peroneal nerve, usually 3 to 7 cm above the popliteal crease.<sup>90,91</sup> The division of the sciatic nerve into its terminal branches may, however, take place anywhere above this level. This accounts for the occasional sparing of either division of the sciatic nerve after distal sciatic nerve block techniques using nerve stimulation.

Although the classic teaching is to perform popliteal sciatic nerve block with the patient in the prone position, it is very

**FIGURE 42-34** Popliteal sciatic nerve block. Transverse sonogram of the sciatic nerve at the apex of the popliteal fossa. AM, Adductor magnus; BF, biceps femoris.

commonly performed in children with the child in the supine position with the leg elevated by an assistant (Fig. 42-34). During US-guided popliteal sciatic nerve block the operator sits on the ipsilateral side facing the head of the patient and the US machine is positioned directly in front. In young children, a linear-array transducer (10-5 MHz) is adequate for imaging the sciatic nerve in the popliteal fossa. In the adolescent child or children with muscular thighs, a curved-array transducer (8-5 MHz) may be preferable. The transducer is positioned just above the apex of the upper triangle of the popliteal fossa in the transverse axis (see Fig. 42-34). It may be necessary to first scan for the sciatic nerve in the middle of the thigh and then trace it distally to the popliteal fossa, where the sciatic nerve is seen as a round, hyperechoic structure. Division of the sciatic nerve into the tibial and common peroneal nerve can also be visualized in children; location of this division varies widely among children. In the popliteal fossa and proximal to the popliteal crease, the tibial and common peroneal nerve are seen as hyperechoic structures superficial and lateral to the popliteal artery.

The block needle is inserted using in-plane technique from the lateral aspect of the thigh with its point of entry being anterior to the tendon of the biceps femoris (if it is palpable). This places the needle in the same orientation as for the lateral approach to the sciatic nerve at the popliteal fossa. The exact point of needle entry will depend on where the sciatic nerve is best visualized. The needle is gradually advanced under US guidance, and the tip is positioned just posterior to the sciatic nerve. This is confirmed by injecting 1 to 3 mL of saline through the needle, after which half of the calculated dose of local anesthetic is injected. The same process is repeated by repositioning the tip of the needle anterior to the sciatic nerve. This ensures that the local anesthetic spreads optimally around the sciatic nerve (see also Fig. 41-30 and Chapter 41 for landmark-guided techniques).

## TRUNCAL BLOCKS

### Rectus Sheath Block

Rectus sheath block is the technique of injecting local anesthetic into the potential space between the rectus muscle and the posterior rectus sheath. This produces anesthesia of the ventral rami of the intercostal nerves as they traverse the rectus muscle to supply the skin of the anterior abdominal wall on either side of

the midline. Because the seventh and eight intercostal nerves also provide motor innervation to the rectus abdominis muscle, a rectus sheath block at this level should also produce relaxation of the muscle. Bilateral rectus sheath blocks are frequently used in children to provide perioperative analgesia during umbilical and paraumbilical hernia.<sup>92</sup> We have also found it to be useful for analgesia after laparoscopic procedures in children in whom the port insertion sites are close to the midline.

The rectus abdominis muscle arises as two tendinous heads from the lateral part of the pubic crest and the anterior pubic ligament. The fibers run vertically upward and are inserted to the front of the chest wall through the xiphoid process and the 5th, 6th, and 7th costal cartilages. The muscle is enclosed in a fibrous aponeurotic sheath, the rectus sheath, which is formed by the aponeurosis of the external oblique, internal oblique, and transversus abdominis muscles. The anterior rectus sheath is complete and covers the muscle from end to end. However, the posterior rectus sheath is incomplete, being deficient above the costal cartilage and below the arcuate line (or the fold of Douglas), which is located midway between the umbilicus and the pubic symphysis. The rectus sheath on both sides is held together in the midline by a raphe, the linea alba, which is formed by the fusion of the fibers of the three aponeuroses that form the rectus sheath. The ventral rami of the 7th to 12th intercostal nerves pass anteriorly and downward from the intercostal spaces and pierce the posterolateral aspect of the rectus sheath before passing anteriorly through the muscle to supply the skin of the anterior abdominal wall. Three transverse fibrous bands (tendinous insertions), one at the level of the umbilicus, one at the level of the xiphoid process, and one midway between the two, divide the rectus muscle into three smaller parts. These fibrous bands are adherent to the anterior rectus sheath and traverse only the anterior half of the rectus muscle. Therefore a potential space exists between the rectus muscle and the posterior rectus sheath that communicates from the xiphisternum to the pubic crest. Local anesthetic injected into this space can spread up and down the sheath and is the basis of a rectus sheath tumor.

A linear-array transducer (13-10 MHz) with a small footprint (25 mm) is used for imaging in children (E-Fig. 42-2). The operator stands or sits on one side of the anesthetized child, and the US machine is positioned directly opposite on the contralateral side. The transducer is positioned in the longitudinal axis midway between the umbilicus and the xiphisternum. The rectus muscle is seen as a hypoechoic structure between the hyperechoic anterior and posterior rectus sheath (see E-Fig. 42-2). Deep to the posterior rectus sheath the hyperechoic peritoneum can be recognized by its typical peritoneal sliding movement and the “comet-tail” artifacts produced. The fibrous bands (tendinous insertions) in the rectus sheath can also be recognized in the longitudinal sonogram as hyperechoic areas on the anterior surface of the hypoechoic muscle that do not traverse the whole muscle belly.<sup>93,94</sup> The linea alba can be recognized on a transverse sonogram, and the posterior deficiency of the rectus sheath is also readily recognized below the level of the arcuate line.

The block needle is inserted using in-plane technique in a caudal to cranial direction (E-Fig. 42-3). When the tip of the needle is visualized in the potential space between the rectus muscle and the posterior rectus sheath, a test injection of saline (1 to 3 mL) is performed to confirm the longitudinal spread of the injectate between the muscle and the rectus sheath and the widening of the space (see E-Fig. 42-3, *C* and *D*). Injection into the muscle will offer resistance to injection and is readily

recognized in the sonogram. The needle should be repositioned, and the typical spread of the test injection under the rectus muscle should be confirmed before a calculated dose of the local anesthetic is injected. For umbilical hernia surgery, bilateral rectus sheath blocks are performed just above the umbilicus on either side (see also Fig. 41-16 and Chapter 41 for landmark-guided techniques).

### Ilioinguinal and Iliohypogastric Nerve Blocks

Ilioinguinal and iliohypogastric nerve blocks are used to provide analgesia after inguinal hernia repair, orchidopexy, or hydrocele surgery. The analgesia is comparable to caudal epidural analgesia, and it offers the advantage of not affecting micturition after surgery,<sup>95</sup> making it ideal for analgesia in children undergoing an outpatient procedure. Currently, anatomic landmarks and tactile sensations are relied on to perform the block,<sup>95</sup> which unfortunately can result in failure in up to 20% to 30% of cases. Moreover, it can also lead to complications such as femoral nerve palsy,<sup>96,97</sup> pelvic hematoma,<sup>98</sup> and bowel perforation.<sup>99</sup> A US-guided ilioinguinal iliohypogastric nerve block has been described in children.<sup>21,100</sup> Compared with the traditional landmark-based method, US-guided ilioinguinal iliohypogastric nerve block is accomplished more accurately, using smaller volumes of local anesthetic, and has a greater success rate.

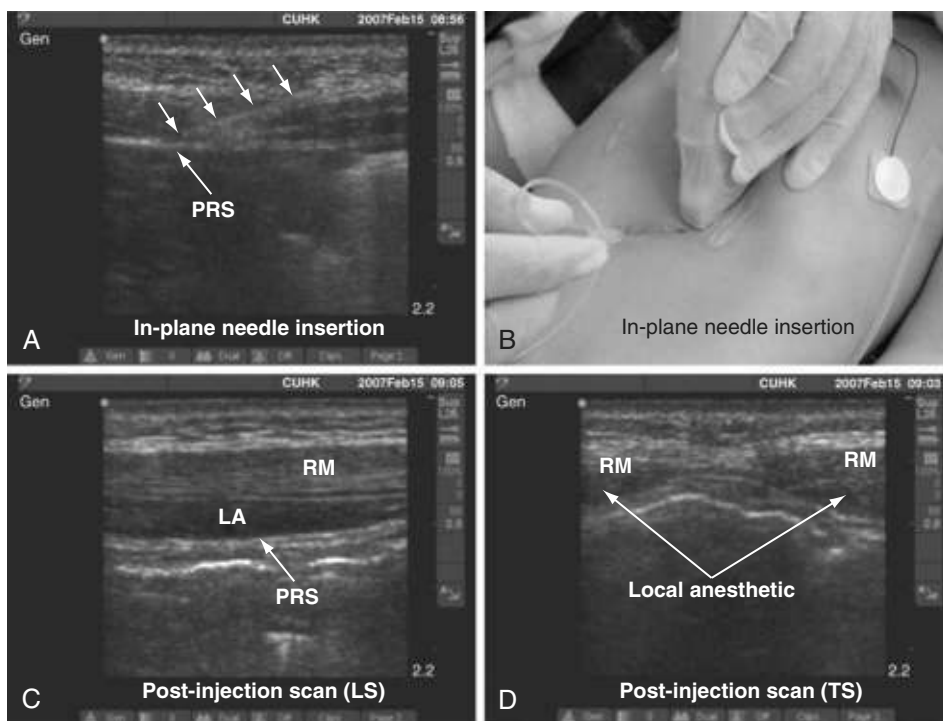

The ilioinguinal and iliohypogastric nerves are branches of the primary ventral ramus of L1, which arises from the lumbar plexus. It also receives contributions from the T12 spinal nerve. Superomedial to the anterior superior iliac spine (ASIS), the two nerves pierce the transversus abdominis muscle to lie between it and the internal oblique muscle. The iliohypogastric nerve is situated superior to the ilioinguinal nerve and continues inferomedially for a short distance, after which their ventral rami transverse the internal oblique muscle to lie between the internal and external oblique muscles before giving off branches that pierce the external oblique muscle to provide cutaneous sensation. The iliohypogastric nerve supplies sensory innervation to the skin over the inguinal region. The ilioinguinal nerve continues antero-inferiorly with the spermatic cord or the round ligament of the uterus in the inguinal canal and becomes superficial by emerging through the superficial inguinal ring to innervate the skin of the upper medial aspect of the thigh and either the skin of the upper part of the scrotum and the root of the penis or the skin covering the labia majora and mons pubis.

A linear-array transducer (13-10 MHz) is used for the imaging and the ilioinguinal and iliohypogastric nerves, which are best visualized close to the ASIS. The operator stands on the ipsilateral side to be blocked, and the US machine is positioned directly opposite on the contralateral side. The transducer is positioned close to the ASIS and parallel to a line joining the ASIS and the umbilicus (Fig. 42-35). The ilioinguinal and iliohypogastric nerves are identified as two small, rounded structures lying side by side between the internal oblique and transversus abdominis muscle (see Fig. 42-35). The external oblique is frequently identified only as a hyperechoic aponeurotic layer at the point of needle insertion. Deep to the transversus abdominis muscle the peritoneum and the bowel are also visualized (see Fig. 42-35).

The block needle is inserted in the long axis (in-plane) of the US beam in a medial to lateral direction (Fig. 42-36). We prefer this orientation because it facilitates visualization of the needle (in-plane) and, in the event that the needle is inadvertently inserted too deep, further passage is obstructed by the iliac bone,

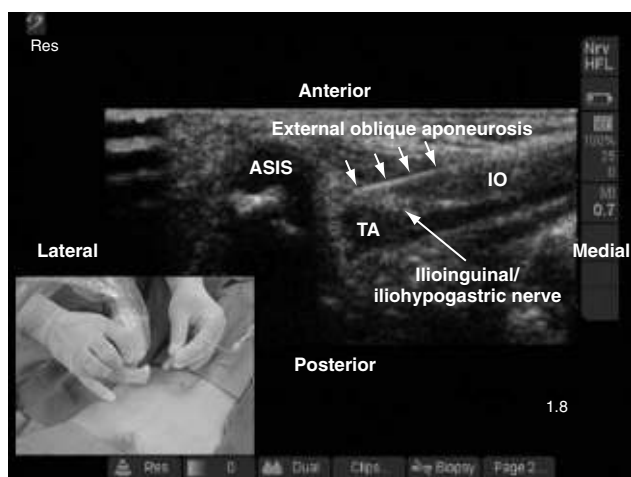

**E-FIGURE 42-2** Longitudinal sonogram of the rectus muscle showing the anterior and posterior rectus sheath.

**E-FIGURE 42-3** Rectus sheath block. The in-plane needle insertion technique. LA, Local anesthetic; LS, longitudinal sonogram; PRS, posterior rectus sheath; RM, rectus muscle; TS, transverse sonogram.

**FIGURE 42-35** Transverse sonogram of the inguinal region showing the ilioinguinal and iliohypogastric nerves and its relation to the abdominal musculature. ASIS, Anterior superior iliac spine; IO, internal oblique; TA, transverse abdominis.

thus reducing the potential for a major complication such as bowel perforation. When the tip of the needle is close to the two nerves, a test injection is performed with 0.5 to 1 mL of normal saline. Correct position of the needle tip is confirmed by observing the widening of the tissue plane between the internal oblique and the transversus abdominis muscle. A calculated dose of a long-acting local anesthetic (0.2 mL/kg) is then injected through the needle, and the spread of the local anesthetic to both nerves is visualized (see also Fig. 41-14 and Chapter 41 for landmark-guided techniques).

### Transversus Abdominis Plane (TAP) Block

The sensory supply of the abdominal wall is provided by the anterior rami of the T7 to L1 thoracolumbar nerves. T7 to T9 innervate the skin above the umbilicus, T10 innervates the skin around the umbilicus, and T11, T12 (cutaneous branches of the subcostal nerve), and L1 (iliohypogastric and ilioinguinal nerves) innervate the skin below the umbilicus. These nerves pass infero-anteriorly in a plane between the internal oblique and transversus

abdominis muscles, also known as the transversus abdominis plane (TAP). The lateral cutaneous branch is given off at the midaxillary line and innervates the abdominal wall up to the lateral edge of the rectus abdominis muscle. The segmental nerve then courses anteriorly and medially toward the midline in the TAP to penetrate the lateral margin of the rectus sheath and emerge anteriorly through the rectus muscle as the anterior cutaneous branch. The lateral and anterior cutaneous branches of the thoracolumbar nerves supply the skin from the midline to the anterior axillary line. The thoracolumbar nerves, as they course through the TAP, also supply muscular branches to the abdominal musculature.

Local anesthetic injected into the TAP plane produce sensorimotor blockade (segmental) of the abdominal wall, and two techniques, the posterior TAP block and subcostal TAP block, have been described.<sup>101,102</sup> In the posterior TAP block the local anesthetic is injected in the TAP plane between the iliac crest and the costal margin, and during a subcostal TAP block the local anesthetic is injected into the TAP plane just below the costal margin at the midclavicular line. Anesthesia and analgesia produced by a TAP block is unilateral; thus it is useful for surgical procedures (e.g., orchidopexy, herniotomy, appendectomy) in which the incision does not cross the midline. Bilateral TAP blocks are indicated for abdominal surgical procedures in which the surgical incision is in the midline or across the midline. It is also the authors' practice to perform bilateral TAP blocks for laparoscopic procedures. Because TAP blocks do not produce visceral analgesia, they should be used as part of a multimodal analgesic regimen for perioperative analgesia. Currently, published data on the use of TAP blocks for perioperative analgesia in children are limited<sup>101,103</sup> but may be useful as an alternative when central neuraxial blocks are contraindicated (e.g., in children with underlying coagulopathy or spinal dysraphism).

For a posterior TAP block, a high-frequency linear array transducer (15-7 MHz) is placed midway between the iliac crest and the costal margin along the midaxillary line (Fig. 42-37, A). For infants and young children, a linear transducer with a small footprint (25 mm) is preferred. The operator stands or sits on one side of the anesthetized child, and the US machine is positioned directly opposite on the contralateral side. The various layers of the abdominal wall are identified on the sonogram (see Fig. 42-37, B). From superficial to deep, they include a layer of subcutaneous tissue and fat and the three abdominal muscles with their fascial layers (i.e., the external oblique, internal oblique, and the transversus abdominis muscles, respectively). Deep to the transversus abdominis muscle the hypoechoic peritoneum is also visualized (see Fig. 42-37, B). The block needle (50 mm) is inserted 1 to 2 cm medial to the medial edge of the ultrasound transducer (Fig. 42-37, C), depending on the depth at which the TAP is located (can be determined using the electronic caliper in the US system), and in the plane of the US beam. Because the abdominal wall in infants and young children is relatively thin, and to avoid inadvertent deep needle insertion and visceral puncture it is the authors' practice to initially insert the block needle directed toward the US transducer rather than in an anteroposterior direction. Once the needle tip penetrates the skin and enters the abdominal muscle, it is redirected and slowly advanced under direct vision and penetration of the tip through the external oblique and internal oblique muscles, and finally the TAP is identified between the internal oblique and transversus abdominis muscles. A test injection (1 mL) of saline is performed to confirm correct needle placement in the TAP, which is indicated

**FIGURE 42-37** Posterior transverse abdominis plane (TAP) block. **A**, Note how the US transducer is positioned between the iliac crest and the costal margin along the mid-axillary line. **B**, The three layers of the abdominal musculature. **C**, In-plane needle insertion during a posterior TAP block. **D**, Distention of the TAP by the injected local anesthetic (LA). EOM, External oblique muscle; IOM, internal oblique muscle; TAM, transversus abdomen muscle.

by distention of the TAP by the hypoechoic fluid. A calculated dose of a long-acting local anesthetic (0.2 mL/kg) is then injected through the needle, while distention of the TAP is visualized in realtime (see Fig. 42-37, *D*).

For a subcostal TAP block, a high-frequency linear array transducer (15-6 MHz) is placed immediately below the costal margin along the midclavicular line and the block needle (50 to 80 mm) is inserted in the plane of the US beam and from a medial to lateral direction until the tip is identified to be in the TAP. As described earlier, saline 1 to 2 mL is injected to confirm correct needle placement in the TAP. A calculated dose of local anesthetic (0.2 mL/kg) is then injected, and as the local anesthetic hydro-dissects the TAP plane, the block needle is advanced posteriorly in the TAP to improve spread of the local anesthetic. Bilateral subcostal TAP blocks are indicated for midline upper abdominal incision. Currently, no published data exist on the use of subcostal TAP blocks in children and its role in children is still not defined.

### Thoracic Paravertebral Block

Thoracic paravertebral block is the technique of injecting local anesthetic alongside the thoracic vertebra close to the intervertebral foramen.<sup>104</sup> This produces ipsilateral, segmental, somatic, and sympathetic nerve blockade that is effective for relieving postoperative pain of unilateral origin from the chest<sup>105</sup> and abdomen.<sup>106</sup> Traditionally, thoracic paravertebral block is performed using surface anatomic landmarks<sup>106</sup> or a catheter is placed in the paravertebral space under direct vision during thoracic surgery (see Chapter 41).<sup>105</sup> Currently, no published data exist on US-guided thoracic paravertebral block in children, although there are several reports in adults.<sup>107,108</sup> The following section describes how the authors perform real-time, in-plane

US-guided single-shot thoracic paravertebral block and paravertebral catheter placement in young infants.

US-guided thoracic paravertebral block is performed with the child in the lateral position and with the side to be blocked uppermost. The operator sits or stands behind the child, and the US machine is positioned directly in front on the opposite side of the operating table. In most children a 15-6-MHz linear array transducer is adequate for imaging the paravertebral anatomy. However, a high-frequency linear array transducer with a small footprint (25 mm) is ideal for US-guided thoracic paravertebral block in neonates and young infants. For a US-guided thoracic paravertebral block for thoracotomy, the US transducer is placed at the midthoracic region and a transverse scan of the thoracic paravertebral region is performed with the orientation marker directed laterally. On a transverse sonogram of the thoracic paravertebral region and with the US beam being insonated between two adjacent ribs, the paraspinal muscles are identified as hypoechoic structures on either side of the midline and posterior to the spinal osseous elements (Fig. 42-38). The spinous process and lamina are identified as hyperechoic structures. Because the posterior spinal elements are cartilaginous in neonates and young infants, the acoustic window for imaging is relatively large and it is possible to visualize the neuraxial elements in the same transverse sonogram (see Fig. 42-38). Anterior to the lamina and transverse process the pleura can be visualized as a hyperechoic structure that moves synchronously with respiration or ventilation (see Fig. 42-38). A hypoechoic triangular space may also be visualized lateral to the paravertebral region and posterior to the pleura, which represents the apex of the thoracic paravertebral space (see Fig. 42-38).

For a US-guided thoracic paravertebral block, the block needle (50 mm) is inserted lateral to the US transducer and advanced

**FIGURE 42-38** Transverse sonogram demonstrating the sonoanatomy of the right thoracic paravertebral region in a neonate. Note the hyperechoic pleura anteriorly and the hypoechoic apical part of the thoracic paravertebral space (TPVS) posterior to the pleura. Also note the large acoustic window resulting from incomplete ossification of the posterior spinal elements that allows visualization of the neuraxial structures within the spinal canal. CSF, Cerebrospinal fluid; PSM, paraspinal muscles.

**FIGURE 42-39** Transverse sonogram of the right thoracic paravertebral region in a neonate after an ultrasound-guided thoracic paravertebral block. Note the direction of needle insertion and distention of the right thoracic paravertebral and intercostal spaces, adjacent to the level of injection, with the local anesthetic (LA). PSM, Paraspinal muscle.

toward the apical part of the paravertebral space in the plane of the US beam. The advancing needle is visualized in real time, and entry into the apex of the thoracic paravertebral space is confirmed using a test bolus injection (1 mL) of saline. Correct placement of the needle in the paravertebral space is indicated by anterior displacement of the parietal pleura, distention of the paravertebral space, and increased echogenicity of the parietal pleura (Fig. 42-39). A calculated dose of local anesthetic (0.2 mL/kg) is then injected with the needle in situ before a catheter is inserted through the needle, leaving approximately 2 cm of catheter in situ if a continuous thoracic paravertebral block is planned (see also Figs. 41-17, 41-18, and Chapter 41 for landmark-guided techniques).

### Spinal Sonography and Central Neuraxial Blocks

Since the early 1980s, spinal ultrasonography has been used as a diagnostic screening tool in neonates and infants suspected of

**FIGURE 42-40** Longitudinal paramedian sonogram of the thoracic spine in a neonate. CSF, Cerebrospinal fluid.

spinal dysraphism and for detecting spinal tumors, vascular malformations, and trauma.<sup>109,110</sup> Today it is considered the first-line screening test for spinal dysraphism, with a diagnostic sensitivity comparable to that of MRI. Spinal ultrasonography is possible in neonates and infants because the incomplete ossification of the predominantly cartilaginous posterior spinal elements creates an acoustic window that allows the transmission of the US beam. The overall visibility of neuraxial structures decreases with age.<sup>109</sup> Neuraxial structures are best visualized in neonates and infants younger than 3 months of age; progressive ossification of the posterior spinal elements makes detailed sonographic evaluation of the spine difficult beyond 6 months of age unless the child has a persistent posterior spinal defect.<sup>111</sup> Some reports have demonstrated that neuraxial structures can be visualized in older children, although their details are limited. The overall visibility of neuraxial structures also decreases as one progresses up the spine, with the best visibility in the sacral level followed by the lumbar and then at the thoracic level.

In diagnostic radiology, spinal US is most frequently performed with the child in the prone position, whereas in an anesthetized child it is generally performed with the child in the lateral position. Because the neuraxial structures are relatively superficial in children, they are best visualized using high-frequency (10-5 MHz) transducers, which also produce better images than sector transducers. Scans are obtained in both the transverse (axial) and longitudinal (sagittal) axes, and they are performed either through the midline or parallel and lateral (paramedian) to the spinous processes. The paramedian scan is preferable in older children because it avoids the ossified spinous processes that can interfere with US transmission. In neonates and young infants, the spinal canal can be scanned with the transducer placed directly over the spinous processes (i.e., a median longitudinal scan). Beyond this age group a paramedian longitudinal scan provides the best overall view of neuraxial structures.<sup>112-114</sup>

On a longitudinal sonogram, the neonatal spinal cord is seen as a hypoechoic tubular structure with hyperechoic anterior and posterior walls (Fig. 42-40). A thin strip of variable intense echo, "the central echo complex" (see Fig. 42-40), extends longitudinally through the center of the spinal cord and represents the area between the myelinated ventral white commissure and the

**FIGURE 42-41** Longitudinal paramedian sonogram of the thoracolumbar spine in a neonate showing the termination of the spinal cord. CSF, Cerebrospinal fluid.

central portion of the anterior median fissure. This produces the “triplet echoes” that are characteristic of the spinal cord at all levels (see Fig. 42-40). The diameter of the spinal cord varies, being largest in the cervical and lumbar regions and smallest at the thoracic region. Anterior and posterior to the spinal cord are two well-defined linear and hyperechoic echoes that represent the arachnoid-dural layer (see Fig. 42-40). The ligamentum flavum, which is relevant for epidural access, is also readily visualized in young children and appears less echogenic than the dura (E-Fig. 42-4). The dural layers taper distally to close the thecal sac at the S2 level. The epidural space is the hypoechoic area between the dura and the ligamentum flavum (see E-Fig. 42-4), and arterial pulsations also may be visible on US between these two layers. The cerebrospinal fluid (CSF) surrounds the spinal cord as an anechoic layer between the dura and spinal cord (E-Fig. 42-5). The vertebral bodies are seen as echogenic structures anterior to the spinal cord. The spinal cord tapers distally to form the conus medullaris (Fig. 42-41) at the level of first and second lumbar vertebral bodies. The conus medullaris is continuous with the filum terminale, which extends into the sacral canal as a hyperechoic structure. It is surrounded by the roots of the cauda equina, which appear as multiple parallel echogenic lines surrounding the filum terminale (E-Fig. 42-6). Differentiation of the filum terminale from the roots of the cauda equina can sometimes be difficult. The cauda equina typically lies in the anterior half of the spinal canal when the child is in the prone position, but it moves freely within the CSF with change in position and with crying. Slight anteroposterior movement of the spinal cord, superimposed on the arterial pulsations, is commonly seen during real-time imaging.

On a transverse (axial) sonogram, the spinal cord is seen as a round or oval hypoechoic structure, with its bright central echo complex (Fig. 42-42). The spinal cord is fixed laterally by the dentate ligament (see Fig. 42-42), which represents the transversely oriented, echogenic arachnoid duplications that are seen in parts of the thoracic spinal canal. Paired (ventral and dorsal) echogenic nerve roots are seen below the L2 level. Farther caudally in the lumbar region, a transverse scan shows the filum terminale surrounded by the nerve roots of the cauda equina (E-Fig. 42-7). The arachnoid-dura mater complex is hyperechoic and forms the anterior and posterior border of the subarachnoid

**FIGURE 42-42** Transverse sonogram of the thoracic spine in a neonate. CSF, Cerebrospinal fluid.

space with the anechoic CSF and the spinal cord in the thoracic region (see Fig. 42-42) and the cauda equina in the lumbar region (see E-Fig. 42-7). The vertebral bodies are the hyperechoic structures anterior to the spinal canal. The vertebral arches are also echogenic and cast an acoustic shadow anteriorly (see E-Fig. 42-7). The paraspinal muscles appear hypoechoic on US.

### CAUDAL EPIDURAL ANESTHESIA

Single-shot caudal epidural injection is the most frequently used regional anesthetic technique in children and almost always is used in combination with general anesthesia for surgery involving the lower thoracic, lumbar, and sacral dermatomes.<sup>115</sup> Several methods are used to perform a caudal epidural injection.

Detecting the characteristic pop or give as the needle traverses the sacrococcygeal ligament to enter the caudal epidural space is by far the most commonly used method in children.<sup>115,116</sup> However, even in experienced hands it can result in failure, and the overall failure rate varies between 2.8% and 11%.<sup>117</sup> US has been used to guide caudal epidural injection in children.<sup>118,119</sup> The correct position of a needle or catheter in the caudal epidural space is confirmed by real-time US visualization of the needle in the sacral canal or by observing dural displacement after a saline test bolus (0.2 to 0.3 mL/kg to a maximum of 10 mL) injection.

The anesthetized child is positioned in the lateral position with the knee and hips flexed. The operator sits or stands behind the child, and the US machine is positioned directly in front. A linear-array transducer (13-10 MHz) is used to image the sacrum. A transducer with a wide footprint is preferable because it allows a greater length of the spine to be examined in a single view. The transducer is initially positioned directly over the sacral cornua in the transverse axis (Fig. 42-43). On a transverse sonogram at the level of the sacral hiatus, the sacral cornua are seen as two hyperechoic reverse U-shaped structures, one on either side of the midline. Connecting the two sacral cornua and deep to the skin and subcutaneous tissue is a hyperechoic band, the sacrococcygeal ligament (see Fig. 42-43). Anterior to the sacrococcygeal ligament is another linear hyperechoic structure, which represents the posterior surface of the sacrum. The hypoechoic area between the sacrococcygeal ligament and the bony posterior surface of the sacrum is the sacral hiatus (see Fig. 42-43). The two sacral cornua and the posterior surface of the sacrum produce a US

**E-FIGURE 42-4** Longitudinal midline sonogram of the lumbar spine in a neonate. CSF, Cerebrospinal fluid; SP L2, spinous process of L2; SP L3, spinous process of L3; SP L4, spinous process of L4.

**E-FIGURE 42-8** Longitudinal sonogram of the sacrum.

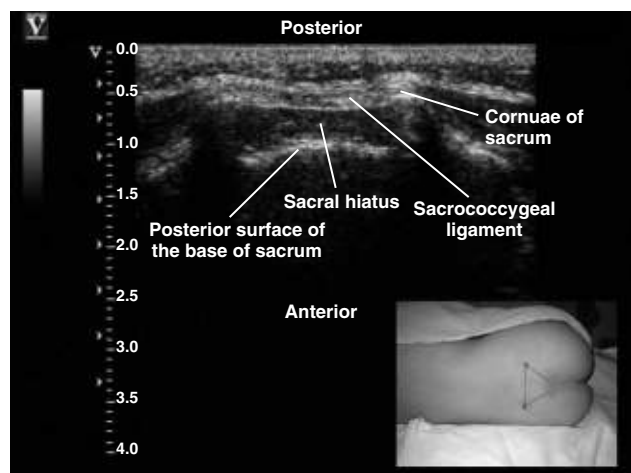

FIGURE 42-43 Transverse sonogram of the sacrum ("frog eye sign").

image that we refer to as the "frog-eye sign" because of its resemblance to the eyes of a frog (see Fig. 42-43). On a longitudinal sonogram of the sacrum, the sacroccygeal ligament, the base of the sacrum, and the sacral hiatus can be clearly seen (E-Fig. 42-8). In neonates and young infants the tapered end of the thecal sac with CSF, the anterior and posterior epidural space filled with fat, and the cauda equina may be visualized in the sacral canal (see E-Fig. 42-8).

For US-guided caudal epidural injection, either in-plane or out-of-plane technique can be used. We prefer the in-plane approach, and the needle is advanced under real-time guidance into the sacral canal through the sacroccygeal ligament. During insertion, the needle is maintained at an angle (approximately 20 degrees) so that it is parallel to the posterior surface of the sacrum. Correct position of the needle in the caudal epidural space is confirmed objectively by performing a test bolus injection of saline and observing in real time the displacement of the dura (E-Fig. 42-9).<sup>119,120</sup> Anterior displacement of the posterior dura is more frequently seen than posterior displacement of the anterior dura. If dural displacement is not seen in the US image, it implies that the needle or catheter is not in the correct position, the needle or catheter is not in the plane of US imaging, or the needle is intravascular. The needle should be withdrawn and the procedure repeated until the typical dural displacement is visualized. The calculated dose of local anesthetic is then injected in aliquots. The cephalad spread of the local anesthetic within the epidural space also can be visualized in real time. Depending on the volume of local anesthetic injected, progressive widening of the epidural space and a resultant compression of the thecal sac occur (see E-Fig. 42-9). These changes are visualized in the sacral canal and at the lumbar and thoracic levels. In some cases the thecal sac is almost completely obliterated in the sacral and lumbar region (see E-Fig. 42-9). Because the compression and obliteration of the thecal sac occurs in a caudal to cranial direction, it indicates that there is a net cranial displacement of CSF.

US guidance during a caudal epidural injection in children offers several advantages. It is safe, noninvasive, radiation free, simple, and quick to perform; it provides real-time images that are easy to interpret; and, unlike the nerve stimulation technique, is not affected by the use of neuromuscular blocking drugs or epidural local anesthetics. Moreover, US can demonstrate the underlying caudal anatomy, which is useful in children with

cutaneous markers of dysraphism when it can be used to screen the underlying spinal anatomy. Thus many children who may have otherwise been excluded from a caudal block can benefit from its effects. It is also a useful tool for teaching and learning of caudal anesthesia (see also Fig. 41-6 and Chapter 41 for landmark-guided techniques).

### Epidural Catheterization

Continuous epidural analgesia via an indwelling epidural catheter is a well-established method of providing perioperative analgesia in children.<sup>121</sup> The loss-of-resistance technique<sup>5,122</sup> is the most frequently used method of identifying the epidural space. Although popular, this technique relies on the operator's tactile sensation and can rarely result in dural puncture and serious neurologic complication, such as spinal cord injury. Alternative methods for identifying the epidural space in children have been described<sup>123</sup> but have not gained widespread acceptance. Epidural catheters have been successfully placed in young children under US guidance.<sup>122,124</sup> Compared with the traditional loss-of-resistance method, when epidural catheterization is performed using the loss-of-resistance method in conjunction with US guidance, fewer bony contacts occur during the procedure and the time required for catheter placement is reduced. The spread of local anesthetic in the epidural space can also be visualized in real time. In addition, the underlying anatomy and the depth from the skin to the ligamentum flavum, dura, and epidural space can be assessed before needle insertion. However, epidural catheterization under US guidance requires two anesthesiologists who are familiar with epidural anesthesia and spinal sonography in children. The first anesthesiologist performs the scan in the longitudinal paramedian axis and maintains a steady image while the second anesthesiologist performs the needle insertion through the midline. Entry of the needle into the epidural space is confirmed by the loss of resistance to saline and observing the local sonographic changes resulting from the saline injection (i.e., anterior displacement of the posterior dura, widening of the epidural space, and compression of the thecal sac). US-guided epidural catheterization in young children is a very demanding procedure and requires a great deal of skill and dexterity. It should be undertaken only by pediatric anesthesiologists who have acquired adequate training and skill in US-guided regional anesthesia (see Chapter 41 for landmark-guided techniques).

### Assessment of Indwelling Epidural Catheters

For optimal epidural anesthesia or analgesia, the epidural catheter tip must be located in the correct dermatomal level. This is often achieved by directly placing the catheter in the desired level via the lumbar or thoracic route. Even with this approach, and in particular when loss of resistance is used to locate the epidural space, it is not possible to determine with any certainty the exact location of the catheter tip. Epidurography can locate the catheter tip,<sup>125</sup> but this exposes the child to radiation and the risk of anaphylaxis from the contrast medium (see Figure 41-7). An epidural catheter inserted via the caudal route can be advanced to the lumbar or thoracic epidural space. However, this is technically difficult in children older than 1 year of age,<sup>126</sup> and even in children younger than 6 months of age, the catheter can be misplaced in the sacral, lumbar, and even the cervical region.<sup>127,128</sup> Whether styleted epidural catheters are easier to advance from the caudal to the thoracic epidural space than nonstyleted ones is not known, although better success has been reported with styleted catheters.<sup>129</sup> Even if a catheter is successfully advanced

**E-FIGURE 42-9** Longitudinal sonogram of the spine after a single-shot caudal epidural injection at the (A) lumbosacral, (B) lumbar, (C) thoracolumbar, and (D) thoracic level. Note the displacement of the anterior and posterior dura, widening of the epidural space, and the compression of the thecal sac at the various levels. AES, Anterior epidural space; CE, cauda equina; PES, posterior epidural space; SC, spinal cord.

to the thoracic epidural space, radiographic confirmation is still required to confirm the position of the catheter tip.<sup>127</sup> Electric nerve stimulation through an indwelling styleted epidural catheter and observation of myotomal contractions have been used to locate the position of the catheter tip.<sup>130</sup> In experienced hands this technique has a success rate of 89%. However, this test cannot be performed if neuromuscular blocking drugs or local anesthetics have been administered. Epidural electrocardiography also can be used to locate the position of a thoracic epidural catheter<sup>131</sup> and is not affected by the use of neuromuscular blocking drugs or local anesthetics in the epidural space. This method relies on matching the evolving electrocardiogram (ECG) recorded from the tip of a specially adapted epidural catheter, as it is advanced, to the surface ECG recorded at the target vertebral level. However, this method is not specific because even a subcutaneous electrocardiographic electrode at the same position relative to the heart will produce a similar electrocardiographic pattern.

US has been used to directly visualize the position of epidural catheters in children (E-Fig. 42-10).<sup>132,133</sup> US localization is non-invasive, does not involve exposure to radiation or contrast medium, and is not affected by the use of neuromuscular blocking drugs or epidural local anesthetics. It also provides real-time images of the catheter during catheter insertion. However, not all epidural catheters or their tips can be identified using US, and it may be limited by the acoustic window available for scanning in children of different ages. Gently jiggling the catheter and observing tissue movement within the epidural space also has been used to facilitate epidural catheter localization.<sup>133</sup> Injecting saline with air bubbles may improve catheter localization using US, but the use of air in the injectate can lead to inadvertent air embolism or a patchy block.<sup>134</sup> Therefore it is suggested that observing surrogate markers such as the widening of the epidural space, dural displacement, and compression of the thecal sac, subsequent to a saline test injection, may be more accurate in locating the position of an epidural catheter in children.

### ADVANTAGES OF ULTRASOUND IMAGING

US-guided regional anesthetic blocks appear to offer several advantages. US imaging is noninvasive and simple to use and does not involve exposure to radiation. It allows the target nerves and the surrounding structures to be directly visualized during block placement, which is particularly advantageous in children with difficult or variant anatomy, obesity, or amputated limbs in whom the evoked motor responses cannot be visualized. US is also useful in young children because the majority of regional anesthetic procedures in this age group are performed under general anesthesia when the use of a muscle relaxant makes nerve stimulation impractical. US guidance also helps determine the best possible site and maximum safe depth for needle insertion, allows real-time guidance of the needle and needle tip to the target site, avoids unintended vascular or pleural puncture, and allows visualization of the spread of the injected local anesthetic in real time. Together, these should lead to fewer needle insertions, improved comfort during block placement in awake and sedated children, reduced complications, improved quality of block, and greater success rates. However, limited studies exist comparing US with conventional methods of performing regional nerve blocks in children. Cumulative evidence (from adults and children) suggests that US speeds the execution of peripheral nerve and central neuraxial blocks, reduces the discomfort experienced during block placement, reduces the amount of

local anesthetic required, speeds the onset of sensory blockade, improves the quality of sensorimotor blockade, and prolongs the duration of sensory block. Additional studies are required to determine whether US guidance reduces complications related to regional anesthesia in children.

## Education and Training

Learning US-guided nerve block techniques takes time and patience. The state of the art of regional anesthesia demands a high degree of manual dexterity and hand-eye coordination and an ability to conceptualize 2D information into a 3D image. In addition, to produce good-quality US images, the anesthesiologist must also possess a sound knowledge of anatomy, the physical principles of US, and musculoskeletal imaging. Therefore individuals who intend to perform US-guided regional anesthesia should start by learning the basics of US and US-guided interventions by attending a course or workshop and by working with individuals who already possess these skills. Initial experience of musculoskeletal scanning can also be acquired in volunteer situations, and US-guided interventions can be practiced using a US phantom.<sup>135-139</sup> Once the basic skills are acquired, it is best to start by performing superficial peripheral nerve block procedures (e.g., axillary brachial plexus block, femoral and sciatic nerve block) under supervision before attempting deeper blocks (e.g., lumbar plexus block), which can be technically demanding even for an experienced operator. Whenever possible, it is advisable to use a peripheral nerve stimulator in conjunction with US during the learning phase of US-guided nerve blocks. With proficiency, it is possible to perform most techniques without nerve stimulation. Fortunately, the learning curve is steep<sup>140</sup> and most anesthesiologists are able to acquire the required skills very quickly, probably owing to their inherent good hand-eye coordination and ability to think in three dimensions. It is preferable to perfect these techniques in adults or older children before performing them in young children. US-guided epidural techniques, other than single-shot caudal epidural injections, demand a high degree of skill and dexterity and should be performed only by anesthesiologists experienced in US-guided regional anesthesia.

## Summary

US-guided RA is a promising alternative to anatomic landmark-guided techniques, and almost all regional anesthetic techniques that are commonly performed in children can be performed using US guidance. US imaging is noninvasive, is easy to use, does not involve exposure to radiation, and is not affected by the type of anesthesia administered. US allows the anesthesiologist to visualize the target nerves and surrounding structures in real time during block placement, which is particularly advantageous in children because the majority of regional anesthetic procedures in this age-group are performed under general anesthesia. Currently, the use of US for regional anesthesia in children is still in its infancy and the evidence to support its use is sparse. USGRA is facing the same challenges for widespread acceptance that laparoscopic surgery faced during the 1980s. Today, laparoscopy is the standard of surgical care. We envision that as more anesthesiologists who care for children acquire the skills necessary to perform USGRA and embrace this technology, US guidance will be the standard of care in pediatric regional anesthesia in the future.

Summary

**THE PRACTICE OF PAIN MANAGEMENT** in children continues to advance. Since the early 1980s, clinicians have come to recognize that neonates and infants experience pain and process those learning experiences. Research has demonstrated the adverse long-term consequences of unrelieved pain, including harmful neuroendocrine responses, disrupted eating and sleep cycles, and increased pain perception during subsequent painful experiences.<sup>1-3</sup> Disparities in pain treatment led organizations, such as the Agency for Healthcare Research and Quality (AHRQ) and the American Pain Society (APS), to provide guidelines and the Joint Commission (formerly the Joint Commission on Accreditation of Healthcare Organizations [JCAHO]) to issue mandates that further enhanced the practice of pediatric pain management.<sup>4-6</sup> The availability of reliable and valid pain assessment tools for children and governmental incentives encouraged the inclusion of children in analgesic drug trials. Sufficient research data regarding children's pain became available, making it possible to develop pediatric evidence-based pain management guidelines. Many children's hospitals now have dedicated specialized multidisciplinary pain teams that manage acute and chronic pain. The increasing use of regional analgesia techniques led to the development of the Pediatric Regional Anesthesia Network (PRAN), a registry of practice patterns and complications of regional anesthetics in children. An enormous expansion of the breadth of techniques for acute pain management in children, the establishment of pediatric pain services, and the investigation and introduction of innovative modalities of therapy all attest to the importance accorded to this aspect of perioperative care.

## Developmental Neurobiology of Pain

Nociceptive pathways in the periphery, spinal cord, and brain develop in a series of stages through the second and third trimester in humans. By 26 weeks postconception, there is sufficient maturation of peripheral and spinal afferent transmission for the late-gestation fetus or preterm neonate to respond to tissue injury or inflammation with withdrawal reflexes, autonomic arousal, and hormonal metabolic stress responses. There are also changes

in responsiveness after injury or repetitive stimulation indicative of central sensitization. In general, preterm neonates have reduced thresholds for withdrawal to noxious thermal and mechanical stimuli compared with older infants and children. One mechanism that may contribute to these low-threshold responses involves projections of low-threshold peripheral afferents to superficial as well as deep laminae in the spinal dorsal horn; later in development these afferents project only to deeper dorsal horn laminae.

Investigators have examined indices suggestive of cortical activation, including near-infrared spectroscopy<sup>7</sup> and electroencephalography,<sup>8</sup> in response to noxious events. Using near-infrared spectroscopy, a unilateral heelstick (performed for clinical purposes) produces signal changes suggestive of contralateral cortical activation.<sup>7-9</sup>

Despite these lines of evidence, the nature of pain in neonates, viewed as conscious suffering, remains unknown. Other investigators have looked for long-term consequences of painful events (with or without treatment) in humans and in animal models. Despite attempts by these investigators to correct for confounding factors, in our view, the interpretation of these studies, especially in humans, should be quite cautious. Neonates who undergo painful procedures are commonly those who are more medically ill. It appears difficult to distinguish consequences of pain per se from the consequences of other factors, such as prematurity, critical illness (including episodes of hypoxia or ischemia), deprivation of tactile and social contact, and nutritional deprivation. Many clinicians and investigators have adopted the view that, in the absence of better information about either the nature of suffering experienced by neonates or the potential adverse consequences of pain in terms of long-term development, caregivers should err on the side of providing, rather than withholding, analgesia. Although this is a compelling perspective, it is important to highlight three concerns: (1) in general, available studies have had difficulty showing effects of routine administration of analgesia (e.g., morphine infusions) on immediate behavioral indices of distress in neonates undergoing intensive care; (2) repeated or prolonged administration of anesthetics and

sedatives in animal models have been shown to have deleterious effects on brain development, (the human implications of these animal studies remain unclear at this time [see also Chapters 6 and 23]);<sup>10-16</sup> and (3) as will be detailed later, younger organisms develop tolerance to opioids and benzodiazepines more rapidly than older organisms, so that the management of tolerance and withdrawal has now become a nearly universal consequence of prolonged administration of these medications to critically ill neonates, infants, and children.

## Pain Assessment

The International Association for the Study of Pain (IASP) has defined *pain* as an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or *described* in terms of such damage. The IASP and others have acknowledged that the inability to communicate verbally, as in the preverbal, nonverbal, or the cognitively impaired, does not preclude the possibility that an individual is experiencing pain and is in need of appropriate pain management.<sup>17,18</sup> Physicians and nurses have been very creative in developing tools to evaluate pain in children of all ages; most of these tools are discussed below. Table 43-1 summarizes various pain assessment tools in terms of appropriate age, target population, ease of use, and practicality.

## SELF-REPORT MEASURES

Because pain is a subjective experience, self-report measures, in which a patient is asked to quantify the severity of the pain between 0 (no pain) and 10 (maximum pain), are considered to most accurately reflect acute pain. Because many children lack the cognitive skills to use such scales, pain assessment measures that include developmentally appropriate self-report tools, behavioral-observational tools, and physiologic-biologic measures have been developed. Given the multidimensional nature of the individual pain experience, and the complexity and inherent biases associated with self-report, use of unidimensional numeric scales alone to reflect pain is overly simplistic.<sup>19-22</sup> Therefore, regardless of the measure used, it must be emphasized that a complete pain assessment is more than just a number attempting to quantify the severity of pain. Estimating the impact of pain on the suffering and the quality of the individual's life, targeting appropriate therapeutic measures, and evaluating the effectiveness of such measures are additional key components of a global and ongoing pain assessment and treatment strategy.

For children to use numeric scales, they must understand the concepts of magnitude and ordinal position, that is, they must be able to identify which of different-sized objects is bigger and place them in order from smallest to largest. They must also be able to arrange geometric figures or numbers in a series (*seriation*).

**TABLE 43-1** Appropriate Pain Assessment Measures by Age-Group: Self Report, Observational/Behavior, and for the Cognitively Impaired

Self-Report Tools	Appropriate Age-Groups	Comments
Faces Pain Scale	3-18 years	Simple and quick to use; extensively validated in healthy schoolchildren with postoperative and cancer pain
Oucher	3-18 years	Photographic for ≥3-year-olds, numeric 0-10 scale for ≥6-year-olds; less clinical utility and feasibility compared to other faces scales
Manchester Pain Scale	3-18 years	Panda bear faces eliminate gender and ethnic bias; tested in emergency department setting
Computer Face Scale	4-18 years	Offers option for continuous rather than categorical format; good construct validity; preferred by children over the Wong Baker Faces Scale; further testing needed
Sydney Animated Facial Expression Scale (SAFE)	4-18 years	Animated version of Faces Pain Scale; rated by children as easiest to use; no psychometric advantage compared to other scales
Visual Analog Scale (VAS)	6-18 years	Simple and quick to use; requires the concepts of order, magnitude, and seriation (the ability to place or visualize in series); widely used across settings; preferred to other self-report tools by children ≥8 years old and adolescents
Numeric Rating Scale (NRS)	7-18 years	Simplest and most commonly used in clinical as well as research settings
<b>Observational/Behavioral Measures</b>		
Comfort Scale	0-18 years	Developed for use in intensive care settings; useful in mechanically ventilated children and in the postoperative setting
Face, Legs, Activity, Cry, Consolability (FLACC)	2 months to 7 years	Excellent pragmatic and psychometric qualities; widely adopted in clinical and research settings; has been translated into several languages other than English
Children's Hospital of Eastern Ontario Pain Scale (CHEOPS)	1-7 years	Good psychometric properties; lengthy with inconsistent scoring among categories; cumbersome; extensively used both in clinical and research settings
<b>Cognitively Impaired Children</b>		
Revised FLACC	All ages	Allows for scoring individualized pain behaviors; good psychometric properties; highest clinical utility compared to the Non-Communicating Children's Pain Checklist—Postoperative Version (NCCPC-PV) and Nurses' Assessment of Pain Intensity (NAPI)
Non-Communicating Children's Pain Checklist (NCCPC)	All ages	Requires 5-minute observation period; comprehensive but cumbersome; used in clinical and research setting
University of Wisconsin Pain Scale	All ages	Inconsistent scoring style compared to other clinical scoring systems; scoring style may permit flexibility but limits precision
The Pain Indicator for Communicatively Impaired Children	All ages	Useful for pain assessment in cognitively impaired children in the home setting.

**FIGURE 43-1** A, The Wong-Baker Faces Pain Scale. B, The Bieri Faces Pain Scale. (B modified from Bieri D, Reeve RA, Champion GD, et al. The Faces Pain Scale for the self-assessment of the severity of pain experienced by children: development, initial validation, and preliminary investigation for ratio scale properties. *Pain* 1990;41:139-50.)

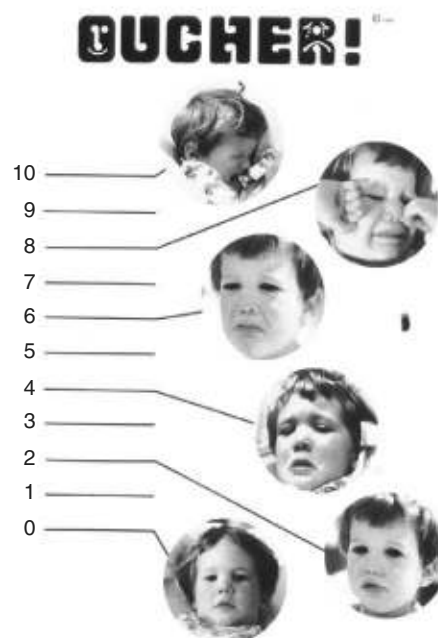

These skills are typically not present until 7 years of age; thus several pain assessment tools that most commonly use graphic facial displays representing different degrees of pain expression are used to facilitate self-report of pain in young children.

### Faces Pain Scales

Faces pain scales comprise a series of line diagrams of faces with expressions of increasing distress.<sup>23-28</sup> Some versions have a smiling face whereas others have a neutral face to represent the “no pain” end of the scale (Fig. 43-1). Unlike the numeric scales, the faces scales do not require the concept of magnitude or seriation and can therefore be used by preschool aged children. The Wong Baker Faces Pain Scale has been extensively studied and its reliability and validity confirmed in children 3 to 18 years of age. Strong correlations have been reported between the Wong Baker Scale scores and other faces scales, the Visual Analog Scale (VAS), as well as nurses’ ratings based on behavior.<sup>29-32</sup> Recent data suggest that versions with the smiling face at the no-pain end of the spectrum, such as the Wong Baker Scale, may overestimate pain because children without pain, but with distress from other sources, may be reluctant to choose the smiling face.<sup>28</sup> The Wong-Baker scale was preferred by children to the numeric rating scale, the graphic rating scale, and the Color Analog Scale.<sup>23,25,30,33</sup> Overall, the Faces Pain Scale–Revised is the faces scale with the largest support for its validity.<sup>34</sup>

### Oucher

The Oucher combines a photographic faces scale with a 0 to 10 vertical numeric scale. Different versions of the Oucher incorporate photographs of Caucasian, African American, Asian, and Hispanic children to minimize biases related to ethnicity (Fig. 43-2 and E-Fig. 43-1, A to C).<sup>35,36</sup> Strong correlations have been demonstrated between Oucher scores and those obtained using the Pieces of Hurt tool, faces pain scales, and VAS.<sup>37-39</sup> The Oucher also demonstrates responsiveness, that is, the ability to detect change in pain intensity before and after surgery and after administration of an analgesic.<sup>37</sup> The numerical rating component of the Oucher requires that the child be able to count to 10 and has been used successfully in children older than 6 years.

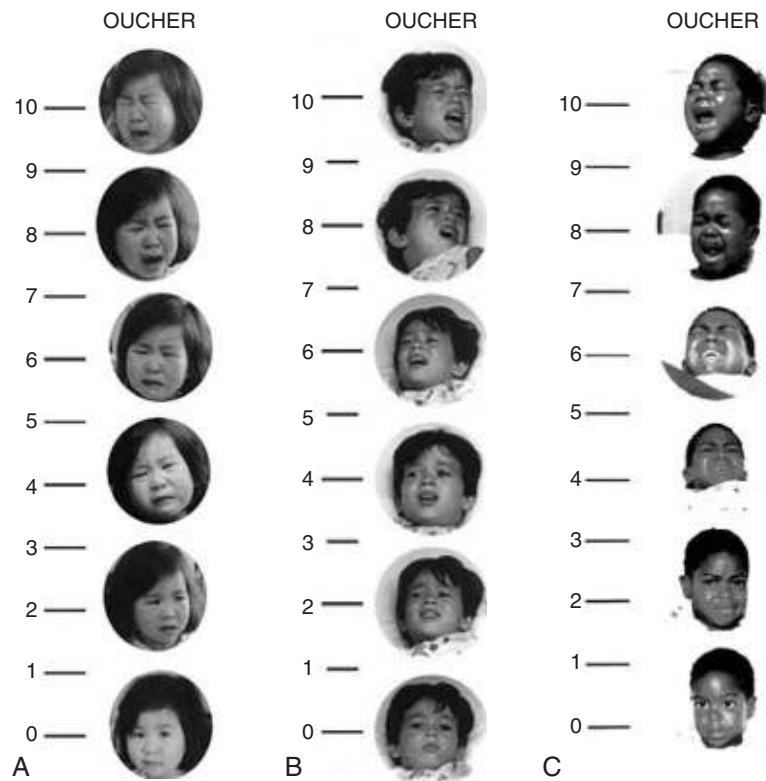

**FIGURE 43-2** The Oucher Pain Scale. The Caucasian version of the Oucher Pain Scale.

### The Manchester Pain Scale

The Manchester Pain Scale (Fig. 43-3), which was designed to overcome the gender and ethnic biases of the Oucher, is composed of a pain ruler on which panda facial images are superimposed.<sup>40</sup> It includes verbal descriptors of the extent of pain and how pain possibly interferes with normal functions. A study of children presenting to an emergency department found a very good correlation between scores assigned using the Manchester Scale and the Oucher.<sup>40</sup>

### Novel Self-Report Tools

These self-report tools use a categorical format and the static faces do not allow for “fine tuning” of the ratings before a final

**E-FIGURE 43-1** Ethnic versions of the Oucher Pain Scale. **A**, Asian. **B**, Hispanic. **C**, African American.

FIGURE 43-3 The Manchester Pain Scale.

assessment regarding the severity of pain is reached.<sup>41</sup> In recent years, there has been interest in developing computer-based self-report assessment tools that use a continuous rather than categorical format.<sup>42</sup>

The Computer Face Scale allows the child to adjust the shape of the mouth of a cartoon face from smiling to frowning and simultaneously to adjust the eyes from completely open to completely closed.<sup>41,43</sup> The suggested benefits of this scale include increased sensitivity (given the ability to select from a wide range of faces) and computerized storage of the results, with ready access and data display. Preliminary work with this scale has demonstrated its construct validity and it was preferred by children over the Wong Baker Faces Scale.<sup>41</sup>

The Sydney Animated Facial Expression Scale (SAFE) is an animated version of the Faces Pain Scale<sup>44</sup> and comprises of a series of 101 faces (Video 43-1). To administer this scale, the child pushes the left or right arrow key on a computer causing the expression of the single face to change until it corresponds with the child's pain intensity ([www.usask.ca/childpain/research/safe](http://www.usask.ca/childpain/research/safe)). At this point, a keystroke records a score between 0 and 100. The SAFE scale was rated to be easiest to use by children aged 4 to 16 years compared with other scales, including the Faces Pain Scale, the Color Analog Scale, and Pieces of Hurt,<sup>45</sup> although it offered no psychometric advantage over the other scales. At this time, further research with this tool is needed before its role can be clearly defined.

## Numeric Scales

### Visual Analog Scale

Several versions of the VAS are available, including horizontal and vertical lines, word anchors representing extremes of pain, and lines with divisions and numeric values (Fig. 43-4). When using the vertical versions of this scale, the severity of the pain increases as one ascends the ladder. Although moderate to strong correlations have been reported between the VAS, faces pain

FIGURE 43-4 Numerical self-report scales. A, Horizontal Visual Analog Scale. B, Vertical Visual Analog Scale.

scales, and the Oucher,<sup>37,46</sup> the effect of user age on VAS ratings are conflicting.

### Numeric Rating Scale

The Numeric Rating Scale (NRS) is the simplest and most commonly used numeric scale in which the child rates the pain from 0 (no pain) to 10 (worst pain). Its validity has been established with good correlations between NRS and Faces Pain Scale-Revised scores in children 7 to 17 years of age and NRS and VAS scores in children 9 to 17 years of age.<sup>47</sup> An important caveat when using numeric scales is to be sure of the denominator that the child is using. For example a pain score of 9 on a 0 to 100 scale would reflect mild pain and may not require treatment whereas a score of 9 on a 0 to 10 scale would reflect severe pain that warrants aggressive treatment.

### Selection Criteria

Selection of a self-report tool for a child requires careful consideration of the age and cognitive and developmental level. Figure 43-5 depicts the percentages of children of different ages who are able to self-report their pain and the tools most appropriate for various age ranges. Children who are unable to use a self-report tool may be able to report their pain intensity using simple words, such as "small," "medium," and "big." However, self-reports of pain are subject to the modulating influences of a number of factors, including the child's previous pain experience and response to treatment, psychosocial factors, and parental preferences and influences. In many cases, therefore, it may be necessary to complement self-reported pain scores with behavioral observations, particularly in preschool-aged children. Regardless of the tool selected, assessment of postoperative pain is greatly facilitated by the introduction of the concept of rating pain and of the tool itself during the preoperative preparation of the child.

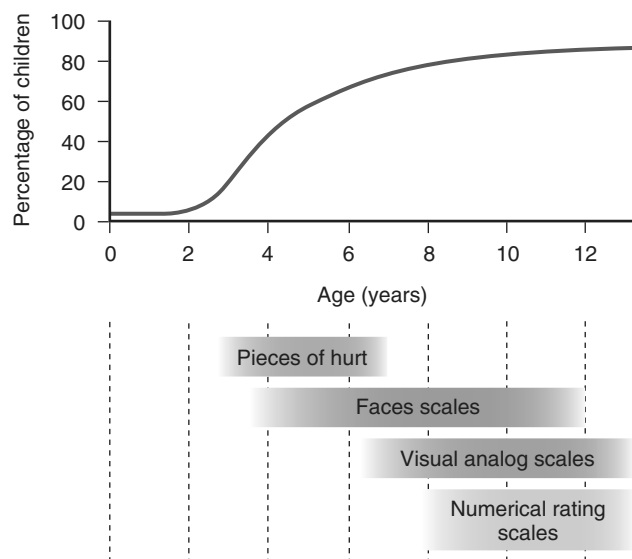

FIGURE 43-5 Self-report tools most appropriate for different age ranges.

TABLE 43-2 Content Validity of Behavioral Pain Tools: Categories of Behavior in Pain Assessment Tools

FLACC	CHEOPS	OPS	TPPPS	Büttner/ Finke
Face	Facial expression		Facial pain expression	Facial expression
Legs	Leg movement	Movement		Leg position
Activity	Torso movement	Agitation	Bodily pain expression	Position of torso
				Motor restlessness
Cry	Cry	Cry	Vocal pain expression	Cry
Consolability	Touching of the wound	Blood pressure		Consolability
	Verbal report of pain	Verbal complaint and body language		

CHEOPS, Children's Hospital of Eastern Ontario Pain Scale; FLACC, Face, Legs, Activity, Cry, Consolability scale; OPS, Objective Pain Scale; TPPPS, Toddler Pre-school Preoperative Pain Scale.

## OBSERVATIONAL-BEHAVIORAL MEASURES

Despite several age-appropriate methods for self-reporting, assessing pain in children who are unable or unwilling to self-report depends on observations of their behaviors. Five behaviors that have been shown to be reliable, specific, and sensitive when predicting analgesic requirements are facial expression, vocalization or cry, leg posture, body posture, and motor restlessness.<sup>48</sup> Variations in these behaviors have been used in several observational pain tools. Table 43-2 describes the content validity of some of the observational tools that are commonly used in clinical practice. Behavior checklists provide a list of pain behaviors that are marked as present or absent and the extent of pain is estimated on the basis of the number of behaviors present at the

time of the assessment.<sup>49,50</sup> Behavior rating scales also incorporate a rating of the intensity or frequency and duration of each behavior.<sup>51</sup> Global rating scales provide a rating of the observer's global impression of the child's pain.

## Children's Hospital of Eastern Ontario Pain Scale

The Children's Hospital of Eastern Ontario Pain Scale (CHEOPS), one of the earliest behavioral rating scales (Table 43-3),<sup>52</sup> incorporates six categories of behavior scored individually from 0 to 2 or 1 to 3 and then sums them to provide a pain score ranging from 4 to 13. Scores of 6 or less indicate no pain. Its validity and reliability for brief painful events and for postoperative pain has been well established, with good to excellent correlations with faces pain scales and the VAS.<sup>46,53</sup> However, the time required to complete the evaluation and inconsistent scoring among categories of the CHEOPS makes it cumbersome and impractical to use in a busy clinical setting.

## Face, Legs, Activity, Cry, Consolability Scale

The Face, Legs, Activity, Cry, Consolability (FLACC) scale was developed in an effort to improve on the pragmatic qualities of the existing behavioral pain tools by providing a simple framework for quantifying pain behaviors in children.<sup>51</sup> This tool includes five categories of behaviors previously found to reliably correlate with pain in young children, including: facial expression, leg movement, activity, cry, and consolability (Table 43-4).<sup>48</sup> The acronym FLACC facilitates recall of these categories, each of which is scored from 0 to 2 to provide a total pain score ranging from 0 to 10. The FLACC tool has been extensively tested and determined to have good inter-rater reliability and excellent validity based on changes in pain scores from before to after analgesic administration and excellent correlation with the Objective Pain Scale (OPS), the CHEOPS, the Toddler Preschool Preoperative Pain Scale (TPPPS), and good correlation with self-reported pain scores using faces pain scales.<sup>51,53-55</sup> The FLACC scale has been translated into several languages, including Chinese, Swedish, French, Italian, Portuguese, Norwegian, and Thai.

## Comfort Scale

The Comfort scale (Table 43-5), developed for use in an intensive care setting, consists of six behavioral and two physiologic measures, each of which has five response categories, thereby allowing detection of subtle changes in the child's distress.<sup>56</sup> Initial evaluation of the Comfort scale found acceptable inter-rater reliability and good correlations with VAS scores in 37 mechanically ventilated infants.<sup>56</sup> Another study evaluated the reliability and validity of the Comfort scale as a postoperative pain instrument in children after thoracic or abdominal surgery.<sup>57</sup> This study found good to excellent inter-rater agreement for all categories except respiratory response, for which there was moderate agreement. Additionally, strong correlations between Comfort and VAS pain scores support the use of the Comfort scale as a postoperative pain measurement instrument in children.

After a systematic review of observational pain measures, the FLACC and the CHEOPS<sup>52</sup> scales were recommended for assessment of pain associated with medical procedures, the FLACC for postoperative pain, and the Comfort Scale for pain in children in critical care.<sup>19</sup> Despite the extensive science supporting the use of behavioral tools, it may be difficult to separate behaviors caused by pain from those caused by other sources of distress in some children.<sup>58</sup> Accurate pain assessment in children,

**TABLE 43-3** Children's Hospital of Eastern Ontario Pain Scale (CHEOPS)\*

Item	Behavioral	Score	Definition
<b>Cry</b>	No cry	1	Child is not crying.
	Moaning	2	Child is moaning or quietly vocalizing silent cry.
	Crying	2	Child is crying, but the cry is gentle or whimpering.
	Scream	3	Child is in a full-lunged cry; sobbing; may be scored with complaint or without complaint.
<b>Facial</b>	Composed	1	Child has neutral facial expression.
	Grimace	2	Score only if definite negative facial expression.
	Smiling	0	Score only if definite positive facial expression.
<b>Child Verbal</b>	None	1	Child is not talking.
	Other complaints	1	Child complains, but not about pain, e.g., "I want to see mommy" or "I am thirsty."
	Pain complaints	2	Child complains about pain.
	Both complaints	2	Child complains about pain and about other things, e.g., "It hurts; I want my mommy."
	Positive	0	Child makes any positive statement or talks about others things without complaint.
<b>Torso</b>	Neutral	1	Body (not limbs) is at rest; torso is inactive.
	Shifting	2	Body is in motion in a shifting or serpentine fashion.
	Tense	2	Body is arched or rigid.
	Shivering	2	Body is shuddering or shaking involuntarily.
	Upright	2	Child is in a vertical or in upright position.
	Restrained	2	Body is restrained.
<b>Touch</b>	Not touching	1	Child is not touching or grabbing at wound.
	Reach	2	Child is reaching for but not touching wound.
	Touch	2	Child is gently touching wound or wound area.
	Grab	2	Child is grabbing vigorously at wound.
	Restrained	2	Child's arms are restrained.
<b>Legs</b>	Neutral	1	Legs may be in any position but are relaxed; includes gentle swimming or discrete movements.
	Squirming/kicking	2	Definitive uneasy or restless movements in the legs and/or striking out with foot or feet.
	Drawn up/tensed	2	Legs tensed and/or pulled up tightly to body and kept there.
	Standing	2	Standing, crouching, or kneeling.
	Restrained	2	Child's legs are being held down.

\*Recommended for children 1 to 7 years old; a score greater than 6 indicates pain.

**TABLE 43-4** The FLACC Behavioral Pain Scale

Categories	SCORING		
	0	1	2
Face	No particular expression or smile	Occasional grimace or frown, withdrawn, disinterested	Frequent to constant frown, clenched jaw, quivering chin
Legs	Normal position or relaxed	Uneasy, restless, tense	Kicking, or legs drawn up
Activity	Lying quietly, normal position, moves easily	Squirming, shifting back and forth, tense	Arched, rigid, or jerking
Cry	No cry (awake or asleep)	Moans or whimpers, occasional complaint	Crying steadily, screams or sobs, frequent complaints
Consolability	Content, relaxed	Reassured by occasional touching, hugging, or being talked to, distractible	Difficult to console or comfort

Each of the five categories, (F) Face; (L) Legs; (A) Activity; (C) Cry; (C) Consolability, is scored from 0 to 2, which results in a total score between 0 and 10. ©2002, The Regents of the University of Michigan. All Rights Reserved.

therefore, requires careful consideration of the context of the behaviors. Input from the parents or caregivers may be valuable as proxy measures, although some parents may lose objectivity in such a situation. Similarly, a regular caregiver may best assess older children with significant developmental delay. When in doubt regarding the source of distress, a trial of analgesics is appropriate and may be both diagnostic and therapeutic.

### LIMITATIONS OF PAIN ASSESSMENT

It remains unclear whether integration of routine pain assessment into clinical practice significantly improves patient outcomes. A critical review of the studies that addressed this question determined that in 2 of 6 studies, children experienced a reduction in pain intensity when a standardized pain assessment tool was used, in 2 studies there was no change in pain intensity, and in

TABLE 43-5 Comfort Scale

	1	2	3	4	5
<b>Alertness</b>	Deeply asleep	Lightly asleep	Drowsy	Fully awake and alert	Hyper-alert
<b>Calmness or Agitation</b>	Calm	Slightly anxious	Anxious	Very anxious	Panicky
<b>Respiratory Response</b>	No coughing and no spontaneous respirations	Spontaneous respiration with little or no response to ventilation	Occasional cough or resistance to ventilator	Actively breathes against ventilator or coughs regularly	Fights ventilator; coughing or choking
<b>Physical Movement</b>	No movement	Occasional, slight movement	Frequent slight movement	Vigorous movement limited to extremities	Vigorous movement including torso and head
<b>Blood Pressure</b>	Less than baseline	Consistently at baseline	Infrequent increases of 15% or more (1 to 3 episodes during observation period)	Frequent increases of 15% or more (>3 episodes)	Sustained increase >15%
<b>Muscle Tone</b>	Muscles totally relaxed; no muscle tone	Reduced muscle tone	Normal muscle tone	Increased muscle tone and flexion of fingers and toes	Extreme muscle rigidity and flexion of fingers and toes
<b>Facial Tension</b>	Facial muscles totally relaxed	Facial muscle tone normal; no facial muscle tension evident	Tension evident in some facial muscles	Tension evident throughout facial muscles	Facial muscles contorted and grimacing

2 studies pain intensity decreased when pain assessment was combined with pain management interventions.<sup>59</sup> Studies that examined sustainability of the benefits over time reported conflicting results, and most studies were identified to have major methodologic problems.<sup>60,61</sup> Additional investigation is required to determine whether routine pain assessment has any effect on pain outcomes.

Despite the large body of evidence supporting the psychometric properties of numerous structured pain assessment tools described previously and elsewhere, there remains considerable variability in the interpretation of the clinical relevance of pain scores.<sup>22</sup> Attempts have been made to define what range of pain scores is associated with a perceived need for medicine or what magnitude of change in pain score is associated with a perception of better or worse pain.<sup>62-64</sup> A survey of 6- to 16-year-old hospitalized children found that a median pain score of 3 on a 0-to-6 Faces Pain Scale was associated with the child's perceived need for medicine.<sup>62</sup> Others have reported that a 10-mm change in a 0-to-100-mm VAS score was the minimum difference whereby children in the emergency department perceived their pain to be slightly better or slightly worse.<sup>63</sup> In the postoperative period, children with a median pain score of 6 on a 0-to-10 NRS scale perceived the need for an analgesic whereas those with a score of 3 felt there was "no need" for treatment.<sup>64</sup> In addition, children felt "a little better" or "worse" if the NRS scale changed by at least 1. Despite these findings, there was large variability and overlap in scores associated with these outcomes.

It has been suggested that the widespread adoption of a pain score as the fifth vital sign may contribute to the overprescribing of analgesics and sedatives.<sup>65</sup> A review of trauma center site surveys reported a fivefold increase in deaths from excessive pain medicines during two time periods (1994 through 1998 and 2000 through 2004). Evaluations of the effectiveness of pain treatment algorithms based on numerical pain scores have yielded conflicting results. One study reported increased prescription for opioid and nonopioid analgesics, an increased administration of non-opioids, and reduced pain scores in children who received postoperative pain treatment based on a pain score-based algorithm.<sup>66</sup> Children whose pain management was algorithm-based

experienced more nausea, but no other adverse effects. In contrast, hospitalized adults whose pain management was based on a numerical pain treatment algorithm, experienced a twofold increase in episodes of oversedation and a 49% increase in opioid-related adverse drug events.<sup>67</sup> This latter study highlights the potential for harm when numeric pain scores alone are used guide decisions regarding pain treatment. A comprehensive approach to pain assessment that includes consideration of the child's self-reporting (when available), combined with behavioral observation and the overall clinical context, is required to direct treatment decisions.<sup>68</sup>

#### SPECIAL CONSIDERATIONS FOR THE COGNITIVELY IMPAIRED CHILD

Children who are cognitively impaired experience pain more frequently than cognitively intact children because of a number of inherent conditions, such as spasticity, muscle spasms, the need for assistive devices for positioning and mobility, and the need for invasive surgical procedures. Indeed, as many as 60% of children with cerebral palsy undergo orthopedic surgery by 8 years of age, and many of them require repeated procedures.<sup>69</sup> Yet both children and adults who are cognitively impaired receive fewer analgesics than those who are cognitively intact with similar painful conditions.<sup>70,71</sup> Barriers to effective pain management in the cognitively impaired include the complexity of pain assessment in those who cannot verbalize their pain, outdated beliefs that these children have altered or blunted pain perception, limited evidence for the safety and efficacy of analgesic regimens, and an exaggerated concern regarding opioid adverse effects, particularly respiratory depression. Difficulties with pain assessment have led to the virtual exclusion of these children from clinical drug trials, leading to deficits in our knowledge of how to effectively manage their pain. A survey of clinicians who treat children who are cognitively impaired identified inadequate pain assessment tools and inadequate training and knowledge of providers as significant barriers to effective pain management, despite respondents' beliefs that children who are cognitively impaired perceive pain to a similar extent as cognitively intact children.<sup>72</sup>

### The University of Wisconsin Pain Scale for Preverbal and Nonverbal Children

This scale is composed of five behavior categories with four descriptors for each (E-Table 43-1).<sup>73</sup> The overall rating using this tool is not a sum of scores of individual behaviors but a score assigned on a 0- to 5-scale based on the clinician's judgment relative to assessment of individual categories. The scoring style of this tool does allow for flexibility, but limits its precision. This scale has been tested in 59 preverbal children and 15 children who were nonverbal because of cognitive impairment. Although these investigators reported good validity and reliability in their overall sample, the reliability and validity of this tool for the subset of children with cognitive impairment was not reported.

### The Non-Communicating Children's Pain Checklist—Postoperative Version

This tool comprises a checklist of 27 pain behaviors across six categories.<sup>74</sup> Each of these behaviors (E-Table 43-2) is scored on a 0- to 3-point scale based on the frequency of observation of that behavior over a 10-minute observation period. The scores of all items are summed to provide a total pain score. This tool has been evaluated in 25 children who were cognitively impaired,<sup>74</sup> with good inter-rater reliability in four of the six behavior categories and good correlations between the Non-Communicating Children's Pain Checklist—Postoperative Version (NCCPC-PV) scores and VAS scores. Although this checklist provides a comprehensive pain assessment method for children with cognitive impairment undergoing surgery, it may be cumbersome for frequent and repeated pain assessments in the clinical setting.

### The Pain Indicator for Communicatively Impaired Children

One group of investigators interviewed parents and/or caregivers of 30 communicatively impaired children regarding cues they used to identify pain in their child.<sup>75</sup> Six core pain cues were reported by 90% of the caregivers as signs of definite or severe pain in their child (E-Table 43-3). Each of these cues is scored on a 4-point Likert scale (not at all, a little, often, all the time), based on the frequency of occurrence of the behavior over the observation period. Caregivers of children with severe cognitive impairment, who evaluated this scale at home over a 7-day period, reported no significant relationship between crying and the presence of pain. Yet, they found that a "screwed up or distressed

looking face" had the strongest relationship with the presence of pain. In fact, they found that facial expression alone correctly identified 71% of children in pain and 93% of those not in pain, with an overall correct classification rate of 87%. This tool provides a simple method of assessing pain in children with cognitive impairment in the home setting. Further testing of this tool is required in the hospital setting, and using shorter observation periods, to determine its feasibility of use by clinicians.

### Face, Legs, Activity, Cry, Consolability Observational Tool

Initial evaluation of the FLACC tool in children with cognitive impairment found a good correlation between scores assigned independently by different observers and by parent global ratings of pain.<sup>76</sup> Although measures of exact agreement between observers were acceptable for the face, cry, and consolability categories, measure of agreement for the legs and activity categories were less acceptable, likely because of coexisting motor impairments such as spasticity. The FLACC tool was therefore revised to incorporate additional descriptors of behaviors most consistently associated with pain in children with cognitive impairment (Table 43-6).<sup>77</sup> Inter-rater reliability for the total FLACC scores, as well as for each of the categories, improved when the evaluation included the revised FLACC (r-FLACC) in 52 cognitively impaired children. Also, good correlation between FLACC, parent, and child scores supported its criterion validity. FLACC scores were noted to decrease after an opioid was administered, supporting the construct validity of the tool. The pragmatic attributes of the r-FLACC were compared with those of the Nurses' Assessment of Pain Intensity (NAPI) and the NCCPC-PV.<sup>78</sup> Clinicians using these tools to score pain rated the complexity as less and the relative advantage and overall clinical utility of the FLACC and the NAPI to be greater compared with the NCCPC-PV, suggesting that these tools may be more readily adopted into clinical practice.

## Strategies for Pain Management

Pain is a complex phenomenon that occurs because of the transmission of nociceptive stimuli from the peripheral nervous system through the spinal cord to the cerebral cortex. Pain perception is further influenced by emotions, behavior, and previous pain experiences via multiple synapses in the limbic system,

TABLE 43-6 Revised FLACC for Pain Assessment in the Cognitively Impaired\*

	0	1	2
<b>Face</b>	No particular expression or smile	Occasional grimace/frown; withdrawn or disinterested [Appears sad or worried]	Consistent grimace or frown; frequent/constant quivering chin, clenched jaw [Distressed-looking face; expression of fright or panic]
<b>Legs</b>	Normal position or relaxed	Uneasy, restless, tense [Occasional tremors]	Kicking, or legs drawn up [Marked increase in spasticity, constant tremors or jerking]
<b>Activity</b>	Lying quietly, normal position, moves easily	Squirming, shifting back and forth, tense [Mildly agitated (e.g., head back and forth, aggression); shallow, splinting respirations, intermittent sighs]	Arched, rigid, or jerking [Severe agitation head banging; shivering (not rigors); breath holding, gasping or sharp intake of breath; severe splinting]
<b>Cry</b>	No cry (awake or asleep)	Moans or whimpers, occasional complaint [Occasional verbal outburst or grunt]	Crying steadily, screams, or sobs; frequent complaints [Repeated outbursts, constant grunting]
<b>Consolability</b>	Content, relaxed	Reassured by occasional touching, hugging, or "talking to"; distractible	Difficult to console or comfort [Pushing away caregiver, resisting care or comfort measures]

\*Revised descriptors for children with disabilities shown in brackets.

**E-TABLE 43-1** University of Wisconsin Children's Hospital Pain Scale for Preverbal and Nonverbal Children

	0	1	2-3	4-5
<b>Vocal/Cry</b>	No cry	Occasional whimpers	Moaning, gentle cry, or whimpering	Consistent cry that increases in volume and duration
<b>Facial</b>	Smiling, calm, relaxed	Neutral expression, frowning, occasional grimace	Occasional tense expression, slightly negative expression (e.g., grimace), brow bulge, shallow nasolabial furrow	Marked distress; brow bulge, eyes squeezed shut, open mouth, taut tongue, deepening of nasolabial furrow
<b>Behavioral</b>	Neutral, moves easily, interacts with people or environment, strong rhythmic suck on pacifier	Easy to console with holding, or sucking; winces when touched or moved	Consoles with moderate difficulty; sucks for very short periods, followed by crying; cries out when moved/touched	Inconsolable; absent or disorganized sucking; high-pitched cry or scream when touched or moved
<b>Body Movement/Posture</b>	Normal motor activity, baseline muscle tone	Fidgeting; mild hypertonicity above baseline	Moderate agitation or moderate immobility; intermittent flexion; moderate hypertonicity above baseline	Thrashing, flailing, incessant agitation or strong voluntary immobility; pronounced flexion; strong hypertonicity above baseline
<b>Sleep</b>	Sleeping quietly with easy respirations; normal sleep/rest periods	Restless while asleep	Sleep periods shorter than normal, awakes easily, sleeps intermittently	Unable to sleep or sleeping for prolonged periods of time interrupted by jerky movements
<b>Overall Rating (circle)</b>	0	1	2-3	4-5

frontal cortex, and thalamus. Given the complexity of the pain mechanism, effective treatment of pain requires the use of multimodal therapies that target multiple sites along the pain pathways, as illustrated in Figure 43-6. Analgesics with additive or synergistic activity and different adverse effect profiles should be selected so that adequate analgesia can be provided with fewer adverse consequences. Thus pain can be treated at the peripheral level using local anesthetics, peripheral nerve blockade, nonsteroidal antiinflammatory drugs (NSAIDs), antihistamines, or opioids. At the spinal cord level, pain can be treated with local anesthetics, neuraxial opioids,  $\alpha_2$ -adrenoceptor agonists, and *N*-methyl-D-aspartate (NMDA) receptor antagonists. Finally, at the cortical level systemic opioids,  $\alpha_2$ -agonists, and voltage-gated calcium channel  $\alpha_2\delta$  proteins (targets for anticonvulsants) can be used.<sup>79</sup> Most cases of moderate to severe pain are best treated with a combination of analgesic techniques.

The strategy for postoperative pain management is an integral part of the preanesthetic plan, so that informed consent for procedures, such as placement of peripheral or regional blocks, can be obtained (see Chapters 41 and 42). Additionally, appropriate teaching for techniques, such as patient-controlled analgesia (PCA), should begin in the preoperative period. An honest discussion with the child that, although some discomfort is inevitable, every effort will be made to minimize pain after

surgery, decreases the anxiety related to the perioperative experience. This, together with the use of nonpharmacologic techniques, may even reduce the need for opioids and other analgesics. Selection of an analgesic regimen requires careful consideration of a number of factors, including scope and requirements of the surgical procedure, age and cognitive abilities of the child, the child's previous pain experience and response to treatment, underlying medical conditions that might alter the response to pain medications, and child and family preferences. The goal should be for the child to emerge from anesthesia in reasonable comfort, because it is generally easier to maintain analgesia in a pain-free child than to achieve analgesia in a child with severe pain. Figure 43-7 presents a flowchart describing strategies for assessment and management of acute postoperative pain in a child.

#### SURGICAL CONSIDERATIONS

The scope and requirements of the surgical procedure, as well as specific postoperative issues, should be discussed with the surgical team before choosing an analgesic regimen, particularly if a regional technique is planned. For example, the site of placement of an epidural catheter and choice of epidural solution will differ in a child with a vertical midline incision from a child with a transverse suprapubic incision. With certain procedures,

**FIGURE 43-7** Flowchart for assessment and management of acute postoperative pain in a child. D/C, Discontinue; IV, intravenous; LA, local anesthetic; NSAIDs, nonsteroidal antiinflammatory drugs; PCA, patient-controlled analgesia; PO, orally; PR, per rectum.

an epidural catheter may intrude into the surgical field or access to the catheter site in the postoperative period may be obscured by a cast or dressing. In such cases, the catheter may be tunneled subcutaneously away from the surgical field. Alternatively, one or more epidural catheters may be placed under direct vision by the surgeon at the end of the procedure (e.g., spinal fusion or selective dorsal rhizotomy).<sup>80-83</sup> Postoperative pain is managed by the pain service, using infusion of local anesthetic and/or opioid solutions through the catheter.<sup>80</sup> Painful muscle spasms after certain procedures are often well managed with continuous epidural analgesia.<sup>80,84,85</sup> Refractory spasms of the bladder, which can be quite problematic after some surgeries (e.g., ureteral reimplantation), can also be effectively treated with NSAIDs (e.g., ketorolac) or anticholinergics.<sup>86</sup> Intravesical bupivacaine has

also been used to manage bladder spasm.<sup>87,88</sup> Muscle spasms after orthopedic surgery may be prevented by dense levels of regional blockade, but may also require supplementation with oral or parenteral benzodiazepines if epidural analgesia alone is ineffective. Epidural blockade may favorably alter diaphragmatic mechanics after thoracotomy and upper abdominal surgery. This effect is likely a result of the motor blockade of the intercostal muscles and alteration in the resting length of the diaphragm, and not solely a result of reversal of diaphragmatic inhibition.<sup>89-92</sup> However, it remains uncertain whether analgesia alone, achieved by systemic opioids or central neuraxial blockade, is of value in diminishing postoperative diaphragmatic inhibition or significantly improving postoperative pulmonary function.<sup>93,94</sup> Effective analgesia, however, does improve child

compliance with measures such as deep breathing and early mobilization, thereby reducing the incidence of postoperative complications.<sup>95</sup>

### Child-Related Considerations

#### *Age and Cognitive Abilities*

Analgesic techniques, such as infiltration of the wound with local anesthetics, peripheral nerve blocks, or regional blockade that minimize the use of opioids and central respiratory depressants, may be ideal for preterm or very young infants with impaired central respiratory drive.<sup>96,97</sup> Acetaminophen can be a useful adjunct, because when used within its recommended dose range it has a large therapeutic window with few untoward effects. Although the judicious use of opioids is not contraindicated, preterm or term infants younger than 1 month of age who receive these medications require careful observation and monitoring to detect respiratory depression.<sup>98</sup> The use of local anesthetics in infants also requires more careful attention to dose, to avoid accumulation and toxicity.

Although analgesia for the preterm infant was often neglected in the past, we now understand that these infants have reduced thresholds to painful or noxious stimuli when compared with older children.<sup>99</sup> Most of the neural pathways that conduct nociception from the periphery through the central nervous system (CNS) are present and functional at 24 weeks gestational age, although the central connections, particularly in the thalamocortical pathways that are involved in the integration and perception of conscious pain, are not as well developed.<sup>100-102</sup> Controversy remains as to the meaning and implications of this neural immaturity. Opioid receptors and responses are present in the spinal cord at the time of birth, although spinal glial inflammatory mechanisms are immature. Because these mechanisms are central to the cyclooxygenase (COX-1 and COX-2) responses, this may imply that there is limited or no analgesic response to NSAIDs and COX inhibitors in preterm infants or neonates, whereas opioid responses are active. GABAergic pathways, which play an important role in the effects of analgesics and anesthetics, can be either excitatory or inhibitory, depending on the stage of development.<sup>103</sup> The neuroplasticity that is characteristic of these infants may be a double-edged sword. Animal models and some clinical evidence suggest that repeated noxious stimuli may result in heightened sensitivity to nociceptive input and adverse behavioral sequelae.<sup>2,10,104-107</sup> On the other hand, nerve injury in infant animals may result in less pain than it does in older animals.<sup>106,107</sup> In humans, the neural injury to the brachial plexus after shoulder dystocia during delivery rarely results in chronic pain.<sup>108</sup> It may be that there are both vulnerable periods and periods of greater resiliency during development, so that the consequences of pain in our youngest children may not be easily predictable.

Older infants and toddlers who are expected to experience moderate to severe pain may be adequately treated with oral opioids when oral intake resumes. Alternatively, low-dose continuous opioid infusions, nurse-controlled analgesia,<sup>109</sup> or regional blockade may be required in those undergoing extensive surgery. Nonpharmacologic techniques, such as child life therapy and the presence of a comforting parent, can do much to supplement analgesic therapy.

Preschool and school-aged children have greater fears and better understanding of the postoperative experience than do their younger counterparts. Most cognitively intact children 7 years of age or more are able to understand the concept of patient-controlled analgesia (PCA), which may be helpful in

giving a sense of control back to the child during a period in which all other aspects of control are removed.<sup>110</sup> Such issues of control and dependency assume even greater importance in adolescents; allowing them to participate in decision-making will contribute to the success of any analgesic technique.<sup>110</sup> Regional techniques are excellent for providing analgesia in all age groups and are associated with a reduced incidence of adverse effects compared with systemic opioids (e.g., nausea, vomiting, excessive sedation, dysphoria and respiratory depression). Children with significant developmental delay require special consideration of their physical disability, as well as cognitive abilities, although in most cases the pharmacologic actions of the drugs are not altered.

#### *Previous Pain Experience*

A detailed history regarding the child's previous pain experience, analgesic history, response to treatment, and adverse effects from previous analgesic regimens should be carefully considered when selecting a pain management technique. An opioid-naïve child undergoing surgery for the first time requires smaller doses of opioids for a smaller duration compared with a child with chronic pain who has developed opioid tolerance as a result of long-term or repeated opioid use. Analgesic selection should also be modified based on the effectiveness of analgesics for that particular child in the past. For example, a child with a history of not responding to codeine may be deficient in the cytochrome P-450 2D6 isoenzyme (see also Chapter 6). These children cannot metabolize codeine (methyldorphine) to morphine (its active moiety) and experience reduced analgesia after codeine. Ineffective conversion of codeine to morphine may be present in up to 7% to 10% of Caucasian children, whereas the incidence of fast metabolizers is 5% in North America. These incidences differ with ethnicity, with a significantly greater incidence of polymorphisms in North African descendants.<sup>111-115</sup> On the other hand, another polymorphism, present in about 0.5% of children, results in rapid demethylation of codeine to morphine, producing exaggerated sedation and respiratory depression when codeine is administered.<sup>116,117</sup> Overall, we strongly discourage routine use of codeine as a first-line opioid for children. Oxycodone, hydrocodone, hydromorphone, or morphine are superior alternatives to codeine. Alternatively, if pain is of moderate or smaller intensity, another class of analgesics (e.g., NSAIDs) can be substituted.

## Pharmacologic Treatment of Pain

### NONOPIOID ANALGESICS

Nonopioid analgesics may be used as sole agents for the treatment for mild pain and as important adjuncts for the multimodal treatment of moderate to severe pain. Although most nonopioid analgesics produce dose-dependent responses, they are limited by a ceiling effect in the analgesia achieved, that is, larger doses of the medication provide no additional analgesia. Hence, more severe pain is resistant to therapy from these medications alone.<sup>118</sup> Therefore they are frequently prescribed in combination with opioids to reduce both the opioid requirements and the adverse effects (Table 43-7).

#### *Acetaminophen*

Acetaminophen is the most common antipyretic and nonopioid analgesic used in children. It exerts its analgesic effects by blocking central and peripheral prostaglandin synthesis, reducing substance P-induced hyperalgesia, and modulating the production

**TABLE 43-7** Oral Dosing Guidelines for Commonly Used Nonopioid Analgesics

Medication	Individual Dose for Children <60 kg (mg/kg)	Individual Dose for Children ≥60 kg (mg)	Dosing Interval (hours)	Maximum Daily Dose for Children <60 kg (mg/kg)	Maximum Daily Dose for Children ≥60 kg (mg)
Acetaminophen	10-15	650	4	75 <sup>†</sup>	3000
Ibuprofen	6-10	400-600	6	40	2400
Naproxen	5-6	250-375	12	10	1000
Diclofenac	1	50	8	3	150
Ketorolac*	0.5	30	6-8	2	120
Tramadol	1-2	50	6	8	400

\*Ketorolac should be administered for a maximum of 5 days or 20 doses up to 15 mg per dose for children <50 kg or 30 mg per dose for children >50 kg.

<sup>†</sup>See text for new age-related dosing.

of hyperalgesic nitric oxide in the spinal cord.<sup>119-121</sup> In addition, it has been suggested that acetaminophen produces analgesia via activation of descending serotonergic pathways.<sup>122-124</sup> However, it is likely that its primary site of action may be inhibition of prostaglandin H<sub>2</sub> synthetase at the peroxidase site.<sup>123</sup> Effective analgesic and antipyretic effects have been described with plasma concentrations of 5 to 20 µg/mL<sup>125-129</sup>; a target effect-site concentration of 10 µg/mL reduces pain after tonsillectomy by 3.6/10 pain units.<sup>130</sup> The total daily dose of acetaminophen via any route is age- and weight-based but should not exceed 75 mg/kg for children; term and preterm infants require further downward dosing adjustment (60 mg/kg and 45 mg/kg, respectively).

The recommended dose for oral administration is 10 to 15 mg/kg every 4 hours. Acetaminophen has a wide margin of safety when administered in the recommended therapeutic dose range. However, hepatotoxicity has been reported with doses only slightly above the recommended 10- to 15-mg/kg/dose orally for a total of five doses or 75 mg/kg/day, suggesting that acetaminophen may have a narrow therapeutic index in some children.<sup>131,132</sup> Because of these reports and on the advice of a U.S. Food and Drug Administration panel, the manufacturers have reduced the maximum single dose of oral acetaminophen in adults to 650 mg and the maximum daily dose to 3 grams. Acetaminophen is available in a wide variety of formulations, alone or in combination with decongestants, for oral use in a variety of cold remedies, and with opioids for the treatment of moderate to severe pain. There are currently more than 600 over-the-counter acetaminophen-containing products, increasing the risk of an overdose because children may take more than one formulation that contains the drug. Frequent review of medications and parental education is needed to minimize the risk of overdose. In the past, pediatric liquid formulations of acetaminophen as in infant drops were commonly supplied in larger concentrations than that in elixirs, resulting in dosing errors. The current recommendation is to standardize liquid formulations to a single concentration of 32 mg/mL. Acetaminophen can be given orally before surgery; both gastric fluid volume and pH are unchanged after acetaminophen was administered orally 90 minutes before induction of anesthesia.<sup>133</sup>

Slow and unpredictable absorption of acetaminophen after rectal administration results in variable blood concentrations, with peak concentrations reached between 60 and 180 minutes after administration.<sup>128,134,135</sup> There is a dose-response relationship for rectal acetaminophen. The morphine-sparing effects of 40 mg/kg and 60 mg/kg of rectal acetaminophen were greater than those of 20 mg/kg and placebo in children undergoing

ambulatory surgery.<sup>136</sup> In children undergoing orthopedic surgery, a loading dose of 40 mg/kg rectal acetaminophen followed by 20 mg/kg every 6 hours yielded serum concentrations of 10 to 20 µg/mL, with no evidence of accumulation over a 24-hour period.<sup>134</sup> This dosing scheme is now the one most commonly recommended when the rectal route is employed.

Intravenous (IV) formulations of paracetamol (acetaminophen) and its prodrug propacetamol have been used in Europe and Australia for several years and are now available in the United States. IV acetaminophen is available as a 10 mg/mL solution and should be infused over at least 15 minutes in a dose of 10 mg/kg, with a total daily dose not to exceed 75 mg/kg. The maximum dose, regardless of weight, is 750 mg every 6 hours (3 grams per day).

After IV administration of acetaminophen, analgesic onset occurs in 15 minutes and that of antipyresis in 30 minutes.<sup>137,138</sup> IV paracetamol rapidly penetrates the blood-brain barrier in children, yielding detectable concentrations in the cerebrospinal fluid (CSF) within 5 minutes of administration, and peak CSF concentrations within 57 minutes after injection (compared with 2 to 3 hours after rectal or oral administration), thus explaining the fast onset of its analgesic and antipyretic effects.<sup>139</sup> A large multicenter trial reported that 1 gram of IV paracetamol and 2 grams of IV propacetamol (equivalent to 1 gram acetaminophen) provided superior analgesia with a reduced need for morphine compared with placebo in adults after lower extremity joint replacement.<sup>140</sup> The propacetamol group experienced a greater incidence of local skin reactions and pain on injection compared with the IV paracetamol group. A controlled randomized trial reported that both rectal acetaminophen, 40 mg/kg, and IV acetaminophen, 15 mg/kg, administered after induction of anesthesia in children undergoing adenotonsillectomy, provided good analgesia for the first 6 hours after surgery.<sup>141</sup> However, children who received acetaminophen rectally had a greater duration of analgesia and did not require rescue analgesia as early as those in the IV group.<sup>141</sup> This is attributable to the slow absorption of rectal acetaminophen causing sustained effective concentrations. A prospective randomized trial comparing rectal acetaminophen to IV propacetamol in infants after craniofacial surgery reported that the IV formulation provided superior analgesia,<sup>142</sup> in part because of reduced bioavailability of acetaminophen by the rectal route.

Another controlled randomized study compared the analgesic efficacy and side effects of fentanyl-placebo versus fentanyl-acetaminophen administered via PCA in 6- to 24-month-old children undergoing ureteroneocystostomy.<sup>143</sup> Children in the

acetaminophen group required significantly less fentanyl and demonstrated a reduced incidence of vomiting and excessive sedation compared with those in the placebo group. Lastly, a large retrospective study reported no differences in alanine transaminase and  $\gamma$ -glutamyl transferase concentrations, and a progressive decrease in aspartate aminotransferase levels, in term and preterm neonates before, during and after IV acetaminophen injection.<sup>144</sup>

### Nonsteroidal Antiinflammatory Drugs

NSAIDs provide excellent analgesia for mild to moderate pain resulting from surgery, injury, and disease. Their principle mechanism of action is via inhibition of the enzyme prostaglandin H<sub>2</sub> synthetase at the COX site, causing a reduction in the production of prostaglandins at the site of tissue injury, and attenuation of the inflammatory cascade. In addition to their peripheral effects, the NSAIDs have also been shown to exert a direct spinal action by blocking the hyperalgesic response induced by activation of spinal glutamate and substance P receptors.<sup>145</sup> Decreased production of leukotrienes, activation of serotonin pathways, and inhibition of excitatory amino acids, NMDA-mediated hyperalgesia, and central inhibition of prostaglandin biosynthesis have been proposed as additional mechanisms of action.<sup>146,147</sup> The COX-1 enzyme is present in the brain, gastrointestinal tract, kidneys, and platelets and is expressed constitutively. It preserves gastric mucosal integrity and function, platelet aggregation, and renal perfusion. COX-2 expression is induced by inflammation or tissue injury. Selective COX-2 inhibitors reduce inflammation but have less effect on gastric mucosal function and have fewer effects on platelet aggregation, thereby resulting in fewer adverse effects. Their deleterious effects on renal perfusion, however, are no different than the nonselective COX drugs, because COX-2 is constitutively expressed in renal tissues and may be involved in prostaglandin-dependent renal homeostatic processes.<sup>148</sup> The risks of renal toxicity increase in the presence of hypovolemia, cardiac failure, preexisting renal dysfunction, or with the concurrent use of other nephrotoxic drugs. Reports of thrombotic cardiovascular and CNS events after both long-term and short-term use in adults led to withdrawal of two of the COX-2 inhibitors, rofecoxib and valdecoxib from the market.<sup>149,150</sup> Similar data are unavailable to date in children; consequently, the risk of these agents causing thrombotic complications in children remains unknown. Most pediatric studies have evaluated the use of nonselective COX medications. In adult studies, COX-2 inhibitors have generally, but not always, produced analgesia roughly equivalent to that of traditional NSAIDs. Ibuprofen, one of the oldest orally administered NSAIDs, has been used extensively for treatment of fever and pain related to surgery, trauma, arthritis, menstrual cramps, and sickle cell disease. A large, controlled, randomized, double-blind study reported a greater decrease in VAS pain scores with ibuprofen than with acetaminophen or codeine in children presenting to the emergency department with acute pain after musculoskeletal trauma.<sup>151</sup> Additionally, more children who received ibuprofen had VAS scores less than 30 on a 0-to-100-mm VAS scale than in the other two groups. The recommended dose of ibuprofen is 6 to 10 mg/kg every 6 hours. Like acetaminophen, ibuprofen is available in a variety of formulations and concentrations, placing children at risk for an overdose. For pediatric use, ibuprofen is available as:

- Concentrated drops containing 50 mg ibuprofen in 1.25 mL
- Oral suspension containing 100 mg of ibuprofen in 5 mL

- Junior-strength chewable tablets or caplets containing 100 mg of ibuprofen in each

Diclofenac provides effective analgesia after minor surgical procedures in children. It is available only as an oral tablet in the United States, but it is available as a suppository and in the injectable form in several countries. The pediatric dose of diclofenac is 1 mg/kg every 8 hours orally, 0.5 mg/kg rectally, and 0.3 mg/kg IV.<sup>152</sup> The oral and rectal doses reflect bioavailabilities of 0.36, 0.35, and 0.6 for suspension, dispersible tablets, and suppository, respectively. When diclofenac was administered rectally, the relative bioavailability was greater and the peak concentration was reached earlier than after enteric coated tablets administered orally.<sup>153</sup> Children who received diclofenac experienced comparable analgesia to those who received caudal bupivacaine or IV ketorolac for inguinal hernia repair.<sup>154-156</sup> In children undergoing tonsillectomy and/or adenoidectomy, diclofenac yielded superior analgesia with less supplemental opioid dosing, less nausea and vomiting, and earlier resumption of oral intake compared with acetaminophen.<sup>157,158</sup> Although there are occasional reports of increased bleeding and restlessness in the recovery room in children who received diclofenac compared with those who had received papaveretum during tonsillectomy,<sup>159</sup> a Cochrane review established that NSAIDs did not cause any increase in bleeding that required a return to the operating room (OR) for children. There was significantly less nausea and vomiting with NSAIDs compared with alternative analgesics, suggesting their benefits outweigh their negative aspects.<sup>160</sup>

Ketorolac, indomethacin and ibuprofen are the only injectable NSAIDs available in the United States. Indomethacin is the only NSAID used for closure of patent ductus arteriosus in preterm neonates. The IV formulation of ibuprofen is only labeled for adults in the United States. Clinical trials are currently under way in children. Ketoprofen and diclofenac are other injectable NSAIDs that are available outside the United States. A large multicenter study compared the risks of serious adverse events from IV ketorolac, ketoprofen, and diclofenac in more than 11,000 adults undergoing major surgery.<sup>161</sup> The results indicated that 1.4% of adults experienced a serious adverse outcome, including surgical site bleeding (1%), death (0.17%), severe allergic reactions (0.12%), renal failure (0.09%), and gastrointestinal bleeding (0.04%), with no differences in outcomes among the groups; similar large-scale studies are not available for children.

Ketorolac has been shown to provide postoperative analgesia similar to opioids, in children of all ages.<sup>162-165</sup> Its benefits include lack of opioid adverse effects (respiratory depression, sedation, nausea, and pruritus) making it an attractive choice for the treatment of postoperative pain. However, in common with all NSAIDs, it carries risks of platelet dysfunction, gastrointestinal bleeding, and renal dysfunction. Ketorolac (1 mg/kg) given to 18 preterm and term neonates undergoing painful procedures in the OR or the neonatal intensive care unit,<sup>163</sup> revealed reduced pain scores (Neonatal Infant Pain Scale) with no incidents of systemic or local bleeding and no hematologic, hepatic, or renal complications (note that this dose is twice the usually recommended dose of 0.5 mg/kg). Similarly, no adverse effects on surgical drain output, renal or hepatic function tests, or oxygen saturation after major surgery were noted in 37 infants and toddlers between 6 and 18 months of age.<sup>166</sup> Children in that study received continuous morphine infusions postoperatively, confounding the evaluation of the analgesic efficacy of ketorolac. Finally, ketorolac has been used to supplement opioid analgesia, with no increase in renal or bleeding complications in infants and children after

open heart surgery.<sup>167-169</sup> Nevertheless, because ketorolac can reduce renal blood flow, many recommend that its course be limited to 48 to 72 hours, and that renal function be checked if a course of administration greater than 72 hours is required. In single dose studies, the pharmacokinetics (PK) of ketorolac in infants less than 12 months of age appear to be homogeneous, although there was a trend toward reduced clearance in the infants less than 6 months of age.<sup>170</sup>

In an effort to avoid the respiratory depressant effects of opioids after airway surgery, several studies investigated the safety and benefits of ketorolac in children undergoing tonsillectomy.<sup>171-175</sup> These early reports of ketorolac adversely skewed analyses of the adverse effects of NSAIDs after tonsillectomy. All but one of these studies<sup>171</sup> found a two- to fivefold increase in bleeding complications, including measured blood loss, ease of achieving hemostasis, and bleeding episodes in the postanesthesia care unit (PACU), necessitating reexploration and hospital admission in some cases. Two of these studies were terminated prematurely, when preliminary data showed an unacceptably greater risk of bleeding in children who had received ketorolac.<sup>172,175</sup> In one of these two studies, ketorolac was given at the end of surgery after hemostasis had been achieved.<sup>172</sup> The benefits of ketorolac, including adequacy of analgesia, resumption of oral intake, and reduction in nausea, vomiting, and sedation were modest. This issue is further confounded by conflicting results yielded by two meta-analyses that evaluated the related literature. In one of these, the use of aspirin, but not of NSAIDs (diclofenac or ibuprofen), significantly increased the risk of post-tonsillectomy hemorrhage compared with either acetaminophen with codeine or tramadol for postoperative analgesia.<sup>176</sup> The other reported no increase in intraoperative blood loss, postoperative bleeding, or admission because of bleeding, but did show a statistically significant increase in the rate of reoperation for bleeding in children who received an NSAID in the postoperative period compared to those who did not.<sup>177</sup> Taken together, these data suggest that the use of NSAIDs during or after tonsillectomy is best avoided, and alternative analgesics, such as acetaminophen and tramadol, be considered to reduce opioid requirements. A large multicenter study in adults found that the risk of gastrointestinal and operative site bleeding associated with ketorolac was larger and clinically important when ketorolac was used in larger doses, in older subjects, and for more than 5 days.<sup>178</sup>

Another contentious issue regarding NSAIDs relates to their effects on bone healing and their use in children undergoing spinal fusion. Prostaglandins play an integral role in bone metabolism and significantly influence bone resorption and formation; however, their effects on bone formation predominate. NSAIDs inhibit the formation of prostaglandins, thereby raising the concern that they could promote nonunion after spinal fusion. Studies in rabbits and some studies in adults have reported a greater incidence of nonunion or pseudarthrosis, particularly with the use of large doses of ketorolac.<sup>179,180</sup> However, no differences in curve progression, hardware failure, pseudarthrosis, or need for reoperation have been found in children and adolescents who received ketorolac in the immediate postoperative period compared with those who did not.<sup>181-183</sup> Of note, the majority of the pediatric data are from otherwise healthy children with idiopathic scoliosis, making it problematic to extrapolate these data to children with comorbidities or those with neuromuscular scoliosis. There is no unique advantage of the IV route with NSAIDs. There is also no evidence that IV ketorolac is a

more potent analgesic than comparable (i.e., equipotent) doses of a number of other NSAIDs, administered by oral or rectal routes.<sup>184</sup>

A recent meta-analysis of the use of NSAIDs for postoperative pain included 27 studies and compared 567 children who received NSAIDs to 418 children who did not.<sup>185</sup> This study found that coadministration of NSAIDs and opioids during the perioperative period decreased opioid requirement in the PACU and the first 24 hours after surgery, decreased pain intensity in the PACU, and postoperative nausea and vomiting (PONV) during the first 24 hours postoperatively. Additionally, coadministration of acetaminophen with NSAIDs and opioids reduced pain intensity for the first 24 hours postoperatively. Other investigators demonstrated up to a 30% opioid-sparing effect in children who receive acetaminophen and diclofenac in addition to PCA. Therefore, in the absence of contraindications, it has been recommended that NSAIDs be used as part of a multimodal regimen to manage postoperative pain and to decrease opioid consumption in children.<sup>185</sup>

### Tramadol

Tramadol is a synthetic analogue of codeine that exerts its analgesic properties by two complementary mechanisms. One of its metabolites has a weak affinity for the  $\mu$  opioid receptor with no affinity for the  $\delta$  or the  $\kappa$  receptors. In addition to its mild opioid effects, it also inhibits serotonin and norepinephrine uptake. Its main advantages over opioids include reduced incidences of respiratory depression, sedation, nausea, and vomiting. Additionally, because it does not inhibit prostaglandin synthesis, it does not cause the adverse effects commonly reported with NSAIDs, including peptic ulceration and renal and platelet dysfunction. Adverse effects associated with its use include nausea and vomiting (9% to 10% of cases), pruritus (7%), and rash (4%).<sup>186</sup> It is known to cause dizziness and its use has been associated with seizures. Tramadol is available only in tablet form alone or in combination with acetaminophen in the United States. However, it is available in a liquid formulation (and as oral drops for infants), as a suppository, and as an injectable solution in other countries, allowing for greater flexibility of dosing. Therefore, it has been used to provide analgesia by a number of routes, including oral, rectal, IV (including PCA devices), into the caudal epidural space, and by local infiltration.

Tramadol is used for postoperative pain treatment in children undergoing ambulatory surgery and has also been used when transitioning from IV opioids to oral analgesics. Two doses of tramadol (1 mg/kg and 2 mg/kg orally) were compared in children who were being transitioned from morphine PCA. Children who received 2 mg/kg required fewer supplemental analgesics with no difference in adverse effects compared with those who had received 1 mg/kg.<sup>186</sup> Tramadol, 2 mg/kg IV, produced similar analgesia and sedation, with fewer episodes of oxygen desaturation compared with morphine 0.1 mg/kg IV, in children with obstructive sleep apnea undergoing adenotonsillectomy.<sup>187</sup> Tramadol has also been found to produce a similar analgesic effect as that of ilioinguinal and iliohypogastric nerve blocks in children undergoing herniorrhaphy.<sup>188</sup> The tramadol group, however, experienced a greater incidence of nausea and vomiting. Tramadol PCA has also been found to provide adequate analgesia with less sedation, earlier awakening, and earlier extubation in children undergoing atrial or ventricular septal defect repair compared with those who received morphine via PCA.<sup>189</sup>

Tramadol has also been effective when administered via the neuraxial space. Caudal tramadol (2 mg/kg) produced reliable postoperative analgesia comparable to that produced by caudal morphine (30 µg/kg) in children undergoing inguinal hernia repair.<sup>190</sup> No additional pain medications were required in the first 24 hours in more than 90% of children in each group. Rigorous drug-specific neurotoxicity studies, however, are lacking. Another study compared the analgesic efficacy of 2 mg/kg tramadol administered IV or by peritonsillar infiltration in children undergoing adenotonsillectomy.<sup>191</sup> Both groups experienced excellent analgesia in the first hour. However, the local infiltration group experienced more prolonged analgesia and required fewer rescue doses of acetaminophen compared with the IV group. Overall, tramadol appears to be an analgesic of medium potency with a low incidence of adverse effects that may be used alone for mild to moderate pain and for its opioid-sparing effect in children with severe pain.

### Ketamine

There has been increasing interest in the use of ketamine, an NMDA-receptor antagonist, in the treatment of both chronic and acute pain. Its professed benefits include an opioid-sparing effect, avoidance of opioid tolerance, prevention of central sensitization and wind-up, mitigation of opioid-induced hyperalgesia, and provision of synergistic analgesia in multimodal regimens by virtue of its own antinociceptive properties. Case series in children with intractable pain resulting from advanced stages of cancer have reported reduction in opioid requirement, decreased opioid adverse effects, improvement in pain control and function, and increased ability to interact with their families.<sup>192-194</sup>

Studies evaluating the use of ketamine alone or in combination with opioids for acute postoperative pain in children have yielded equivocal results. In one study, children undergoing tonsillectomy who received IV ketamine 0.5 mg/kg after induction or at the end of surgery experienced reduced pain scores and required fewer rescue analgesics compared with those who received placebo.<sup>195</sup> All children in this study received a standardized analgesic regimen, including rectal diclofenac before the start of surgery and oral acetaminophen at scheduled intervals postoperatively. Another study reported reduced pain scores and reduced requirement for rescue analgesics in children who received ketamine as a bolus dose and by infusion that began before the start of a tonsillectomy, compared with those who received a single bolus dose of ketamine at the end of surgery.<sup>196</sup> Intramuscular (IM) ketamine 0.5 mg/kg has also produced equivalent analgesia in terms of similar pain scores and need for rescue analgesics compared with IM morphine 0.1 mg/kg as sole analgesics for tonsillectomy.<sup>197</sup> Other studies have found no such benefits when ketamine was compared with placebo for tonsillectomy, urologic, and orthopedic surgery.<sup>198-201</sup>

A meta-analysis of 35 randomized controlled trials compared 567 children who received ketamine as an adjuvant analgesic by a variety of routes for a variety of surgical procedures with 418 who did not receive ketamine.<sup>202</sup> This study found that, although the use of ketamine was associated with reduced pain intensity in the PACU and a reduced need for nonopioids, it did not demonstrate an opioid-sparing effect. A systematic review of 37 studies included 4 studies in children, two of which demonstrated beneficial effects of ketamine administered as an adjuvant analgesic and two found no benefits.<sup>203</sup> The investigators could draw no conclusions regarding the use of ketamine as an adjuvant analgesic. The use of ketamine in all the above studies was

associated with only a few mild and self-limiting adverse effects. Further investigation is needed to evaluate the benefits of low-dose ketamine for acute postoperative pain before its routine use can be recommended.

### OPIOID ANALGESICS

Opioids are indicated for moderate to severe pain after surgery or trauma, for acute painful crisis in children with sickle cell disease, as well as for chronic painful conditions such as cancer. Opioids mimic the effects of endogenous ligands known as endorphins, exerting their effects by binding to specific opioid receptors located at presynaptic and postsynaptic sites in the brain, spinal cord, and peripheral nerve cells. Opioid receptors in the CNS are classified as  $\mu$ ,  $\kappa$ ,  $\delta$ , and  $\sigma$ .<sup>204-206</sup> Activation of these receptors causes neuronal inhibition by decreasing the release of excitatory neurotransmitters from presynaptic terminals. The  $\mu$  receptors are further subdivided into  $\mu_1$  receptors, responsible for supraspinal analgesia and physical dependence, and  $\mu_2$  receptors, responsible for respiratory depression, bradycardia, physical dependence, and gastrointestinal dysmotility.<sup>207</sup> Activation of the  $\kappa$  receptors causes analgesia without significant respiratory depression, whereas activation of the  $\sigma$  receptors causes dysphoria, tachycardia, tachypnea, hypertonia, and mydriasis. The  $\delta$  receptors modulate the activity of the  $\mu$  receptors.

Drugs that exert their effects on opioid receptors are classified as agonists, antagonists, partial agonists, and mixed agonist-antagonists. Agonists are neurotransmitters that bind to a receptor and exert their pharmacologic effects. Antagonists, on the other hand, bind to the receptor but do not initiate any effects; yet by occupying the receptor they block the effects of agonists. Partial agonists have reduced intrinsic activity and produce less than a maximal response. They act as antagonists as well because they block the agonists from access to the receptor. The mixed agonist-antagonist drugs act as agonists at certain opioid receptors and antagonists at others. E-Table 43-4 depicts the various opioid receptors, their effects, as well as the drugs that exert activity on each of them. The opioids that are used most commonly in the management of pain are  $\mu$ -receptor agonists, including morphine, hydromorphone, the fentanyl, methadone, hydrocodone, and oxycodone. Of these, morphine is the opioid that is most commonly used as first-line therapy for moderate to severe pain in children and, consequently, is the agent with which clinicians have the greatest experience. Table 43-8 lists the relative potencies and suggested initial doses of the opioids in common clinical use. Developmental pharmacology, PK, and side effects of opioids are discussed in depth in Chapter 6.

### Delivery Techniques

The blood concentration of opioids must be maintained within a therapeutic range to provide effective analgesia and avoid undesirable adverse effects, such as excessive sedation and respiratory depression. Both the dose and the route by which the opioid is delivered determine how well one is able to maintain the blood concentration within this therapeutic window and minimize adverse effects.

### Oral Administration

Oral administration of opioids at regular intervals can lead to reasonably constant blood concentrations if dosed appropriately. Oral opioids are well-tolerated and suitable for children with mild to moderate pain, for those who undergo outpatient surgery, or as adjuncts to regional anesthetics. For those with regional

**E-TABLE 43-4** Classification of Opioid Receptors

Receptor	Effect	Agonist	Antagonist
mu ( $\mu$ )	$\mu_1$ -Supraspinal analgesia, physical dependence $\mu_2$ -Hypoventilation, bradycardia, physical dependence, euphoria, ileus	Morphine, codeine, hydromorphone, fentanyl, sufentanil, alfentanil, meperidine, methadone	Naloxone, pentazocine, nalbuphine
delta ( $\delta$ )	Modulate $\mu$ receptor activity, weak analgesia, euphoria	Enkephalins	Naloxone, metenkephalin
kappa ( $\kappa$ )	Analgesia, sedation, hypoventilation, miosis	Dynorphin, pentazocine, butorphanol, nalbuphine, buprenorphine, nalorphine	Naloxone
sigma ( $\sigma$ )	Dysphoria, hypertonia, tachycardia, tachypnea, mydriasis	Pentazocine, ketamine	Naloxone

**TABLE 43-8 Opioid Analgesics: Relative Potency and Initial Dosing Guidelines\***

Drug	Potency Relative to Morphine	Oral Dose	Intravenous Dose	PO:IV Dose Ratio
Morphine	1	0.3 mg/kg every 3-4 hours Sustained release: 20-35 kg: 10-15 mg every 8-12 hours 35-50 kg: 15-30 mg every 8-12 hours	Bolus: 0.1 mg/kg every 2-4 hours Infusion: 0.03 mg/kg/hr	1:3 1:6 for opioid-naïve child
Hydromorphone	5-7	0.04-0.08 mg/kg every 3-4 hours	Bolus: 0.02 mg/kg every 2-4 hours Infusion: 0.006 mg/kg/hr	1:4
Fentanyl	80-100	NA	Bolus: 0.5-1 µg/kg every 30 minutes to 2 hours Infusion: 0.5-2 µg/kg/hr	NA
Codeine	0.1	0.5-1 mg/kg every 4-6 hours	NR	NA
Oxycodone	1-1.5	0.1-0.2 mg/kg every 4-6 hours	NA	NA
Hydrocodone	1-1.5	0.1-0.2 mg/kg every 4-6 hours	NA	NA
Methadone†	1	0.1-0.2 mg/kg every 6-12 hours	0.1 mg/kg every 6-12 hours	1:2
Nalbuphine	0.8-1	NA	50-100 µg/kg every 3-6 hours	4-5:1

Modified from Berde CB, Sethna NF. Analgesics for the treatment of pain in children. *N Engl J Med* 2002;347:1094-103.

IV, Intravenous; NA, not applicable; NR, not recommended; PO, oral.

\*Recommended doses are for infants >6 months of age. For younger infants, reduce initial doses to 25% of these doses and increase as needed.

†Methadone has a long half-life and can accumulate, causing delayed sedation or respiratory depression. If sedation or respiratory depression occurs, doses should be withheld until sedation resolves. Then the drug is restarted at a smaller dose and extended dosing interval.

anesthetics, oral administration of an opioid before the block dissipates may provide a virtually pain-free recovery period. In most cases, oral opioids are better tolerated after resumption of oral intake.

Hydrocodone and oxycodone are two of the most commonly prescribed oral opioids. Both are available in a variety of formulations either alone or in combination with acetaminophen. Oxycodone causes significantly less nausea and vomiting than codeine and is usually better tolerated postoperatively when oral intake has resumed. Both hydrocodone and oxycodone are available in liquid form, making them easy to prescribe for infants and young children. Oxycodone is available in 1 mg/mL and 20 mg/mL strengths. The 1 mg/mL strength is easy to dose and administer to infants, whereas the 20 mg/mL strength is reserved for older children with chronic pain and should rarely be used to treat acute postoperative pain. Although the different formulations allow flexibility in dosing, extreme caution is required in prescribing and dispensing the correct concentration to avoid a potentially lethal overdose. Another important caveat when prescribing combination formulations of oral opioids and nonopioid adjuvants (such as acetaminophen) is to ensure that the recommended daily dose of the adjuvant is not exceeded. For children who require large doses of the opioid component to treat their pain, it may be necessary to prescribe the medications separately.

Although codeine has been widely used as an oral opioid analgesic, our strong preference is to avoid prescribing it in almost all situations, for several reasons. First, in recommended doses, it is a weak analgesic. Second, because it is a prodrug that requires conversion via demethylation to morphine (as detailed in Chapter 6), there is marked developmental and pharmacogenetic variation in this conversion that may result in ineffective conversion and thus reduced analgesia in some cases, or an overdose in others. Third, when the dosing is escalated, the frequencies of adverse effects, such as nausea, vomiting,

constipation, and dysphoria increase. It is important to note that with active metabolites of codeine excreted in breast milk, there has been a report of an opioid overdose in a neonate who was breastfed by a mother who was an extensive metabolizer.<sup>208</sup>

Methadone is a synthetic opioid with a very prolonged elimination half-life (mean of 19 hours) in children between 1 and 18 years of age, and a large bioavailability (approximately 80%) after oral administration. Oral or IV methadone has been considered a good alternative to the use of continuous opioid infusions because repeated dosing at intervals of every 4 to 8 hours can achieve relatively stable plasma drug concentrations.<sup>209</sup> Although it is used most frequently to facilitate weaning of opioid-tolerant children, it has also been recommended for postoperative analgesia and for transitioning children from parenteral to oral opioid therapy.<sup>210-212</sup> Methadone is especially useful for children with cancer, burns, or other serious illnesses who require a long-acting oral opioid, because it is available in an elixir formulation. Unlike some sustained-release formulations of other opioids, oral methadone is also relatively inexpensive. Note that crushing tablets of most sustained-release formulations of other opioids renders them into immediate-release, relatively short-acting medications. Methadone should be thought of as virtually a combination analgesic. It is supplied as a racemic mixture. The *l*-isomer acts as a  $\mu$  opioid, whereas the *d*-isomer acts as an antagonist at the NMDA subclass of excitatory amino acid receptors. Action at NMDA receptors makes methadone uniquely effective in the treatment of neuropathic pain. This NMDA-blocking action, and a differential activation of receptor-mediated endocytosis versus protein kinase activation,<sup>213,214</sup> may lead to a relatively slower rate of development of tolerance for methadone compared with some other opioids. Despite these advantages of methadone, it requires careful titration and repeated reassessment to avoid delayed oversedation. This challenge in methadone dosing is due, in part, to its slow and widely variable clearance, as well as to its effects on NMDA antagonism, generating incomplete cross tolerance

on conversion to methadone from other opioids. In opioid-naïve subjects, a single dose of IV morphine is roughly equipotent to a single dose of methadone. Although morphine has active metabolites, the slower clearance of methadone compared with morphine translates in opioid-naïve subjects, into daily IV methadone requirements that are roughly one-third those of morphine. *However, in the setting of marked opioid tolerance, such as in the case of children with advanced cancer or in the setting of intensive care, the equipotent daily dose of IV methadone may be as small as one-tenth the preceding daily dose of IV morphine.*<sup>129,209,215-217</sup> A convenient web-based calculation tool ([www.globalrph.com/narcoticonv.htm](http://www.globalrph.com/narcoticonv.htm)) has synthesized the information from these and other studies to aid in opioid conversions in both opioid-naïve and opioid-tolerant subjects. In our practice, this calculation tool appears quite useful, although it must be noted that it has not received independent assessment for use in children. Smartphone applications for multiple platforms are also available.

### **Intravenous Administration**

Intermittent IV injections with opioids of short or moderate duration administered on an as-needed basis (pro re nata, or PRN) do not achieve stable blood concentrations and predispose to periods of excessive sedation alternating with periods of inadequate analgesia. Yet this technique remains the most common method of treating postoperative pain in many centers. A partial solution to this problem is to prescribe the opioid at closer intervals (such as 2 hourly) and then use a “reverse-PRN” schedule, in which the medication is offered at the prescribed interval but the child can choose to take it or refuse it. Children should be assessed frequently, with the goal of administering the next dose before moderate to severe pain recurs. The use of a long-acting opioid, such as methadone, has been recommended to provide more prolonged and even periods of analgesia than could be achieved with shorter-acting opioids, approaching the efficacy of continuous infusions.<sup>218</sup> However, careful titration of dosing and frequent assessment of the child are required because of methadone’s slow and variable clearance. Alternatively, administration of shorter-acting opioids via continuous infusion or a PCA device should be considered.

Continuous IV opioid infusions are an excellent means of providing analgesia to children with moderate to severe pain who are unable to use PCA, such as infants, young children, and those who are cognitively impaired or physically disabled.<sup>219</sup> Once a therapeutic blood concentration of the opioid is achieved by administering an initial loading dose, an infusion rate can be selected to maintain that concentration without excessive fluctuations. Additionally, rescue doses of IV opioids may be required for breakthrough pain. Opioids, however, cause a dose-dependent respiratory depression by shifting the CO<sub>2</sub> response curve, reducing its slope, and decreasing the hypoxic ventilatory response. Residual and synergistic effects of sedatives and hypnotics in the early postoperative period further increase the risk of opioid-induced respiratory depression. This is particularly true in preterm and term infants because of age-related differences in elimination and clearance of opioids and other sedating medications (see also Chapter 6). This is of particular concern with the use of continuous opioid infusions because inappropriate dosing or prolonged elimination may lead to drug accumulation, placing children at risk for side effects. In a recent prospective audit of 10,726 opioid infusions in the UK and Ireland, the overall risk of permanent harm was found to be 1 in 10,000 cases, and serious events without permanent harm 1 in 383, with half of

the serious events being respiratory depression.<sup>220</sup> Therefore, the rate of the infusion should be carefully selected, based on the child’s age, comorbidities, and clinical condition. Additionally, children who receive opioid infusions should be monitored and assessed frequently for depth of sedation and respiratory rate. The onset of sedation is an important clinical index of incipient respiratory depression and should alert the nursing staff and physicians to decrease the infusion rate and observe the child more closely. Use of continuous pulse oximetry is widely recommended during continuous opioid infusions, especially in opioid-naïve children and other children at increased risk for respiratory depression. Another method of IV opioid delivery is via PCA, which is discussed below. With any infusion technique, scrupulous attention must be paid to protocols for checking pump settings to avoid errors. Pump programming errors, none of which caused serious harm, but which had the potential to do so, occurred in 17 instances in the UK audit, all from a single center, highlighting the critical importance of system safeguards to prevent patient harm.<sup>220</sup>

### **Intramuscular and Subcutaneous Routes**

Intermittent IM and subcutaneous injections of opioids are obsolete because they are frightening and unpleasant for children and are often perceived as worse than the pain for which they are administered.<sup>221</sup> Additionally, they have the PK disadvantage of unpredictable and erratic uptake if regional blood flow is impaired, and they produce pronounced wide swings in blood concentrations. The goal of maintaining an even level of analgesia is thus nearly impossible to achieve with these routes of administration. An important exception is the use of indwelling subcutaneous catheters for continuous infusions and PCA as in palliative care.

### **Selection of Opioids for Parenteral Use**

Morphine is the opioid most commonly used for postoperative analgesia and has been extensively studied in all pediatric age groups. After major abdominal, thoracic, and orthopedic surgery, children who received continuous morphine infusions had reduced pain scores compared with those who received intermittent IM or IV injections.<sup>222-224</sup> However, other investigators were only able to demonstrate reduced pain scores with continuous morphine infusions compared with intermittent IV injections of morphine in children between 1 and 3 years of age, and not in infants in the first year of life.<sup>225,226</sup> Similarly, evidence of the beneficial effects of opioid analgesia in ameliorating the postoperative response to surgical stress are conflicting. A significant reduction in serum  $\beta$ -endorphin concentrations has been reported in neonates after the initiation of a continuous infusion of morphine in the postoperative period.<sup>227</sup> In neonates whose lungs were mechanically ventilated, both epinephrine and norepinephrine concentrations decreased significantly after the initiation of morphine or fentanyl infusions.<sup>228</sup> However,  $\beta$ -endorphin concentrations decreased only in the children who received fentanyl. When the effects of continuous infusions of morphine were compared with those of intermittent IV injections of morphine on the stress response in children between 1 and 3 years of age, reduced glucose concentrations in the continuous infusion group suggested only a modest ablation of the stress response in this age group.<sup>225</sup>

Several studies have described the PK of morphine administered as a continuous infusion and evaluated the pharmacodynamic effects of morphine on respiratory indices in neonates,

infants, and children after various surgical procedures. In children 14 months to 17 years of age who underwent cardiac surgery,<sup>229</sup> morphine infusions were adjusted between 10 and 50  $\mu\text{g/kg/hr}$  to minimize discomfort and avoid excessive sedation. Supplemental boluses of 100  $\mu\text{g/kg}$  morphine were administered for breakthrough pain. Steady-state morphine concentrations were achieved in 4 hours. Those children who could self-report their pain reported good analgesia with morphine concentrations in excess of 12 ng/mL. Morphine infusions of 10 to 30  $\mu\text{g/kg/hr}$  yielded mean serum concentrations between 10 and 22 ng/mL with less than 2% experiencing evidence of respiratory depression ( $\text{PaCO}_2$  greater than 50 mm Hg). Furthermore, children who received morphine infusions of 10 to 30  $\mu\text{g/kg/hr}$  breathed spontaneously after extubation of the trachea, and those who were weaned from assisted to spontaneous ventilation maintained a normal  $\text{PaCO}_2$ . On the other hand, 60% (3 of 5 children) who received a greater infusion rate of morphine, 40 to 50  $\mu\text{g/kg/hr}$ , experienced hypercarbia ( $\text{PaCO}_2$  48 to 66 mm Hg). A subsequent study by the same investigators evaluated the severity of respiratory depression in infants and children aged 2 days to 18 months treated with morphine. Of those whose morphine concentrations exceeded 20 ng/mL, approximately 70% experienced respiratory depression ( $\text{PaCO}_2$  greater than 55 mm Hg and/or a depressed slope of the  $\text{CO}_2$  response curve) compared with 15% to 28% of those whose concentrations were less than 20 ng/mL.<sup>230</sup> The investigators suggested a steady-state morphine concentration of 20 ng/mL as a threshold concentration for respiratory depression in this age group.

Previous studies determined that the clearance of morphine is impaired in preterm infants and that clearance increases with postconception age.<sup>231</sup> Additionally, morphine clearance is impaired in full-term infants up to 1 to 2 months of age, at which time it is comparable with that in older children and adults.<sup>98,232</sup> Preterm and full-term neonates, therefore, have a narrower therapeutic window for morphine analgesia compared with older children. Indeed, these groups have reduced morphine requirements postoperatively, requiring fewer rescue doses of morphine when receiving continuous infusions or intermittent bolus doses.<sup>233</sup> Therefore, opioids should be carefully titrated in infants in a monitored environment with significantly reduced continuous infusion rates. Based on PK modeling and morphine clearance predictions, a target morphine concentration of 10 ng/mL can be achieved with morphine infusions ranging from 5  $\mu\text{g/kg/hr}$  in term neonates to 16  $\mu\text{g/kg/hr}$  in 1- to 3-year-old children (see Chapter 6).<sup>234</sup>

Pharmacodynamic differences between infants and children have been postulated as the mechanism responsible for the greater sensitivity of infants (compared with older children) to the respiratory depressant effects of opioids. However, this may not be the case. Although rodent data suggest that the brain concentrations of opioids in neonates are greater than those in older children at similar serum concentrations,<sup>235</sup> these findings may not be applicable to humans. Neonatal rats have a relatively immature brain and a far more permeable blood-brain barrier than that in human infants. Consequently, the rodent may not be an appropriate model to depict the human condition.<sup>236</sup> It appears that the "increased sensitivity" is related, at least in part, to PK variables, perhaps in some measure as a result of a neonate's decreased conjugating ability.

Regardless of the mechanism, respiratory depression remains the most feared adverse effect of opioids administered by any route. Neonates and infants younger than 6 months of age are

at greater risk for opioid-induced respiratory depression because the ventilatory responses to airway obstruction, hypoxemia, and hypercapnia are immature at birth and mature over the first several months of life in preterm as well as full-term infants (see also Figs. 4-8 and 4-9). Indeed, there was a 4.5% incidence of failure to wean from the ventilator and a 13.5% incidence of apnea (30 seconds or more that required intervention) or severe respiratory depression in spontaneously breathing neonates who received opioids for postoperative pain.<sup>237</sup> Another report of a 3-year surveillance period for adverse drug reactions described 15 children aged 2 days to 17 years who experienced opioid-induced respiratory depression.<sup>238</sup> Respiratory depression in the latter study was defined as apnea, hypoxemia, cyanosis, a marked decrease in respiratory rate, or a need for naloxone. Although this study was unable to define the incidence of respiratory depression because the denominator was unknown, it did identify several predisposing factors, including age younger than 1 year (7 of 15 children), drug errors (including prescription and administration errors; 6 of 15 children), concurrent medical problems (diminished respiratory reserve, hepatic, and/or renal impairment), and concurrent sedative drugs. The prospective UK audit found 14 cases of respiratory depression (out of 10,726 total infusions, or 0.13%), 10 with nurse-controlled anesthesia (NCA), 2 with continuous infusions, and 2 with PCA.<sup>220</sup> Potentially contributing risk factors in half of the cases included very young age and neurodevelopmental, respiratory, or cardiac disease. In contrast to the above studies, no case of respiratory depression was reported in 110 children older than 3 months of age who received opioid infusions postoperatively.<sup>239</sup> Interpretation of this literature is confounded by different monitoring techniques and different definitions of respiratory depression. For instance, in the latter study, a 4.5% incidence of clinically significant hypoxemia was reported but was not included in their definition of respiratory depression. Additionally, children in that study were monitored with hourly documentation of respiratory rate, but oxygen saturation was not monitored after discharge from PACU, thereby reducing their ability to detect the more subtle episodes of respiratory depression. In summary, the results of these studies suggest that children who receive opioids require careful monitoring for respiratory depression, with appropriate age-based reduction of dosage, particularly for neonates and infants younger than 6 months of age.

The most common adverse effect of opioid therapy is nausea and vomiting. One study reported nausea and vomiting in 34 of 80 children (42.5%) who received postoperative morphine infusions. These were well managed with antiemetic therapy in all but 2 children who required discontinuation of the opioids.<sup>239</sup> In the same study, the incidence of pruritus and urinary retention were both 13% and that of dysphoria was 7%. Seizures have been reported in two neonates who had received bolus doses of morphine followed by infusions of 32 and 40  $\mu\text{g/kg/hr}$  and whose serum morphine concentrations were 61 and 90 ng/mL, respectively.<sup>240</sup> Irregular jerking movements, as well as one case of a generalized seizure, have been reported in children 1 to 15 years of age receiving postoperative morphine infusions.<sup>222</sup> Metoclopramide, 0.10 to 0.15 mg/kg (100 to 150  $\mu\text{g/kg}$ ) given IV, is an effective antiemetic but may also cause sedation and dystonia. The serotonin-receptor antagonist antiemetics, such as ondansetron and dolasetron, have the advantage of virtually eliminating the risk of dystonic or oculogyric reactions that occur with phenothiazines, butyrophenones, and metoclopramide. However, headaches occur in a small number

of those who receive serotonin-receptor antagonists. A “micro-dose” naloxone infusion (0.25 to 1.0  $\mu\text{g/kg/hr}$ ) reverses the incidence of both nausea and pruritus after opioids without affecting the analgesia or opioid consumption.<sup>241,242</sup> A more recent dose-escalation study demonstrated that doses of 1 to 1.65  $\mu\text{g/kg/hr}$  resulted in greater efficacy in reducing side effects, particularly pruritus, without degrading analgesia.<sup>242</sup> It is likely that these results may be generalized to other routes of opioid administration.

Opioid-induced bowel dysfunction reported in more than 90% of patients on opioid therapy, occurs by blocking propulsive peristalsis, inhibiting secretion and increasing reabsorption of intestinal fluids, and decreasing the activity of excitatory and inhibitory neurons in the myenteric plexus. Bowel dysfunction manifests as abdominal distension and bloating, delayed gastric emptying, and constipation. Aggressive prophylactic measures, including osmotic, lubricant, or stimulant laxatives, should be prescribed early in the course of treatment. A newer selective gastrointestinal peripheral  $\mu$ -opioid receptor antagonist, methylnaltrexone, was approved for use in adults in 2008. Although adult studies have shown promising results with the use of this agent,<sup>243,244</sup> its pediatric use has been described in only one case report.<sup>245</sup> A neonate who experienced a severe ileus during fentanyl administration after major abdominal surgery was noted to have resolution of the signs within 15 minutes of IV methylnaltrexone (0.15 mg/kg). She received 5 daily doses of methylnaltrexone without reversal of analgesia or occurrence of withdrawal.<sup>245</sup>

Fentanyl may be a useful substitute for morphine in children with hemodynamic instability, in whom a decrease in peripheral vascular tone is undesirable, and in whom histamine release caused by morphine is not well-tolerated. Additionally, its rapid onset of analgesia makes it ideal for children with severe escalating pain who require urgent pain relief. Fentanyl is metabolized by the liver into an inactive metabolite, norfentanyl, which is excreted via the kidneys. It is 80 to 100 times more potent than morphine. Although its elimination half-life is significantly less than that for morphine, its context-sensitive half-life during chronic infusion increases exponentially as a result of growing tissue storage (see Chapter 6). Like morphine, the elimination half-life of fentanyl in neonates is nearly twice that in adults, predisposing them to a greater risk for accumulation compared with older infants.<sup>246,247</sup> As with morphine, a reduction in hepatic blood flow in very young infants further decreases fentanyl conjugation. For a given bolus of fentanyl, plasma concentrations in infants between 3 months and 1 year of age are less than those in older children and adults.<sup>248</sup> This finding is consistent with the almost twofold greater clearance of fentanyl in children compared with neonates. In children 18 days to 14 years of age who were mechanically ventilated, the clearance of fentanyl was age related yet quite variable, with the slowest clearance occurring in infants younger than 6 months of age and the most rapid in those between 6 months and 6 years of age.<sup>249</sup> The clearance of fentanyl is slow in preterm infants, with the clearance correlating with the postnatal age.<sup>250</sup>

Fentanyl is known to cause all of the adverse effects reported with opioids, including pruritus, nausea, vomiting, constipation, and sedation. Respiratory depression and chest wall and glottic rigidity, however, are its most feared adverse effects. One study compared the incidence of respiratory depression in full-term and former preterm infants and young infants receiving 2  $\mu\text{g/kg}$  bolus doses of fentanyl every 2 hours or a continuous infusion of

1  $\mu\text{g/kg/hr}$  after abdominal or thoracic surgery.<sup>251</sup> Randomization was terminated prematurely because of a sixfold greater incidence of apnea that required intervention in the bolus dose group compared with the continuous infusion group (89% vs. 14%). The continuous infusion arm was continued for another 20 children, resulting in a 25% incidence of apnea in this group. In contrast, the incidence of respiratory depression (based on transcutaneous  $\text{PaCO}_2$  measurements and the incidence of apnea) for a given plasma fentanyl concentration in infants 1 to 12 months of age and children 1 to 5 years of age was less than that in adults undergoing hernia repair or other peripheral surgery.<sup>252</sup> Differences in surgical procedures and the inclusion of preterm infants in the former study may account for the significant difference in the incidence of apnea found in these two studies.

Although chest wall rigidity usually occurs after the rapid bolus administration of high-dose fentanyl, it has also been reported in an infant after a low-dose continuous infusion of fentanyl. Chest wall rigidity was reported in 9% of preterm and full-term neonates who received an average of 4.9  $\mu\text{g/kg}$  over a 2 to 3 minute period for a procedure or for perioperative analgesia.<sup>253</sup> In every case, naloxone reversed the chest wall rigidity. Additionally, a case of chest wall rigidity has been reported in a preterm neonate after high-dose fentanyl was administered to the parturient before a cesarean section.<sup>254</sup> Although administration of naloxone has been used successfully to treat cases of chest wall rigidity, severe cases associated with rapid oxygen desaturation may require the use of neuromuscular blocking drugs and mechanical ventilation.

The use of continuous fentanyl infusions in infants and children has been associated with a rapid development of tolerance, as indicated by a steady increase in infusion rate to maintain the desired effect<sup>255,256</sup> and a large incidence of opioid withdrawal syndrome after termination of the infusion.<sup>256,257</sup> The incidence of opioid withdrawal is directly related to the total dose administered and the duration of infusion.<sup>256,257</sup> Neonatal abstinence syndrome has been reported in 21 of 37 neonates (57%) after continuous fentanyl infusions during extracorporeal membrane oxygenation.<sup>256</sup> Both a total fentanyl dose in excess of 1.6 mg/kg and extracorporeal membrane oxygenation that lasted more than 5 days were predictors of opioid withdrawal. A similar incidence has been reported in 23 children 1 week to 22 months of age who received continuous fentanyl infusions during mechanical ventilation.<sup>257</sup> This study also found that a total dose of 1.5 mg/kg of fentanyl over 5 days was associated with a greater than 50% incidence of withdrawal symptoms. Furthermore, a total dose of 2.5 mg/kg as a continuous infusion over 9 days was 100% predictive of the occurrence of withdrawal. Finally, movement disorder and irritability have been reported after withdrawal of fentanyl infusion in five infants who were mechanically ventilated.<sup>258</sup> None of the infants who developed the movement disorder had received another opioid after withdrawal of fentanyl, whereas five of eight controls who did not develop withdrawal during the same period had received a substitute opioid. These data suggest that opioid withdrawal occurs earlier and with greater frequency after fentanyl infusions compared with other opioids. Therefore it seems prudent to use fentanyl infusions for pain relief during periods of hemodynamic instability, such as in the early postoperative period, and to transition to another opioid, such as morphine, as soon as the child is stabilized. Children who require fentanyl infusions for 5 days or more should undergo a slow taper (e.g., 10% decrease every 12 hours) or be transitioned to another parenteral or oral opioid regimen.

Hydromorphone has a spectrum of action similar to that of morphine. Adult opioid equipotency data suggest that it is 3.5 to 7 times as potent as morphine.<sup>259-261</sup> The only pediatric study that was performed in children with mucositis pain after bone marrow transplant reported that a 7:1 conversion ratio of morphine to hydromorphone, underestimated hydromorphone requirements by 27%.<sup>262</sup> These data suggest that a 5:1 conversion ratio may be more appropriate, particularly in children with chronic pain. Despite its widespread use, there are very few studies that evaluated the use of hydromorphone in children. A Cochrane review of studies related to the use of hydromorphone for acute and chronic pain in adults and children found little difference between the analgesic efficacy and adverse effect profile of morphine and hydromorphone.<sup>263</sup> However, several of the studies in this review included small numbers of patients, some were of low quality and only four of them included children. It remains common practice to prescribe a trial of hydromorphone in children who experience unacceptable side effects with morphine.

Meperidine is an opioid that has been used clinically for many years.<sup>264,265</sup> Its potency is approximately one-tenth that of morphine. Accumulation of its active metabolite, normeperidine (which has CNS stimulant properties), after repeated doses of meperidine, places children at risk for seizures.<sup>266</sup> Therefore, its use has been restricted to the treatment of postoperative shivering<sup>267,268</sup> or rigors after amphotericin. A single dose of dexmedetomidine (0.5 µg/kg) has been used successfully for the treatment of postoperative shivering and may replace meperidine for this indication.<sup>269</sup> Although its short-term use continues by some clinicians for procedural sedation and analgesia, it is preferable to use other analgesics for this purpose. Meperidine is not recommended for PCA or as a continuous infusion in children.

### Patient-Controlled Analgesia

PCA was first studied in adults in 1965. The initial interest with this technique was as a research tool for the study of pain. By the early 1970s, it was identified as an excellent strategy for treating pain in the clinical setting, with studies demonstrating that pain relief was achieved by PCA with relatively smaller doses of opioids and with greater patient satisfaction than with conventional methods.<sup>270</sup> However, it was not until the late 1980s that PCA was studied in children.<sup>271</sup> Since that time, it has become the preferred method for opioid delivery in children older than 5 to 6 years of age for acute pain, as well as chronic pain associated with cancer or sickle cell disease.<sup>262,271-274</sup> The primary benefit of PCA is that it allows children to titrate the analgesic to the extent of their pain. The goal is for the child to self-regulate a blood opioid concentration within the therapeutic range. Most children strike a balance between adequate pain relief on the one hand and adverse effects of the drug on the other. This approach, which grants the child some degree of autonomy, is the rationale given for the fact that pain is an entirely subjective and individual experience and that opioid metabolism and pain perception are quite variable among individuals. It also reduces the apprehension that older children and adolescents have about pain relief because they can control it and they can tailor the opioid delivery to the extent of pain they have at a given time, for example, before physical therapy, removal of tubes or drains, dressing changes, or getting out of bed. Additionally, the use of PCA avoids delays in administration of analgesics associated with standard "as needed" orders of IV opioids and allows smaller doses of opioids to be delivered more frequently without increasing

nursing workload. Therefore, PCA is thought to provide more consistent pain relief with less total opioid dosing, resulting in fewer side effects, such as sedation, nausea, and vomiting. Purportedly, children using PCA report better analgesia and reduced pain scores compared with children who have to rely on the nursing staff to administer analgesics when they are in pain. These and other benefits of PCA have been extensively touted in the medical literature,<sup>274-276</sup> as well as in the lay press.<sup>277</sup> Recently, however, risks associated with PCA use have also been highlighted and are discussed later.<sup>278-280</sup> Recognition of these risks has led to recommendations for careful dosing and monitoring of all children who are receiving opioids, particularly those receiving continuous infusions and those with specific risk factors.<sup>281</sup>

Child training is a necessary part of PCA, because successful use of PCA requires that both the child and family understand how it works.<sup>282</sup> The instructions should be clear that the pump should be activated whenever the child feels pain, that children cannot give themselves "too much medication" because of the computer lockout interval, that the child should not wait for severe pain to activate the pump, and that a dose can also be given in anticipation of painful stimuli, such as ambulation or chest physiotherapy. Most importantly, PCA does not mean *parent-controlled* analgesia, and parents should never activate the pump unless specifically authorized to do so by the primary care or pain service physician (see Nurse/Caregiver-Controlled Analgesia, later).<sup>281</sup>

### PCA Equipment

PCA devices are microprocessor-driven pumps that are connected to the child's IV line via Y tubing. For safety reasons, the IV tubing should incorporate a one-way valve to prevent backflow of the PCA drug up the tubing and an unintended delivery of a large bolus of opioid. Alternatively, PCA may be delivered through a separate IV line. These pumps allow programming of the individual dose to be administered, the minimal interval between doses (lockout interval), and the maximal cumulative allowable dose over a 4-hour period. Some pumps allow programming of a maximum number of doses per hour. Most pumps allow delivery of a continuous basal infusion (CBI) in addition to the demand dose. All PCA pumps should have a locking mechanism, so that neither the settings nor the medication cartridge can be changed without using a key, making the device virtually tamper proof. The child is able to self-administer the preprogrammed doses by pushing a button. A liquid crystal display on the pump displays the programmed settings, the cumulative dosage, the number of doses administered, and the number of times that the button was pushed but no dose was given because either it was during the lockout interval or the 4-hour limit had been reached. This information allows clinicians to track opioid usage and make appropriate changes to the PCA prescription based on the usage pattern. Most children 5 to 6 years of age and older are able to push the button themselves. In general, a child who is able to play video games has the cognitive skills required to push a button to achieve a desired response and can, therefore, use PCA quite effectively.

### Choice of Drug and Drug Dosages

Morphine remains the most common opioid administered via PCA, with hydromorphone and fentanyl being second-line drugs usually reserved for children who are intolerant to morphine. Suggested initial dosages for opioids via PCA for opioid-naïve

**TABLE 43-9 Patient-Controlled Analgesia Dosing Guidelines**

Drug	Demand Dose ( $\mu\text{g/kg}$ )	Lockout Interval (minutes)	Continuous Basal Infusion ( $\mu\text{g/kg/hr}$ )	4-Hour Limit ( $\mu\text{g/kg}$ )
Morphine	10-20	8-15	0-20	250-400
Hydromorphone	2-4	8-15	0-4	50-80
Fentanyl	0.5	5-10	0-0.5	7-10

children are presented in Table 43-9. Children with opioid tolerance will require adjustments to these settings, taking into account the previous opioid history and the opioid doses that the child was receiving before the acute painful stimulus. Indeed, one study reported that children with sickle cell disease self-administered more than double the dose of morphine via PCA, required more nonopioid adjuvant analgesics, reported greater pain scores, and stayed in the hospital for twice the duration compared with non-sickle cell disease-affected children after laparoscopic cholecystectomy.<sup>283</sup>

Fentanyl PCA has been used with success as a first-line and a secondary drug in children with cancer pain, as well as acute postoperative pain.<sup>276,284</sup> Most of the adverse effects, including nausea and pruritus, were mild and easily managed. However, some reported an overall incidence of apnea and hypoxemia of 3.5% in 212 children receiving PCA, of whom 144 had received fentanyl.<sup>276</sup> Finally, children who received tramadol PCA after heart surgery were extubated earlier and had less sedation, comparable pain scores, and a similar incidence of emesis as those who received morphine PCA.<sup>189</sup> The IV formulation of tramadol is not yet available in the United States, but some studies from Europe and China support its use in the postoperative period.<sup>189,285</sup> The benefits that hydromorphone PCA offers over morphine PCA in the chronic and acute pain settings require further investigation.

### Pump Settings

Most PCA pumps have five settings to adjust:

- A *loading dose* of opioid ranging from 0.025 to 0.1 mg/kg morphine divided into incremental doses is usually given to establish adequate analgesia before therapy is turned over to the child, because self-administered doses with this technique are generally small. A sufficient interval between incremental doses must be allowed, so that the morphine achieves its peak effect before the next dose, thereby avoiding an overdose. If PCA is started in the PACU, opioid doses administered during surgery must be considered before prescribing a loading dose. Additionally, it may be desirable to administer the loading dose via the PCA pump so that it is included in the initial 4-hour or hourly limit of the PCA. That is because children who receive IV-PRN doses of opioids in the PACU, followed by initiation of PCA, may be at risk for oversedation and respiratory depression resulting from opioid stacking. Children who have received opioids toward the end of surgery, those who awaken in comfort, or those who receive nerve blocks may not need a loading dose and may start to use the demand doses as needed on awakening.
- A *patient bolus dose*, that is, the dose that will be administered with each child's activation of the pump, must be prescribed. These small boluses are usually in the range of 0.01 to 0.02 mg/kg of morphine in opioid-naïve subjects.
- A *lockout interval* of usually 5 to 15 minutes prevents a child from activating the pump until the full effect from the

previous bolus is achieved, and it should correspond to the time from IV injection to the peak effect of the drug.

- A *continuous basal infusion* ranging from 0.00 to 0.02 mg/kg/hr of morphine (or more, in opioid-tolerant subjects) may be used in selective cases (see later).
- A *maximum hourly dose or a 4-hour limit* may be chosen to limit the cumulative amount of drug a child can administer. Once this limit is reached, the child cannot activate the pump until the 4-hour limit has passed. Four-hour limits allow for increased flexibility in dosing over greater periods of time and pain intensity. Typically, the maximum hourly dose ranges from 0.05 to 0.1 mg/kg and 4-hour limits from 0.25 to 0.4 mg/kg of morphine in opioid-naïve subjects. This amount may be chosen based on the average hourly use of morphine during the past 24 hours or, in children started on PCA immediately after surgery, at the reduced range of the dosage scale. Figure 43-8 presents sample PCA orders, including choice of drugs, dosing, and suggested monitoring.

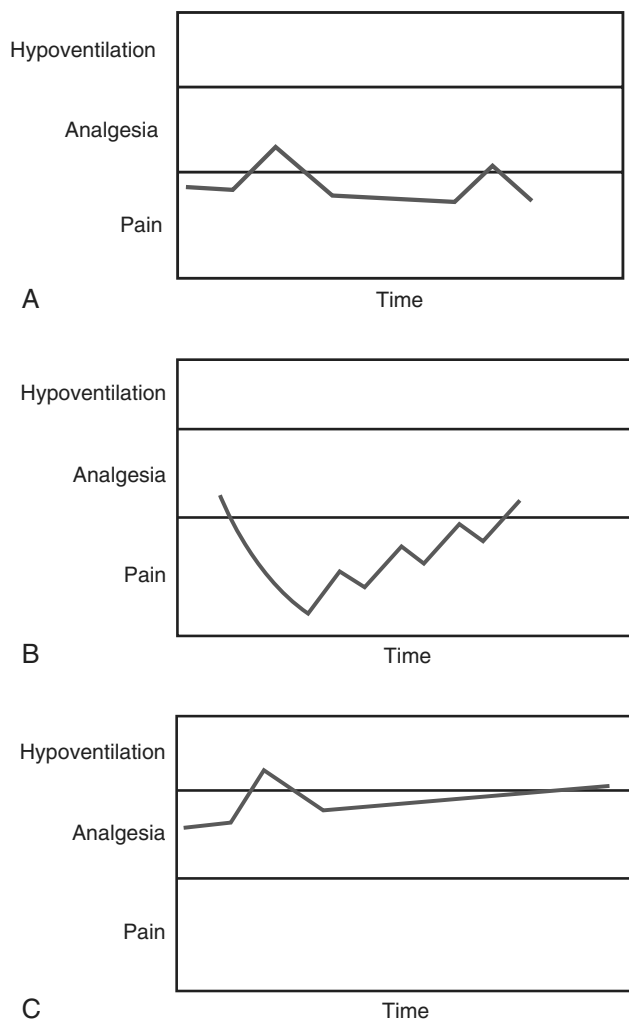

### Continuous Basal Infusions (CBI)

The use of a CBI of the opioid to supplement child-administered doses remains a subject of controversy. The rationale for the use of CBI is to maintain near-therapeutic plasma opioid concentrations, particularly during periods of sleep when there may be no self-administered doses, as illustrated in Figure 43-9, *A*. On the other hand, as depicted in Figure 43-9, *B*, a child who receives only PCA bolus dosing with no CBI is likely to awaken with unrelieved pain that may require multiple doses to again achieve adequate pain relief. Decreased nocturnal awakenings secondary to pain, improved restfulness or sleep patterns, reduced total opioid consumption, fewer adverse effects, and improved analgesic effectiveness have all been proposed as potential reasons in favor of using CBI. However, the use of CBI commits the child to receiving a fixed dose of opioid regardless of the level of sedation, and has the theoretical potential for overriding one of the inherent safety features of PCA, that is, an excessively sedated or somnolent child is unlikely to push the button and therefore receives no additional opioid but, with a fixed infusion, drug may accumulate (Fig. 43-9, *C*), with the potential for hypoventilation.<sup>286</sup> Furthermore, it has also been argued that programming errors with CBI can lead to more serious adverse events because the opioid medication is delivered regardless of the child's level of sedation.<sup>285,287</sup>

Some adult studies have suggested that the use of CBI has limited benefit in terms of efficacy and is associated with a greater incidence of opioid adverse effects, including respiratory depression.<sup>288-290</sup> Studies in children, however, have yielded conflicting results.<sup>273,274,291-295</sup> Children 7 to 19 years of age who received PCA with CBI after orthopedic surgery reported significantly reduced pain scores compared with those who received PCA boluses alone or IM morphine.<sup>274</sup> There were no differences in morphine consumption or in opioid adverse effects among the three groups, with no incidents of respiratory depression.

FIGURE 43-8 Sample patient-controlled analgesia orders. (Modified from the University of Michigan Hospitals &amp; Health Centers.)

**FIGURE 43-9** Patient-controlled analgesia (PCA) with an appropriate dose of continuous basal infusion. **A**, Use of an appropriate dose of continuous basal infusion (CBI) maintains near-therapeutic plasma opioid concentrations during sleep with rapid increase to analgesic concentrations as soon as the child awakens and activates the PCA button. **B**, Chart depicts plasma opioid concentrations in a child who is receiving PCA bolus doses only, with no CBI. Plasma concentrations decrease significantly when the child is asleep, necessitating multiple doses to achieve analgesic concentrations. **C**, An excessive dose of CBI results in opioid accumulation with delayed hypoventilation even when the PCA button is not activated. (Reproduced with permission from Berde CB, Solodiuk J. Multidisciplinary programs for management of acute and chronic pain in children. In: Schechter NL, Berde CB, Yaster M, editors. Pain in infants, children and adolescents. 2nd ed. Philadelphia: Lippincott Williams and Wilkins; 2003, p. 476.)

Notably, child satisfaction was greatest in the PCA with CBI group. Similar pain scores with improved sleeping patterns have also been reported with the use of PCA with CBI, compared with those who received PCA alone, on the first two postoperative nights in children after abdominal surgery. No incidents of respiratory depression or excessive sedation were reported in either group.<sup>273</sup> Children who received CBI with PCA or NCA in one study reported slightly reduced pain scores without differences in morphine use or adverse effects after spine fusion surgery compared with those who received PCA or NCA alone.<sup>295</sup> In contrast, others have reported greater morphine use and a greater

incidence of hypoxemia with similar pain scores in children who received PCA plus CBI after surgery compared with those who received PCA alone.<sup>293,294</sup> A subsequent study found that children who received PCA with a CBI of morphine (4 µg/kg/hr) experienced fewer adverse effects and less hypoxemia than children who received PCA with 20 µg/kg/hr CBI or those who received PCA bolus doses alone, noting similar pain scores in all three groups.<sup>292</sup> Both of the PCA with CBI groups reported better sleep at night than did the PCA alone group. Differences in opioid doses, age groups, and surgical procedures may account, in part, for these apparent conflicting observations in the pediatric studies. Based on these studies and our own experience, we hold the view that the use of CBI may be beneficial in some children, although it requires careful selection of dose, based on the surgical severity and the child's comorbid conditions and vigilant monitoring to ensure safety. CBI should be used as a routine for most children with pain resulting from cancer, for most children with mucositis resulting from cancer treatment or bone marrow transplantation, and for a significant percentage of children with sickle cell vasoocclusive episodes. At our institutions, the standard practice is to use CBI, unless limited by somnolence or hypoventilation, for the first night for a majority of children undergoing selected major painful surgeries, such as scoliosis surgery, pelvic osteotomies, and thoracotomies.

#### Nurse/Caregiver-Controlled Analgesia

Activation of the PCA pump by the bedside nurse, a parent, or a caregiver (such as a grandparent) has been used with success in children who are unable to push the button because of young age or because of physical or cognitive impairments.<sup>275,276,295-297</sup> In much of the literature, and in some policy statements by the Joint Commission and other organizations, there is, in our view, too little distinction between activation of PCA pumps by nurses and activation by nonclinician surrogates. The term *caregiver* is used variably in this literature; here it is used to mean nonclinician surrogates. In pediatrics, this means primarily parents and other family members. A small study of 12 children who received NCA after spine fusion surgery reported adequate analgesia, parent and nurse satisfaction, and no complications.<sup>295</sup> Children who received NCA received smaller total morphine doses compared with those who were able to use the PCA device themselves, likely because of the tendency for nurses to underestimate their patients' pain. A larger observational study of 212 children who received parent- or nurse-controlled analgesia with morphine, fentanyl, or hydromorphone reported effective analgesia (pain scores 3/10 or 2/5 or below) in more than 80% of children.<sup>276</sup> Pruritus occurred in 8% and vomiting in 15% of the children on the first day of treatment. Nine children (4.2%) required naloxone for the following: apnea (N = 4), hypoxemia (N = 1), excessive sedation (N = 3), or to facilitate extubation (N = 1). Six of these children had significant comorbid conditions, and 5 received additional sedatives. These investigators emphasized the importance of close monitoring to minimize risk and permit early intervention when using nurse/caregiver-controlled analgesia (NCA/CCA). Another study found that the incidence of overall adverse events in opioid-naïve children who received NCA was similar to that in children who received PCA after surgery (22% and 24%, respectively).<sup>297</sup> However, children who were able to self-administer PCA required only minor interventions (stimulation, reduction in opioid dosage, or supplemental oxygen), whereas those who received NCA were more likely to require more aggressive interventions, such as opioid reversal,

airway management, or escalation of care. This study found that cognitive impairment and opioid dose on the first postoperative day were independent predictors of adverse events. Although the mean time to the occurrence of adverse events was 16 to 27 hours, some events occurred during the third postoperative day, suggesting that monitoring, including continuous pulse oximetry, should be continued as long as the PCA is used. In a study of children with cancer, five respiratory and/or neurologic serious adverse effects were reported, with 1 child requiring naloxone during the 576 days of treatment with NCA/CCA.<sup>296</sup> In that study, pulse oximetry was used only at the discretion of the provider, perhaps reducing the investigator's ability to recognize hypoxemia in some children. Furthermore, the reduced incidence of adverse events may be explained by the fact that most children in that study were not opioid naive and may have developed some degree of opioid tolerance. A study of 10,000 pediatric patients receiving NCA further confirms the safety and tolerability of this delivery method.<sup>109</sup>

For safety reasons, however, it is important to distinguish between authorized and unauthorized use of the PCA button by an individual other than the child. Several reports describe serious adverse events, including excessive sedation, severe respiratory depression, respiratory arrest, and death, attributed to unauthorized activation of the PCA device by parents, spouses, other family members, and health care providers.<sup>297-301</sup> The practice of PCA by proxy has therefore come under scrutiny and its safety questioned by the Joint Commission and the Institute for Safe Medication Practices (ISMP).<sup>302-304</sup> In 2004, the Joint Commission issued a sentinel event alert based on PCA errors reported to the U.S. Pharmacopeia. Of 460 errors that resulted in death or some level of harm to the patient, 15 resulted from PCA by proxy, including 12 attributed to family members, 2 to a nurse, and 1 to a pharmacist.<sup>302</sup> In interpreting this report and some other reports, it should be emphasized that many do not cite denominator data (total numbers of patients receiving PCA vs. NCA/CCA), so that it is difficult to assign numbers for relative or absolute risks of these techniques. Recognition of these risks has led the Joint Commission and ISMP to strongly recommend that specific policies and procedures be developed and implemented related to the use of PCA by individuals other than the child. Such policies must address the following issues:

- Appropriate selection of children. Many pediatric centers restrict parent-controlled analgesia to children with chronic pain, those who require palliative care, and in special circumstances for children who undergo repeated and extensive surgery. In pediatric centers worldwide, NCA is increasingly being used, with appropriate observation, for both opioid-naïve and opioid-tolerant children.
- The specific process of identifying suitable caregivers who will be allowed to activate the PCA button.
- Communication among clinicians, including the primary service physician, the pain service team, and the primary bedside nurse, regarding the suitability of CCA.
- An educational plan for health care providers involved in the decision-making.
- Education of caregivers, including pain assessment, recognition of opioid adverse effects, and scenarios when not to activate the PCA button (e.g., when the child is asleep or somnolent). The caregiver should be encouraged to call the nursing staff when in doubt.
- Monitoring protocols, including assessment of sedation depth, respiratory status, and pain assessment at regular intervals. It

must be emphasized that the primary responsibility for monitoring the safety and effectiveness of analgesia remains with the nursing staff. Electronic monitoring, including pulse oximetry, is widely used in this setting.

With carefully defined policies and procedures, adequate education of clinicians and caregivers, prevention of unauthorized dosing, and vigilant monitoring, it may be possible to reduce the frequency of adverse events from PCA, NCA, and, especially, CCA. However, large outcomes studies are needed after implementation of such policies to confirm the safety and efficacy of practice based on these recommendations. Our view is that NCA is a well-established practice and should be encouraged as a generally safe and effective means for delivering opioids to children who are unable to self-administer.

### Risks and Adverse Events with PCA

Despite its numerous benefits, the use of PCA has been associated with a wide range of adverse effects, adverse events, and unfavorable outcomes in adults.<sup>278,279,299,305-308</sup> Although some adverse effects from PCA therapy may be attributed to the opioid drugs themselves or to patient comorbidities, a significant number of harmful effects occur as a result of human error, with incorrect prescribing, dispensing, administration, or equipment failure. E-Table 43-5 describes the causes of PCA medication errors as identified by the ISMP.<sup>303-305,309</sup> Increasing awareness of preventable adverse events from PCA has led to improved pump technology directed at minimizing the likelihood of programming errors, including the development of smart PCA pumps that use bar-coded syringes and an integral bar-code reader to prevent incorrect programming of drug concentration. Potential PCA pump errors have been reduced with these "smart pumps."<sup>310</sup> Children are at greater risk for medication-related adverse events resulting from calculation errors in drug doses (because all doses are based on body weight or body surface area) and to developmental differences in PK. However, data for PCA-related adverse events in children are limited.<sup>280,311-313</sup> The reported incidence of respiratory depression in children receiving PCA ranges from 0% to 25%.<sup>297,311,312,314,315</sup> Risk factors for respiratory depression identified by these studies include cumulative opioid dose, use of basal infusions, concomitant administration of sedatives, and comorbid conditions, including renal failure and cognitive impairment. Recognition of the risks from PCA<sup>316,317</sup> has led organizations, such as the ISMP, to emphasize the importance of monitoring children who use PCA and of detailed child and staff education regarding its use.<sup>318</sup>

### Monitoring the Child Using PCA

Despite the recommendation from the ISMP that practitioners should identify children at risk for opioid-related respiratory depression and define the appropriate level of monitoring, there remains no consensus regarding the risk-to-benefit ratio and effectiveness of any specific forms of monitoring for children receiving PCA, NCA, or CCA. The Anesthesia Patient Safety Foundation (APSF) recommended the use of continuous respiratory monitoring (minimally pulse oximetry and a continuous measure of respiratory rate) for children receiving PCA, neuraxial, or serial doses of parenteral opioids.<sup>319</sup> Additionally, the APSF recommended that reliable alerting methods, such as audible alarms, central stations, or pagers, be implemented to ensure timely and appropriate clinician response to deteriorating respiratory status of those receiving opioid therapy. Recently a nurse notification system was implemented at one of the

**E-TABLE 43-5** Causes of Patient-Controlled Analgesia Errors

Improper child selection	Extremes of age: preterm infant, neonate Significant airway, neurologic, or respiratory compromise
Inadequate child education	Inability to identify PCA button Mix-up with nurse call button
Unauthorized activation of PCA device	Individuals not authorized by medical team, such as parents and other caregivers, pushing PCA button
Inadequate staff training	Inadequate knowledge of programming of PCA pump Inability to recognize excessive sedation and/or respiratory depression
Prescription errors	Inappropriate opioid selection Incorrect conversion Dosing error: units $\mu\text{g}$ vs. mg, decimal point
Dispensing errors	Wrong drug or concentration Incorrect labeling Incorrect transcription of prescriptions
Pump programming errors	Wrong drug, concentration, settings Failure to double check settings against prescription and with second practitioner
Inadequate monitoring	Frequency of monitoring Pulse oximetry, capnography as indicated Prompt recognition of adverse effects and timely intervention
Flaws in equipment design	Default opioid concentrations Dosing units: mL vs. mg Activation button resembles nurse call button No audible signal when child receives PCA dose Pumps that do not require review of all settings before infusion starts

PCA, Patient-controlled analgesia.

authors' institutions, where pulse oximetry alarms generated automated nurse call-light notification after 15 seconds, a page to the bedside nurse and charge nurse after 1 minute, and an emergency group page after 3 minutes of sustained oxygen desaturation.<sup>297</sup> The impact of implementing such technology on the incidence of PCA-related adverse events requires investigation. It must be emphasized that pulse oximetry can detect hypoventilation only if the child is breathing room air. Oximetry is *not* a measure of ventilation but rather of oxygenation. The use of supplemental oxygen interferes with the ability of pulse oximetry to detect respiratory depression by delaying the onset of desaturation.<sup>320,321</sup>

Side stream sampling of end-tidal CO<sub>2</sub> via a nasal cannula or noninvasive capnography detects respiratory depression earlier and more frequently than does pulse oximetry or periodic checks of respiratory rate in adults who are receiving opioids via PCA, or for procedural sedation/analgesia.<sup>322,323</sup> Although similar data for children receiving PCA therapy are not available, studies in children undergoing procedural sedation in the emergency department and intensive care unit have reported that capnography detected respiratory events that would have been unrecognized by pulse oximetry, periodic respiratory rate monitoring, and/or clinical examination.<sup>324-327</sup> Additionally, these studies identified instances of respiratory depression that were recognized by abnormal capnography before oxygen desaturation was detected. Thus capnography may provide the earliest warning of impending respiratory compromise and may alert clinicians to carefully evaluate the children under their care and adjust opioid doses accordingly. Conversely, in real-world practice, capnography cannulas can be difficult to maintain in proper position in children on a busy postoperative ward, readings can be influenced by mouth breathing, and this technology also has the potential for false-positive and false-negative conclusions. Newer technology incorporates a fully integrated PCA system with modules for continuous monitoring of oxygen saturation and end-tidal CO<sub>2</sub>.<sup>328</sup> Some of these pumps also have a feature that shuts off PCA delivery if preset threshold parameters for oxygen saturation and end-tidal CO<sub>2</sub> are reached. Studies evaluating the benefits of such technology in reducing PCA-related adverse events in children are needed. Although electronic monitoring has an important role in patient safety, all available methods are imperfect. Moreover, they generate frequent false alarms that annoy children and families, disturb the restorative sleep of both children and parents, and contribute to desensitization of nurses' vigilance. Despite these limitations of electronic monitoring, it has been reported that the use of computerized physician order entry and involvement of dedicated pediatric pain teams improved compliance with routine monitoring and increased the likelihood of early identification of adverse events.<sup>329</sup>

### REGIONAL BLOCKADE AND ANALGESIA

The use of local anesthetics, both with and without the addition of central neuraxial opioids and other adjuncts, offers many advantages in the postoperative setting. Blockade with long-acting local anesthetics, or continuous peripheral nerve blockade with infusion of local anesthetics via catheters and elastomeric infusion pumps can provide postoperative analgesia for outpatient surgery so that a child can be discharged home in comfort. Reducing or eliminating the need for systemic analgesics diminishes the potential for adverse effects associated with their use (see Chapters 41 and 42). Regional blockade affords the ability to provide excellent analgesia to children who might otherwise

not tolerate larger doses of opioids. This group includes some neonates, especially preterm and former preterm infants who are at risk for apnea; children with problems of central ventilatory control, respiratory disease, precarious airways; or those who risk obstruction with sedation (e.g., children with obstructive sleep apnea).

There are few absolute contraindications to regional blockade. Anatomic anomalies, such as myelodysplasia, sacral dysgenesis, and other abnormalities, either disrupting the epidural space or making access to it impossible, may prevent the performance of a caudal or epidural block. A report of epidural analgesia in children with myelodysplasia, however, suggests that catheters may be used safely in these children when placed at a level above the anatomic neural abnormality.<sup>330</sup> In cases involving these types of anatomic anomalies, we encourage consultation with experts in pediatric regional anesthesia, prior review of imaging studies, and consideration of fluoroscopic guidance. A needle and block should never be placed through infected tissue or in close proximity to it. Children with burn injuries may be candidates for continuous regional techniques, provided the burned area is distant from the catheter insertion site (see Chapter 34). We do not believe that the benefits of regional analgesia outweigh the potential risks inherent in inserting catheters through burned tissue or close to it.

Sepsis presents a similar problem. In general, it is not advisable to place caudal or epidural catheters in children who are septic, for fear of seeding the epidural space during a period of bacteremia. Peripheral nerve, plexus, or intrapleural catheters may pose less of a problem in this regard, but there are no data to provide guidance regarding this issue. Coagulopathy and thrombocytopenia are relative contraindications to regional anesthesia, with mild abnormalities in hemostasis not necessarily precluding a regional block. In unusual cases, and with proper consideration of risk-benefit issues, fresh frozen plasma or platelets can be infused at the time of a regional procedure to provide temporary correction of coagulopathy. The considerations regarding regional anesthesia, coagulopathy, and anticoagulation are complex and have been reviewed extensively for adults by consensus groups from the American and European Societies of Regional Anesthesia, and suggested guidelines regarding regional blockade in the anticoagulated patient can be found in Table 41-7.<sup>331</sup> In the absence of additional pediatric data, we recommend that clinicians review these adult publications as provisional guides for pediatric regional anesthesia as well. When placing a catheter for continuous blockade, consideration of the state of coagulation must include the time of catheter withdrawal as well as placement. If a child is to receive postoperative anticoagulation, for example, a continuous block should not be considered unless anticoagulation therapy can be stopped for 2 hours before the catheter is removed.

When a nerve repair or revision is planned for an extremity, some surgeons may wish to assess motor or sensory function postoperatively. In these cases, consultation with the surgeon should precede a plan for postoperative regional analgesia. If the surgery involves the legs, a caudal or lumbar epidural catheter can be used with opioids or adjunctive drugs such as clonidine without local anesthetics. Very dilute concentrations of local anesthetics (e.g., 0.05%-0.075% bupivacaine or ropivacaine) often can provide some additive analgesia if needed without significantly impairing motor function.

There is no consensus on the timing of a regional block (at the beginning or end of the surgical procedure). Placing a

single-injection caudal block before incision confers a similar duration of postoperative analgesia, after a brief surgical procedure of 1 hour or less, as placing it at the end of surgery. For example, the times from recovery until the first request for analgesics after caudal blocks placed before incision or after surgery for inguinal herniorrhaphy were similar.<sup>332</sup> For more prolonged procedures, the block may be renewed with a second caudal injection before emergence or a catheter placed and redosed at appropriate intervals (usually approximately 1.5 hours). A volume of half of the original dose is usually sufficient if less than 2 hours have elapsed. A reduced concentration of local anesthetic is usually effective for postoperative analgesia. Adjunctive additives, such as clonidine, have also been shown in some studies to prolong the action of "single shot" central neuraxis and some peripheral blocks (see later discussion) permitting a single-injection block placed before the incision to augment both intraoperative and postoperative analgesia for longer operations. In cases of major surgery on the extremities and shoulders, there is a growing trend toward placement of indwelling plexus or peripheral nerve catheters for local anesthetic infusions for several days, both for adults and children, as detailed subsequently in the section on catheter techniques.<sup>333,334</sup>

Evidence suggests that placing a block at the beginning of surgery offers several potential advantages.<sup>335</sup> Although preemptive or preventive analgesia is a reproducible phenomenon in laboratory studies, the results in humans have been conflicting. For example, initial studies in adults demonstrated a dramatic decrease in the incidence of phantom limb pain when an epidural block was administered before an amputation, although subsequent studies did not consistently reaffirm the initial observations.<sup>336-338</sup> Similarly, children who receive intraoperative neural blockade may experience less postoperative pain than those managed with general anesthesia alone, with the duration of analgesia in some cases lasting beyond the pharmacologic action of the block. On the other hand, a blinded study of caudal anesthesia administered either before or after inguinal surgery failed to show a difference in postoperative analgesia.<sup>339</sup>

It is theorized that interruption of nociceptive impulses at the spinal cord level attenuates imprinting of painful stimuli on the sensory cortex or forestalls the development of spinal cord hyperexcitability and "wind up," thereby reducing the neural input and persistent postoperative pain.<sup>338,340-343</sup> It has also become increasingly evident however, that if preemptive or preventative analgesia is to have a beneficial effect, other conditions must be met: the block must be of sufficient duration in relation to the nociceptive stimulus, it must extend into the postoperative period, and it must be effective at preventing central transmission of the nociceptive signals.<sup>335</sup> This third requirement suggests that a multimodal analgesic approach may offer the greatest benefit. The presence of poorly controlled preoperative pain may sensitize the CNS, rendering pain difficult to control via intraoperative or postoperative interventions.<sup>344</sup> Additionally, epidural opioids have been shown to reduce the inflammatory response after surgery in adults, as indicated by interleukin-2 concentrations, suggesting that attenuating the stress response to surgery may improve postoperative analgesia.<sup>345</sup>

Further evidence suggests that local anesthetic infiltration of the incision site, especially when performed in conjunction with a regional anesthetic technique, may be an effective means of providing prolonged analgesia after surgery.<sup>346,347</sup> This simple and effective approach can be used before or at the end of virtually any surgical procedure. A major limitation of wound infiltration

with currently available local anesthetics is that the duration of analgesia is usually only 4 to 6 hours. Because postoperative pain commonly persists for several days, it would be more useful to administer local anesthetics for 2 to 4 days. To achieve this, the surgeon must place a multi-orifice catheter in the tissue planes of the wound during closure, through which local anesthetics can be infused.<sup>334,348-352</sup> Several commercially available kits using these "soaker hoses" have been shown to be effective. A disposable elastomeric pump, filled with local anesthetic that infuses local anesthetic continuously into the surgical tissues, can be placed at the end of surgery and the child sent home with it infusing for several days. Although this is an effective supplemental strategy to achieve postoperative analgesia, practitioners should be aware of complications that have been reported in adults.<sup>353</sup> *A note of caution: the concentration of local anesthetics, such as bupivacaine, and the infusion rate must be carefully prepared to avoid a local anesthetic overdose if such an approach is planned, particularly after chest surgery and in neonates and small infants.* A novel method of providing prolonged analgesia that is currently under investigation involves injection of a suspension of biodegradable polymer microspheres or lipospheres that contain bupivacaine. Dexamethasone can further prolong the duration of this method of block. After injection, these microspheres release bupivacaine in a controlled manner to provide blockade of peripheral nerves for periods of 2 to 6 days, depending on dose, formulation, and site of injection.<sup>354-357</sup> An alternative experimental approach to providing prolonged analgesia is the use of modified neurotoxins. Site 1 sodium channel blockers, such as tetrodotoxin and neosaxitoxin, have very strong affinity for sodium channels in vitro. Tetrodotoxin and neosaxitoxin are nonneurotoxic, and do not significantly block sodium channels in the myocardium.<sup>358</sup>

In animals, the combination of these toxins with bupivacaine, epinephrine, or clonidine markedly prolongs the nerve block and reduces systemic toxicity. Neosaxitoxin shows no cardiotoxicity in animals,<sup>359</sup> and has shown promise in a recent Phase 2 clinical trial for abdominal surgery in adults.<sup>360</sup>

Peripheral nerve and plexus blocks tend to provide blocks of greater duration than do central neuraxial blocks, the former lasting 8 to 12 hours, and on occasion exceeding 24 hours. Depending on the nature of the surgery, this may permit the child to transition to nonopioid analgesics at the time the block wears off, thereby eliminating or reducing the use of opioids and their potential untoward effects. Children undergoing outpatient surgery may be discharged after a single-injection regional block, but follow-up the next day with the family is necessary to ensure that the block has receded and no complications have developed. This is especially the case after peripheral nerve blocks. Parents must further be cautioned that there may be some degree of motor blockade present, and that the blocked limb must be protected from injury. If a lower extremity is blocked, assistance with ambulation is mandatory. Techniques for regional anesthesia and analgesia are discussed in detail in Chapters 41 and 42.

### Choice of Local Anesthetics, Additives, and Dosing

Dilute long-acting local anesthetics, such as bupivacaine 0.125% to 0.25% or ropivacaine 0.1% to 0.2%, are the most commonly used local anesthetics for regional blockade. In Europe and Canada, levobupivacaine is available and has the advantage of smaller risk of toxicity than bupivacaine (see Chapter 41). Ropivacaine and levobupivacaine have the dual advantages when compared with bupivacaine of a relatively prolonged duration of action and decreased motor blockade. Epinephrine (1:200,000)

is often added to bupivacaine to decrease systemic absorption and increase duration of action but *should be omitted when a digital or penile block is performed, because of the risk of inducing ischemia by direct vasoconstriction*. (Note that the avoidance of epinephrine for digital blocks is based on limited and historical evidence, and current proponents of the practice have not found adverse complications to occur).<sup>361-363</sup>

Initial studies concluded that the optimal concentration of bupivacaine that provides maximum sensory blockade without motor blockade for caudal analgesia was 0.125%,<sup>364</sup> although subsequent studies demonstrated that the optimal concentration was actually 0.175% (7 mL of 0.25% bupivacaine combined with 3 mL of saline).<sup>365</sup> More concentrated solutions of bupivacaine (0.2% to 0.25%) may be used for blocks that do not significantly affect motor function, such as for an ilioinguinal-iliohypogastric nerve block after herniorrhaphy. Bupivacaine 0.5% offers no advantage in most settings, and limits the volume that can be administered because of the risk of toxicity. The maximum allowable dose of bupivacaine is 2.5 mg/kg. Furthermore, the use of solutions with many different concentrations may increase the risk of calculation errors and potential overdoses. For this reason, it is prudent to restrict the choice of the concentrations of local anesthetics to a manageable number. Our clinical impression is that thoracic epidural analgesia after Nuss bar placement may be enhanced with a denser blockade. For these blocks, motor block is of less significance because most lung expansion is produced by the diaphragm.<sup>92</sup> For thoracic epidural blocks, we use ropivacaine 0.2% with an opioid and clonidine.

Ropivacaine, an *l*-enantiomer amide local anesthetic, is widely used in children, particularly in neonates and infants.<sup>366-369</sup> In both pediatric and adult studies, the duration of analgesia after ropivacaine is similar to that after bupivacaine. Although data in adults suggest that there is a more selective sensory than motor blockade, this has not been demonstrated in studies of immature animals or children.<sup>366-368,370-376</sup> Ropivacaine, is less cardiotoxic than bupivacaine. In terms of developing terminal apnea, infant rats tolerate 1.5 times the dose of ropivacaine as compared with bupivacaine. The doses for the onset of respiratory distress and seizures are similarly increased with ropivacaine.<sup>368</sup> These differences are more pronounced in infant rats than in adult rats. Animal data suggest that the toxic thresholds for both CNS and cardiovascular toxicity are increased 20% to 30% with this agent in both adults and infants, although seizures can still occur with ropivacaine if the dose exceeds the toxic threshold. The authors recommend using a levorotatory enantiomer (levo-enantiomer), such as ropivacaine, in preference to bupivacaine in infants younger than 6 months of age, because of the potential increased margin of safety.<sup>369,377</sup> Another local anesthetic with a similar decreased toxicity is levobupivacaine (the levorotatory isomer of bupivacaine). This drug possesses properties similar to bupivacaine with a moderate reduction in the toxicity risks inherent with bupivacaine.<sup>378-380</sup> Levobupivacaine has become difficult to obtain in the United States, although it is commonly used in place of bupivacaine elsewhere.<sup>381</sup>

Opioids have been injected in the epidural and intrathecal space for analgesia in children, both with and without local anesthetics. Central neuraxial opioids have been used for more than two decades to produce effective analgesia in children. However, opioids administered into the central neuraxis have the potential to cause delayed respiratory depression, and are generally avoided in the outpatient setting to ensure the safety of children after discharge.<sup>382</sup> Their use is described in detail later.

Adjuvant drugs have been added to the local anesthetic administered for caudal blockade to prolong the duration of the sensory block, an obviously desirable attribute for a single-injection block. However, their use is not without controversy. Many drugs have been injected into the epidural space with only limited laboratory evidence for safety and lack of neurotoxicity, and some caution is necessary.<sup>383</sup> Clonidine, 0.5 to 2 µg/kg, has been shown to lack evidence of neurotoxicity. It increases the duration of analgesia after bupivacaine in caudal blocks by approximately 3 hours, with insignificant hemodynamic effects, mild sedation, and no delay in recovery times.<sup>384-390</sup> Despite these reported beneficial effects of clonidine, one double-blind investigation found no difference between IV and caudally administered clonidine in a dose of 2 µg/kg as an adjunct to caudal blocks using bupivacaine, and another found no difference in duration or quality of analgesia when compared with caudal bupivacaine alone.<sup>391,392</sup> Conversely, when clonidine was used in conjunction with levobupivacaine, children who received clonidine in the caudal space demonstrated a significant delay in the need for rescue analgesia and reduced pain scores compared with those who received IV clonidine, suggesting that the prolonged analgesia occurs at a spinal cord site of action.<sup>389,390,393</sup> Caudal clonidine produces less nausea, itching, ileus, and urinary retention than opioid additives, although it may increase postoperative somnolence or respiratory depression at doses in excess of 1 µg/kg, particularly in the neonate.<sup>392,394-396</sup> The clearance of clonidine in infants is approximately one-third that of older children.<sup>397</sup> The preponderance of evidence supports the use of clonidine to prolong the analgesic effect of central neuraxial blocks, but we caution against the use of more than 1 µg/kg for outpatient procedures, especially in younger infants, because of an increased risk of respiratory depression.

*Preservative-free* ketamine has also been used for caudal analgesia, both alone and in combination with bupivacaine. Doses of 0.5 mg/kg appear to provide adequate analgesia, without untoward behavioral effects, such as those reported with IV or oral administration of ketamine.<sup>398</sup> When combined with bupivacaine, the duration of analgesia approached 24 hours.<sup>203,399,400</sup> In a comparison with IV ketamine, caudal (*S*)-(+)-ketamine significantly prolonged the duration of analgesia, despite similar plasma concentrations.<sup>400</sup> One clinical study suggested a specific spinal site of action. *Only preservative-free ketamine should be used because preservatives have been associated with neurotoxicity*.<sup>401,402</sup> In the United States, preservative-free ketamine is currently unavailable.<sup>386,403</sup>

When performing a regional block, the total safe dose of local anesthetic should be calculated first and the volume and concentration of the solution adjusted if necessary, to avoid administering a toxic dose. Because most infants and children will have a regional block placed in combination with general anesthesia, surgical concentrations of local anesthetics are not necessary and dilute medications can still provide excellent postoperative analgesia. This is particularly important when performing blocks in infants. For example, a 7-kg infant has a maximal allowable dose of 17.5 mg of bupivacaine (or 2.5 mg/kg). If a 0.25% solution (2.5 mg/mL) were administered, the total volume would be limited to 7 mL. The maximum dose should probably be slightly more restrictive in infants less than 6 months of age. At this age, a cautious approach is to further reduce the allowable dose by 25% to 30%. For example, a 4-kg 2-month-old infant would be permitted to receive 2.7 mL (6.6 mg) of the same solution.

## Choice of Block and Techniques

### *Single-Injection Techniques*

There are many circumstances in which the simplicity and duration of action of a single-injection block is desirable. Both neuraxial blocks and peripheral plexus and nerve blocks can be effective as single-injection techniques. The caudal block remains the most commonly used technique in pediatric regional anesthesia. It provides analgesia of the lower extremity and lower abdomen, and is easily and quickly performed in most infants and children (see Chapter 41). When an operation is performed on both legs it is often preferable to bilateral lower extremity blocks.

The use of ultrasound makes the identification of plexuses and peripheral nerves much easier in an anesthetized child. Peripheral nerve stimulation using Teflon-coated needles remains an effective technique, but is becoming less frequently used as familiarity with ultrasound and its benefits increases. It is plausible, but unproven, that ultrasound reduces the risk of injury to nerves and adjacent structures (see Chapters 41 and 42).<sup>404</sup> To precisely position the needle in the target area and avoid piercing adjacent structures, one must develop skill in coordinating its trajectory with the ultrasound image so that the needle tip does not pass out of the plane of view. Although it remains unknown whether ultrasound and more precise needle placement will reduce nerve injury, there is evidence that it reduces the volume of local anesthetic needed to produce an effective block.<sup>405,406</sup> Ultrasound visualization of the local anesthetic surrounding a nerve or plexus provides reliable confirmation that a block will be successful. Nerve blocks of the lower extremity can, in some circumstances, be used instead of caudal blockade (see Chapters 41 and 42). They provide a field of analgesia limited to the operative site, have a prolonged duration of analgesia (usually at least twice that of caudal block), and eliminate some of the potential undesirable effects of central neuraxis blockade, such as urinary retention, motor blockade (wobbly legs), and, occasionally, numbness. The fascia iliaca block, which produces analgesia in the distribution of the femoral, obturator, and lateral femoral cutaneous nerves, has been described in children as an excellent alternative for postoperative analgesia of a lower extremity.<sup>407</sup> Blockade of the femoral nerve, the sciatic nerve, and the nerves of the ankle is easily performed in children by using similar techniques to those in adults (see Chapters 41 and 42). Regional blockade of the upper extremity may involve an axillary block, interscalene, supraclavicular, or infraclavicular block, or less commonly, blockade of the individual nerves at the level of the arm or wrist. Intercostal nerve blocks may be used after thoracic or upper abdominal surgery. This block may be considered for procedures of limited scope, such as open-lung biopsy or thoracostomy for drainage, but the duration of blockade is limited to several hours. In our view, for most thoracic procedures, the duration of single-injection percutaneous intercostal blockade is generally too short to warrant the risk of pneumothorax. For open-chest procedures, intercostal blocks by the surgeon pose a low risk and may be indicated, although again, their effectiveness is limited by their short duration. Epinephrine is commonly included in the local anesthetic for these blocks to limit the rate of uptake. More extensive surgery anticipated to cause postoperative pain of longer duration may be best managed with a catheter (continuous infusion) technique.

Ilioinguinal-iliohypogastric nerve block provides excellent postoperative analgesia for inguinal herniorrhaphy, a common outpatient procedure in children (see Chapters 41 and 42). It

appears similar in efficacy to a caudal block, with a duration of analgesia of at least 4 hours when bupivacaine with epinephrine is used. For orchiopexy, ilioinguinal nerve block has been found to be as effective as caudal blockade to the T10 level in a randomized and blinded investigation.<sup>408</sup> In our experience, however, postoperative analgesia for procedures that involve considerable manipulation and traction on the spermatic cord and testis may be better managed with caudal blockade. Penile block is effective for both circumcision and distal, simple hypospadias repair. More extensive procedures on the penis, especially repair of penile-scrotal hypospadias, require a caudal, rather than a penile block, to produce effective analgesia.<sup>409</sup> The use of single-injection neuraxial opioids is an additional technique that can provide longer-lasting analgesia, but must be used in inpatients only, because of the need for respiratory monitoring. Intrathecal morphine has been administered to infants and children for several decades and provides long-acting analgesia (up to 24 hours) after a single injection.<sup>410,411</sup> It is absolutely essential that only preservative-free preparations of the drug be used because preservative-containing solutions may result in injury to the central neuraxis. Doses ranging from 5 to 10 µg/kg are usually chosen. Because of the hydrophilicity of this agent, respiratory monitoring is mandated. Respiratory depression, as well as pruritus, nausea, and urinary retention, are reported after intrathecal morphine. We most commonly employ this modality for analgesia after posterior spinal fusion. The drug is often administered by the surgeon under direct vision of the dura, but if administered at the beginning of the case, it has been reported to reduce intraoperative blood loss.<sup>412,413</sup> This route of administration has also been employed before cardiac surgery.<sup>414</sup> The effective intrathecal dose of opioid is roughly one-fifth to one-tenth that of the epidural dose, and the duration of action, especially with morphine, is significantly prolonged. Therefore, observation in a monitored setting must be continued for 24 hours or until no further evidence of respiratory compromise exists (without the use of naloxone). A novel extended-release preparation of morphine uses a liposomal foam suspension of the drug (DepoDur, EKR Therapeutics, Bedminster, NJ.) that is injected in the lumbar epidural space (note that it should not be used intrathecally) and provides 48 hours of analgesia, with no increase in untoward effects compared with conventional neuraxial morphine.<sup>415-418</sup> To date there are no pediatric data, but clinical trials in children are currently in progress.

### *Catheter Techniques*

A catheter placed in the epidural space or adjacent to a nerve or plexus can be used to provide continuous uninterrupted analgesia for prolonged periods after surgery. These catheters are commonly used for about 3 days but may be used for more prolonged periods in selected situations. With proper care, catheters tunneled under the skin may be left in situ for more than 7 days.<sup>419,420</sup> Catheters can also be placed in intrapleural or extrapleural and/or retropleural locations to provide analgesia after thoracic surgery.<sup>421</sup> In our experience, intrapleural analgesia reduces but does not eliminate the need for systemic opioids, especially if thoracostomy drains are present. We rarely use this technique because toxic concentrations of local anesthetic and seizures have been reported.<sup>422</sup> Continuous extrapleural, intercostal, and paravertebral catheters can be placed either through the operative field or percutaneously. In adult studies, and in a smaller series of pediatric studies, these techniques appear to provide excellent analgesia at rest, but with movement they provide only partial

opioid sparing. Some clinicians regard these techniques as providing many of the advantages of thoracic epidural analgesia, with the potential for reducing the risks and adverse effects of thoracic epidural analgesia.

Continuous regional blockade is remarkably effective and safe, although as with any technique, monitoring for untoward effects is necessary to prevent complications. New technology for the delivery of drugs to peripheral nerves and plexuses have made it possible for children to receive the benefits of continuous neural blockade after discharge from the hospital or day surgery unit.<sup>333</sup> Catheters may deliver local anesthetics and other medications via controlled infusion devices that use a pressurized elastomer-bulb reservoir that controls the infusion rate with a flow limiter (ON-Q pump, I-Flow LLC, Lake Forest, Calif.; Infusor, Baxter, Deerfield, Ill.; Accufusor, Moog Medical Devices, Salt Lake City; Easypump, B Braun Melsungen AG, Melsungen, Germany; and others) (E-Fig. 43-2). These devices can be used at home after discharge, for infusion of medication into a tissue plane to provide a continuous field blockade or a continuous peripheral nerve block. Infusion of local anesthetics in the subcutaneous tissues at the incision site or into the surgical plane using these devices provides prolonged analgesia in both adults and children. Several types of these infusion systems are available, including ones that have options for fixed, variable, or continuous infusion rates with a bolus option. The latter two must be used with caution in smaller children in whom local anesthetic toxicity from excessive dosage may be a risk; we generally use the fixed-rate devices. When continuous peripheral nerve or plexus blocks are used for outpatients, a carefully designed system must be in place to follow these children, to avoid complications and achieve early detection of potentially adverse events. Daily follow-up, either by visiting nurses or by phone, is mandatory. We are aware of a small number of anecdotal cases of possible excessive doses of local anesthetic from a continuous infusion pump used at home that resulted in adverse effects, although no catastrophic events have been reported.

**CAUDAL AND EPIDURAL CATHETERS.** With experience and proper equipment, the lumbar route is feasible at any age, but specific expertise is required for infants and toddlers. Practitioners who have less experience with lumbar epidural catheterization in children should consider placing the catheter via the caudal route for children less than 6 years of age. In infants and children up to about 6 years of age, catheters may be advanced freely from the caudal canal cephalad to lower thoracic levels with excellent success.<sup>423</sup> This is possible in part because young children have a less developed vascular plexus and more compact and globular fat than do older children and adults.<sup>423,424</sup> However, other authors describe less reliability with caudal-to-thoracic advancement of catheters in children larger than 10 kg.<sup>425</sup> This has been attributed to the more mature composition of the contents of the epidural space and the lumbar lordosis that occurs with walking. With age, the epidural fat appears to lose the spongy gelatinous character noted in infants and the spaces between the fat globules become less distinct.<sup>423,424</sup> Catheters made of nylon or polyamide may be less likely to kink beneath the skin and seem to thread more easily than those made of Teflon or other materials. The catheter should never be advanced if resistance is felt. Similar difficulties in advancing catheters that resulted in catheters looping backwards, or kinking, or puncturing the dura have been reported in neonates weighing less than 3.5 kg.<sup>426</sup> In one series of 20 preterm infants, epidurography revealed misplaced catheters in 3 infants or 15%. New data

suggest that misplacement of threaded catheters in all ages may be more common than is generally recognized.<sup>427</sup> In this series of 724 epidurograms, unexpected misplacement was detected in 11 or 1.5%, including 3 intravascular catheters, despite negative test doses, 2 intrathecal without cerebrospinal fluid aspiration, 4 that were intraperitoneal, and 1 each in the rectum and psoas compartment. These authors recommended epidurography in all cases, although this is not the current standard of practice. If specific dermatomal placement of a catheter is sought, one should consider obtaining an imaging study to confirm the dermatomal level of the tip of the catheter, and the aforementioned data suggest that imaging might be advisable whenever a catheter is advanced to a level substantially more rostral than its insertion level.

As an alternative to epidurography, a nerve-stimulating catheter may be used, which allows real-time monitoring of the location of the tip of the catheter as it is advanced cephalad (with the stylet in place, using one system available in Canada), or at least confirmation of tip location on removal of the stylet (using a convenient modification of equipment readily available in the United States).<sup>428,429</sup> The technique requires the use of saline loss-of-resistance and avoiding air bubbles in the epidural space or in the catheter-connector-injection system, because air impedes electrical conduction. In addition, neuromuscular blockade must be avoided because it abolishes the motor response. Used in conjunction with a nerve stimulator set to very low milliamperage (approximately 6 mA), the muscles supplied by a nerve root will twitch as the catheter approaches the segments that supply that dermatome, thereby confirming the catheter tip's location. Specifically, twitches in the feet and ankles occur with catheter tips around L5 to S1, hip flexion occurs with catheter tips around T12 to S1, abdominal muscle twitches without hip flexion imply thoracic positioning above T12, intercostal muscle twitches imply midthoracic tip positioning. Finger twitches would imply advancement to around T1. This technique can also be used to detect catheter malpositioning. Bilateral twitching at a current less than 0.6 mA generally implies subarachnoid positioning. Unilateral twitches in a narrow motor distribution at a current less than 1 mA may suggest advancement out a root foramen. Unilateral twitches at a current less than 1 mA in a very broad motor distribution may indicate subdural positioning. Absence of twitches as the current is increased to about 15 mA (in the absence of air bubbles or neuromuscular blockade) generally indicates that the epidural catheter is not in the epidural space. Our experience is that the use of one of these confirmatory techniques can help avoid problems with failed or incomplete blocks in the postoperative period.

Choice of drugs for epidural infusions depends on a number of factors, including site of surgery, site of the epidural catheter tip, and child risk factors. Local anesthetics, lipophilic opioids, and, to some extent, clonidine all have more restricted cephalad distribution of action during infusions, compared with hydrophilic opioids, such as hydromorphone or morphine. Consequently, optimal positioning of the catheter tip during insertion can improve the analgesic action postoperatively. Experience in adults suggests that when local anesthetics are used, analgesia is optimized when the tip of the epidural catheter is positioned at or slightly above the dermatomal levels involved in the surgery. This effect may be more pronounced when children are moving than when they are at rest. Positioning at levels slightly above the dermatomal levels involved in surgery is more relevant for surgery in lumbosacral dermatomes compared with upper

**E-FIGURE 43-2** ON-Q pump (I-Flow LLC, Lake Forest, Calif.): an elastomeric infusion device for ambulatory continuous regional blockade. The pump bulb is filled with local anesthetic and pressurized. The flow restrictor is readily set to the desired flow rate, and the system is disposable.

thoracic dermatomes because of the greater distance between root level and dorsal horn level in these two circumstances.<sup>430</sup>

Placement of catheters at thoracic levels requires consideration of risk-benefit trade-offs. Therefore, if a catheter tip is at the lumbar or caudal level and the surgery is in thoracic and upper abdominal dermatomes, continuous infusions containing local anesthetics alone or with lipophilic opioids, such as fentanyl or sufentanil, are likely to be ineffective. Increasing the infusion volume is limited by maximum allowable systemic local anesthetic concentrations. In this circumstance, a reasonable alternative is to administer hydrophilic opioids (e.g., morphine or hydromorphone) through lumbar or caudal catheters. The hydrophilic properties of these opioids permit a greater rostral spread, such that a wider range of dermatomes can be covered after caudal or lumbar catheter placement, with only small increases in dose for surgical sites remote from the catheter tip. This same characteristic, unfortunately, also appears to increase the risk for adverse effects, including respiratory depression, as a result of rostral spread of morphine to the central respiratory center in the brainstem. Hydromorphone may offer some advantages because its rostral spread is intermediate compared with fentanyl and morphine and it causes slightly less pruritus compared with morphine.<sup>431,432</sup> Lumbar administration of hydromorphone spreads sufficiently to provide thoracic analgesia.<sup>433</sup> It should be noted that the potency of hydromorphone relative to morphine in the epidural space, is less than when it is administered systemically (2-3:1 epidural vs. 5:1 systemic).<sup>434</sup> Such a technique, however, precludes the optimal use of local anesthetics, and the considerable benefit that may accrue from a multimodal approach to regional analgesia.

A thoracic epidural catheter can be placed in an awake, sedated, or anesthetized child. Some clinicians are hesitant to perform thoracic epidural puncture in anesthetized children because of the inability to use child reports (e.g., paresthesia or lancinating pain) as an indicator of improper catheter or needle placement. However, there are few, if any, data to suggest that the risk of inserting a thoracic epidural catheter in an anesthetized child by an experienced clinician is actually greater than attempting such placement in an awake child who may not be able to remain still, nor is it clear that a well-sedated child can accurately report sensations of paresthesia or differentiate the discomfort of needle passage from more ominous pain.<sup>435</sup> The prospective data from the British National Epidural Audit do not support the contention that there is increased risk with this practice, and those data are corroborated by the PRAN study, which found no neural injury regardless of patient state during epidural placement.<sup>436-438</sup> We believe that data and experience support the safety of placement of thoracic epidural catheters in anesthetized children by anesthesiologists trained and experienced in this procedure, although the tolerances for error are smaller than in adults and older children.<sup>439-441</sup>

It is extremely important to secure caudal catheters to the skin with a clear occlusive dressing, to avoid contamination or dislodgment and to allow daily inspection of the site. In addition, tincture of benzoin or other adhesive solution reduces the incidence of catheter and dressing displacement. For a caudal catheter, the use of an adhesive-edged plastic drape, covering the area from the gluteal crease over the dressing, also helps prevent fecal soiling of the dressing by children who are in diapers. Despite these precautions, if a dressing becomes detached and the insertion site is contaminated it is prudent to remove the catheter. The use of lumbar catheters removes the insertion site from the

diaper area and thereby further reduces the potential for contamination of the catheter and the insertion site.

Successful management of children with an epidural catheter requires carefully coordinated monitoring protocols, nursing management, and medical management of drug selection and dosing. As with PCA or continuous-infusion opioids, the orders should be standardized and written in consultation with the nursing staff, so that misinterpretations are less likely to occur (Fig. 43-10). Because the single most sensitive monitor of children receiving epidural opioids is the nurse, rather than a mechanical or electronic device, education of the nursing staff is of paramount importance to ensure safety. Nursing staff can also assess the adequacy of analgesia and thereby help to titrate the drug dose. Catheter insertion sites should be inspected at least once daily by the pain service, both for the integrity of the dressing and for any evidence of erythema or skin infection (Fig. 43-11). *When continuous infusions are used, the tubing connecting the infusion pump to the catheter should not have any injection ports and it should be clearly labeled as an epidural catheter to preclude unintended epidural administration of drugs intended for IV use.* We use color-coded tubing and a color-coded drug cassette for the continuous administration of regional agents. Although the same pumps are used for IV PCA administration, it is immediately obvious what route the drug is intended for simply by recognizing the tubing and cassette color.

A variation of traditional epidural analgesia and PCA is the technique of patient-controlled epidural analgesia (PCEA).<sup>442</sup> With this variation of traditional PCA, children are generally maintained with an infusion of epidural analgesics (frequently opioid alone or an opioid-local anesthetic mixture) and have the capability of self-administering supplemental doses when needed. When using this technique, the background infusion is used to provide the majority of the analgesia and the child can add to this when needed. It must be emphasized that the time needed for a bolus dose to effect a change with epidural administration is more prolonged than it is with IV agents. Therefore, with PCEA, lockout intervals are greater (often 15 to 30 minutes) than with PCA.<sup>443,444</sup> The considerations one would employ for choosing this technique include the same child-monitoring factors for IV PCA and epidural analgesia, and maximum local anesthetic doses must be carefully calculated to cover the contingency of the greatest possible activation of the PCEA demand doses. "Smart pump" technology has been demonstrated to improve safety of this technique.<sup>445</sup>

**SELECTION OF DRUGS AND DOSES.** Local anesthetics, opioids, and adjuvant agents were discussed previously; this section addresses the specifics of drug choices for continuous infusion through indwelling catheters. Many drugs and combinations have been administered via continuous infusion to the epidural space to provide postoperative analgesia.<sup>390</sup> The most common choices involve mixtures of local anesthetics and opioids, such as bupivacaine and fentanyl, although, increasingly, clonidine is being added (Table 43-10). Continuous infusions for peripheral nerve and plexus blocks are generally limited to local anesthetics, as evidence for the efficacy of other agents in these blocks is equivocal at best.

The choice of drug is based on several factors: the age and size of the child, the operation, and the underlying medical conditions that may decrease the margin of safety of one of the agents. The volume of solution required to fill the epidural space on a milliliter-per-kilogram basis appears to decrease with age; therefore, older children and adolescents may require less volume

**TABLE 43-10** Commonly Used Medications for Epidural Administration

	Dose Range	Untoward Effects	Comments
<b>Local Anesthetics</b>		Motor block	Reduce dose by 30% in infants younger than 6 months of age
Bupivacaine	0.2-0.4 mg/kg/hr		
Ropivacaine	0.2-0.5 mg/kg/hr		Levo-enantiomer; may have 20%-30% less toxicity than racemic amino amides
Levobupivacaine	0.2-0.5 mg/kg/hr		
Chloroprocaine	1%-1.5%; 0.2-0.8 mL/kg/hr (neonates)		
<b>Opioids</b>		Respiratory depression, sedation, pruritus, urinary retention	
Fentanyl	0.3-1 µg/kg/hr		Lipophilic; use when catheter tip is positioned near surgical dermatomes and wide spread is not needed
Hydromorphone	1-2.5 µg/kg/hr	Most rostral spread of opioids	Hydrophilic; use when surgery is more extensive and/or catheter tip is positioned farther from surgical dermatomes
Morphine	1-5 µg/kg/hr		
<b>Adjuncts</b>			
Clonidine	0.1-0.5 µg/kg/hr	Sedation, respiratory depression at greater doses, hypotension (possibly postural) at high doses	Increased risk of apnea with high doses in neonates

**FIGURE 43-11** Superficial skin infection at the site of an epidural catheter insertion. The catheter was withdrawn, and the problem resolved with local skin care only.

than infants and young children, based on weight. In children over 1 year of age, continuous infusions of ropivacaine up to 0.4 mg/kg/hr for up to 72 hours produced stable blood concentrations of unbound ropivacaine without evidence of accumulation or toxicity.<sup>446,447</sup> In very young or preterm infants, however, the risk of accumulation of the amino-amide local anesthetics, and thus the potential for toxicity, is particularly problematic.<sup>448,449</sup> Neonates are at increased risk for potential local anesthetic toxicity because of decreased protein binding (resulting in increased unbound drug) and possibly immature drug metabolism. The manifestations of local anesthetic toxicity in infants and neonates may be more difficult to recognize than in adults. Hence, we recommend a conservative maximum infusion dose for bupivacaine of 0.2 mg/kg/hr for no more than 48 hours in neonates.<sup>450-452</sup> Because safe infusion rates of bupivacaine in the neonate frequently provide insufficient analgesia when wide dermatomal coverage is needed, the amino-ester local anesthetic chloroprocaine may be used in an epidural infusion instead.<sup>453</sup>

Although the amino-amide local anesthetics are slowly cleared in neonates and young infants, the amino-ester chloroprocaine is cleared extremely rapidly, even in preterm infants, via ester hydrolysis, with an elimination half-life of several minutes.<sup>453</sup> This permits large doses and infusion rates with a reduced risk for systemic toxicity. Previous concerns regarding neurotoxicity after chloroprocaine involved a succession of formulations with preservatives, including metabisulfite, methylparaben, and ethylenediaminetetraacetic acid, although the current formulation is preservative-free. An epidural solution of 1% to 1.5% chloroprocaine can be infused at rates of 0.2 to 0.8 mL/kg/hr. If chloroprocaine is not available, the levorotatory enantiomers ropivacaine or levobupivacaine may be preferable to bupivacaine in this age group, because of their better toxicity profile.

When a block is not previously established in the OR, it is useful to dose catheters with local anesthetic (without opioids) at a volume of 0.05 mL/kg per spinal segment or between 0.5 and 1 mL/kg of local anesthetic, not to exceed 5 mg/kg of lidocaine, or 2.5 mg/kg of bupivacaine or ropivacaine. Some clinicians administer a loading dose of opioid as well, such as 1 µg/kg of fentanyl or 1 to 3 µg/kg of hydromorphone. Bupivacaine infusion rates should not exceed 0.4 mg/kg/hr (e.g., 0.4 mL/kg/hr for 0.1% bupivacaine) for children, because toxicity may result.<sup>454</sup> Similarly, starting epidural fentanyl infusion rates should not exceed 1 µg/kg/hr. The upper limits of the epidural fentanyl dose should be determined by clinical effect. If epidural local anesthetic infusions are begun without either opioids or clonidine (e.g., 0.0625% to 0.125% bupivacaine) and inadequate analgesia occurs at infusion rates of 0.3 to 0.4 mL/kg/hr (a maximum dosage of 0.4 mg/kg/hr), further increases in local anesthetic infusion rate or concentration should be avoided. Instead, correct placement of the catheter should be confirmed (e.g., with an epidurogram or chloroprocaine/lidocaine test dose) if dermatomal levels cannot be unequivocally determined. If the catheter is properly located, an epidural opioid or clonidine can be added to the local anesthetic infusion. It is imperative to confirm that an epidural catheter is properly functioning immediately after an infant or child arrives in the PACU, or if there is any question of its proper location later. If an amino-amide local anesthetic has been given during or after surgery as an initial bolus followed

by a continuous infusion, then use of a repeat bolus dose of these amino amides may result in a “stair casing” of plasma concentrations, with a risk for systemic toxicity. Although administration of epidural or systemic opioids may provide analgesia, they may not clarify the site of the epidural catheter. For this reason, confirmation of the catheter location is imperative whenever the clinical picture is not clear. Several means of accomplishing this are described later.

Local anesthetic and opioid combinations (e.g., 0.1% bupivacaine or ropivacaine with fentanyl 2 to 3 µg/mL or hydromorphone 3 to 5 µg/mL at infusion rates of 0.2 to 0.4 mL/kg/hr), via lumbar epidural catheters or caudal catheters advanced to a lumbar position, provide adequate analgesia in the majority of children undergoing lower abdominal or lower extremity surgery. Fentanyl alone (0.3 µg/kg/hr) has been shown to provide 90% effective postoperative analgesia after a levobupivacaine block was established during surgery.<sup>455</sup> Epidural opioids should be used with great caution, or at considerably reduced doses, in children at risk for apnea or hypoventilation (e.g., former preterm infants, children with chronic respiratory failure or disorders of central control of ventilation, or those with obstructive sleep apnea). In very young infants, epidural infusions of both local anesthetics and opioids and other adjuvants can be used safely, but require increased surveillance and reduced initial infusion rates. This is because (1) drug clearance may be reduced; (2) protein binding, which is decreased, may increase the free serum drug concentrations; and (3) titration to clinical end points (e.g., pain scoring) is less precise. A double-blind randomized study demonstrated that the combination of 0.1% bupivacaine with 1 µg/mL of fentanyl provided superior analgesia compared with local anesthetic alone, with no increase in adverse effects, when infused through thoracic catheters in infants under 6 months of age after thoracotomy.<sup>456</sup> In contrast, another study found no incremental benefits in children after abdominal surgery from the addition of fentanyl to epidural catheters with greater local anesthetic concentrations (e.g., 0.125% bupivacaine at 0.3 mL/kg/hr).<sup>455,457</sup> The use of fentanyl as an adjunct may increase PONV.<sup>457</sup> In some centers, application of epidural infusions, especially with opioids, for children younger than 3 to 6 months of age is

restricted to intensive care areas. Acetaminophen or NSAIDs can also be administered if adjunctive analgesia is needed.

If the catheter tip is positioned at the thoracic dermatomes, bupivacaine-fentanyl<sup>185,95,458-461</sup> or ropivacaine-fentanyl solutions may be used for thoracic and upper abdominal surgery.<sup>462</sup> Infusion rates may need to be decreased for thoracic catheters compared with lumbar catheters because the capacitance or volume of the epidural space appears to be less than in lumbar regions. The authors have noted that some older children and adolescents require greater than expected infusion rates to achieve adequate dermatome levels for analgesia. Using hydromorphone in place of fentanyl may be of benefit in these instances, as its greater hydrophilicity results in wider spread. If thoracic placement is not possible, other agents may be administered through lumbar or caudal catheters. For example, epidural bolus doses of morphine 0.03 mg/kg (30 µg/kg) may be administered every 6 to 12 hours as needed.<sup>463</sup> Because the time to onset of analgesia is between 30 and 90 minutes, the doses must be administered at the earliest sign of return of pain. Alternatively, an epidural morphine infusion may be administered at a rate of 0.005 mg/kg/hr (5 µg/kg/hr; doses usually range from 4 to 8 µg/kg/hr) after a small initial bolus. We now rarely use epidural morphine and prefer a continuous epidural infusion of hydromorphone when greater spread is desired, as its adverse effect profile appears to be preferable. Studies in adults suggest an epidural potency ratio of between 2 and 3:1, compared with 5:1 for systemic morphine.<sup>433</sup> For thoracic or upper abdominal epidural infusions, hydromorphone is commonly administered at infusion rates of 0.001 to 0.003 mg/kg/hr (1 to 3 µg/kg/hr). When mixed with a local anesthetic for lumbar epidural infusion, concentrations of 3 to 5 µg/mL of hydromorphone yield a solution that results in an appropriate infusion rate of both drugs.

Hydrophilic opioids, especially when administered by infusion, require prolonged careful observation (see later discussion). If somnolence, shallow breathing, or hypopnea occurs, the infusion must be stopped, not simply decreased, until these effects subside, and appropriate therapy instituted (Table 43-11). Rather than administering a large dose of naloxone, it is preferable to titrate it at 1 µg/kg every 1 to 2 minutes until the respiratory

**TABLE 43-11 Treatment of Untoward Effects of Epidural Opioids**

Adverse Effect	Treatment	Infusion Rate
Pruritus	Naloxone, 0.5-1 µg/kg IV or infusion at 0.25-1 µg/kg/hr Nalbuphine, 0.025 mg/kg IV every 6 hours	No change, or decrease opioid concentration, or decrease by 10%-20% (if dermatome level permits)
Nausea and vomiting	NPO for 24 hours Naloxone, 0.5 µg/kg IV or infusion at 0.25-1 µg/kg/hr Ondansetron 0.1 mg/kg (maximum 4 mg) IV every 6 hours Metoclopramide, 0.1-0.15 mg/kg IV every 6-8 hours	Decrease opioid concentration or decrease by 10%-20% (if dermatome level permits)
Urinary retention	Bladder catheterization (one time; some institutions keep urinary catheters in these children routinely) Naloxone, 0.5 µg/kg IV or infusion at 0.25-1 µg/kg/hr Indwelling urinary catheter	Decrease opioid concentration
Respiratory depression; * child unarousable, hypoxemic, hypercarbic, or apneic	Oxygen by mask; assisted ventilation if needed Naloxone, 5-10 µg/kg IV Transfer child to monitored setting until episode is fully resolved. Consider naloxone infusion (0.25-1 µg/kg/hr)	Discontinue infusion; consider possibility of intrathecal catheter migration (check by aspirating)

IV, Intravenous; NPO, nothing by mouth.

\*Stop infusion until the child is alert, if using morphine or hydromorphone.

drive improves, assuming that the airway can be adequately supported. In this manner, analgesia can be preserved. The duration of action of naloxone is considerably less than the respiratory depressant effect of the neuraxial opioids, thus continued respiratory monitoring is required and usually an infusion of naloxone (0.25-1 µg/kg/hr) until resolution of the respiratory depression. Common epidural infusions and alternative modalities for pain management of sample cases are provided in Appendix 43-1.

The sympathetic blockade that may occur in older children as a result of epidural or plexus blocks with local anesthetics may also be used advantageously to provide postoperative vasodilation in children undergoing replantation or vascularized flaps of the extremities.

Adjuvant agents, particularly clonidine, can be administered continuously via epidural catheter, most commonly in combination with or in place of local anesthetics and opioids. The primary analgesic effect appears to be via an  $\alpha$ -adrenergic mechanism. Although epidural clonidine has been found to be less potent in terms of analgesic efficacy compared with epidural opioids, such as fentanyl, it has occasionally been substituted for neuraxial opioids because it is associated with a smaller incidence of untoward effects, such as respiratory depression, nausea, and pruritus.<sup>464-467</sup> This also suggests that the combination of all three agents, each at smaller concentrations than required individually, might be beneficial at reducing the incidence of adverse effects while optimizing analgesia, but carefully controlled studies have yet to be performed.

### Risks and Untoward Effects

Adverse effects associated with regional analgesia can be grouped according to those caused by the technique (e.g., the catheter) and those related to the medications (e.g., local anesthetics, opioids, other adjuvants). Three recent large prospective studies have confirmed the safety of regional anesthetics in children, detecting very small complication rates.<sup>436-438,468</sup>

**Local anesthetics** in the dilute concentrations used for postoperative analgesia have a very small incidence of untoward effects. Motor blockade occurs less frequently with dilute concentrations, but can be observed even with small concentrations of bupivacaine, such as 0.1%. As discussed earlier, children with neuromuscular disorders causing motor weakness should be observed carefully for exacerbation of their motor weakness. Motor weakness and blockade can result in several problems. Inability or difficulty in ambulation may impede recovery. The inability of a child to move a limb can result in skin breakdown or peripheral nerve compression injuries, especially if meticulous attention to frequent repositioning does not occur. We are aware of a case of complex regional pain syndrome in the distribution of the peroneal nerve that arose in this manner. Motor blockade should be avoided, if at all possible, and frequent examinations may quantify motor function using the Bromage score, if possible (Table 43-12). At our institutions, motor function is assessed every 8 hours along with the other vital signs pertinent to regional blockade (see Fig. 43-10). If motor blockade occurs, the clinician should (1) reduce the concentration of local anesthetic, (2) pay strict attention to padding and to frequent repositioning of the extremity involved, and (3) consider stopping the infusion until motor function returns. *Rapid onset of more profound motor block during epidural infusion should raise immediate concern about erosion of the catheter into the subarachnoid space.* Motor blockade may occur more frequently with peripheral nerve or plexus analgesia than with epidural blocks, and is subject to the same precautions.

**TABLE 43-12 Bromage Score\* for Assessment of Motor Function of the Legs**

Full motor function: can flex hip, knee, and ankle	0
Can't flex hip (unable to perform straight-leg lift)	1
Can't flex hip or knee	2
Can't flex hip, knee, or ankle	3

\*Note that alternative scoring schemes for the Bromage scale exist that range from 1-4 (sometimes denoted I-IV) that directly correspond to the 0-3 scale depicted here.

When children are discharged home with a peripheral nerve catheter, it is particularly important to teach the parents how to deal with motor blockade.

The PK of bupivacaine have been studied in infants and children after both single-injection doses<sup>469</sup> and continuous infusions. Data suggest that in children younger than 6 months of age, reduced protein binding increases the free fraction of circulating bupivacaine, which increases the risk of bupivacaine toxicity.<sup>470</sup> Neonates and infants with impaired hepatic blood flow may be at particular risk for bupivacaine accumulation. Seizures and cardiac arrest have been reported when large doses of bupivacaine have been administered, usually after excessive infusion rates or unintended intravascular injection. Limited information is available regarding extended administration over days, although low concentration solutions (and therefore low total doses) reduce the risk for toxicity. *l*-Enantiomers of amino amides (ropivacaine and levobupivacaine) have toxic thresholds that are greater than that of bupivacaine by as much as 30%, and such drugs should be considered in smaller children and for blocks that require greater infusion rates and for greater durations. A particular “hidden” risk occurs when a block is functioning less than optimally and bolus doses are administered in an attempt to broaden the dermatome level. Even though the infusion rate is kept within the recommended range, the bolus doses can raise the blood concentration above the toxic threshold. *Whenever a local anesthetic is administered by continuous infusion, nursing and medical staff must be aware of the signs and symptoms of local-anesthetic toxicity, be vigilant in monitoring for the early detection of those signs, and be familiar with the use of lipid rescue protocols to treat toxicity if it occurs.* The use of lipid emulsion for treating local anesthetic toxicity is discussed in detail in Chapter 41. Tachyphylaxis during prolonged administration of local anesthetics is a theoretic consideration, although no systematic studies have addressed this phenomenon in children. In animal models, tachyphylaxis is accelerated by hyperalgesia and prevented by agents that prevent hyperalgesia at spinal sites. One rationale for coadministration of opioids or clonidine in epidural infusions may be to reduce the incidence or severity of tachyphylaxis. As discussed in Chapter 41, hemodynamic stability is maintained in children younger than 6 years of age during spinal or epidural blockade, even with extensive sympathetic blockade. As children approach school age, however, rapid position changes may produce hemodynamic responses after extensive sympathetic blockade, and this must be considered in children who receive continuous epidural blockade. Orthostatic changes may be exacerbated when epidural clonidine is infused, and extra caution should be taken.

**Neuraxial opioids** confer several potential adverse effects, including respiratory depression, nausea, urinary retention, and pruritus. Indeed, despite their proven analgesic efficacy, not all authorities are proponents of their use because of these effects,

preferring other adjuvants instead.<sup>471</sup> The most effective means of treating or preventing the adverse effects is the use of opioid antagonists or mixed agonist-antagonists. This approach directly targets the etiology of the signs rather than simply treating their manifestations. Low-dose naloxone infusions, which have been shown to be effective in children receiving parenteral opioids, are also effective for treating the adverse effects of neuraxial opioids, although pediatric data are lacking.<sup>472-476</sup> We have used similar rates to those shown effective in the PCA studies, beginning at 0.25 µg/kg/hr.<sup>241</sup> This infusion rate can be titrated upwards as needed to 1 µg/kg/hr without adversely affecting analgesic efficacy.<sup>242</sup>

The most worrisome and dangerous complication is respiratory depression. The lipophilic agents (fentanyl and sufentanil) have the widest therapeutic indices. This results from greater receptor binding in the substantia gelatinosa of the spinal cord adjacent to the area of drug administration, thus limiting the rostral spread of the drug. Despite the fact that the hydrophilic opioids, hydromorphone and morphine, pose a greater risk for respiratory depression, the incidence remains low. Nevertheless, reports in the pediatric literature of respiratory depression after epidural administration of morphine demonstrate that vigilance in monitoring is mandatory.<sup>382,477,478</sup> The incidence of complications with caudal morphine is reduced if a dose of 0.033 mg/kg (33 µg/kg) or less is used in children older than 1 year of age.<sup>463</sup> The adequacy of analgesia at this dose was virtually unchanged from 0.1 mg/kg (100 µg/kg), with the exception of a prolongation of action with the greater dose. *The hallmark of impending overdose of central neuraxial opioids is increasing sedation and decreasing DEPTH AND RATE of respirations. It is important to recognize that the depth of respiration must be assessed, not just the rate, because children frequently develop decreased tidal volume before the respiratory rate decreases, leading to alveolar hypoventilation and the potential for hypercarbia and hypoxemia.*<sup>479</sup>

In addition to clinical assessment, quantitative capnography and pulse oximetry can be valuable monitors for these children and provide more useful information than impedance-type respirometers, which count only respiratory rate. Impedance-based respiratory monitors may continue to register breathing efforts when significant airway obstruction exists, as long as the chest wall is still moving, thereby potentially delaying the recognition of respiratory depression. Because electronic monitors that alarm only in the child's room can be ignored, it is important that these monitors are configured to either alarm at the nurses' station and in the hallways, or notify the nurse directly using portable communication devices. Such advanced communication systems are now commercially available and may help to provide early warning of impending complications, although the risk of false alarms, and the complacency caused by their frequent activation, must also be considered. Again, it is emphasized that no monitor can replace vigilance and frequent clinical assessment.

Oversedation, diminished respiratory depth, and slowing of the respiratory rate are treated by decreasing the rate of opioid administration and, if necessary, administering small incremental doses of naloxone (0.5 to 1 µg/kg) every few minutes until the adverse effects are reversed (see earlier discussion). A continuous low-dose infusion of naloxone, as described earlier (0.25 to 1 µg/kg/hr) may need to be started. More profound respiratory depression, including inability to arouse the child and apnea, must be treated more aggressively. In this circumstance, the infusion should be discontinued, positive-pressure ventilation with oxygen instituted if respirations are very slow, shallow, or absent, and up

to 5 to 10 µg/kg of naloxone administered IV. As long as respirations are adequately supported, there is no need to administer very large doses of naloxone. *The new development of respiratory depression in a child receiving what appears to be an appropriate opioid dose, should always raise the question of catheter migration into the subarachnoid space. Whenever central neuraxial opioids are administered, facilities must be immediately available at the child's bedside for resuscitation, in the unlikely event of respiratory depression.* It is recommended that emergency equipment, including a bag-valve device, appropriate sizes of masks and airways, and suction, be at the child's bedside or in a "code cart" that is accessible within seconds, should the need arise. Naloxone should similarly be immediately available, without the need to obtain the drug from the pharmacy. All children receiving continuous regional analgesia should also have an IV line (a heparin lock is adequate in those children not requiring IV fluids).

Pruritus is a common adverse effect associated with epidural or intrathecal opioid use, occurring in as many as 30% to 70% of children. Antihistamines are less effective antipruritics in this situation, because the primary mechanism is a central opioid, not a histamine, effect. Thus opioid antagonists, used in small doses, are most effective. Again, low-dose infusions of naloxone can be employed with good results.<sup>242,472,473,475,476</sup> Some practitioners have found low-dose nalbuphine to be effective to antagonize pruritus (25 to 50 µg/kg every 6 hours, PRN).<sup>473,474</sup> Although we have found this treatment to be effective, others have found it to be no more effective than placebo in reducing pruritus in children.<sup>480</sup>

Nausea and vomiting can also occur in association with opioids (both systemic and neuraxial) and may be more common with morphine than with fentanyl. Children who are fasted during the first 24 hours after surgery do not vomit excessively, even when given caudal morphine.<sup>481</sup> As with all other opioid adverse effects, nausea and vomiting respond to the previously mentioned doses of naloxone or mixed agonist-antagonists, such as nalbuphine. Some antiemetics, such as antihistamines and butyrophenones (e.g., droperidol), may cause sedation and should be used with caution. Serotonin receptor antagonists, such as ondansetron (0.1 to 0.15 mg/kg, maximum 4 mg) or dolasetron (0.35 mg/kg, maximum 12.5 mg), may be effective and not cause sedation.<sup>482</sup> Metoclopramide in doses of 0.1 to 0.15 mg/kg (100 to 150 µg/kg) IV every 6 to 8 hours may provide adequate relief, with less sedation than other drugs of its class. It is sometimes prudent to decrease the infusion rate of the epidural (if the block level permits) or the opioid concentration in the infusate when untoward effects require treatment. If additional analgesia is required, acetaminophen, oral NSAIDs, or ketorolac may be administered. Untoward effects of epidural opioids and their treatment are summarized in Table 43-11.

Urinary retention is a relatively common complication of neuraxial opioids. Studies of single-injection caudal blocks have found that this complication does not occur when epidural local anesthetics are used, only when neuraxial opioids are added.<sup>372</sup> Neuraxial opioids depress detrusor contractility in a dose-dependent manner, and this effect may actually outlast the analgesic effect of the drug by hours.<sup>483,484</sup> Different approaches have been used for this problem, including indwelling urinary catheterization and the use of opioid antagonists.<sup>485</sup>

Concerns have been raised that regional analgesia could mask or delay the detection of compartment syndrome of an extremity because of the intensity or quality of analgesia produced by neural blockade.<sup>486</sup> Despite the theoretical worries, this has not

been demonstrated in numerous studies, and indeed, the opposite has been observed, that the onset of pain in a patient with previously adequate analgesia from an epidural or nerve block is an early warning sign that may herald the onset of compartment syndrome.<sup>487,488</sup> The concentration of local anesthetics used for postoperative analgesia appears to be inadequate to mask the intensity of pain caused by compartment syndrome. In addition, epidural blockade is not effective in controlling the discomfort from intense pressure (as demonstrated by the parturient's ability to perceive pressure during labor contractions despite being pain-free). The loss of effective analgesia in a child at risk of compartment syndrome should raise suspicion and prompt investigation before any changes are made to the analgesic regimen (see also Chapter 30).

### Catheter-Related Complications

Inadequate analgesia must prompt an examination of the child and a review of the operative procedure and the analgesic technique. The dermatome level should be determined using differentiation between cold and warm sensation in children who are cognitively and developmentally able to cooperate. Presence of a dermatome level suggests a successful block of inadequate height. No demonstrable blockade suggests a primary malfunction, although low concentrations of local anesthetic may make differentiation of the level difficult in some children. If there were difficulties during catheter placement coupled with a lack of effective analgesia when the child emerges from general anesthesia, the catheter is likely malpositioned. We often use epidurography in this situation to determine whether the catheter is in the epidural space. Misplacement in various locations has been reported, including the subdural space, paravertebral space, tissue planes adjacent to the spine, and even in an epidural blood vessel after a negative test dose.<sup>427,489-491</sup> The catheter's location can be easily visualized on a plain radiograph (or with fluoroscopy in the OR) after the injection of a small volume of nonionic contrast agent. Contrast agent in the epidural space has a characteristic "bubbly" appearance, with the contrast agent centrally located over the spinal column (Fig. 43-12). The existence of a median raphe in the epidural space has been postulated and may be the cause of unilateral multi-dermatome blockade.<sup>492</sup> This has been demonstrated on epidurography when unilateral blockade has occurred (Fig. 43-13). A single unilateral dermatomal band of analgesia or temperature-sensation change may indicate that the catheter has passed through a spinal foramen. In some cases, simply withdrawing the catheter 1 or 2 cm may allow proper repositioning within the epidural space. A functional, rather than anatomic, method of confirming epidural placement is the "chloroprocaine test," which has the advantage of both providing rapid analgesia (with a properly located catheter) and confirming the site of placement. A chloroprocaine test is presented in Figure 43-14.

On occasion, a collection of fluid may be found at the skin insertion site and pooling under the dressing. Experience suggests that in most cases this is not, as one may fear, cerebrospinal fluid, but rather edema fluid, or occasionally local anesthetic solution, tracking along the catheter's course and leaking through a hole in the skin from the subcutaneous tissues. Local anesthetic solutions would test negative for glucose and protein, whereas cerebrospinal fluid and edema fluid would test positive for glucose and protein. It usually requires no special treatment except reinforcing the dressing. It subsides as the edema and third space fluids are mobilized in the first days after surgery. If troublesome

**FIGURE 43-12** An epidurogram shows the appearance of the contrast agent centered in the spinal column and also the bubbly appearance of the contrast agent, presumably produced by the epidural fat and plexus.

**FIGURE 43-13** Epidurogram taken with fluoroscopy demonstrating unilateral spread of contrast agent. The contrast agent appears to have a very sharp edge precisely in the center of the spinal column, demarcating one side of the epidural space from the other.

and persistent leakage occurs, a drop of collodion or Dermabond (Ethicon, Inc. Cornelia, Ga.) over the skin site may be effective in sealing the hole.

The catheter site should be inspected daily to ensure that the dressing is intact and to assess for the presence of infection. Infections are exceedingly rare, perhaps in part because of the bactericidal properties of the local anesthetics themselves.<sup>493</sup>

## PROCEDURE FOR THE CHLOROPROCAINE TEST

An anesthesiologist is present for the procedure with use of standard monitors and supplies for providing respiratory or hemodynamic support.

1. A loading dose of chloroprocaine 3% is divided in five equal increments, each given at 1- to 2-minute intervals (over 5-10 minutes total) according to weight approximately as follows: (doses may be adjusted according to clinical circumstances)

Weight Group	Increment Volume	Total Volume
0-10 kg	0.125 mL/kg	0.6 mL/kg
10-20 kg	0.1 mL/kg	0.5 mL/kg
20-35 kg	2.5 mL (fixed volume)	12.5 mL (fixed volume)
35-60 kg	3 mL (fixed volume)	15 mL (fixed volume)
≥60 kg	3.5 mL (fixed volume)	17.5 mL (fixed volume)

2. Incremental dosing is stopped before giving the full dose if there are clear signs of bilateral lower extremity sensory or motor block, or a very definite reduction in heart rate (e.g., 30 beats per minute) and blood pressure (e.g., 25 mm Hg drop in systolic pressure). In most cases, because you are performing this test because of signs of pain, there is some tachycardia and hypertension relative to baseline values at the start of the test. Transient cessation of crying in an infant or toddler is not a sufficiently specific positive response to warrant interruption of the test.
3. A catheter positioned in the **thoracic** epidural space will generally not show lower extremity sensory or motor block with the chloroprocaine test, but should give a very clear drop in heart rate and blood pressure, as well as a clear and persistent reduction in pain reports or pain behaviors.
4. If the chloroprocaine test is positive (i.e., confirms epidural placement), this implies that a stronger or different epidural solution is needed for steady-state pain relief. Because hydromorphone is sufficiently hydrophilic to spread from lumbar to thoracic spinal levels, **switching the solution from bupivacaine-fentanyl to bupivacaine-hydromorphone will provide good steady-state pain relief in >90% of these cases.** A typical loading dose of hydromorphone of 2 g/kg (0.002 mg/kg) will provide analgesia within 30 minutes in most cases.

If the chloroprocaine test fails to confirm epidural placement, the catheter is repositioned, removed, or replaced according to clinical circumstances.

**FIGURE 43-14** Chloroprocaine test to determine regional catheter function as performed at Children's Hospital, Boston. (Personal communication, C. Berde.)

Although colonization of catheters, usually with *Staphylococcus epidermidis* and other gram-positive organisms, appears common, adult and pediatric studies have shown that this is not associated with neuraxial infection.<sup>494,495</sup> In the UK epidural audit, there were three cases of deep tissue infection and 25 local infections reported out of 10,660 epidural catheters.<sup>436</sup> Tunneling a catheter subcutaneously may reduce the risk of bacteriologic contamination and permit the use of a catheter for a greater period of time.<sup>420</sup> A study of the microbiology of the infusion fluids and delivery systems has demonstrated that catheter-related infections of the deep tissues, including epidural abscess, appear to have their origin in local skin infections that track along the catheter's path or via a bacteremia.<sup>496</sup> *Any sign of local infection is cause for immediate catheter removal.* Epidural abscess is a catastrophic complication that can be generally avoided if the catheter is removed early, when only a localized cutaneous infection is present.<sup>497</sup> Clinical signs include fever, malaise, and back pain. Specific neurologic signs, paresthesias, and motor symptoms (e.g., flaccid paralysis as cord compression develops, eventually progressing to spasticity) may occur late in the course, if early warning signs are not heeded, but may progress rapidly once established. Children who develop fever or sepsis need to be evaluated on an individual basis. If a clear source for the fever is found, it is acceptable to leave the catheter in place with regular and frequent observation and reassessment, although we remove it if a child is overtly septic or if the situation is unclear.

### Intrapleural Catheters

Continuous intrapleural analgesia has been used in children after thoracic, upper abdominal, and retroperitoneal surgery, although this technique has fallen out of favor in recent years as familiarity with paravertebral and thoracic epidural blockade has increased.<sup>498-500</sup> A standard epidural catheter can be introduced to the intrapleural space in the same fashion as for a thoracentesis, that is, over the *upper* margin of the rib to avoid the neurovascular structures. The catheter is threaded several centimeters, anchored at the skin site with a suture to prevent its migration, and affixed with a clear occlusive dressing. Infusing 0.25% bupivacaine with epinephrine (1 : 200,000) at 0.5 mL/kg/hr has provided effective analgesia.<sup>498</sup> Because the local anesthetic solution flows with gravity, the position of the child is important in determining the efficacy of analgesia. The risks associated with this technique include rapid uptake of drug into the circulation from the large and efficient absorptive surface of the pleura. Although none of the children in the initial reports of this technique had signs of clinical toxicity, total blood concentrations of bupivacaine (bound and unbound) reached the toxic range of 4 µg/mL after 24 hours of therapy in some children. Anecdotally, seizures have been reported with intrapleural analgesia in children. Given these concerns, *hourly bupivacaine infusion rates should generally not exceed 0.5 mg/kg/hr.*<sup>452</sup> Ropivacaine or levobupivacaine may be safer alternatives than bupivacaine because of their reduced risk of cardiotoxicity. The potential also exists for paresis

of the phrenic, recurrent laryngeal, and vagus nerves, and the thoracic sympathetic chain, as well as for direct effects on the diaphragm. Pneumothorax remains a risk with percutaneous placement through a closed chest. In our experience, epidural analgesia is more effective and has a wider margin of safety than intrapleural analgesia for major thoracoabdominal surgery. Thoracic paravertebral block has also been described in children, and is another preferable alternative with less risk of local anesthetic toxicity (see Chapter 41). With the widespread use of ultrasound guidance, thoracic paravertebral catheters are being used much more commonly in major pediatric centers.<sup>501-503</sup>

### Plexus Catheters

Catheters may be placed adjacent to the brachial plexus via an axillary, infraclavicular, or supraclavicular approach with the latter two affording improved stability and security of the catheter.<sup>352,504,505</sup> Ultrasound guidance is rapidly becoming the standard of practice for regional anesthesia in children (see Chapter 42). The prolonged duration of analgesia after a single-injection brachial plexus block reduces the need for an indwelling catheter in many instances, although it may be useful in some operative circumstances, and for postoperative management of reimplantation of an arm or hand, because sustained vasodilation from the block may improve revascularization.<sup>506</sup> Specialized kits for peripheral nerve and plexus cannulation are commercially available. These catheters are inserted using the same landmarks and techniques as for placing a single-injection block. After initial dosing, 0.125% bupivacaine or 0.2% ropivacaine at 0.1 to 0.2 mL/kg/hr may be infused. Potential complications of continuous brachial plexus blockade include infection and nerve injury, although these are quite rare and none have been reported to PRAN to date).<sup>438</sup> In a retrospective study of complications from axillary catheters in adults, the rate of localized infection was less than 3 per 1000 and of new neurologic symptoms was 5 per 1000.<sup>507</sup>

### Peripheral Nerve Catheters

Catheter techniques have been used with increasing frequency for peripheral nerve blocks in outpatients and inpatients, in part because of the increased use of ultrasound guidance to confirm placement. Infusions can be delivered with conventional infusion pumps or disposable elastomeric controlled infusion devices described earlier. We usually use conventional infusion pumps for inpatients owing to reduced cost and to the increased safety that may be inherent in the familiarity of the inpatient nurses with such systems. The disposable devices permit the child to be discharged home and still receive long-lasting analgesia with a regional anesthetic. This technique can be used for many of the nerve blocks mentioned in Chapters 41 and 42 and is most commonly used for femoral or fascia iliaca, sciatic, and brachial plexus blocks. Most commonly, 0.2% ropivacaine is used at rates of 0.1 to 0.2 mL/kg/hr.<sup>352</sup> An organized system of daily follow-up by telephone or visiting nurses is essential for safety and efficacy of such a service, but both limited published and anecdotal experience suggests that ambulatory analgesia with peripheral neural blockade can be an effective modality in pediatric outpatients.<sup>333,508</sup>

### Fascial Plane and Wound Catheters

Catheters with multiple side holes can be placed in a fascial plane or wound bed by the surgeon at the time of closure and local anesthetics infused over several days for postoperative analgesia.

There are very limited data in children, but such techniques have been reported to be effective.<sup>508,509</sup> There are no studies to date comparing infusion rates; volumes of 2 to 5 mL/hr of 0.2% ropivacaine have most commonly been used, infused via the elastomeric pumps previously described.

### Removal of Catheters and Transition to Oral Analgesics

The transition from continuous regional blockade to oral analgesics should ideally be achieved without a significant decrement in the quality of pain relief for the child and should permit the clinician to revert to more aggressive modalities, should the decision prove to be premature. The duration of continuous blockade is, of course, in large part dependent on the type of operation and the underlying medical and/or surgical problems of the child. Some children do well with transition to oral analgesics on the morning after surgery. This is often the case for the child who has undergone an uncomplicated ureteral reimplantation. For more painful procedures, such as Nuss bar placement for pectus excavatum in an adolescent, strong analgesics will be required for a greater duration. The norm in this situation is 3 days. We find it most effective to begin the transition from regional analgesia to oral therapy early in the morning. As soon as the regional infusion is discontinued, a dose of oral analgesic, usually an oral opioid, such as oxycodone, in combination with acetaminophen, is administered. This ensures that the oral agents have provided their full effect before the block recedes. The catheter is not removed until the child has demonstrated that the oral agents provide adequate comfort without any residual analgesia from the block, so that blockade can be reestablished if transition fails. The oral agents are best administered on a schedule, rather than as needed, for the first 12 to 24 hours after transition.

Children who are anticoagulated require special consideration before removing epidural catheters. Although there are no specific pediatric data, the recommendations of the consensus panel of the American Society for Regional Anesthesia are generally accepted.<sup>331</sup> The report notes *"the initiation of systemic therapeutic heparin therapy for medical or surgical indications in the presence of a neuraxial catheter potentially increases the risk of hematoma formation during catheter removal"* and that systemic heparinization is recommended to be discontinued for 2 to 4 hours before catheter removal. At least 1 hour should elapse before heparin therapy is restarted, and careful neurologic assessment should be performed for at least 12 hours after removal of the catheter. Fractionated or low molecular weight heparins pose a risk as well, compounded by several different regimens in common clinical use (once-a-day vs. twice-a-day dosing) and the inability to assess the degree of anticoagulation with commonly available tests of coagulation (prothrombin time and partial thromboplastin time). The consensus panel recommends that catheters should be removed no sooner than 10 to 12 hours after the last dose of low molecular weight heparin, and dosing should resume no sooner than 2 hours after the catheter's removal.

## Pain Management in the Cognitively Impaired Child

The goals of pain management in the child with cognitive impairment are to minimize discomfort, maximize function, and improve the quality of life. With these goals in mind, the child's pain management plans should include multimodal pharmacologic and nonpharmacologic strategies tailored to the severity

and etiology of pain. The World Health Organization's analgesic ladder provides a framework for decision-making related to analgesic use based on severity and persistence of pain.

### OPIOID ANALGESICS

The use of opioids in children with cognitive impairment has been limited by concerns regarding potential adverse effects and a perceived reduced margin of safety because of diminished cardiorespiratory reserve and neurologic impairment. Indeed, a recent study identified cognitive impairment to be an independent predictor of adverse events from PCA/NCA.<sup>297</sup> It is, therefore, necessary to carefully balance the goals of providing adequate analgesia while minimizing adverse events related to analgesic treatments. For moderate to severe pain, the judicious use of opioids in small doses titrated to effect are a suitable option. Children with cognitive impairment may lack the cognitive and motor skills to use PCA devices successfully. In these children, NCA or CCA will permit titration of small amounts of opioids to effect, without significantly increasing nursing workload.<sup>510</sup> A study of children whose postoperative pain was managed by parent- or nurse-controlled analgesia, reported low pain scores and modest opioid requirements with the use of basal infusions in addition to bolus dosing, in the majority of children.<sup>511</sup> Adverse effects included nausea and vomiting, and pruritus requiring treatment, in 14% and 32% of children, respectively. Supplemental oxygen was required in 79% of the children, and respiratory depression requiring naloxone was noted in 2.8%. The management of two children was remarkable, in that one had received an average morphine dose of 0.045 mg/kg/hr and four concomitant sedatives, including diphenhydramine, diazepam, droperidol, and chloral hydrate, and the second had only received a small dose of morphine and no other sedatives, but the basal infusion of morphine was implicated as the cause of respiratory depression. Both recovered without sequelae. The above studies highlight the importance of frequent and careful assessment of pain, depth of sedation, and respiratory status (using continuous pulse oximetry and/or noninvasive capnography) to ensure the safety and the comfort of children with cognitive impairment receiving opioid therapy.

### NONOPIOID ANALGESICS

Nonopioid adjuvants, such as acetaminophen, nonsteroidal anti-inflammatory drugs, or tramadol, should be added to provide synergistic analgesia and to reduce opioid requirements. They may be administered orally or via gastrostomy tubes. IV ketorolac provides excellent analgesia in children who have not initiated oral intake after surgery, although the risks of platelet dysfunction must be considered if ongoing bleeding is an issue. The  $\alpha_2$ -agonist clonidine has also been used for its synergistic analgesic effects. However, it has the potential to cause sedation and hypotension.

Muscle spasms and clonus are an ongoing source of pain in children with cognitive impairment, and may be exacerbated after surgical procedures, particularly orthopedic and neurosurgical procedures. Diazepam and baclofen have been effective for treating acute painful muscle spasms after surgery in children with spasticity. Because benzodiazepines have a synergistic respiratory depressant effect when used in conjunction with opioids, they must be used judiciously.

### EPIDURAL AND REGIONAL ANALGESIA

Epidural analgesia has been used with success in children with cognitive impairment who are undergoing lower extremity

orthopedic procedures, selective dorsal rhizotomy, and Nissen fundoplication.<sup>80,512</sup> Epidural catheters may be technically difficult to place in some children with cognitive impairment because of contractures and spine deformities. However, when feasible, this technique provides excellent analgesia, reduces muscle spasms, and promotes overall child comfort, with a small incidence of sedation and respiratory depression. Some children will still experience muscle spasms and will require intermittent doses of midazolam or oral diazepam. Intermittent bolus epidural morphine or continuous fentanyl and bupivacaine provided excellent analgesia in 91 of 92 children with cerebral palsy undergoing subumbilical procedures.<sup>512</sup> The children who received epidural morphine experienced a 6.5% incidence of excessive sedation and hypopnea and a 7.6% incidence of oxygen desaturation to less than 90%. Other adverse effects included emesis (52%), pruritus (29%), and urinary retention (70%). These authors recommended the use of fentanyl and bupivacaine in an effort to avoid the excessive sedation and hypopnea observed in the children who received epidural morphine. Urinary catheters are also routinely placed, given the frequency of urinary retention, particularly when neuraxial opioids are used. Epidural morphine infusions have been compared with morphine PCA in children with cerebral palsy undergoing selective dorsal rhizotomy.<sup>80</sup> Epidural catheters were placed under direct visualization by the neurosurgeon at the end of surgery. Children in the epidural group experienced reduced pain scores and fewer muscle spasms and tolerated activity better in the early postoperative period than did the PCA group. Respiratory depression did not occur in any of the groups, and the incidence of vomiting and pruritus was similar between groups. In summary, these studies support the attributes and safety of epidural analgesia in children with cognitive impairment.

Children with cerebral palsy who received continuous infusion of local anesthetics via catheters tunneled into the incision site following orthopedic surgery experienced significantly lower pain scores and required less oral analgesics on the first two postoperative days, compared to controls who received oral analgesics alone.<sup>508</sup> Although data related to peripheral and plexus blocks in cognitively impaired children are limited, our experience suggests that these, too, are safe and effective in this population, and can contribute to reducing the reliance on systemic analgesics and, thereby, their adverse effects.

Emerging data must be used to guide treatment plans and protocols that incorporate frequent evaluation and careful monitoring of children with cognitive impairment. Involvement of a multidisciplinary pain team that includes the primary care provider, pain specialist, psychologist, nurse, physical therapist, and occupational therapist is required to provide the level of expertise required to care for these children with special needs.

## Summary

Postoperative analgesia is an integral and essential component of any pediatric anesthetic plan. Contemporary knowledge of anatomy, physiology, PK, and pharmacodynamics in infancy and childhood permits the anesthesiologist to apply advanced anesthetic and analgesic techniques with excellent efficacy and safety to all children. Clinical examples of postoperative management strategies are presented in Appendix 43-1. The optimal use of these modalities requires an understanding of the techniques outlined in this chapter, as well as the integration of multiple medical and nursing disciplines in the assessment and care of

these children. A well-organized pediatric pain service and an educated nursing staff are the keys to the successful management of acute pain, which, in turn, can be expected to result in improved care for infants and children.<sup>513</sup>

The effects of a small-dose naloxone infusion on opioid-induced side effects and analgesia in children and adolescents treated with intravenous patient-controlled analgesia: a double-blind, prospective, randomized, controlled study. *Anesth Analg* 2005;100:953-8.

*This study demonstrated that a low-dose naloxone infusion significantly reduced the incidence and severity of opioid-induced adverse effects, including pruritus and nausea, without affecting opioid-induced analgesia. These data address the important clinical problem of opioid-induced adverse effects that frequently limits the utility of opioids in the treatment of pain.*

Michelet D, Andreu-Gallien, Bensalah T, et al. A meta-analysis of the use of nonsteroidal anti-inflammatory drugs for pediatric postoperative pain. *Anesth Analg* 2012;114:393-406.

*This meta-analysis shows that perioperative NSAID administration reduces opioid consumption and PONV during the postoperative period in children. In 27 randomized controlled trials, perioperative administration of NSAIDs reduced opioid requirement in the PACU and for the first 24 hours after surgery, decreased pain intensity in the PACU and PONV during the first 24 hours postoperatively. Results from this study suggest that multimodal analgesia should be used in an effort to reduce opioid consumption and adverse effects in children undergoing surgery.*

Morton NS, Errera A. APA national audit of pediatric opioid infusions. *Pediatr Anesth* 2010;20:119-25.

*This very large prospective audit of opioid infusions of all types (continuous, PCA, NCA) confirmed the safety of these techniques, but highlights the potential complications and pitfalls that are always present. Respiratory depression and pump programming errors each occurred in about 1 of 766 cases and 1 of 631 cases respectively, and there was one permanent injury (1 of 10,000 cases).*

Polaner DM, Taenzer AH, Walker BJ, et al. Pediatric Regional Anesthesia Network: a multi-institutional study of the use and incidence of complications of pediatric regional anesthesia. *Anesth Analg* 2012 Jun 13 [Epub ahead of print].

*This is the first report from this network in the United States that prospectively examined the incidence of adverse events and complications in nearly 15,000 regional blocks in children. There were no permanent complications detected. PRAN now has over 37,000 cases accrued. These data are similar to those reported in the French study.*<sup>468</sup>

Voepel-Lewis T, Burke CN, Jeffreys N, et al. Do 0-10 numeric rating scores translate into clinically meaningful pain measures for children? *Anesth Analg* 2011;112:415-21.

*This study provides important information regarding the clinical interpretation of NRS pain scores in children. >10 NRS scores were found to be reliably associated with the child's perceived need for medicine, perceived pain relief, and satisfaction with pain treatment. However, a significant overlap in scores associated with the above outcomes suggests that the use of specific cutoff scores to guide treatment decisions would be inappropriate in children.*

# Appendix 43-1 Clinical Examples of Postoperative Analgesic Management Strategy

43

## Case 1

A 2-year-old child, ASA 1 (American Society of Anesthesiologists physical status classification system, category 1), presented for inguinal hernia repair, weight 15 kg.

### CONSIDERATIONS

- Mildly painful surgery
- Outpatient setting—avoidance of nausea and oversedation is helpful

### ALTERNATIVES

1. Ilioinguinal nerve block: bupivacaine 0.25% with epinephrine 1:200,000, 0.5 mL/kg  $\times$  15 kg = 7.5 mL (3.75 mL on each side)
2. Wound infiltration with bupivacaine 0.25% with epinephrine 1:200,000, 0.5 mL/kg  $\times$  15 kg = 7.5 mL (3.75 mL on each side)
3. Caudal block using bupivacaine 0.125% to 0.25% with epinephrine 1:200,000, 0.5 to 0.75 mL/kg  $\times$  15 kg = 7 to 11 mL
4. Add acetaminophen, 10 to 15 mg/kg every 4 to 6 hours (oral), or ibuprofen, 6 to 10 mg/kg every 6 hours, as needed at home.

## Case 2

A 6-month-old, 6-kg child, ASA 1, presented for ureteral reimplantation.

### CONSIDERATIONS

- Moderately painful surgery, bladder spasms
- Urinary retention is not an issue
- Pain assessment using behavioral tools such as FLACC

### ALTERNATIVES

1. Epidural analgesia
  - Need to cover approximately 10 dermatomes (5 sacral, 5 lumbar); initial bolus,  $10 \times 0.05$  mL/kg/dermatome  $\times$  6 kg = 3.0 mL.
  - Bupivacaine 0.1% with fentanyl, 2  $\mu$ g/mL, starting at 0.2 mL/kg/hr  $\times$  6 kg = 1.2 mL/hr
  - Apnea monitoring, pulse oximetry, and frequent observation
  - Add acetaminophen as needed, 10 to 15 mg/kg every 4 hours (oral) or 10 mg/kg every 6 hours (IV), or 35 to 40 mg/kg initial dose (rectal) followed by 20 mg/kg every 6 hours (rectal) not to exceed 100 mg/kg/day (rectal).
  - Add ketorolac 0.5 mg/kg every 6 hours for 48 hours for bladder spasms as needed.
2. Continuous intravenous morphine infusion
  - Loading dose of up to 0.075 to 0.1 mg/kg  $\times$  6 kg = 0.45 to 0.6 mg in incremental doses if needed
  - Infusion starting at 0.02 mg/kg/hr (20  $\mu$ g/kg/hr)  $\times$  6 kg = 0.12 mg/hr
  - Apnea monitoring, continuous pulse oximetry, and frequent observation
  - Add acetaminophen as needed.

### 3. Nurse-controlled analgesia with morphine

- Loading dose 0.05 to 0.1 mg/kg  $\times$  6 kg = 0.3 to 0.6 mg administered via PCA pump in PACU
- Continuous basal infusion of 0.01 to 0.02 mg/kg/hr
- Bolus dose of 0.02 to 0.03 mg/kg
- Lockout interval: 8 to 15 minutes
- Four-hour limit of 0.25 to 0.3 mg/kg
- Apnea monitoring, continuous pulse oximetry, and frequent observation
- Add acetaminophen as needed.

## Case 3

A 6-week-old, 3-kg child, ASA 3, presented for thoracoabdominal incision for excision of a Wilms tumor.

### CONSIDERATIONS

- Painful surgery
- Pain assessment using behavioral tools such as FLACC
- Impairment of respiration
- Many dermatomes involved
- Bladder catheter warranted

### ALTERNATIVES

1. A continuous epidural infusion (catheter inserted through the caudal approach and threaded to the mid-portion of the surgical incision)
  - Need to cover approximately 16 dermatomes (5 sacral, 5 lumbar, 6 thoracic): Initial bolus  $16 \times 0.05$  mL/kg/dermatome  $\times$  3 kg = 2.4 mL loading dose. The infusion could be chloroprocaine 1.5% with fentanyl 0.4  $\mu$ g/mL or chloroprocaine 1.5% with clonidine 0.2  $\mu$ g/mL
  - To be infused at a starting rate of 0.3 mL/kg/hr up to 1.2 mL/kg/hr
  - Apnea monitoring, continuous pulse oximetry, and frequent observation
  - *Note that the concentration of clonidine and fentanyl per mL of local anesthetic solution is reduced compared with that which would be used with older children because of the more rapid epidural infusion rate used to take maximal advantage of the local anesthetic.*
2. Nurse-controlled analgesia with morphine
  - Loading dose of 0.05 to 0.1 mg/kg  $\times$  6 kg = 0.3 to 0.6 mg administered via PCA pump in PACU
  - Continuous basal infusion of 0.01 to 0.02 mg/kg/hr
  - Bolus dose of 0.02 to 0.03 mg/kg
  - Lockout interval: 8 to 15 minutes
  - Four-hour limit of 0.25 to 0.3 mg/kg
  - Apnea monitoring, continuous pulse oximetry, and frequent observation
  - Add acetaminophen as needed 10 to 15 mg/kg every 4 hours (oral) or 35 to 40 mg/kg initial dose (rectal) followed by 20 mg/kg every 6 hours (rectal) not to exceed 100 mg/kg/day. IV acetaminophen 10 mg/kg every 6 hours may also be added.

## Case 4

An 8-year-old, 18-kg girl with cerebral palsy, severe cognitive impairment, ASA 3, presented for femoral osteotomy.

### CONSIDERATIONS

- Painful surgery
- Altered/individual pain behaviors: use specific tools for pain assessment such as r-FLACC
- Potential for altered pain perception
- Increased risk of opioid-induced respiratory depression
- May need benzodiazepines for muscle spasms

### ALTERNATIVES

1. Continuous epidural analgesia
  - Need to cover approximately 10 dermatomes (5 sacral, 5 lumbar); initial bolus,  $10 \times 0.05 \text{ mL/kg/dermatome} \times 18 \text{ kg} = 9 \text{ mL}$ .
  - Bupivacaine 0.1% with fentanyl,  $2 \mu\text{g/mL}$ , starting at  $0.2 \text{ mL/kg/hr} \times 18 \text{ kg} = 3.6 \text{ mL/hr}$
  - Apnea monitoring, pulse oximetry, and frequent observation
  - Add acetaminophen as needed, 10 to 15 mg/kg every 4 hours (oral) or 35 to 40 mg/kg initial dose (rectal) followed by 20 mg/kg every 6 hours (rectal) not to exceed 100 mg/kg/day (rectal). IV acetaminophen 10 mg/kg every 6 hours may also be added.
2. Femoral nerve, fascia iliaca, or lumbar plexus block
  - There is the need to block the distribution of the femoral nerve and possibly (depending on the location of the incision) the lateral femoral cutaneous and obturator nerves.
    - Single-injection block of the peripheral nerves will provide analgesia for 8 to 16 hours; a continuous catheter technique will provide greater duration of analgesia.
    - Blockade of just the upper leg is provided without risks of urinary retention or motor block of the contralateral leg
    - 0.2% ropivacaine or 0.125% to 0.25% bupivacaine; initial dose of  $0.3 \text{ mL/kg} = 5.4 \text{ mL}$ , followed by infusion of  $0.2 \text{ mL/kg/hr} = 3.6 \text{ mL/hr}$
    - Add acetaminophen and diazepam as needed.
3. Continuous intravenous morphine infusion
  - Loading dose of up to  $0.05 \text{ to } 0.1 \text{ mg/kg} \times 18 \text{ kg} = 0.9 \text{ to } 1.8 \text{ mg}$  in incremental doses if needed
  - Infusion starting at  $0.02 \text{ mg/kg/hr}$  ( $20 \mu\text{g/kg/hr}$ )  $\times 18 \text{ kg} = 0.36 \text{ mg/hr}$
  - Apnea monitoring, continuous pulse oximetry, and frequent observation
  - Add acetaminophen as needed.
  - Consider IV/PO diazepam, 0.05 mg/kg, for muscle spasms.
4. Nurse-controlled analgesia with morphine
  - Loading dose  $0.05 \text{ to } 0.1 \text{ mg/kg} \times 18 \text{ kg} = 0.9 \text{ to } 1.8 \text{ mg}$  administered via PCA pump in PACU
  - Continuous basal infusion of 0.01 to 0.02 mg/kg/hr
  - Bolus dose of 0.02 to 0.03 mg/kg
  - Lockout interval: 8 to 15 minutes
  - Four-hour limit of 0.25 to 0.3 mg/kg
  - Apnea monitoring, continuous pulse oximetry, and frequent observation
  - Add acetaminophen as needed.
  - Consider IV/PO diazepam, 0.05 mg/kg, for muscle spasms.

## Summary

THE PRACTICING PEDIATRIC ANESTHESIOLOGIST sees chronic pain in one of three main venues: a child coming to the operating room for a procedure, after a request for a consultation from a colleague of another specialty, or when making acute pain management rounds. In this chapter, we focus on the essential approaches to children with chronic pain and provide guidelines to help the children and colleagues who request your assistance.

## Chronic Pain in Children

Chronic pain affects a large number of children.<sup>1</sup> Back pain has been reported in up to 50% of children by the mid-teens,<sup>2</sup> and abdominal pain occurs weekly in up to 17%.<sup>3</sup> Other conditions such as headaches, complex regional pain syndrome (CRPS), fibromyalgia, limb pain, chest pain, and joint pain are common and affect quality of life.<sup>4-7</sup>

Several chronic medical conditions are strongly associated with pain and blur the boundaries between acute and chronic pain treatment, including sickle cell disease, cystic fibrosis,<sup>8</sup> epidermolysis bullosa,<sup>9</sup> and cancer. These children require frequent hospitalizations, and their pain can be severe. Because the children present with pain in the hospital, treatment often follows the model for acute pain management based on medication use. However, psychosocial factors heavily influence the child's ability to cope and can improve or worsen the child's suffering, depending on personal and family factors.<sup>10,11</sup> It is appropriate to seek psychology, child life, and physical therapy consultations as part of the therapeutic plan. The ultimate goal for each of these medical conditions is to stabilize the child's condition and return her or him home. For many, the painful disease and dysfunction continue, and having a long-term plan that is integrated with acute management is vital.

## Multidisciplinary Approach

The model of care that appears to work optimally for children with chronic pain is one in which multiple disciplines are involved in developing a coordinated care plan.<sup>4,12</sup> In the outpatient setting, there is a pain physician, a psychologist, nurses, and a physical therapist. Sometimes, a neurologist or psychiatrist may be involved. Anesthesiologists managing children with chronic pain should make use of these disciplines when recommending a plan of care. Advocating for the involvement of other therapeutic specialties can advance the patient's care beyond suggesting a regional block or medication.

## THE PAIN PHYSICIAN

The consulting anesthesiologist in an inpatient setting may be called on to provide care for one of three reasons. First, the patient may need a regional nerve block, such as an epidural steroid injection for magnetic resonance imaging-confirmed discogenic pain or epidural catheter placement to assist physical therapy. This consultation is fairly straightforward and is an extension of basic regional anesthesia principles. Second, a child who has been prescribed opioids chronically or other medications that have implications for anesthesia or postoperative pain management may present for consultation. The anesthesiologist must investigate possible drug interactions and determine which chronic medications have been prescribed; this approach is an extension of basic perioperative anesthesia skills. Third, a consultation may be requested to assess and diagnose the source of pain. This scenario is the most complex and requires taking a detailed history and performing a thorough physical examination. These children often require multidisciplinary care beginning with the initial evaluation and extending through treatment.

### THE PSYCHOLOGIST

Pain is more than just a physical phenomenon. It can cause and be worsened by stress, suffering, family dysfunction, social tension, anxiety, and depression.<sup>5,13</sup> Pain can disrupt almost any aspect of the life of the child or family. Family and school problems can worsen a painful condition and dramatically reduce a child's level of function. The family is always involved in the child's suffering and should therefore be included in the pain evaluation process.

Families often are wary about seeing a psychologist and are afraid of being stigmatized. It is important to emphasize that pain is what the child says it is, regardless of whether an obvious organic cause is identified. The child is being treated as a person, not just as the painful body part, and this approach should be emphasized for the child's family.

Psychology-based therapy includes relaxation training, biofeedback, hypnotherapy, coping skills training, and psychotherapy. Biofeedback is a modality that trains the child to become more aware of his or her body, enhancing the sense of control over it. Therapies aimed at parental and familial aspects of the child's pain include teaching strategies for behavioral interventions (e.g., distraction), activity pacing, consistent discipline, coaching skills training, stress management, and occasionally, family therapy.

### THE PHYSICAL THERAPIST

Physical therapy is a crucial component of evaluating and treating chronic pain. The painful condition can cause loss of muscle strength and range of motion. Alterations in the use of a limb affect the biomechanics and daily function of the body. Children can become deconditioned and require a conditioning program to regain lost strength and stamina. These changes affect the original pain site and generate secondary pain problems that need to be addressed.

Physical therapy can benefit many painful conditions (e.g., myofascial pain improves with stretching and range-of-motion exercises) and is the cornerstone of treatment for others (e.g., chronic regional pain syndromes [CRPS]).<sup>14</sup> Emphasizing self-reliance and responsibility for their own care is an important aspect of caring for adolescents. However, young children and older ones in pain cannot be expected to work aggressively at home without beginning with a structured program. Parental involvement is especially important for younger children, but the caretakers must be taught to be encouraging and supportive while not making them the child's taskmasters.

Therapies provided by physical therapy include stretching, strengthening, and reconditioning programs. Range-of-motion exercises and endurance training are also important. Aquatic therapy is very useful for children who cannot bear weight on lower limbs or have limited range of motion or strength. Massage, heat, and cold therapies are helpful adjuncts to increase functioning and enhance other physical therapy modalities.

Transcutaneous electrical nerve stimulation (TENS) is an effective,<sup>15</sup> low-risk, analgesic therapy that is usually provided under the guidance of a physical therapist. TENS is excellent for localized pain. The fact that it is portable, can be used discreetly, and has few side effects makes it attractive for use at school. Because tolerance to TENS can develop with prolonged use, children need to limit use to no longer than 2 hours at a time. They can take a break for an amount of time equal to the TENS use and then restart it.

### THE NURSE

Pain nurses play a major role in hospital-wide education of floor nurses regarding assessment and treatment of pain, including the use of epidural and patient-controlled analgesia (PCA) pumps. When starting to see chronic pain patients, the first personnel recruitment should be an advanced practice nurse who can be trained to triage, perform the initial evaluation and intake assessment, and assist with all subsequent pain-related issues that do not require the direct input of a physician.

### THE CONSULTANT

Anesthesiologists should be cognizant of their limitations and judiciously use of consultants to help make or confirm diagnoses and fashion the best treatment plan. Neurologists typically are well versed in headache management and in the use of many of the medications used for neuropathic pain. Physical medicine and rehabilitation specialists can assist in structuring a treatment plan for a variety of musculoskeletal pains and are accomplished in the treatment of spasticity.

## General Approach to Management

Most children with chronic, noncancer pain are adolescents who require special considerations in terms of their history and physical examination. Because they are between childhood and adulthood, their behavior can fluctuate broadly and often. It is important to address them directly but also involve the parents to the extent needed to obtain the relevant and complete history. The clinician should not try to be "cool" with the adolescent patient, because teenagers tend to find that approach condescending and will respond negatively. The examiner should instead find a point of common interest and use it to establish greater rapport.

Adolescents tend to be very image conscious. They may or may not want to discuss body functions such as defecation or menstruation, even when these functions are directly relevant to the problem. If patients seem uneasy with the questions, the physician should proceed in a straightforward manner, acknowledge their feelings, and reassure them that the information is needed to help them. When discussing these pediatric patients with parents, clinicians should use a phrase such as "children and young adults" rather than just "children" because even 12 and 13-year-olds like to think they are no longer children.

### HISTORY

The basic history focuses on the pain: location, duration, quality, intensity, aggravating and alleviating factors, associated symptoms, therapies that have been tried, and which tests have been performed and by whom. Pain intensity is often assessed by a 0 to 10 numeric rating scale for children older than approximately 8 years of age. The child must be asked about the current pain level and about the best and worst pain levels to obtain an idea of the pattern of pain and when it peaks. Quality descriptors include *burning*, *sharp*, *aching*, *throbbing*, *tingling*, *numb*, *weird*, and others; each may give a clue about the type of pain the child is experiencing. Odd descriptors, burning, and tingling suggest neuropathic pain; sharp, tight, and aching may indicate bony or muscular causes; throbbing suggests a vascular component; cramping or pain that comes in waves often suggests spasms of a muscle or hollow viscus.

A vital part of the chronic pain evaluation process is to look for *red flags*, which are signs or symptoms that may indicate a

serious illness. Some of the red flag signs and symptoms for major pain types can be found in Tables 44-1, 44-2, and 44-3. For example, a child with back pain who also has weak legs and incontinence may have a tethered spinal cord. Headache that is worse in the morning and associated with vomiting suggests increased intracranial pressure. Back pain with loss of ankle jerk suggests compression of the S1 nerve root.

A complete pain evaluation comprises further history regarding medications, allergies, family history, and a thorough review of systems. Certain painful conditions, such as migraine headaches,<sup>16</sup> fibromyalgia,<sup>17</sup> irritable bowel syndrome,<sup>18</sup> and sickle cell disease, have a genetic basis. Knowing the family history can assist in making the diagnosis. The child sometimes may model his or her behavior after a family member. For example, if a

parent has a “bad back” and is functionally compromised, the child also may complain of back pain. This does not mean the child is faking the complaints but simply patterning the behavioral response to pain after a model that he or she understands. Treatment can include reassurance, cognitive behavioral therapy, and gentle physical therapy to restore the child’s functional ability and help him or her with any underlying issues. Family and social histories can be useful in fashioning a treatment plan in conjunction with the general history, physical examination, and relevant testing.

### PHYSICAL EXAMINATION

The physical examination should focus on the area of interest, but a brief general examination is also important. A full screening examination, including a neurologic examination, takes only a few minutes and can be combined with the social history. A systemic illness may manifest as a localized complaint; for example, diabetes can manifest as abdominal pain or leukemia as focal bone pain.

When examining a child of the opposite sex, the physician should have a nonfamily observer of the same gender as the child present. Some children are very conscious of their bodies and may consider routine examination maneuvers as invasions of their privacy. The occasional child has a history of being abused and can be further traumatized by even a standard examination. Physicians can demonstrate examination techniques that may make the child uneasy. For example, a pinprick examination requires a needle or sharp object; the examiner should touch his or her own skin with a pin first to demonstrate that blood is not being drawn. Children are often fascinated by the deep tendon reflexes and usually have fun with that examination. Children with chronic pain often have had many examinations, and doing something a little different or fun can help them accept the current evaluation and enhance rapport.

### ANCILLARY DATA

By the time chronic pain patients have reached a pain clinic, they usually have undergone several investigative tests, and those data should be reviewed. After it becomes clear that there is no life-threatening illness, the focus should shift away from further testing. This is often a hard transition for families and children to accept, especially if no concrete diagnosis has been made to explain the pain. It is a challenge for them to embrace the thought that the pain itself is the disease rather than something that is still undiagnosed. Any study that may help to explain the pain or make a diagnosis that had not been entertained should be recommended. However, pursuing tests and imaging in an unfocused manner wastes resources and causes families to postpone treatment while waiting for a diagnosis. Until the patient wholeheartedly endorses the treatment plan and becomes active in it, the child or adolescent’s pain will continue unabated.

## Chronic Pain Conditions

Any part of the body can hurt, but in practical terms, several diagnostic clusters represent most pediatric pain conditions. The frequency and intensity of the pain can be striking. One study on the 3-month prevalence, characteristics, consequences, and provoking factors of chronic pain described the experience of 749 children and adolescents in one elementary and two secondary schools<sup>19</sup>: 83% experienced pain during the preceding 3 months. The leading sources of pain were headaches (60.5%,

**TABLE 44-1 Red Flag Signs and Symptoms for Abdominal Pain**

Persistent right upper or right lower quadrant pain
Dysphagia
Persistent or cyclic vomiting
Gastrointestinal blood loss
Family history of inflammatory bowel disease, celiac disease, or peptic ulcer disease
Pain that wakes the child from sleep
Arthritis
Nocturnal diarrhea
Involuntary weight loss
Deceleration of linear growth
Delayed puberty
Unexplained fever
Hepatosplenomegaly, masses, or perianal lesions
Bilious emesis
Costovertebral angle tenderness

**TABLE 44-2 Red Flag Signs and Symptoms for Secondary Headache**

Persistent vomiting
Focal neurologic signs
Meningeal signs
Unexplained fever
Increased intracranial pressure
Changes in behavior or mental status
Sudden onset of severe headache
Morning headaches
Headaches awakening the child from sleep

**TABLE 44-3 Red Flag Signs and Symptoms for Back Pain**

Unexplained fever
Night sweats
Weight loss
Night pain
Constant pain
Bowel function changes
Urinary retention
Neurologic changes in legs: trouble walking, footdrop, weakness, loss of reflexes, sensory changes

also perceived as most bothersome), abdominal pain (43.3%), extremity pain (33.6%), and back pain (30.2%). Many subjects reported associated sleep problems, restriction in hobbies, and eating problems. School absenteeism reached 48.8% in the population with pain. The use of health care resources by children and adolescents with pain was extensive: 50.9% visited the physician's office, and 51.5% reported use of pain medication.

### ABDOMINAL PAIN

Abdominal pain is a major source of distress in children that causes anxiety and invites a large amount of testing. This painful condition, formerly referred to as *recurrent abdominal pain*, is now described as *functional gastrointestinal disorders* (FGIDs).<sup>20</sup> Specific criteria exist for the major categories so that FGIDs are no longer considered diagnoses of exclusion. The pain is thought to be caused by abnormal interactions between the enteric nervous system and central nervous system.<sup>21</sup> Research suggests that peripheral sensitization and abnormal central processing of afferent signals at the level of the central nervous system play roles in the pathophysiology of visceral hyperalgesia—a decreased threshold for pain in response to changes in intraluminal pressure.<sup>22</sup> The history and physical examination focus on excluding warning signs and symptoms of underlying disease (see Table 44-1).<sup>20,23</sup> The role for testing, endoscopy, and radiographic evaluation is limited.

Multidisciplinary treatment of FGIDs includes medication, psychological interventions, and education, which often need to be ongoing. The most important aspect of the treatment plan is to establish realistic goals, which frequently means return of function rather than complete elimination of pain. Although the literature for treatment is sparse, tricyclic antidepressants such as amitriptyline, nortriptyline, or doxepin have been used effectively for FGID-related pain. Anticonvulsants also are useful because they modify nerve conductivity and transmission. Antacids, antispasmodic agents, smooth muscle relaxants, laxatives, and antidiarrheal agents can be added to address symptoms. Data support the use of peppermint oil capsules in managing irritable bowel syndrome, although gastroesophageal reflux can be a limiting adverse effect.<sup>24</sup> Children with functional bowel disorders can have abnormal bowel reactions to physiologic stimuli, noxious stressful stimuli, or psychological stimuli (e.g., parental separation, anxiety). Children benefit from cognitive-behavioral therapy, coping skill development, biofeedback, hypnosis, and relaxation techniques (Table 44-4).<sup>25,26</sup>

### HEADACHE

Headaches can be categorized as primary or secondary. Primary headaches include migraine, tension, cluster, and trigeminal neuralgia headaches. Secondary headaches are those attributable to head and neck traumas; muscle spasms; vascular disorders; non-vascular intracranial disorders; infection; eye, ear, cranium, nose, sinus, and teeth or mouth diseases; homeostatic disturbances; and psychiatric disorders. Headaches represent one of the more poorly tolerated types of chronic pain, with greater medication use than for other types. Of 77 children with long-term headaches who were followed up to 20 years after the initial diagnosis, 27% were headache free, and 66% had improved.<sup>27</sup>

Migraines (especially migraine without aura) and tension-type headaches are the most common types of pediatric headaches. The prevalence of migraine ranges from 2.7% to 10%. It occurs more frequently in boys than girls between 4 and 7 years of age, and then the prevalence equalizes between 7 and 11 years of age.

**TABLE 44-4** Care Pathway for Abdominal Pain

<b>Evaluation</b>
Medical examination
Behavioral medicine assessment
Review of records, treatments, history, and physical findings
Consultations with pediatrics, surgery, and gastroenterology specialists as indicated by presence of red flags; assessment may include laboratory testing, ultrasound, computed tomography or magnetic resonance imaging, endoscopy, lactose testing
<b>Treatment of Functional Gastrointestinal Disorders</b>
<i>Medications:</i> tricyclic antidepressants; consider selective serotonin reuptake inhibitors or serotonin-norepinephrine reuptake inhibitors; peppermint oil
<i>Behavioral medicine:</i> important and effective to de-medicalize therapy; de-emphasize testing and search for organic diagnoses; redirect focus to treatment and improved function
<i>Physical therapy:</i> not usually involved; trial of transcutaneous electrical nerve stimulation (TENS) if abdominal wall origin found
<i>Other therapy:</i>
Blocks are rare, except in palliative situation; celiac plexus with local anesthetic and steroid; epidural
Trigger point injections if abdominal wall trigger points found
Acupuncture
Hypnosis
Meditation
Dietary management

After 11 years of age, three times more girls than boys have migraines.<sup>28,29</sup> Studies are not routinely recommended in the absence of focal neurologic findings. However, the practitioner must be alert to red flag signs and symptoms that warrant imaging and laboratory studies to rule out an underlying condition as a cause of the headaches (see Table 44-2).

There is a genetic component to migraine and chronic tension headaches; 50% to 77% of children with migraines have a positive family history for migraine headaches, especially on the maternal side. The clearest genetic link has been established for familial hemiplegic migraine.<sup>16</sup>

Children with frequent headaches often suffer from medication overuse headaches due to chronic or repeated use of over-the-counter analgesics. If possible, children should be weaned off analgesics gradually.

Treatments for migraine and tension-type headaches overlap greatly. Pharmacologic interventions can be divided in two types. In the first, abortive treatment focuses on stopping the acute headache. In the second, prophylactic therapy is indicated for patients with more than two headaches per month, for children with severe attacks, and for those with frequent headaches unresponsive to medication (Table 44-5).<sup>30</sup>

Older medications that have been used successfully to prevent headaches in adolescents include amitriptyline and trazodone. These medications tend to make children drowsy and are prescribed 30 to 60 minutes before bedtime each night. Younger children appear to respond well to the antihistamine cyproheptadine. Overall, few evidence-based recommendations can be made; the lack of randomized, controlled pediatric trials precludes an evidence-based recommendation.<sup>31</sup> However, the anticonvulsant topiramate is a promising medication for the prevention of migraine headaches.<sup>32-34</sup>

Evaluation
Medical examination
Behavioral medicine assessment
Physical therapy if neck or upper back tightness occurs
Review of records, treatments, history, and physical findings
Magnetic resonance imaging and neurology consultations as indicated by red flag signs and symptoms
Treatment
<i>Medications:</i> tricyclic antidepressants, topiramate, trazodone, cyproheptadine
<i>Behavioral medicine:</i> biofeedback, relaxation, coping and pacing skills
<i>Physical therapy:</i> transcutaneous electrical nerve stimulation (TENS) unit on shoulders, posterior neck; stretching
<i>Other therapy:</i>
Yoga
Acupuncture
Meditation
Occasional neck trigger point injection or occipital nerve block

**TABLE 44-6** Care Pathway for Complex Regional Pain Syndromes

Evaluation
Medical examination
Behavioral medicine assessment
Physical therapy assessment
Review of records, treatments, history, physical findings, and radiographic studies
Treatment
<i>Medications:</i> tricyclic antidepressants, gabapentin, oxcarbazepine
<i>Behavioral medicine:</i> very important, especially in refractory cases
<i>Physical therapy:</i> activate, range of motion, desensitization, strength training. Structured home program extremely important; may use transcutaneous electrical nerve stimulation (TENS) unit
<i>Other therapy:</i>
Consider intravenous regional block for hand or foot
Consider lumbar sympathetic block catheter and admission for structured program for lower extremity complex regional pain syndrome (CRPS) that is refractory despite best efforts of patient and family
Consider high thoracic epidural or continuous brachial plexus catheter for upper extremity CRPS

### COMPLEX REGIONAL PAIN SYNDROME

Type I and type II CRPS are different only in the presence of a documented nerve injury in type II (formerly called *causalgia*). Pain is an obligatory feature, often occurring alongside allodynia or hyperalgesia. There must be evidence at some time (not necessarily at the time of diagnosis) of edema, changes in skin blood flow, or abnormal sudomotor activity in the region of pain. There are often features of a motor disorder such as tremor, dystonia, and weakness that sometimes lead to a loss of joint mobility. Nail and hair growth can also be affected. In the past, three distinct stages were described. However, it may be that there are phenotypic subtypes instead of stages.<sup>35</sup>

From a clinical standpoint, the typical pediatric CRPS patient is older than 10 years of age, Caucasian, female, and very active or a high achiever from an active family, and the child or adolescent presents with lower extremity pain.<sup>36</sup> A genetic predisposition is suggested by the clinical observation that CRPS is rare in the African American population. The rarity of CRPS in preadolescent children suggests a developmental aspect to its origin.

It is important to obtain a detailed history of the mechanism of trauma and the signs and symptoms. The examiner should specifically look for pain, allodynia, hyperalgesia, and hyperpathia. Edema and color changes do not have to be present at the time of diagnosis, but there should be a history of such changes in the recent past (Fig. 44-1). A complete neurologic examination includes testing muscle strength, reflexes, sensory responses (e.g., cold, touch, pinprick), capillary refill, temperature, and color differences. The physician should also look for deep tissue hyperalgesia. Occasionally, noninvasive or invasive testing may be helpful, but it is not sensitive or specific. These evaluations may include an electromyogram with nerve conduction velocity (EMG/NCV), quantitative sensory testing (QST), and quantitative sudomotor axon reflex testing (QSART) to detect small fiber dysfunction; thermography; and bone scans. Sympathetic ganglion blocks are not considered necessary for diagnosis, but they can be part of the therapeutic approach.

The therapeutic goal for CRPS is restoration of function. It may seem simple, but in daily practice, this may represent the

**FIGURE 44-1** Complex regional pain syndrome involves the patient's left foot and ankle. Notice the cyanosis and mottling. The affected foot was cool, and allodynia was prominent. Left foot toenails had not been trimmed in 3 months.

biggest challenge for the physician and the child. The therapeutic approach to the child with CRPS is multidisciplinary, with a focus on the psychosocial and physical aspects of the disease (Table 44-6). Education is important, and the information available on the Internet is ubiquitous, although it is often discouraging and not applicable to children with CRPS. No isolated treatment technique has been helpful for this condition. Children and physicians should follow an algorithm and adjust the therapeutic strategy every 4 weeks if the child does not respond satisfactorily to chosen measures.

The mainstay of CRPS treatment is physical therapy. However, the pain can be severe and disabling enough to prevent active

participation by the child in the physical therapy program. Pharmacologic therapy is often initiated to facilitate physical therapy. Medications for neuropathic pain (described later) take time to titrate to effect. It is reasonable to use nonsteroidal antiinflammatory drugs (NSAIDs) and opioids for a short time until the primary medications take effect. The psychology team must play an active role in the overall treatment program. Psychosocial issues must be aggressively addressed. With physical therapy, psychology, and medications, most children achieve good results and disease resolution. In unusual refractory cases, for which interdisciplinary outpatient programs are insufficient, inpatient pain rehabilitation programs are recommended.

The role of interventional therapy in the treatment of CRPS is to alleviate the pain and provide the child with the opportunity to tolerate and advance in physical therapy. Sympathetic nerve blocks are widely used in adults although a systematic review revealed a lack of randomized, controlled trials to confirm the effectiveness of this approach in short-term and long-term pain relief.<sup>37</sup> Interventional therapies can be a double-edged sword, representing an easy solution that can demotivate the child from taking an active role in his or her physical therapy. However, pain may be too severe to allow physical therapy and thereby accelerate loss of function.

Several techniques enjoy popularity among pediatric pain specialists. For isolated limb CRPS, intravenous regional blockade with local anesthetic and adjuncts such as clonidine, ketamine, or ketorolac is performed. General anesthesia or deep sedation is frequently required because placement of intravenous catheters in the affected limb and inflation of the tourniquet are poorly tolerated. More invasive alternatives include placement of a lumbar sympathetic plexus catheter (Fig. 44-2) and a tunneled epidural catheter in the upper thoracic or lumbar area. The duration of infusion ranges from 3 to 5 days to as long as 4 to 6 weeks, and the procedure requires extensive logistical support. An alternative approach is to place a peripheral nerve catheter for a continuous block.<sup>38</sup> Spinal cord stimulation and intrathecal drug delivery are rarely used for pediatric CRPS due to the overall good prognosis with more conservative treatment and the continued growth of the skeleton, which can change the area of paresthesias in the case of spinal cord stimulators.

## MUSCULOSKELETAL AND RHEUMATOLOGIC PAIN

Musculoskeletal pain is a recognized problem in children and adolescents, and back pain commonly affects adolescents.<sup>39,40-42</sup> Although many factors are blamed for musculoskeletal pain (e.g., heavy backpacks, participation in sports, sedentary lifestyle, scoliosis, increased body mass index), only a few have been proved to contribute to musculoskeletal pain. According to one study, in more than half of cases the cause could not be identified, and only a minority of children had an underlying disease process (e.g., spondylolysis, infection, tumor, disk problem). Radiologic findings correlated poorly with the pain and failed to distinguish between individuals with pain and those without pain.<sup>42</sup> Selected red flags for back pain are provided in Table 44-3. A care pathway for the evaluation and treatment of back pain in children and adolescents is presented in Table 44-7.

A special group of children with musculoskeletal pain are those with rheumatologic diseases. Most children referred to the rheumatologist's office complain of musculoskeletal pain. Only some of them are diagnosed with a true rheumatologic disease; juvenile idiopathic arthritis is the most common form. Besides pain, the diseases often manifest as morning stiffness, fatigue, and sleep problems. The process may progress and cause joint deformities and destruction due to osteoporosis, with resulting growth abnormalities and functional disability. Management combines pharmacologic and nonpharmacologic interventions. The mainstay of therapy is the use of NSAIDs, acetaminophen, and rarely, opioids for severe breakthrough pain. The rheumatologist may prescribe agents such as methotrexate, cyclophosphamide, or systemic corticosteroids for severe flare-ups. Splints, physical therapy, and psychological interventions such as cognitive-behavioral therapy are often used.<sup>43</sup> Children with Ehlers-Danlos syndrome or other connective tissue disorders suffer from unstable joints that become very painful from repeated dislocations and mechanical stress.

Some young women present with fatigue, poor sleep, and pain or unusual tenderness in multiple sites. Fibromyalgia is more common in adolescents than expected, and it can be a significant problem. Therapy includes education, medications, and general restorative therapy, with a focus on aerobic reconditioning. Traditionally, tricyclic antidepressants and cyclobenzaprine have

**FIGURE 44-2** Lumbar sympathetic block. **A**, In the lateral view, the Tuohy needle is in the proper position. Notice the prepsoas spread of contrast agent. **B**, The dye spreads and clears due to injection of local anesthetic through the catheter. The catheter is tunneled and can be left in place for a week.

**TABLE 44-7** Care Pathway for Back Pain

<b>Evaluation</b>
Medical examination
Behavioral medicine assessment
Physical therapy assessment
Review of records, treatments, history, and physical findings
Consultation with specialists in orthopedics; magnetic resonance imaging or computed tomography, as indicated by history and examination findings
<b>Treatment</b>
<i>Medications:</i>
Tricyclic antidepressants
Muscle relaxants (e.g., baclofen, cyclobenzaprine)
Anticonvulsant (if radicular component)
Nonsteroidal antiinflammatory drug of choice
Cyclooxygenase-2 inhibitor for gastrointestinal or bleeding issues
If disk disease with radicular pain is documented, up to three epidural steroid injections may be helpful
<i>Behavioral medicine:</i> biofeedback, coping skills, and relaxation techniques
<i>Physical therapy:</i>
Stretching, postural rehabilitation, general reconditioning, and lifting techniques
Limit bed rest; reactivate
Transcutaneous electrical nerve stimulation (TENS)
Exercise program
<i>Other therapy:</i>
Acupuncture
Yoga
Chiropractic (older patients, lumbar only)
Massage
Trigger-point injections
Additional modalities for specific indications include back bracing, surgery, bisphosphonate therapy

been used, and duloxetine and milnacipran are helpful in adults.<sup>44,45</sup> As with many chronic pain conditions, cognitive-behavioral approaches are valuable components of treatment.<sup>46</sup>

Musculoskeletal pain is a particularly difficult problem in children with cerebral palsy.<sup>47</sup> Spasticity itself can be painful, and the daily stretching exercises are reported to be painful by many children. Some children with cerebral palsy are nonverbal, making assessment even more difficult. The parents or guardians can provide information about how the child expresses pain and how the pain manifests during daily life. If diaper changes seem to hurt, the practitioner should suspect hip or perineal pain. Pain after eating or a history of hard stools may point to constipation-based abdominal pain. A careful and sometimes staged examination is required. A thoughtful, empirical approach to therapy and judicious use of radiologic and laboratory evaluations can often lead to the diagnosis (Table 44-8).

#### **PAIN IN SICKLE CELL DISEASE, TRAIT, AND VARIANTS**

Sickle cell disease is a hereditary disorder characterized by abnormal hemoglobin S (see Chapter 9). About 8% of African Americans carry the sickle gene. The homozygous form (sickle cell disease [HbSS]) manifests as a hemolytic anemia with unique vaso-occlusive features. The heterozygous form (sickle cell trait [HbAS]) is milder and manifests as a borderline anemia and rarely with vaso-occlusive features. Sickle cell/hemoglobin C disease

**TABLE 44-8** Care Pathway for Nonverbal Patients

<b>Evaluation</b>
Medical examination
Often tricky; go slowly
May need more than one visit to complete the examination
Try to isolate body part during examination, to avoid generalized effect
Watch facial or vocal and parent reaction to each examination maneuver
Behavioral medicine assessment: often not possible
Physical therapy assessment: often already engaged in therapy
Review of records, treatments, history, and physical findings
Video documentation: parent may be able to capture pain behaviors for examiner to view
<b>Treatment</b>
<i>Medications:</i> often on multiple agents at baseline and coordination with other practitioners is important; apply general principles in choosing medications; long-acting opioid is sometimes beneficial for refractory musculoskeletal pain; watch for worsening of constipation.
<i>Behavioral medicine:</i> often not possible if patient's cognitive ability is too low, but the family sometimes can benefit because they carry a large burden when caring for children with multiple medical problems
<i>Physical therapy:</i> often already engaged; if not, engage for musculoskeletal pain or help therapist focus efforts of a particular region of the body
<i>Other therapy:</i>
Nerve blocks can be used to identify painful areas, if more than one seems active
Rarely, a patient must be brought to the operating suite for an infusion of remifentanyl to differentiate opioid responsiveness from potentially centralized or behavioral pain phenomena; the latter may respond to anticonvulsant therapy
Intrathecal baclofen (and occasionally morphine)
Surgical therapy for selected conditions
<b>Cautions</b>
Site of pain is often unclear.
Do not forget to look in the ears.
If patient is spastic, strongly consider hip pathology (e.g., subluxation, bursitis, infection).
Constipation, gallbladder pain, and gastroesophageal reflux are possible. These patients often require more testing than verbal patients.
Be careful with use of nonsteroidal antiinflammatory drugs because gastroesophageal reflux can be a problem and reporting abdominal pain as a signal of gastrointestinal side effects may not be possible.

(HbSC) has a clinical presentation similar to that of HbSS, but its vaso-occlusive episodes are fewer and usually less intense.

From a pain management perspective, the homozygous HbSS genotype manifests as acute pain attacks (e.g., pain crisis, vaso-occlusive episodes, acute chest syndrome) or as underlying chronic pain with acute exacerbations (e.g., avascular necrosis, vertebral collapse, joint involvement). Treatment frequently requires a multidisciplinary approach with close cooperation between the hematologist, psychologist, and pain physician.<sup>48</sup> Most of the episodes can be managed at home with NSAIDs or acetaminophen, supplemented with opioids such as codeine or oxycodone or with tramadol. In severe cases, children often are hospitalized and treated with intravenous opioids, although they should be gradually weaned off the opioids as the primary process improves. For episodes of localized, hard-to-control pain or if acute chest syndrome develops, epidural analgesia can provide

**TABLE 44-9** Care Pathway for Sickle Cell Disease

<b>Evaluation</b>
Medical examination
Behavioral medicine assessment: may be limited to social support in acute setting
Review of records, treatments (need opioid exposure history for dosing), and history
Hematology almost always directly involved, with focused evaluation
<b>Treatment of Vaso-occlusive Episodes</b>
<i>Medications:</i> opioid (often requires basal infusion for the first days); nonsteroidal antiinflammatory drug; consider neuropathic medication for hyperalgesia
<i>Behavioral medicine:</i> can be helpful, although learning techniques in the acute setting may be difficult; introducing this modality early in life may be more helpful
<i>Physical therapy:</i> transcutaneous electrical nerve stimulation (TENS) for localized pain
<i>Other therapy:</i> Regional anesthesia may be helpful. Strongly consider thoracic epidural for acute chest crisis.
<b>Treatment of Chronic Problems</b>
<i>Medications:</i> may involve chronic opioids; otherwise follows treatment of particular pain condition
<i>Behavioral medicine:</i> per particular pain condition; early involvement may reduce need for hospitalizations
<i>Physical therapy:</i> per particular pain condition; may have joint, bone, and deconditioning issues from recurrent vaso-occlusive episodes

excellent relief.<sup>49</sup> Rarely, children require opioid maintenance with long-acting preparations of morphine or oxycodone (Table 44-9). Hyperalgesia over the affected area suggests peripheral or central sensitization, although the role for neuropathic medications is undefined.

## Pain Pharmacotherapy

Pain treatment has received less study in children than adults, as it is true for much pediatric pharmacologic therapy. In the absence of U.S. Food and Drug Administration (FDA)-approved indications and experimental data, off-label use of many medications used to treat chronic pain is common. In this situation, the decision to use a particular medication is most often based on extrapolation from adult literature, expert consensus, applied theory, and clinical judgment (see Chapter 6). Three categories of medications are available for consideration: nonopioid analgesics (i.e., NSAIDs and acetaminophen), opioid analgesics, and a broad spectrum of adjuvant analgesics, including anti-convulsants, antidepressants, muscle relaxants, local anesthetics, *N*-methyl-D-aspartate (NMDA) receptor antagonists,  $\alpha_2$ -agonists, and corticosteroids.

### NONSTEROIDAL ANTIINFLAMMATORY DRUGS AND CYCLOOXYGENASE-2 INHIBITORS

NSAIDs come from various chemical groups (e.g., salicylates, propionic acid, oxicams, naphthylalkalones, fenamates). The mechanism of action is inhibition of cyclooxygenases (COXs) at the prostaglandin  $H_2$  synthetase enzyme. COX-1 is constitutive and always present, and COX-2 is inducible and produced in the body under proper conditions. NSAIDs have different

selectivities for COX-1 or COX-2; selective COX-2 inhibitors have predominant action on inducible COX-2. The benefit of selective blockade is decreased risk of gastrointestinal bleeding. Celecoxib is the only selective COX-2 inhibitor available in the United States.

The analgesic and antiinflammatory actions of NSAIDs exhibit a dose-dependent response until they reach maximum effect; beyond which there is no further benefit of dose increase (i.e., ceiling effect). Unlike opioids, there is no development of physical dependence or tolerance with NSAIDs.

The choice of NSAID is empirical and based on clinical judgment. If the child provides a history of good response to a particular NSAID, we tend to continue the same medication or adjust the dose. If the response is inadequate, we select a different medication until we find an effective one. In children with a history of gastrointestinal adverse effects, we prescribe combination preparations with protective agents (e.g., misoprostol) or a histamine<sub>2</sub> ( $H_2$ ) receptor or proton pump inhibitor, or we switch to a selective COX-2 inhibitor. Preexisting renal disease and disorders that reduce actual or effective intravascular volume vastly increase the risk for renal toxicity, and NSAIDs must be used cautiously in these situations.

### OPIOIDS

The use of opioids for treating chronic nonmalignant pain has been associated with many myths and controversies. Their use in the past was reserved for children with acute and cancer-related pain. In selected cases, with appropriate monitoring, opioids can improve quality of life and functional capacity without significant risk of addiction, tolerance, and toxicity. However, a history of substance abuse (mainly in adolescent and young adult populations) and a family member with substance abuse and a dysfunctional social situation are red flags for opioid prescribing.

Opioid agonists are used almost exclusively; agonist-antagonists have less popularity because of their ceiling effect and the potential to precipitate withdrawal when administered alongside a pure agonist. We typically use opioids in two scenarios. The first features opioids as a bridge while titrating other classes of medications to effect or while awaiting physical therapy or an intervention to exert its effect. In the second scenario, we use opioids as maintenance analgesics in carefully selected children (e.g., chronic musculoskeletal pain in a child with cerebral palsy, children with juvenile rheumatoid arthritis or Ehlers-Danlos syndrome). Medication is titrated in increments toward the main goals of optimal (although rarely complete) pain relief, improved function, and minimal adverse effects. Escalations are seen usually with exacerbations of the primary disease process. Common opioid adverse effects that occur with long-term use can be found in Table 44-10.

A special medication in this group is methadone. Besides being an opioid agonist, methadone is also reasonably effective in controlling neuropathic components of pain. There are a few exceedingly important caveats for its use. It has a long half-life and presents a risk of accumulation leading to sedation and respiratory depression. The usual 1:1 methadone to morphine equianalgesia ratio does not work for dose conversion. The greater the dose of opioid being converted, the more skewed the conversion ratio; the methadone to morphine ratio ranged from 1:2.5 to 1:14.3 in one study.<sup>50</sup> Because of the long half-life, dose adjustments should be made no more frequently than every 5 days. A unique adverse effect of methadone among opioids is its potential to prolong the QT interval and modestly increase

**TABLE 44-10 Opioid Side Effects Associated with Chronic Use**

Immunosuppression

the dispersion of repolarization on the electrocardiogram.<sup>51</sup> Because the dispersion of repolarization is less than 100 msec, it remains unlikely that methadone can trigger torsades de pointes.

When a child who is taking long-term opioids presents in the operating room, a thorough medication history is essential for developing a perioperative plan. If the child has not taken a morning dose of opioid, that dose should be replaced by the intravenous route to avoid withdrawal. It is essential to convert the home medication into morphine equivalents, and the daily dose of home opioids should be provided as a baseline, with all further dosing being in addition to the baseline, to avoid pain at the time of emergence. Because of tolerance to long-term opioids, larger doses than usual may be required, and it is advisable (as in all children) to titrate to comfort in the immediate postoperative period and use the amount required to achieve optimal analgesia. Opioid consumption during the perioperative period may be more than three times that observed in patients not taking chronic opioids. Sparing use of opioids in the perioperative period results in poor pain management and withdrawal phenomena.<sup>52,53</sup>

## ADJUVANT DRUGS

### Anticonvulsants

Anticonvulsant medications have been widely used in the pharmacologic treatment of chronic pain since the 1960s. Often referred to as membrane stabilizers, anticonvulsants work on neural receptors, ion channels, and nerve conductivity. They modify the level of excitatory and inhibitory neurotransmitters and activation of nerve cells. They are most effective in controlling neuropathic pain. First-generation agents (e.g., carbamazepine) have been used less often due to significant adverse effects, and they have been replaced by second-generation agents that have a better adverse effect profile.

Therapeutic effect is achieved with all membrane stabilizers by gradual titration. The purposes of this approach are to avoid development of adverse effects by allowing enough time for the child to develop tolerance (mainly to sedation) and to find the lowest effective dose for the child. The treatment course usually lasts 3 to 6 months. At the end, the child is gradually weaned off the medication in reverse order of its titration. Although weaning is not necessary to prevent seizures, rapid discontinuation may result in pain and in sleep or mood disturbances. Gradual weaning allows rapid re-escalation in case the pain begins to return in children for whom the pain has been controlled but

not completely eliminated. In that case, we would determine the child's minimal effective dose. If pain recurs, we continue medication for 3 to 6 months longer.

Although use of anticonvulsants for pain in children represents an off-label use and studies are lacking (even for adults), this class of medications is a mainstay of therapy for selected pain conditions in children. The choice of drug is based on thoughtful consideration and expert consensus, as with all therapies for which randomized, controlled trials are lacking.

### *Gabapentin and Pregabalin*

Gabapentin is an anticonvulsant with a complex mechanism of action. Its name is deceiving; gabapentin does not interact with the  $\gamma$ -aminobutyric (GABA)-ergic system. It binds to the  $\alpha_2$ -delta subunit of the voltage-dependent calcium channel<sup>54</sup> and reduces the release of glutamate in the dorsal horn of the spinal cord. This leads to decreased production of substance P, less activation of  $\alpha$ -amino-3-hydroxy-5-methylisoxazole-4-propionate (AMPA) receptors on noradrenergic synapses, decreased transmitter release, and decreased neuronal activity.<sup>55</sup> This mechanism is shared by gabapentin and pregabalin.

Gabapentin is usually a drug of first choice due to good tolerability, minimal adverse effects, and positive clinical experiences. Besides sedation, patients can retain sodium and water, develop peripheral edema, and gain weight. In teenagers, gabapentin can cause mood swings, irritability, and suicidality. Despite these concerns, we use gabapentin frequently after a detailed explanation and discussion with the patient and parents. We use two titration schedules. For younger children, the target dose is 10 to 15 mg/kg/dose three times per day. In older children weighing more than 60 kg, we use adult-type titration to effect. Gabapentin does not have to be adjusted in liver failure patients because it is not metabolized by the liver; however, the dosage needs to be adjusted in children with compromised renal function. Pregabalin is chemically related to gabapentin but has fewer adverse effects and a significantly faster titration schedule. It is approved for postherpetic neuralgia, diabetic neuropathy, and fibromyalgia in adults; experience in children is growing.

### *Topiramate*

Best studied for the treatment of migraine headaches, topiramate can be applied to the full spectrum of neuropathic pain states.<sup>33</sup> Because a unique adverse effect is appetite suppression, we may choose it for a patient with neuropathic pain who is concerned about weight gain. Topiramate has carbonic anhydrase-inhibiting properties and can result in metabolic acidosis and lead to renal stones in some cases.

### *Oxcarbazepine*

Oxcarbazepine is the second-generation relative of carbamazepine and has potential for the treatment of neuropathic pain states. Although rare, Stevens-Johnson syndrome can occur with oxcarbazepine and with several other anticonvulsants. Hyponatremia also may occur in addition to adverse effects common to anticonvulsants, such as sedation, difficulty concentrating, ataxia, and mood instability.

### *Carbamazepine, Valproic Acid, and Phenytoin*

The effectiveness of carbamazepine, valproic acid, and phenytoin has been discussed elsewhere.<sup>56</sup> Carbamazepine has proved effective in the treatment of trigeminal neuralgia, spasticity in multiple sclerosis, and spinal cord injury (compared with tizanidine).

Phenytoin has been used alone or in combination with buprenorphine for cancer pain, and it has provided good pain relief in more than 60% of patients.

Despite their effectiveness, the use of these medications is limited because of the possibility of serious adverse effects. For carbamazepine and phenytoin, adverse effects include liver and renal toxicity (regular laboratory tests are necessary), aplastic anemia, Steven-Johnson syndrome, and a syndrome of inappropriate secretion of antidiuretic hormone (SIADH)-like picture. Valproate lacks renal side effects but can cause pancreatitis.

### Antidepressants

Two major groups of antidepressants are used in the treatment of chronic pain: tricyclic antidepressants (TCAs) (e.g., amitriptyline, nortriptyline, desipramine, doxepin, imipramine) and the newer selective serotonin reuptake inhibitors (SSRIs) (e.g., fluoxetine, paroxetine) and serotonin-norepinephrine reuptake inhibitors (SNRIs) (e.g., venlafaxine, duloxetine, milnacipran).<sup>57</sup> The efficacy of TCAs in the treatment of neuropathic pain has been confirmed in meta-analyses.<sup>58,59</sup> The doses required to control chronic pain are usually less than those used in the treatment of depression. The effectiveness of antidepressants has been demonstrated in neuropathic and nonneuropathic pain such as fibromyalgia and low back pain.

When prescribing antidepressants, we recommend vigilance about the potential increase in suicidal ideation and attempts in adolescents and young adults. We inform patients and families in detail to ensure that they will communicate with us about such ideation. We refer patients at greater risk for psychiatric comorbidity to a psychologist for evaluation before prescribing this class of medications.

#### Tricyclic Antidepressants

The major limiting factor in prescribing TCAs is their adverse effects. Onset of adverse effects can be reduced by slow dose escalation, as is done with anticonvulsants. The most frequent side effect is sedation, which is often beneficial in chronic pain patients who have difficulties sleeping. We prescribe the drug to be taken at bedtime. It is important to monitor the child in the mornings for carryover sedation. In such cases, it is reasonable to decrease the dose or encourage the child to take the medication earlier in the evening. Because of the anticholinergic effects of TCAs, children often notice a dry mouth and may experience constipation, urinary retention, or weight gain.

TCAs prolong the cardiac QT interval, which can cause a lethal arrhythmia. We obtain a careful history of cardiac symptoms and conduction abnormalities in the child and family members. It is reasonable to order a baseline electrocardiogram to rule out congenital prolonged QT interval before initiation of therapy. Because concomitant use of SSRIs, SNRIs, or tramadol can decrease the seizure threshold in children with a seizure disorder, their simultaneous use is discouraged. Amitriptyline and nortriptyline are the most commonly used medications of this group. The usual starting dose for both medications is 5 to 10 mg orally at night, which is increased to 20 or 25 mg at night 1 week later. Analgesic effects can be seen in 1 to 3 weeks, as with antidepressant effects. Nortriptyline is a metabolite of amitriptyline, with similar utility for pain but less sedation. If top-range dosing is required, periodic electrocardiographic monitoring for QTc changes is suggested.

#### Selective Serotonin and Norepinephrine Reuptake Inhibitors

Venlafaxine starting dose is 37.5 mg/day in adults, which can be increased by 37.5 mg every week up to 300 mg/day. Adverse

effects include headaches, nausea, sweating, sedation, hypertension, and seizures. If the dose is less than 150 mg/day, the effects are mostly serotonergic. If it exceeds 150 mg/day, the effects are mixed serotonergic and noradrenergic. Duloxetine has antidepressant effects and analgesic effects for neuropathic pain, fibromyalgia, and back pain.<sup>45,57,60</sup> It is usually started at 20 to 60 mg daily to a maximum dose of 120 mg/day. The major adverse effects are nausea, dry mouth, constipation, dizziness, and insomnia. Use of both medications in younger children is best left to those who prescribe the medications frequently because dosing has not been well established in the pediatric age group.

### Muscle Relaxants

Muscle relaxants are frequently used as an adjunct to other medications (mostly NSAIDs) in patients with myofascial pain.

#### Cyclobenzaprine

Cyclobenzaprine is a centrally acting muscle relaxant. Its major adverse effects are somnolence, dizziness, and asthenia. The usual starting dose is 5 mg at night, which can be increased to 10 mg after 5 to 7 days unless the child has difficulties awakening in the morning. The dose can be escalated up to 10 mg three times per day.<sup>61</sup>

#### Baclofen

Baclofen is one of the most powerful centrally acting muscle relaxants. It interacts with the GABA<sub>B</sub> receptor subtype. It is usually indicated in patients with spasticity such as children with cerebral palsy or multiple sclerosis. In children 2 to 7 years old, the daily dose is 10 to 15 mg, divided into two or three doses. The dose can be escalated every 3 days by 5 mg to a maximum dose of 40 mg/day. In children older than 8 years of age, the maximum dose is 60 mg/day. Baclofen is one of a few medications approved for intrathecal administration by implanted pumps and is usually administered to children with spasticity (e.g., cerebral palsy, spinal cord injury).

#### Tramadol

Tramadol is a unique analgesic. It is a very weak  $\mu$ -receptor opioid agonist. It also blocks monoamine reuptake in the central nervous system (similar to antidepressants). For the latter reason, tramadol is a popular analgesic for neuropathic pain, especially for controlling paresthesias, allodynia, and touch-evoked pain. The likelihood of tolerance or development of dependence is small, although it has been reported. Despite its weak opioid properties, sudden discontinuation of tramadol can cause withdrawal symptoms.

The doses used for chronic pain vary from 25 mg up to 100 mg four times per day (400 mg/day maximum).<sup>62</sup> The dose should be limited in renally impaired children with creatinine clearance less than 30 mL/min up to a maximum of 200 mg/day and in those with impaired liver function up to 100 mg/day.

Common adverse effects include nausea, vomiting, sedation, constipation, diarrhea, dizziness, headache, seizures, and hallucinations. Rare side effects include orthostatic hypotension, syncope, and tachyarrhythmia.

### Local Anesthetics, $\alpha_2$ -Adrenergic Receptor Agonists, Topical Agents, and N-Methyl-D-Aspartate Receptor Antagonists

Many drugs are used in the treatment of chronic pain, and they have a wide array of mechanisms of action. Oral medications with local anesthetic properties such as mexiletine have been used

in the treatment of neuropathic pain in patients with CRPS. The  $\alpha_2$ -adrenergic receptor agonist clonidine finds its application in the same arena. It is used orally, as a transdermal patch, or added to local anesthetic solutions in intravenous regional techniques. The major limiting factor in the use of these drugs is their adverse effect profile, which includes hypotension, sedation, bradycardia, and nausea (especially with mexiletine).  $\alpha_2$ -Adrenergic agonist blocking properties are also part of the mechanism of action of the muscle relaxant tizanidine.

The topical agent capsaicin, derived from hot chili peppers, is also helpful in managing neuropathic pain, but its application can cause a burning sensation where applied, which is often poorly tolerated. The topical lidocaine patch has been effective in the controlling symptoms of postherpetic neuralgia and has been used for localized myofascial pain, hyperpathia, and allodynia in other neuropathic conditions.<sup>63</sup> Pharmacokinetic studies in adults have found minimal lidocaine blood concentrations, suggesting a large margin of safety,<sup>64</sup> although similar studies have not been carried out in children.

NMDA receptor antagonists such as ketamine, amantadine, or dextromethorphan have anecdotal evidence supporting their utility in the treatment of neuropathic pain. It is also thought that NMDA receptor antagonists exert an opioid-sparing effect. An important limiting factor of the broader use of ketamine in the treatment of chronic pain symptoms is the potential for psychotropic side effects.

## Complementary Therapies

Alternative therapies have appealed to patients for a long time. Because traditional medical therapies have a high failure rate, patients continue to search for better treatments. Many types of therapies are useful in treating chronic pain. As a consultant, the anesthesiologist should consider suggesting some of these therapies when they seem appropriate. TENS and biofeedback have been discussed earlier.

Acupuncture and its derivative, acupressure, originated in China and constitute an important part of traditional Chinese medicine (Fig. 44-3). In acupuncture, the body energy or qi (pronounced *chi*) circulates in body meridians and collaterals. Meridians and collaterals are pathways that represent body organ

FIGURE 44-3 Acupuncture needles in situ.

systems called the Zang-Fu organs. In Chinese medicine, pain is caused by obstruction in the circulation of qi in these channels due to multiple causes. Acupuncture has been used in acute and chronic pain conditions such as neck and back pain, dental pain, musculoskeletal and arthritic pain, CRPS, migraine, facial pain, and fibromyalgia. The data from randomized, controlled trials is controversial or insufficient to support or deny efficacy of acupuncture.<sup>65</sup>

## Summary

The pediatric anesthesiologist may be called on to assist with the care of a child or adolescent with chronic pain. The basic tenets of care apply, and a careful history and focused physical examination remain key components of the evaluation. Determining that the child is not being physically harmed by the painful condition (i.e., ensuring safety) is the first step, followed by focused diagnostic evaluation and therapy. Treatment for all but the simplest painful conditions employs multiple disciplines in a coordinated attack on the pain. The input of psychologists is a prominent part of chronic pain management, and psychological treatment is not a sign of psychiatric disease or malingering but a tool that can be powerful and effective. Physical therapy and judicious use of medications round out the approach to most chronic pain problems in children. The occasional use of interventional modalities and opioids is warranted, but success is limited if the problem is viewed in a unidimensional manner. Many patients benefit from alternative approaches to therapy, and these disciplines can be used in a prudent fashion to expand the range of therapies that can be recommended.

Endoscopic Procedures

## Summary

THE APPROACH TO PROVIDING ANESTHESIA outside the operating room (OR) for children (also known as non-operating room anesthesia [NORA] or off-site anesthesia) varies greatly among organizations and even from one anesthesia provider to another. NORA practice is not as standardized as anesthesia delivered within the OR setting. As such, it is a difficult topic to cover using an evidence-based approach. Although most anesthesiologists would agree (generally) on the optimal methodology for delivering anesthesia to a 2-year-old child for inguinal hernia repair, much more variability (in terms of drugs used, airway management techniques, and general organization) exists in providing anesthesia for a magnetic resonance imaging (MRI) scan. This issue is made even more confusing by the fact that procedures that are performed with sedation in one institution may be accomplished with general anesthesia in another. Furthermore, a procedure that is performed under sedation with an *anesthesia* provider in one institution may have sedation provided by a specialist *other* than an anesthesiologist at a different institution.<sup>1</sup>

The discussion of anesthesia services outside the operating room must also include the recognition that the level of sedation or anesthesia for a given child at any moment during a procedure is often a matter of some conjecture. Almost any procedure that involves pain, or the requirement for absolute movement control in a child, necessitates deep sedation or general anesthesia. The distinction between these two states—defined by the presence or absence of movement in reaction to painful stimuli—is often difficult to determine.<sup>2</sup> For anesthesiologists, the difference

between these two states is more of semantic interest than practical importance. Anesthesia services are often requested outside the OR when sedation is actually what is required. Finally, anesthesia is often provided outside of the OR for patients with significant comorbidities undergoing routine procedures. Many of these children would be managed with sedation by other specialists were it not for the complexity of the coincident condition(s). Comorbid conditions that require referral to an anesthesiologist vary with institutions but common (generally accepted) examples include:

1. Extremely young age, including well children younger than 1 month of age
2. History of significant prematurity (younger than 32 weeks at birth) and post-conceptual age younger than 60 weeks.
3. History of ongoing apnea and bradycardia episodes
4. Craniofacial anomalies or any known difficult functional or anatomic airway problem
5. Cyanotic congenital heart disease or cardiomyopathy
6. Any serious coexisting disease such as sickle cell disease or muscular dystrophy that would qualify a patient as American Society of Anesthesiologists (ASA) III-IV.
7. Procedures that require elective airway control (intubation) or respiratory control such as breath holding

With these considerations in mind, this chapter focuses on issues specifically related to the delivery of anesthesia and deep sedation outside of the OR *provided by anesthesiologists*. Issues

concerning minimal, moderate, and deep sedation, as well as issues involving care by providers other than anesthesiologists, are covered Chapter 47.

## Standards and Guidelines

Anesthesia outside of the OR must meet the same standards as anesthesia given in the OR. Specifically, Medicare's *Conditions for Participation* for hospitals are enforced by The Joint Commission (TJC) regardless of location of care. The *Conditions for Participation* are principles that are articulated to surveyors as instructions in the Interpretive Guidelines published in January, 2011, and available at [http://www.cms.gov/SurveyCertificationgeninfo/downloads/SCLetter11\\_10.pdf](http://www.cms.gov/SurveyCertificationgeninfo/downloads/SCLetter11_10.pdf). These guidelines describe appropriate training, credentialing, and oversight of sedation and anesthesia providers and some of the specific requirements for care documentation. The ASA has developed templates for the required policies that help institutions meet the standards of the new Interpretive Guidelines. These resources can be downloaded from the ASA website at <http://www.asahq.org>. With particular reference to NORA, there are several notable templates, as follows:

1. Preanesthesia Evaluation Policy, Form and Note (template)
 

Within 48 hours immediately before the delivery of the first dose of medication for the purpose of inducing anesthesia, a qualified practitioner must perform a preanesthesia evaluation of the patient that includes, at a minimum: a) a review of the medical history, including anesthesia, drug and allergy history, and b) an interview, if possible, given the patient's condition, and examination of the patient. In addition, the following must be reviewed and updated within 48 hours prior to anesthesia:

  - a) Notation of the anesthesia risk.
  - b) Identification of potential anesthesia problems.
  - c) Additional preanesthesia data or information, if applicable and as required in accordance with standard practice prior to administration of anesthesia (i.e., stress tests).
  - d) Development of the plan for the patient's anesthesia care, including the type of medications for induction, maintenance and postoperative care and discussion with the patient (parents) of the risks and benefits of the delivery of anesthesia.
2. Intraoperative record policy. Standard data elements and timing must be included in the intraoperative record—just as in the OR.
3. Postanesthesia Evaluation Policy, Note and Form (template)
 

A postanesthesia note must be completed within 48 hours after surgery. The person completing the evaluation does not have to be the person who delivered the anesthetic. The elements of the postanesthesia note include assessment of the following: a) respiratory function, b) cardiovascular function, c) mental status, d) temperature, e) pain, f) nausea and vomiting, and g) postoperative hydration.

NORA Services must be organized in such a way as to meet the *Conditions for Participation* (and thus TJC) standards mentioned earlier, just as they are met in the OR environment. Depending on how NORA is organized in a particular institution, this can be challenging. The departments that require anesthesia services must appreciate the need to meet these standards and allow for the infrastructure to meet or exceed them, particularly in the preanesthesia and postanesthesia timeframes.

## Off-Site Anesthesia: Structure

Anesthesia services outside of the OR can be organized in various ways. In some institutions these services are organized through an off-site anesthesia unit or sedation unit. These units have the advantage of providing all anesthesia-related care through one location that contains all of the personnel and equipment required for anesthesia. Ideally, these units provide for preanesthesia assessment, induction, procedure location, and a recovery area. Children may be transported to remote locations when equipment (such as MRI) cannot be brought to the sedation unit. The advantages of this organizational scheme are clear. The uniform environment leads to maximum consistency in the equipment and personnel that interact with children and their families and thus adds to safety, efficiency, parent satisfaction, and effectiveness of care. Many experts (along with TJC) advise the formation of specialty teams or microsystems for provision of anesthesia out of the OR. Microsystems are coordinated groups of professionals who deliver a specific service, to achieve the best outcomes by developing reliable, efficient, and responsive systems that have the capability of meeting the individual needs of one child, continually improving care for the next child, and creating a great place to work for all staff. The sedation microsystem should be made up of pediatric anesthesiologists and nursing, technical, and administrative personnel who are familiar with the service and dedicated to this care.<sup>3</sup> The microsystem can provide structure and expertise for this care. As members gain expertise and comfort with the off-site environment, their care is consistent and reproducible, leading to less confusion with other services. Such systems of care lead to improved effectiveness (decreasing failed anesthesia and sedation cases) and improve patient and family and staff satisfaction.<sup>4-6</sup>

Another option for anesthesia organization outside the OR is the use of standard same-day unit admission and assessment services and postanesthesia care unit recovery capability while providing induction and procedural anesthesia at the site of the procedure (e.g., endoscopy suite or hematology and oncology unit). This organizational paradigm makes use of existing anesthesia ancillary services but often requires patient transport before and after anesthesia.

Finally, anesthesia services outside of the OR may be primarily organized at the site of procedural care. Most typically these services are organized in radiology departments or gastrointestinal procedure suites, where a majority of pediatric sedation and anesthesia takes place outside of the OR. For this organizational setup, the procedure unit itself may be outfitted for admission and preanesthesia assessment. An anesthetizing location can be provided and recovery of children can be accomplished in a space contiguous within the immediate location of the procedural equipment. This kind of organization is most common in children's hospitals, where high volumes of procedures are performed in a given location such as the MRI scanner.<sup>7</sup> In locations such as this, where anesthesia services are required on a daily basis for a multitude of children, the investment in the infrastructure for anesthesia support services makes economic sense in addition to optimizing patient care.

### PERSONNEL REQUIREMENTS

The environment and the demands of providing anesthesia outside of the OR are unique regardless of the specific organization that has been chosen for NORA. To create the kind of functioning sedation microsystem discussed earlier, several

common themes lead to optimal safety and effectiveness of off-site anesthesia care:

1. Anesthesia providers should rotate on this service and have a frequency of experience with the environment and ancillary personnel that allow familiarity among the anesthesiologists, nurse anesthetists, respiratory therapists, registered nurses, patient care technicians, biomedical engineers, and child life specialists. This familiarity should be based on a common understanding of the routines and protocols for standard procedures and a common agreement on the goals of the service.
2. Effective and efficient communication among personnel is critical to optimize outcomes. Logically, help from all members of the care team, including the supervising anesthesiologist, should be available within time frames that would allow optimal outcomes for children with critical events—specifically within 3 to 4 minutes. The use of cell phones, Internet phones, or other devices to optimize communication in NORA locations is often helpful.
3. The ancillary personnel in each location must be familiar with the needs and processes of providing anesthesia to children.
4. Equipment and monitoring standards should mimic that of the OR environment (see later discussion). Anesthesia carts and machine preparation and setup should mirror the OR environment as much as possible to maximize the similarity to the most common workspace. It is critical to have a system that allows appropriate restocking and security of anesthesia carts in all of the off-site locations. All off-site carts should include a full range of drugs, intravenous equipment, fluids, and airway equipment such as tracheal tubes, laryngeal mask airways (LMAs), laryngoscopes, oral and nasal airways, masks, and suction equipment in sizes that would fit all possible pediatric age groups.
5. Scheduling off-site anesthesia resources is complex and personally demanding. Timing for some procedures is inexact. In addition, anesthesia time requirements can vary with the child and the associated pathology. Success is enhanced by focusing the task of scheduling NORA procedures with one individual (or a small group) (similar to scheduling cases for the OR) who intimately understands the process involved in anesthesia. This type of organization allows the NORA service to have one focal point for communication between the individuals who perform procedures and the anesthesia service, thus maximizing communication among services and minimizing incorrect assumptions of staffing or timing for procedures.

### SPECIFIC ENVIRONMENTAL REQUIREMENTS

Equipment (see earlier discussion) and monitoring standards (see later discussion) must meet those of the main OR environment. Regardless of whether the anesthetizing location is inside or outside the OR, the ASA has established minimum standards for equipment, monitors, and conditions of anesthesia delivery. These guidelines may, of course, be exceeded at any time based on the judgment of the involved anesthesia personnel. The ASA specifically requires that remote locations must have two sources of oxygen ( $O_2$ ) (preferably a central source of piped  $O_2$  and a backup E cylinder), suction, an anesthesia machine if administering inhalational anesthetics, a scavenging system for waste anesthetic gases, a self-inflating hand resuscitator bag able to deliver 90%  $O_2$  and positive-pressure ventilation, standard of care monitors and equipment,<sup>7,8</sup> and sufficient electrical outlets,

illumination, and space. The ASA Standards for Basic Anesthetic Monitoring include the following:

- Pulse oximetry with audible pulse tone and low-threshold alarm
- Adequate illumination and exposure of the patient to assess color
- Anesthesia machine with  $O_2$  analyzer
- Continuous end-tidal carbon dioxide ( $ETCO_2$ ) analysis with an audible alarm
- Continuous electrocardiogram (ECG)
- Arterial blood pressure and heart rate every 5 minutes or more frequently as indicated
- Temperature, if there is potential for clinically significant changes in body temperature

In addition, it is important to make further adaptations in the non-OR setting. Duplicates of critical equipment, such as laryngoscope handles and blades, should be immediately available. In the MRI unit, it is essential to have MRI-compatible laryngoscope blades and handles, as well as compatible monitoring devices. Each site should be carefully evaluated for important items, such as presence or absence of wall-delivered gases ( $O_2$ , nitrous oxide [ $N_2O$ ], and air), location of suction equipment, and Ambu bag. Every site must have backup gas supplies. If pipeline  $O_2$  is not available,  $O_2$  should be drawn from H cylinders (6600 L) rather than the smaller E tanks (659 L).

Many off-site areas do not have wall suction, especially in the MRI environment. MRI-compatible wall suction is not widely available. An alternative method for providing suction in the MRI suite is to mount a suction canister with 30 feet of suction tubing outside the scanner room.<sup>9</sup> The suction tubing can then be threaded through a hole in the console wall to access for use in the MRI unit.

Scavenging systems should be carefully evaluated in out of OR locations. When passive scavenging is not possible, active scavenging may be developed by using the wall-source vacuum or wall suction canisters. Ideally, a scavenging system dedicated solely to waste gases should be present.

Electrical circuitry in off-site locations must be upgraded to meet OR standards. Specifically, although the outlets tend to be grounded and hospital grade, plug and outlet incompatibility may be a problem. Adapters and conversion plugs must be available. Although off-site locations tend not to have as great a risk of electrical shock or electrocution to the child as in the OR, it is important to remember that these sites do not have line-isolation monitors. In the event of excessive leakage of current, the anesthesiologist would not be warned. Although the National Electrical Code no longer requires line-isolation monitors in nonflammable anesthetizing locations, it is strongly recommended in areas with multiple power sources. To ensure child and health care personnel safety, biomedical engineers must be attentive to the safe maintenance of all electrical equipment.

It is in the nature of off-site anesthesia that the physical environment and practice patterns are typically that of another medical specialty. It should also be noted that these other specialties practice under standards developed by their own professional organizations that apply to the procedures within their locations reflecting the different procedure goals. The varying specialties involved include (but are not limited to) gastroenterology, dentistry, cardiology, oncology, intensive care, emergency medicine, and radiology.<sup>10</sup> Anesthesia providers who work in these environments are well served by familiarizing themselves with

the standards for the given specialty area they are working in, as published on the individual websites for the various professional organizations.

## Quality Assurance of Anesthesia Services and Outcome in the Off-Site Areas

This chapter reviews issues related to care delivered by members of anesthesiology departments outside of the OR. In this case the quality improvement (QI) and assurance (QA) activities center in the anesthesiology department. Issues relating to sedation services provided by other services are discussed in Chapter 47. Just as is the case in the OR, it is important to have a consistent tracking tool to follow all clinically important complications. Each department can set its own thresholds for review; however, certain incidents logically require inquiry, as follows<sup>11</sup>:

- Aspiration events
- Unscheduled admissions to the hospital as a direct result of the sedation (i.e., because of protracted emesis, prolonged sedation, respiratory or cardiac complication)
- Failed procedures resulting from inadequate or problematic anesthesia or sedation
- Cardiovascular compromise that requires assistance from an outside rescue team
- Cardiac arrest

Many institutions choose to follow other outcomes such as prolonged nausea and vomiting after anesthesia or O<sub>2</sub> desaturation events. Regardless of the data that the QI committee chooses to review, the process should include anesthesiologists, nurses, and other technical personnel who are routinely involved in anesthesia care and support. It is particularly important to note that in the case of off-site anesthesia, it is critical to include members of the departments that are served by the service in the quality improvement process. The timing of QI meetings depends on the number and acuity of the non-OR anesthesia provided at a given institution. Review committee meetings should be considered not just an opportunity to evaluate complications but also a forum for exchange of ideas, expertise, and information that can lead to improvements in patient care.

## Anesthesia versus Sedation for Non-Operating Room Procedures and Tests in Children

Anesthesiologists can deliver either deep sedation or anesthesia for procedures outside of the OR. The choice of whether to deliver general anesthesia with a secured airway (tracheal tube or LMA) using potent inhalational anesthetics versus deep sedation with facemask O<sub>2</sub> and propofol infusion depends on many factors, including the child's comorbid conditions, the procedure, and the experience and comfort level of the anesthesia provider. Several reviews are available on this topic. For MRI scans, propofol sedation has been suggested as an (overall) safe and effective option in children with airway pathologic conditions or who are premature or very young.<sup>12</sup> Similarly, multiple reports have recommended both propofol sedation and general anesthesia with tracheal intubation (GETA) techniques for endoscopies.<sup>13,14</sup>

No clear evidence exists on which to conclude that one technique is specifically better than another for procedures in which

both techniques are effective and safe, such as MRI or endoscopy procedures. Recognizing this fact, it is still important for anesthesiologists to avoid providing GETA in every case (ignoring the possible advantages that deep or moderate sedation could provide in terms of rapidity of emergence and lack of side effects). It is appropriate to carefully evaluate the nature of the sedation/anesthesia provided in the non-OR setting and consider all of the possible implications of a given technique. For instance, how efficient and effective is the care that is provided? How well does the care provided meet the requirements of the procedure in terms of pain and movement control? What are the nature and rapidity of the emergence from sedation or anesthesia and the time that children should remain in the hospital or ambulatory unit between emergence and discharge after a specific procedure with a given technique? Only after careful analysis can guidelines be established for the optimal technique for a given procedure.<sup>15</sup>

When delivering general anesthesia to children out of the OR, the risk benefit of instrumenting the airway must be carefully evaluated. The LMA is perhaps most useful in the MRI or computed tomography (CT) setting because it maintains spontaneous ventilation, enables the anesthesiologist to monitor ETCO<sub>2</sub> continuously and provides a clear airway in a child who may otherwise have obstruction with a natural airway. With the LMA in place, the child can be maintained with a relatively low level of anesthesia, allowed to breathe spontaneously, and then rapidly awakened at the conclusion of the scan. After the LMA is placed, anesthesia can be provided with either a continuous infusion of propofol or with a low-dose inhalation agent (sevoflurane 1.5% in 50% N<sub>2</sub>O/O<sub>2</sub>). In some circumstances, the LMA may provide a suitable airway in children with bronchopulmonary dysplasia, cystic fibrosis, severe asthma, or active respiratory issues. In children with upper respiratory tract infections, the incidence of mild bronchospasm, laryngospasm, breath holding, and major O<sub>2</sub> desaturation (less than 90%) in those whose airway was managed with an LMA was reduced compared with those whose airway was managed with a tracheal tube.<sup>16</sup> Similarly, the use of LMAs in ex-preterm infants with bronchopulmonary dysplasia resulted in less coughing and wheezing and greater hemodynamic stability than in those managed with tracheal tubes. In children who underwent a vitrectomy for retinopathy of prematurity, the time to discharge after an LMA was less than that after a tracheal tube.<sup>17</sup> LMAs provide more hemodynamic stability during their removal than during tracheal extubation and thus the former may be useful in children with hemodynamic instability.<sup>18</sup>

Others think any instrumentation of the airway theoretically increases the risk of triggering airway reflexes or regurgitation compared with no airway instrumentation. In healthy children, some clinicians prefer a deep sedation technique, for example, for brain MRI that includes a propofol infusion, an optimally positioned upper airway (with a roll under the cervical spine and the neck extended) and noninvasive monitoring (nasal capnometry supplemented with oximetry, an electrocardiogram, and noninvasive blood pressure).<sup>19</sup> Some note that the majority of children do not require an airway during deep sedation for medical procedures. However, in some (e.g., those with excess secretions or upper airway obstruction during the sedation), the following algorithm of airway intervention may be followed to relieve the obstruction: reposition the head and shoulders, insert an oral airway, insert a nasal airway, place an LMA, and finally, if the LMA fails to clear the airway, place a tracheal tube.

## Logistics of Managing Acute Emergencies and Cardiopulmonary Arrest Outside the Operating Room

Although the actual management of a cardiopulmonary arrest should not vary between the OR setting and the non-OR setting, the logistics of performing a resuscitation may be challenged by unanticipated factors, such as personnel who may not be familiar with code situations, an environment that makes performing a resuscitation difficult, or equipment that may be unsafe if used in the particular location (e.g., the MRI environment). It is important that all personnel in the off-site location be familiar with the location and operation of the code cart. The anesthesia cart and the code cart in the off-site location should be stocked in the same precise configuration as all others throughout the hospital and ORs. Standardizing the code carts throughout the hospital ensures that all ancillary personnel can be helpful in locating critical items. If the code cart is kept locked, the key or access code must be readily accessible and in a location that is known to all essential personnel. A hard board on which chest compressions may be performed should also be readily available. Each off-site location should have an identified and rehearsed routine for announcing a code situation and summoning aid. The use of human patient simulation can be very helpful in testing the team response to critical events. Simulators can be used in place in off-site locations to replicate critical events and evaluate the ability of the care team and backup systems to resuscitate a patient. Blike and colleagues used exactly this methodology to document significant variation in the ability of rescuers to resuscitate children from sedation or anesthesia critical events in locations outside the OR.<sup>20</sup>

Of all the non-OR environments in which anesthesiologists are asked to provide care, the MRI scanner poses a unique challenge for cardiopulmonary resuscitation. The MRI environment is divided up into four zones that correlate with the intensity of the magnetic field and the risk to children and health care providers. These zones are delineated in Table 45-1.

In 2009 the ASA published a report titled Practice Advisory on Anesthetic Care for Magnetic Resonance Imaging: A Report by the American Society of Anesthesiologists Task Force on Anesthetic Care for Magnetic Resonance Imaging.<sup>21</sup> This

document advises that in the case of a medical emergency in a patient within the scanner, the anesthesia providers should (1) initiate cardiopulmonary resuscitation while immediately removing the patient from zone IV, (2) call for help, and (3) transport the patient to a previously designated safe location in proximity to the MRI suite. This designated location should contain a defibrillator, vital signs monitors, and a code cart with all resuscitation drugs, airway equipment, O<sub>2</sub>, and suction. Other acute emergencies that are unique to the MRI environment include a “quench” or a fire in the scanner. Quenching occurs when the liquid that cools the magnet boils off rapidly and results in helium escaping from the cryogen bath. The magnetic field of the magnet is rapidly decreased because the coils in the magnet cease to be superconducting and become resistive. In addition to performing the institution’s protocol in reaction to either of these events, the ASA consultants involved in writing the advisory agree that in the event of a quench, (1) the child should be removed from zone IV immediately and (2) O<sub>2</sub> should be administered immediately; (3) because of the powerful magnetic field that can exist after a quench or a fire, emergency response personnel should be restricted from entering zone IV.

## Difficult Airway Management in the Non-Operating Room (Off-Site) Environment

Two potential difficult airway scenarios may occur in non-OR locations: the child with a known difficult airway and the child with an unrecognized difficult airway. Extensive literature addresses these scenarios, but logic would dictate that children who were preidentified as having potentially difficult airways should have their airways secured in the controlled environment of the OR. Regardless of an anesthesiologist’s comfort level and familiarity with the intended off-site environment, the critical backup personnel and the full array of airway equipment are not always available in remote locations. It is important to note that a fiberoptic bronchoscope and light source are not MRI compatible. It is easier to perform a fiberoptic intubation or to have the fiberoptic equipment readily available in an OR. In this environment, both the nursing and anesthesia support staff (technicians, other anesthesiologists, and otolaryngologists) are readily available and prepared to provide assistance. After intubation, the child may be safely transported to the off-site location for subsequent care.

The more difficult scenario is that of the unrecognized difficult airway<sup>22</sup>; this scenario may best be handled by establishing a local management protocol that can be activated when the situation arises. Each institution has peculiar equipment, space, and personnel resources. NORA leaders should establish a local protocol for management of the unanticipated difficult airway in an off-site location. In some cases this might involve bringing advanced airway management equipment to the location in a rapid, organized manner. In other cases the best option would include “temporizing” management with alternative airway devices and transporting the child to a location where a definitive airway can be placed in a controlled manner. For this reason, it is important to have alternative airway devices such as LMAs stocked in all anesthesia carts that are designated for off-site locations. In the event that the lungs cannot be ventilated or the trachea intubated, the LMA can provide a lifesaving temporary airway until more definitive action can be taken.<sup>23,24</sup>

**TABLE 45-1** Descriptions of the American College of Radiology’s Four Zones in the Magnetic Resonance Imaging Suite

ACR Zones	Occupants	Hazards
Zone I	General public	Negligible
Zone II	Unscreened MRI patients	Immediately outside area of hazard
Zone III	Screened MRI patients and personnel	Potential biostimulation interference, access to magnet room
Zone IV	Screened MRI patients under constant direct supervision of trained MRI personnel	Biostimulation interference, radiofrequency heating, missile effect, cryogenics

## Specific Locations for Non-Operating Room Anesthesia

### COMPUTED TOMOGRAPHY

CT involves ionizing radiation and can provide a good modality for differentiating between high-density (calcium, iron, bone, contrast-enhanced vascular and cerebrospinal fluid [CSF] spaces) and low-density ( $O_2$ , nitrogen, carbon in air, fat, CSF, muscle, white matter, gray matter, and water-containing lesions) structures. Because the scan time for current devices is brief, with actual imaging time ranging from 5 to 50 seconds per sequence, many children are able to tolerate CT without sedation or anesthesia. In cases in which anesthesia is required, it is often for those who have a fragile or unstable respiratory or cardiovascular status. Anesthesia or sedation is often required for children who are unable to cooperate (cognitively impaired children and those younger than 2 to 3 years of age) or require CT emergently. Emergent indications for CT include head trauma, unstable respiratory status in need of a pulmonary diagnosis, unexplained changes in mental status, or neoplasm workup in severely debilitated children. Anesthesia management is also necessary with a potentially unstable airway (peritonsillar abscess, anterior

mediastinal mass, craniofacial anomaly, tracheoesophageal fistula, uncontrolled vomiting, or gastroesophageal reflux), or the need for breath holding during acquisition of images (three-dimensional dynamic airway studies) (Figs. 45-1 and 45-2). Some CT units are particularly concerned about children moving when contrast is injected (because of dose restrictions the contrast injection cannot be repeated) and therefore request anesthesia services for any child they cannot confidently predict will stay motionless for the study.

Children with Down syndrome present a particular area of interest for the anesthesiologist working with the CT scanner. These children pose a unique risk for atlantoaxial instability and may require a head or neck CT to evaluate cervical and temporomandibular anatomy, recurrent sinusitis, or choanal atresia. The incidence of atlantoaxial instability varies from 12% to 32%.<sup>25</sup> Many children with Down syndrome require cervical spine radiographs before entering grade school or participating in the Special Olympics. Usually, the parents know the outcome of these tests and can relay the results of cervical spine radiographs. These studies alone do *not* indicate to the practitioner whether the child is at risk of dislocation.<sup>23</sup> Rather, it is the presence of neurologic signs or symptoms that would herald a spine that is "at risk": abnormal wide-based gait, incontinence, increased clumsiness,

**FIGURE 45-1** Three-dimensional dynamic computed tomography scan demonstrating change in caliber of left main-stem bronchus (circle) in an intubated child at end-inspiration (pressure held at 15 to 18 mm Hg) (A) versus end-expiration (B).

**FIGURE 45-2** Three-dimensional CT scan demonstrating change in caliber of left main-stem bronchus (arrows) on inspiration (A) versus expiration (B).

fatigue with ambulation, complaints of numbness, tingling in an extremity, weakness of an extremity, or a new preference for sitting games. In infants, these clinical signs may be difficult to assess. In younger children, developmental milestones (e.g., crawling, sitting up, reaching for objects) should be evaluated. Physical signs may include clonus, hyperreflexia, quadriparesis, neurogenic bladder, hemiparesis, ataxia, and sensory loss. Children with atlantoaxial instability on a radiograph are at less risk for dislocation if they do not exhibit any signs or symptoms of instability. Children who are capable of following commands are asked to perform full neck flexion and extension maneuvers to determine whether pain, sensory, or motor manifestations of cord compression develop.

Perhaps the most controversial issue facing anesthesiologists with regard to CT scans is the issue of oral contrast for CT. Because children lack abundant retroperitoneal fat, they do not have the natural contrast needed to elucidate abdominal images. For this reason, children may be required to ingest (orally or via nasogastric tube) diatrizoic acid (Gastrografin) to opacify the stomach and bowel. Oral contrast is useful in the identification of an intraabdominal abscess, mass, fluid collection, bowel injury, pancreatic injury, or other traumatic injury. The oral contrast comes as Gastrografin 3% and may be diluted to a 1.5% to 2.5% strength concentration. Gastrografin 3% is the full-strength concentration; in this undiluted form, Gastrografin is hypertonic (2200 mOsm/L). At this concentration, it can cause pulmonary edema, pneumonitis, osmotic effusions, and death if aspirated. Fortunately, when Gastrografin is administered to children for CT it is diluted to 1.5% to 2.5% strength, which is thought to be much less dangerous if aspirated. The volume of oral contrast that is administered can be quite large. Neonates typically receive 60 to 90 mL. Infants between 1 month and 1 year of age may receive up to 240 mL. Children between the ages of 1 and 5 years receive between 240 to 360 mL of contrast medium. Risk is introduced when these children require anesthesia within an optimal window after ingestion (usually 30 minutes to 1 hour after receiving the contrast agent) to enhance visualization. By most fasting guidelines (nil per os [NPO]), Gastrografin consumption within 1 to 2 hours of an anesthetic or sedation does not fall within the usual NPO guidelines. Yet, the scan must be completed while the Gastrografin is present in the gastrointestinal tract. Despite the large volume of Gastrografin that may be ingested, there does not appear to be a significant aspiration risk in this population, and many anesthesiologists do not secure the airway with a tracheal tube (Fig. 45-3). A review of the pediatric and adult literature confirms that over the last 35 years only a few case reports have been published of aspiration syndrome attributed to Gastrografin, all in extremely high-risk patients.<sup>24-26</sup> Several investigators have evaluated this issue from different perspectives. In one study, a cohort of 50 patients who received oral contrast after blunt abdominal trauma were evaluated for radiologic evidence of aspiration pneumonia or clinical complications of aspiration.<sup>27</sup> Some of the patients received general anesthesia, and some were neurologically impaired (including several with increased intracranial pressure). In this very high-risk group, only one patient had a question of aspiration on a chest radiograph after the CT scan, and that patient did not develop pulmonary symptoms. Another study evaluated the volume of gastric contents of 365 patients undergoing deep sedation or general anesthesia for abdominal CT scans.<sup>25</sup> Gastric contents exceeded 0.4 mL/kg in 49% of those who received gastric contrast. Two cases of vomiting were recorded. None of the patients in the

**FIGURE 45-3** Four hours after ingestion of Gastrografin, oral contrast is still present in the stomach and small intestine. Although dilute Gastrografin is still frequently present in the stomach at the time of computed tomography, there are as yet no case reports validating an increase in risk of pulmonary aspiration.

study developed clinical evidence of aspiration. When dilute Gastrografin is used, the risks associated with pulmonary aspiration appear to be small, even in children who are moderately to deeply sedated.<sup>28</sup> In spite of this evidence, no large cohort studies have been conducted that have the power to determine the actual incidence of aspiration in this setting. Therefore no accepted standard of care for the airway management of these children has been determined. Some anesthesiologists induce anesthesia with an intravenous or inhalational technique and maintain the anesthetic without securing the airway with a tracheal tube. Others perform rapid-sequence induction and tracheal intubation. The lack of consensus among anesthesiologists and the absence of evidence preclude a clear and consistent recommendation for managing the airway in these children.

## NUCLEAR MEDICINE

Nuclear medicine is one of the oldest functional imaging disciplines. Because of the advances in instrumentation and radiopharmaceuticals, nuclear scanning is becoming an increasingly popular imaging modality. Nuclear imaging can be used to evaluate an incredible range of pathologic conditions. These scans are useful for identification of the extent of disease for a large number of neoplasms.<sup>29</sup> They can also be used to detect epileptic foci in refractory epilepsy, evaluate cerebrovascular disease (e.g., moyamoya disease) and cognitive and behavior disorders, and detect and delineate renal function and disease, including detection of reflux and acute pyelonephritis.<sup>23</sup> Improvements in the hardware for nuclear imaging has greatly decreased the scan time, although even with the advent of two-level emission and transmission scans and combined CT imaging, a child must remain motionless for 20 to 60 minutes. The nuclear medicine environment is quiet, and the scan is pain-free. Accordingly, the indications for anesthesia or sedation include only those children who could not be reasonably expected to hold still for the 20 to 60 minutes, such as those with cognitive or behavioral impairment, young age, or severe pain or who are claustrophobic.<sup>29</sup> Sedation providers should be aware that the equipment in nuclear medicine imaging emits no ionizing radiation, but rather the radiation is contained

within the child and is of very low energy levels. Depending on the nature of the study, the children require intravenous access for administration of the nuclear tracer well in advance of the scan and therefore usually have intravenous access for the anesthesia or sedation. Many nuclear scans also require an empty bladder to avoid interference from concentrated tracer in an enlarged bladder. Accordingly, the bladder is often catheterized after anesthesia is induced and the radioactive urine that is collected is disposed of in a radioactive-safe manner.

Two relatively new nuclear scans that involve anesthesia and present particular challenges are single-photon emission computed tomography (SPECT) and positron emission tomography (PET) scans. SPECT scans use single-photon gamma-emitting radioisotopes and rotating gamma cameras to produce three-dimensional brain images. SPECT scans involve the use of radio-labeled technetium-99m (half-life of 6 hours), which has a high rate of first-pass extraction and intracellular trapping in proportion to regional cerebral blood flow. This scan is useful for localizing seizure foci. It appears to be as accurate as invasive direct cortical mapping in this regard.<sup>30</sup> Injection of the radionuclide during a seizure will tag areas of increased cerebral blood flow and localize the seizure foci. The child should be scanned within 1 to 6 hours of the seizure and injection of the tracer. Logistically this can pose a problem because there is no way to predict exactly when a seizure will occur. Therefore the neurology service needs to communicate to the anesthesiology service the importance of being flexible in providing anesthetic services within the window of time allowed to complete the test whenever the next seizure occurs.

PET scans use radionuclide tracers of metabolic activity such as O<sub>2</sub> usage and glucose metabolism. Radionuclide tracers of glucose may be useful when seeking seizure foci or tumor recurrence.<sup>29,31,32</sup> Unlike SPECT scans, PET scans should be performed during the seizure itself. Because of the short half-life of the glucose tracer (110 minutes), the scan is best completed during the seizure or within 1 hour thereafter. The logistical problem in providing this service is even more difficult than that of SPECT scans. In addition to the need to have a team available to provide anesthesia on very short notice, there is a risk of hypovolemia, especially in infants, who remain on NPO status and without intravenous hydration while anticipating a seizure. It is therefore important to work with the neurology and neurosurgery services to plan these scans in advance, to ensure intravenous access to avoid hypovolemia, and to arrange anesthesia coverage when needed.

### STEREOTACTIC RADIOSURGERY

Stereotactic radiosurgery (gamma knife) is a major advance in the treatment of selected malignant tumors (ependymoma, glioblastomas), vascular malformations, acoustic neuromas, and pituitary adenomas in children.<sup>33,34</sup> Radiosurgery is indicated, especially for those children with a tumor located deep in the brain or in an area that could put the child at significant surgical risk (e.g., speech, motor, cerebellum, brainstem areas) or for the recurrent brain tumor that has failed prior treatment. Radiosurgery involves the use of a single large fraction of radiation that is directed at a specific target with minimal radiation exposure to the surrounding normal tissues. Optimal results are achieved with small tumor volumes (14 cm<sup>3</sup> or less).<sup>35</sup>

Stereotactic radiosurgery requires the coordination of the departments of radiology, radiation therapy, and anesthesiology. The procedure averages 9 hours but can take up to 15 hours. The

stereotactic portion of the procedure begins in the morning in a CT scanner. A stereotactic head frame is applied after induction of general anesthesia and tracheal intubation. Some older children can tolerate the application of the head frame with local anesthesia alone but then develop anxiety because the pressure sensation produced by the head frame that can lead to anxiety, nausea, or vomiting. The vast majority of children require general anesthesia for application of the frame and subsequent imaging and surgery. When the head frame is in place, the key to unlock and remove it should be taped to the frame itself, in the event of a situation necessitating its emergent removal (e.g., vomiting, airway obstruction, or accidental tracheal extubation). For smaller children, nasal intubation may be considered to provide better stability during transport from the radiology suite to the OR. After the head frame is in place and the imaging study is completed, the child is transported (trachea intubated, sedated, and appropriately monitored) to the postanesthesia care unit while the radiologists and neurosurgeons review the images and plan radiosurgery. The postanesthesia care unit stay can range from 3 to 5 hours, during which time these children require continuous physiologic monitoring.

After the images are reviewed and the radiosurgery planning is complete, the child is transported to the stereotactic radiosurgery linear accelerator for treatment. In the treatment room full anesthesia monitoring and an anesthesia machine are present. To minimize radiation exposure to health care personnel, only the child remains in the scanner during treatment, observed at a distance with video cameras focused on both the child and monitors. The actual treatment lasts approximately 1 hour.

After radiosurgery is completed, the child is returned to postanesthesia care unit, where the trachea is extubated under controlled conditions. Risks are inherent with this prolonged anesthesia, which requires multiple transports between sites. One study examined 68 radiosurgery procedures in 65 children and reported four potentially serious anesthesia-related events.<sup>36</sup> In those children who received general anesthesia, serious complications included obstruction of the tracheal tube while in the head frame and lobar collapse requiring prolonged mechanical ventilation.

### RADIATION THERAPY

Radiation therapy for children uses ionizing photons to destroy lymphomas, acute leukemias, Wilms tumor, retinoblastomas, and tumors of the central nervous system. Improved three-dimensional imaging and enhanced computing power have allowed radiation oncologists to conform radiation dose to the shape of the tumor and minimize radiation to the surrounding tissues.<sup>37</sup> The energy absorbed by the tissues is measured in *grays* (Gy), which has replaced the term *rad*. One Gy is equivalent to 100 rad. Although most children receive standard x-ray therapy, specific lesions may respond better to bombardment with electron, proton, or neutron beam therapy. The anesthetic considerations are identical regardless of the type of therapy in this respect.<sup>38</sup> A planning session in a simulator is typically scheduled before the initiation of radiation therapy to map the fields that require irradiation while the child is in a fixed position. For proton beam treatments, a planning session is carried out in a CT scanner. A fiberglass immobilization cast of the head is made while the child is anesthetized with propofol and with a natural airway (Fig. 45-4). This cast allows secure positioning to ensure that the child does not move during treatment, but considerable care is required to configure the mask for optimal airway patency

**FIGURE 45-4** Child in fiberglass mask for radiation treatment of a cerebral neoplasm.

while ensuring proper windows for treatments because the mask may interfere with airway access.

Radiation therapy involves “fractionated” exposure. Repeat sessions are typical. The child must be motionless during therapy to precisely target malignant cells. Radiation therapy is typically administered by dividing the total radiation therapy course among daily or twice-daily sessions. In general, most treatment sessions last between 15 and 30 minutes and the planning simulation session may take as long as 2 hours, depending on the nature and location of the target lesion or area for therapy. For children who require neuraxial treatments for spinal metastases, as many as four fields may be irradiated and in both the supine and prone position. Dividing the total radiation therapy course into discrete daily sessions allows normal tissue repair between sessions while the tumor burden is lessened or destroyed. These children are optimally managed via central venous access that obviates the need for repeated venipunctures. Unless there is a specific airway anomaly, daily anesthetic management typically consists of general anesthesia using a propofol infusion (with or without midazolam pretreatment),<sup>39</sup> blow-by oxygen via nasal cannula or face mask, and spontaneous ventilation monitored with  $\text{ETCO}_2$ . Tachyphylaxis does not appear to be an issue even with multiple, frequent, treatments.<sup>40</sup> One retrospective review of 177 patients undergoing 3833 radiation treatments documented a 1.3% complication rate.<sup>41</sup> This rate compares favorably with the rate of complications for children undergoing propofol-based anesthesia without cancer.<sup>42</sup>

Dexmedetomidine sedation has been used for radiation therapy, but its use has not become widespread, most likely because of the need for a 10-minute loading dose and relatively frequent need for repeated boluses at the doses that have so far been studied.<sup>43</sup> Single-dose IV ketamine 0.5 to 0.8 mg/kg provides effective sedation, albeit with a greater half-life and more adverse effects (e.g., vomiting) than propofol.<sup>44</sup>

One exception to the technique of moderate or deep sedation for radiation therapy is the treatment of retinoblastoma. In this case, the eye must be completely immobile during the treatment. General anesthesia or very deep propofol sedation is indicated in these cases to ensure appropriate irradiating conditions; ketamine, with its side effect of lateral nystagmus, is not appropriate in these cases.<sup>44</sup>

The logistics of radiation therapy anesthesia or sedation are complex, even though the treatments themselves are not challenging. First and foremost, because of the large dose of radiation involved, only the child remains in the room during treatment. All monitoring must be performed via video observation. All radiation therapy units are equipped with video monitoring, but it must be adjusted to allow viewing of the physiologic monitors used for anesthesia. Children are often moved during treatment to allow different angles of access for the radiation treatment, and this must be taken into consideration when placing the monitors and the data or power cords associated with them. As with any anesthetic, positioning of the child must be considered. Many cases of spinal irradiation require the patient to be prone for treatment with the head at a specific angle with respect to the back. In addition, because of the need for the children to be in the close fitting mask during treatments, it is impossible to place an oral airway, LMA, or tracheal tube, thus the importance of monitoring expired carbon dioxide.

Most children undergoing radiation therapy are also receiving adjuvant and simultaneous chemotherapy. As the treatment progresses, nausea, vomiting, and respiratory illness stemming from local radiation effects and chemotherapy can challenge the anesthesiologist. It is important to work with the child's oncologist to manage symptoms and complete the treatment series as close to the planned treatment regimen as possible, because this is critical to the child's survival and maximizing quality of life.

### MAGNETIC RESONANCE IMAGING

MRI, magnetic resonance spectroscopy (MRS), magnetic resonance angiography (MRA), and magnetic resonance venography (MRV) are employed for the evaluation of neoplasms, non-hemorrhagic trauma, vascular lesions, cardiac lesions, orthopedic lesions (including joint disorders, osteomyelitis), central nervous system and spinal cord lesions, craniofacial disorders, detecting the origin of developmental delay, behavioral disorders, seizures, failure to thrive, apnea, cyanosis, hypotonia, and in the workup of mitochondrial and metabolic diseases.<sup>45-48</sup> MRA and MRV are especially helpful in evaluating vascular flow and often can replace invasive angiography in follow-up evaluations of vascular malformations, interventional therapy, or radiotherapy.<sup>49,50</sup> All of these imaging modalities are essentially equivalent in terms of the requirements for the provision of anesthesia or sedation and thus can be considered the same as for MRI in the following discussion.

Most MRI systems are superconducting magnets set up in a horizontal configuration within the bore so that the magnetic field is directed lengthwise to the child. The magnet is cooled by liquid nitrogen to a temperature of 39.2° F (4° C). The strength of the magnetic field in these scanners is described in tesla (T) units and range from 0.5 to 3.0 T. To put this into perspective, a 1.5-T magnet is the equivalent of 30,000 times the earth's magnetic field.

A variety of safety issues with respect to MRI are important, as mentioned in the earlier discussion of management of acute emergencies during anesthesia outside the OR. A useful review of these issues has been published by the American College of Radiology entitled “ACR Guidance Document for Safe MR Practices: 2007.”<sup>51</sup> All individuals who work in the MR environment should be familiar with the primary recommendations in this paper.

First and foremost is the risk of injury from ferromagnetic objects that can become attracted to the magnetic core of

**FIGURE 45-5** Magnetic resonance imaging cart that is not compatible inadvertently brought into scanner room.

the MRI scanner and cause significant morbidity and mortality (Fig. 45-5). In the presence of an external magnetic field, a ferromagnetic object can develop its own intrinsic magnetic field. The attractive forces created between the intrinsic and extrinsic magnetic fields can propel the ferromagnetic object toward the MRI scanner. Numerous injuries have been reported from this mechanism. Objects that have been reported as accidentally attracted to the MRI magnet include a metal fan, pulse oximeter, shrapnel, wheelchair, cigarette lighter, stethoscope, pager, hearing aid, vacuum cleaner, calculator, hair pin, O<sub>2</sub> tank, prosthetic limb, pencil, insulin infusion pump, keys, watches, clipboards, and steel-toe or heeled shoes.<sup>52,53</sup> Mortality can result from projectile disasters, as in the case of a death in 2001 in which a ferrous O<sub>2</sub> tank was inadvertently brought into the MRI scanner after the wall O<sub>2</sub> source failed. The O<sub>2</sub> tank was “pulled” from the hands of the respiratory therapist and crushed the skull of the child being scanned (*New York Times*, July 31, 2001:B1, B5). It is absolutely essential that all portable O<sub>2</sub> tanks are MRI compatible and that anesthesia carts are not brought into the MRI. Many MRI scanner units now have screening protocols that include a small handheld magnet to test whether objects are ferromagnetic and thus at risk of being pulled into the magnet.

The other major potential morbidity related to MRI scanning results from implanted devices (i.e., cardiac pacemakers, spinal cord stimulators, programmable ventriculoperitoneal shunts) that may malfunction in the powerful magnetic field of the MRI scanner and can cause injury. These injuries are most often caused by inappropriate patient screening or unfamiliarity with a particular implant’s MRI compatibility. Recently the U.S. Food and Drug Administration (FDA) changed the terminology for designating MRI safe objects from MRI-compatible and MRI-incompatible to MRI-safe, MRI-unsafe, and MRI-conditional ([www.fda.gov/MedicalDevices/DeviceRegulationandGuidance/GuidanceDocuments/ucm107705.htm](http://www.fda.gov/MedicalDevices/DeviceRegulationandGuidance/GuidanceDocuments/ucm107705.htm)). This terminology will not be applied retrospectively to objects previously designated as MRI-non-compatible. *MRI-safe* is defined as not posing any known hazard in any MR environment. *MRI-conditional* refers

to objects that may or may not be safe, depending on the specific conditions that are present. Examples include a laryngoscope, cardiac occluder device (e.g., for closure of an atrial septal defect), halo vest, or cervical fixation device. *MRI-unsafe* means the object should never be brought into the MRI environment because it poses a potential or realistic risk or hazard.

All implanted objects should be carefully evaluated before a patient or health care provider enters the MRI suite. The website <http://www.MRIsafety.com> is a useful resource for identifying MRI-safe objects. Note that stainless steel or surgical stainless objects may interact with the external magnetic field, potentially resulting in translational (attractive) and rotational (torque) forces. Special attention should be paid to intracranial aneurysm clips (may move and potentially dislodge), vascular stents, cochlear and stapedial implants, shrapnel, intraorbital metallic bodies, and prosthetic limbs. In fact, some eye make-up and tattoos may contain metallic dyes and are at risk of causing skin, ocular, periorbital, and cutaneous irritation and burning.<sup>54-56</sup> Bivona (Smiths Medical, Dublin, Ohio) tracheostomy tubes pose a risk in the MRI environment because of the ferrous material within the tracheostomy tube. Bivona tracheostomy tubes are not FDA approved as MRI-compatible or MRI-safe. These tubes may produce rotational and translational motion on the tracheostomy tube itself, may create artifact on MRI images of the head or neck, and may create a thermal hazard from the heating of the ferrous elements in the magnetic environment. All Bivona tracheostomy tubes should be replaced with an MRI-safe tracheostomy tube or a tracheal tube until the FDA confirms otherwise.<sup>57-58</sup>

Cardiac pacemaker compatibility is a matter of some debate.<sup>59</sup> Historically, the presence of a pacemaker has been considered a contraindication for the MRI environment. Most pacemakers have a reed relay switch that can be activated when exposed to a strong magnetic field and convert the pacemaker to the asynchronous mode. In at least two known cases, patients with pacemakers died from cardiac arrest while in the MRI scanner.<sup>57</sup> Adverse events associated with pacemakers in the MRI scanner include ventricular fibrillation, rapid atrial pacing, asynchronous pacing, inhibition of pacing output, and movement of the device.<sup>58,60</sup>

Since 1996, however, changes in pacemaker electronics have included decreased ferromagnetic content and increased sophistication of the computer capabilities. In 2004, one study reported no changes in pacemaker capabilities or adverse outcomes after 56 patients with pacemakers underwent 62 MRI procedures.<sup>61</sup> Similar results were reported in 68 patients whose pacemakers were reprogrammed to asynchronous or demand mode before undergoing scans in a 1.5-T MRI scanner. Unfortunately, there is a paucity of data on children with pacemakers or implanted defibrillators who underwent MRI scans, particularly with respect to scanners with 3-T field strength. Extreme caution and consultation with local experts is advisable before administering sedation or anesthesia in children with pacemakers in these environments.

Auditory considerations exist with respect to MRI. Specifically, a loud banging sound and vibrations are produced as the forces generated within the gradient coils of the MRI scanner cause the gradient coils to vibrate. The noises generated range from 65 to 95 dB in a 1.5-T magnet. Cases have been reported of temporary hearing loss after an MRI scan.<sup>62</sup> This report suggests that earplugs may prevent the temporary hearing loss associated with MRI. Given these data, earplugs or MRI-compatible headphones are routinely used in children undergoing MRI scans.

Temperature regulation for children during sedation or analgesia for MRI has been the source of significant discussion and speculation. Cool temperatures and humidity are required for proper magnet function. These conditions are a setup for radiant and convective heat loss. Anesthesia limits intrinsic thermoregulation. On the other hand, the MRI generates radiofrequency radiation (RFR) that is absorbed by the child and may offset heat lost to the environment. The specific absorption rate (SAR) is measured in watts per kilogram and is used to follow the effects of RF heating. The FDA allows a SAR of 0.4 watts/kg averaged over the whole body.<sup>63</sup> Data suggest that children can increase their core body temperature by 0.5° C during MRI of less than 1 hour duration in a 1.5-T environment.<sup>64,65</sup> The temperature of infants who underwent MRI scans of the brain increased 0.2° C with a 1.5-T scanner and 0.5° C with a 3-T scanner, with minimal efforts to prevent passive heat loss.<sup>66</sup> Accordingly, it seems appropriate to minimize efforts to avoid passive heat loss in the MRI scanner and to monitor temperature in the 3-T environment particularly for long scans.

Focal heating remains a concern with respect to monitoring equipment in the MRI scanner. For example, the ECG leads should not have frays or exposed wires; *any coils or loops in a conductor such as ECG wires or a pulse oximeter probe can cause tissue burns* (Fig. 45-6). Cases of first-, second-, and third-degree burns after MRI have been reported.<sup>67</sup> To avoid patient injury, the following precautions should be taken: (1) Avoid creating a conductive loop between the child and a conductor (ECG monitoring or gating leads, plethysmographic gating wire, and fingertip attachment), (2) do not leave any unconnected imaging coils in the magnet during imaging, and (3) prevent all exposed wires or conductors from touching the child's skin during the scan.

Many MRI scans require contrast administration. Gadolinium (gadopentetate dimeglumine) is an FDA-approved contrast agent that is intravascularly administered for MRI enhancement. Approved for use in 1998, gadolinium provides greater contrast between normal and abnormal tissue throughout the body. Gadolinium forms a complex with chelating agents that facilitates biodistribution to the extracellular compartment and excretion

via the kidneys. Unlike iodinated contrast agents, gadolinium complexes do not present a significant osmotic load. Gadolinium agents are considered to be safer than iodine agents with respect to adverse reactions. It is reportedly easily removed with dialysis.<sup>68</sup> On the other hand, recent warnings from the FDA suggest that gadolinium-containing contrast agents may be associated with the development of nephrogenic systemic fibrosis (NSF) or nephrogenic fibrosing dermopathy (NFD) in patients with moderate to end-stage kidney disease. The FDA suggests that gadolinium be administered only if necessary in children with advanced kidney failure and that, in those children, prompt dialysis be considered after gadolinium administration for MRA studies (<http://www.fda.gov/Drugs/DrugSafety/DrugSafetyNewsletter/ucm142889.htm>). The incidence of severe anaphylactic reactions to gadolinium is less than that of iodine-based contrast media. The incidence of severe anaphylactic or anaphylactoid reactions is 0.01% to 0.0003%.<sup>69</sup> Care must be taken to ensure the proper dose by weight and creatinine if renal function is compromised. Dosing estimates may be obtained from the following website based on the glomerular filtration rate: <https://www.radiologyprotocols.com> (free trials available for 1 month).

MRI-compatible equipment continues to be developed and improved. Multiple MRI-compatible anesthesia machines (with ventilators), monitors (including wireless models), and infusion pumps are now available. Unfortunately the cost for this equipment is substantial. An MRI-compatible anesthesia machine costs approximately \$60,000, MRI-compatible monitors range up to \$140,000, and compatible infusion pumps are \$12,000 to \$18,000. This cost may be overwhelming, especially in facilities with limited financial resources or limited need for MRI anesthetics. However, it is highly advisable for institutions to make the investment. If patient volume is not high enough or financial backing to support such an investment is lacking, then special planning may be instituted to deliver anesthesia without a full complement of MRI-compatible equipment. Specifically, a non-MRI-compatible anesthesia machine could be used in the following manner: the machine must be positioned outside the MRI suite, and 30 feet of parallel ventilator circuit (Bain Mapleson D) or circle system extension may be threaded through the appropriate-sized hole in the console wall to the child within. Alternatively, intravenous sedation or anesthesia can be delivered using MRI-compatible infusion pumps and O<sub>2</sub> can be delivered using a facemask or nasal cannula. If an MRI-compatible ET/CO<sub>2</sub> monitor is not available, a conventional carbon dioxide (CO<sub>2</sub>) monitor may be situated outside the MRI room and the 30-foot-long tubing threaded through the console wall in a similar fashion to attach to the child within.<sup>66</sup> If GETA is required without an MRI-compatible anesthesia machine, it is safer to anesthetize the child outside the scanner (anesthesia circuit threaded through the console wall and then back out the entrance door to an induction area), secure the airway, and then move the child into the scanner. Similarly, if propofol sedation is intended, the propofol infusion pump can also be situated outside the scanner and equipped with 30 feet of intravenous infusion tubing. It is important to determine whether the pump is able to infuse accurately through the resistance of the long tubing and that the caliber of the tubing is sufficiently large that the length of tubing required does not trigger the pump's high-pressure alarm. An Ambu bag or Mapleson circuit must always be situated in the MRI suite and connected directly to an O<sub>2</sub> source within the scanner. This is critical, especially when the anesthesia machine is far from the child.

**FIGURE 45-6** Burn at site of electrocardiogram pad from a frayed lead.

MRI-safe stethoscopes, stylets, laryngoscope, and flashlights should be available. If they are not available, standard equipment can be used with some modification and testing. The only component of the laryngoscope that is usually *not* MRI-safe is the battery. Replacing the standard battery with a lithium battery may be a simple, safe, and less expensive alternative to purchasing a marketed MRI-compatible and safe laryngoscope. Before introducing any equipment into the MRI environment, a rudimentary safety check should be performed by first passing a handheld magnet over the object to confirm that there is no ferrous material within. As a final safety check, an MRI safety expert should carefully introduce the object into the scanner (before bringing in a child) to confirm safety.

Anesthetic management of children in the MRI suite depends to a large extent on the availability of support personnel and equipment, the anesthesiologist's personal anesthetic practice, and the child's medical history. In clinical practice, the choice of anesthetic varies greatly among anesthesiologists. Airway management may include an LMA, a tracheal tube, or a natural airway (with a roll placed under the shoulders). With an LMA or tracheal tube, either inhalational or intravenous anesthesia may be used to establish a motionless child. With a natural airway, only intravenous sedation or anesthesia with propofol or dexmedetomidine is commonly used.<sup>7,70-75</sup>  $\text{ETCO}_2$  should be monitored; in the case of nasal prongs, a septate design that delivers  $\text{O}_2$  (2 to 4 L/min) through one nostril while aspirating gas for  $\text{CO}_2$  (capnometry) through the other allows for continuous assessment of respirations during spontaneous ventilation. If respiratory problems occur, immediate access to the airway is not possible while the child is in the bore of the scanner; for this reason, some anesthesiologists may prefer to insert an LMA or tracheal tube in all children. Most LMAs are MRI-compatible, although the pilot balloon should be taped to the circuit tubing when imaging the head or neck because it may create imaging artifacts (Figs. 45-7 and 45-8).

Few studies have directly compared general anesthesia with a controlled airway to intravenous sedation or anesthesia techniques during MRI. One randomized study of 200 children

demonstrated no difference in airway complications between the two groups. However, more pauses occurred during scans (for movement, etc.) with propofol sedation, but much less agitation was experienced on emergence after the scan.<sup>76</sup> To ensure MRI scans without interruption in the majority of children, many begin with infusion rates of propofol 200 to 250  $\mu\text{g/kg/min}$  in children and either maintain that infusion rate throughout or taper the infusion rate as described previously.<sup>77</sup> For younger children (infants) and children with severe cognitive dysfunction, infusion rates 20% to 50% greater than 250  $\text{mg/kg/min}$  may be required to prevent movement during MRI scans. Other studies documented agitation<sup>78</sup> and prolonged nausea and vomiting<sup>79</sup> after MRI scans performed under general anesthesia with inhalation agents. Some MRI scans (cardiac, thoracic, or abdominal) require breath holding to obtain adequate images. In such cases, it is necessary to control the airway with an LMA or endotracheal tube and deliver general anesthesia. After reviewing the literature, insufficient evidence exists to recommend a particular anesthetic technique for MRI scans. Anesthesiologists still must consider their own practice environment and expertise, the demands of the scan itself, and the comorbidities of the particular child when selecting an anesthetic technique, particularly for children undergoing a cardiac MRI.

#### INTERVENTIONAL RADIOLOGY AND INVASIVE ANGIOGRAPHY

Interventional radiology has evolved greatly in the last decade; many procedures that previously required operative treatment now can be accomplished with minimal intervention. In spite of the relatively little painful stimulation involved in most of these procedures, general anesthesia is often required particularly in children. Control of movement is often critical, and even the simplest procedures such as angiography often require a general anesthetic to ensure motionless conditions in children. In addition, many procedures require intermittent breath holding to acquire clear images. Furthermore, when the radiologist encounters vasospasm or needs to vasodilate arteries to enhance the images, the anesthesiologist may be requested to induce hypercarbia.

**FIGURE 45-7** Laryngeal mask airway with pilot balloon left adjacent to face.

**FIGURE 45-8** MRI scan of the patient in Figure 45-7 demonstrating artifact (arrow) created by ferrous material in pilot balloon.

**FIGURE 45-9** Effect of hypercarbia on caliber of cerebral blood vessels; hypercarbia may assist the interventional radiologist to pass a catheter into small vessels (*right*).

Interventions involving the abdomen and pelvis have unique considerations;  $N_2O$  can diffuse into the bowel, causing distention and, in some cases, distort or mask the vasculature of interest; it should be used with caution. In addition, when angiographic imaging of the abdomen is required, the interventional radiologist may request that the anesthesiologist administer intravenous glucagon, usually in 0.25-mg increments. Glucagon reduces peristalsis and, as a consequence, reduces motion artifact during image acquisition.<sup>80</sup> Glucagon has been reported to have side effects, including nausea, vomiting, hyperglycemia, depression of clotting factors, and electrolyte disturbances<sup>70</sup>; close monitoring is warranted, particularly in neonates and small infants.

Cerebral angiograms and interventions can be complex and carry significant risk. Cerebral studies may be indicated in the workup or postoperative follow-up of vascular malformation or tumor resections, stroke, hemorrhagic events, vascular disease, and unexplained mental status changes. These interventions typically require GETA to provide hypercarbia and breath holding. Hypercarbia to  $ETCO_2$  values of 50 mm Hg or greater promote vasodilation to allow better access and visualization of cerebral vasculature (Fig. 45-9). During these cases, orogastric and nasogastric tubes, esophageal stethoscopes, and esophageal temperature probes should be used with caution because they may cause artifacts on the angiographic images.

Any child who requires a study for the potential or confirmed diagnosis of moyamoya disease should be treated with utmost precaution. These children should have an anesthetic that minimizes the risk of transient ischemic attacks and stroke during the procedure.<sup>71</sup> Anesthetic care should begin with the preinduction administration of 10 mL/kg of intravenous fluid to minimize the risk of hypotension (and potential cerebral ischemia) on induction of anesthesia. Hypocarbica should be avoided throughout and mild hypercarbia promoted. In the event of vasospasm or difficult access of small, tortuous vessels, locally administered (through the catheter) nitroglycerin in small doses (25 to 50  $\mu$ g) may facilitate visualization and access. Although often effective for discretely vasodilating specific areas, nitroglycerin will generally not have a clinically important systemic effect on blood pressure. Consequently, intraarterial blood pressure monitoring usually is not required. Specific protocols have been suggested for minimizing perioperative strokes in these children.<sup>72</sup> Sedating the child before starting the intravenous line decreases crying and hyperventilation that can lead to cerebral ischemia. Close attention to postoperative pain control can similarly improve outcomes (see Chapter 24).

**FIGURE 45-10** Arteriovenous malformation of the leg with high output cardiac failure.

The anesthetic management of children with vascular malformations who present for embolization or sclerotherapy can be challenging. These lesions, although present at birth, are often discrete and not clearly visible. As the child grows, the vascular malformation may expand rapidly, growing with the child. In one review, only 18% of lesions presented before 15 years of age.<sup>73</sup> This rapid proliferative phase may occur in response to hormonal changes (pregnancy, puberty), trauma, or other stimuli. Vascular malformations may be classified as high-flow or low-flow lesions, depending on which vessels are involved. High-flow lesions may include arteriovenous fistulas, some large hemangiomas, and arteriovenous malformations. Symptoms of high-output cardiac failure predominate in the neonate, and symptoms of stroke, seizures, or hydrocephalus are more common in infants and older children.<sup>73</sup> The potential for pulmonary edema should be anticipated and assessed in the physical examination and past medical history (Fig. 45-10). Low-flow lesions consist of venous, intramuscular venous, and lymphatic malformations. Surgical resection of symptomatic vascular malformations may be hazardous, as well as unsuccessful—any vascular element that is not

resected may enlarge and cause further problems. It is for this reason that invasive angiography and embolization is a popular alternative to surgical resection.

When embolizing vascular malformations, radiologists often strive to cut off the feeding vessels with agents such as ethanol, stainless steel coils, absorbable gelatin pledgets and powder, polyvinyl alcohol foam, glues, thread, and ethanol. The choice of agent depends on the clinical situation and the size of the blood vessel. Absolute ethanol (99.9% alcohol) is a powerful sclerosing agent that thromboses vessels even at the level of the capillary bed. It is particularly useful in the embolization of symptomatic vascular malformations. Ethanol causes thrombosis by injuring the vascular endothelium. Ethanol also denatures blood proteins. When permanent occlusion is the goal, polyvinyl alcohol foam and ethanol are often employed because they both occlude at the level of the arterioles and capillaries. Medium to small arteries may be occluded with coils, which are the equivalent of surgical ligation. In trauma situations, when only temporary (days) occlusion is the goal, absorbable gelatin pledgets or powder are employed.<sup>74</sup>

The embolization and sclerotherapy of vascular malformations usually requires a general anesthetic to ensure motionless conditions, especially during high-risk procedures that involve injection of a contrast agent and potentially painful sclerosants. These procedures require careful planning and discussion between the interventional radiologist and the anesthesiologist for safe airway management, intraprocedural and postprocedural care, and disposition. The anesthesiologist must have a basic understanding of the procedure and the risks involved. Some of the risks are inherent to the procedure and the agents used for embolization or sclerotherapy. Pulmonary emboli have been reported after these procedures as a result of the inadvertent migration of embolization material to the lungs. The incidence of pulmonary embolization after cerebral interventions has been reported to be as great as 35% in children after embolization or coiling.<sup>75</sup> Before each procedure, the anesthesiologist and radiologist should discuss the radiologist's specific requirements and concerns and decide on an anesthetic plan. Some procedures, especially embolizations of the head and neck, carry an increased risk of neurologic or cardiovascular complications.<sup>81</sup> It is important that the anesthesiologist anticipate these potential complications and modify the anesthetic technique to permit neurologic assessment soon after extubation.

The anesthesiologist should be familiar with the mechanism of action and potential risks associated with the various agents and devices used for embolization and sclerotherapy. All sclerosants produce local hemolysis when administered into the vascular bed. Large amounts of sclerosant, particularly sodium tetradecyl and ethanol, can cause hemoglobinuria, which can result in renal injury if the child is not adequately hydrated during and after the procedure.<sup>82</sup> Most children have a urine catheter placed to monitor the urine output, facilitate generous hydration, and monitor for hematuria. The anesthesiologist should generously hydrate the child with intravenous saline. On average, it has been our practice to administer as much as 50 mL/kg intravenous fluids over the course of the procedure. When hemoglobinuria is noted during the procedure, the anesthesiologist should notify the radiologist coincident with increasing the rate of fluid administration (Fig. 45-11). Hemoglobinuria may not occur until the end of the procedure, sometimes after a cumulative large dose of sclerosant has been administered or the tourniquet (if used) has been released. During procedures that

FIGURE 45-11 Hematuria after ethanol embolization.

involve lower extremity lesions and tourniquets, hemoglobinuria can develop soon after the tourniquet is released. Promoting diuresis with furosemide 0.5 to 1 mg/kg helps resolve gross hematuria. Occasionally, hemoglobinuria develops 1 to 2 hours after the procedure, usually while in the postanesthesia care unit. It is important to carefully balance fluid administered with urine output. In the event of persistent hemoglobinuria, sodium bicarbonate 75 mEq/L in D<sub>5</sub>W may be administered at two times maintenance rate to alkalinize the urine and minimize precipitation of hemoglobin in the renal tubules.<sup>8</sup>

Administering ethanol to sclerose a vascular malformation has the potential for severe complications.<sup>83</sup> The most infrequent but serious risk is cardiovascular collapse, which is generally preceded by hypoxemia and bradycardia. Most reported cases of cardiovascular collapse involved lower extremity malformations.<sup>84</sup> The cause of the cardiovascular collapse associated with ethanol is unclear, although it is reported to occur uniquely when there is direct release of ethanol into the systemic veins. Collapse can occur after release of tourniquets in extremities that have been injected with ethanol. It is critical that the radiologist communicate with the anesthesiologist whenever ethanol is being injected, as well as before the deflation of the tourniquet. It has been recommended that any child at significant risk of systemic ethanol egress should have a pulmonary artery catheter placed before the procedure to identify changes in pulmonary artery pressure that might herald electromechanical dissociation. Significant increases in pulmonary artery pressure resulting from pulmonary vasoconstriction necessitate interrupting the administration of ethanol until the pressure normalizes. Significant fluctuations in vital signs include an increase in pulmonary artery pressure, a decrease in systemic blood pressure, decrease in ET<sub>CO<sub>2</sub></sub>, or O<sub>2</sub> saturation, cardiac arrhythmias, or full cardiac arrest.

Ethanol can produce a state of intoxication. The ethanol used for embolization and sclerotherapy is 95% to 98% pure. Children who receive greater than 0.75 mL/kg can become clinically intoxicated. Blood levels correlate with the volume of ethanol administered, regardless of the location or type of vascular malformation

(Fig. 45-12). On extubation, these children display either significant agitation or excessive sedation and analgesia; opioids should be administered with caution because they have a synergistic effect with ethanol and potentially cause unwanted respiratory depression. It is generally advisable to administer minimal or no opioids until the child is extubated and confirms the presence of pain. Ketorolac may be administered intravenously after soliciting the agreement of the radiologist, removing the invasive catheters, and ensuring hemostasis has been achieved.

Children with vascular malformations, especially venous malformations, can have preexisting coagulation disturbances that resemble disseminated intravascular coagulation.<sup>85</sup> Children with laboratory indices consistent with preexisting consumptive coagulopathy should have a hematology consultation and, if possible, receive heparin for 2 weeks before the procedure to replenish their fibrinogen levels. The anesthesiologist may be asked to

administer cryoprecipitate or platelets during the procedure to promote clotting and successful sclerosis. The use of ethanol for sclerosis or embolization can also elicit a coagulation disturbance that resembles disseminated intravascular coagulation. There is a statistical relationship between the amount of ethanol administered and the degree of coagulation disturbance elicited.<sup>86</sup> Additional cryoprecipitate or fresh frozen plasma transfusions are given only in severe cases, because the coagulopathy is generally not symptomatic and resolves within 5 days. However, major surgery should be deferred until the coagulation parameters have normalized.

It is important to be aware of the potential morbidity associated with embolization procedures. Type and crossmatch should be performed for all children scheduled for embolization in anticipation of possible major hemorrhage. Embolization therapy has been associated with multiple potentially devastating outcomes, including stroke, cerebral abscess, bleeding, cyanosis, and pulmonary embolism.<sup>87</sup> Postprocedural mortality is reported to be 5% to 6%.<sup>88</sup> It is important to document full return of neurologic status after the child recovers and the trachea is extubated. Vascular malformations involving the airway are particularly challenging (Fig. 45-13). The anesthesiologist and radiologist should review the imaging studies (usually MRI) before the procedure. The scans should be evaluated for patency of the nares, nasopharynx, hypopharynx, and oropharynx, as well as for an uncompromised trachea, carina, and bronchi. MRI will also confirm that there is no malformation in the nares or nasopharynx, which could be damaged or bleed during intubation. Most interventional radiology suites are not situated in the OR. If there is any potential for airway compromise, difficulty in attaining a mask airway, or failure to intubate, the airway should be secured in the OR before transport to the radiology suite. In general, an otolaryngologist or another specialist skilled in bronchoscopy and tracheotomy should be present in the OR prepared to perform bronchoscopy (fiberoptic or rigid) or tracheostomy should the airway be lost.

If postsclerotherapy edema and vascular congestion involving the airway structures are anticipated, the child's trachea should be intubated nasally and remain intubated for 48 hours or

**FIGURE 45-12** Positive relationship between serum ethanol level and amount of ethanol administered. (From Mason KP, Michna E, Zurakowski D, Koka BV, Burrows PE. Serum ethanol levels in children and adults after ethanol embolization or sclerotherapy for vascular anomalies. *Radiology* 2000;217:127-32.)

**FIGURE 45-13** Venous malformation of the face with patient sitting upright (A) and supine (B).

until the swelling subsides. Nasal intubation is preferred to minimize the risk of dislodging the tracheal tube or premature extubation. The decision to have the child remain intubated postoperatively is usually made before the start of the procedure, after the anesthesiologist and radiologist review the MR images together. If the trachea remains intubated postoperatively, the trachea is extubated in the intensive care unit after the presence of an air leak around the tracheal tube is confirmed or a flexible nasal fiberoptic view of the airway can be performed at the bedside. If there is any doubt about the patency or self-sufficiency of the airway, these children should be transferred to the OR for tracheal extubation in a controlled setting with an otolaryngologist present.

Venous malformations involving the head, neck, or airway structures typically swell with dependency or Valsalva maneuver (e.g., crying). Before extubating the trachea, these children should be positioned head-up to promote venous drainage and reduce swelling. Efforts should be made to minimize coughing before tracheal extubation. In the event of respiratory compromise, venous malformations can enlarge when the child coughs, increases intrathoracic pressure, or uses accessory muscles. Attempts at reintubation, cricoid pressure, head extension, and mask ventilation can further enlarge the malformation. Mask ventilation can be challenging, sometimes impossible, if the malformation is swollen and firm. Achieving an occlusive mask seal is particularly difficult when there is swelling of the cheek, tongue, lip, chin, or nares. Venous malformations of the lips and tongue, because of their blue color, can make it difficult to assess the child for hypoxemia in the event of respiratory distress. Reintubation can become impossible in these situations because all of the maneuvers to achieve a mask seal increase venous pressure and swelling. When attempting to reintubate the trachea of a child with intraoral or pharyngeal malformations, special care should be taken to avoid damaging the malformation: even a small nick can create significant bleeding. In the event of oropharyngeal bleeding and inability to mask ventilate and/or intubate, it is critical to have alternative airway devices immediately available. LMAs in particular can be lifesaving. Proper insertion and inflation of the LMA can secure an airway and, more importantly, tamponade bleeding. However, because the LMA rests above the vocal cords, it does not protect the airway from pulmonary aspiration.

### INTRAVASCULAR CONTRAST MEDIA

The use of intravascular contrast media is ubiquitous in interventional radiology and cardiac catheterization. It is important that the anesthesiologist be aware of the risks and potential side effects of these agents. Almost all life-threatening reactions occur immediately or within 20 minutes of contrast agent administration. Low-osmolality ionic and nonionic contrast media are associated with a reduced incidence of adverse events, especially non-life-threatening events compared with high-osmolality contrast media. Serious contrast reactions are estimated at 1 to 2 per 1000 studies using high-osmolality contrast media versus 1 to 2 per 10,000 studies with low osmolality contrast media.<sup>89,90</sup> Adverse reactions include nausea, vomiting, hypotension, urticaria, bronchospasm, anxiety, chills, fever, facial flushing, seizures, pulmonary edema, and cardiovascular collapse. Anaphylactic shock is the most worrisome of all contrast reactions and may occur as early as 1 minute and as late as several hours after administration of the contrast material. Although adverse reactions to intravascular contrast media are unpredictable, some risk factors are

identifiable. These include children who suffer from allergies or an atopic disease, children with asthma, significant cardiovascular disease, and paraproteinemia, and children with prior contrast reactions have an increased incidence of adverse reactions.<sup>91</sup> Children who have been identified as being at increased risk of a contrast reaction should be premedicated with corticosteroids and antihistamines. The American College of Radiology suggests that corticosteroid premedication, along with low osmolality contrast media, should be used for those at risk.<sup>91,92</sup>

Because the contrast agent is hypertonic relative to plasma, attention needs to be paid to the risk of a triphasic response: initial but transient (30 to 60 seconds) hypotension, followed by hypertension as the contrast material draws fluid intravascularly, followed by a hyperosmotic diuresis with the potential for hypotension. Equilibration with the extracellular fluid compartment occurs within 10 minutes, heralded by the onset of diuresis. For this reason, special attention should be paid when administering iodine contrast to any child with a history of congestive heart failure. The initial increase in blood volume may precipitate cardiovascular compromise. Renal failure from contrast media can occur with high- and low-osmolality contrast media. Although the cause of the acute renal failure is not known, risk factors include preexisting renal insufficiency (serum creatine 1.5 mg/dL or greater), diabetes mellitus, dehydration, cardiovascular disease, hypertension, and hyperuricemia. For these at-risk children, good hydration must be maintained, along with careful follow-up of renal function.<sup>93</sup> It should be noted that those with paraproteinemias (multiple myeloma, Waldenström macroglobulinemia) are predisposed to irreversible renal failure from protein precipitation in renal tubules, which is preventable with proper hydration.<sup>94</sup>

### ENDOSCOPIC PROCEDURES

Gastrointestinal endoscopy is a common procedure for pediatric gastroenterologists. Both upper and lower endoscopies involve significant stimulation, which requires deep sedation or general anesthesia in infants and children. A range of sedation and anesthesia options may be used for both simple<sup>95,96</sup> and more complex procedures such as foreign body removal, endoscopic retrograde cholangiopancreatography (ERCP), and percutaneous endoscopic gastrostomy (PEG) placement.<sup>97</sup> The choice of deep sedation versus general anesthesia (with or without a tracheal tube) depends on the medical condition of the child, the risks associated with the specific procedure, and the anticipated duration. Upper esophagogastroduodenoscopy (EGD) in infants (less than 10 kg) generally requires tracheal intubation to avoid airway compression caused by the endoscope pressing the trachealis muscle into the trachea. However, few definitive data exist on this issue (few studies include infants less than 1 year of age). At Dartmouth Hitchcock Medical Center, we have found that if the endoscopist is willing to use the smallest available pediatric scopes, successful sedation or anesthesia without a tracheal tube is possible for infants as small as 6 to 7 kg. In some cases an LMA may be used to secure the airway and the cuff deflated to allow passage of the endoscope and then reinflated once the scope has entered the esophagus. It is advised to hold on to either a tracheal tube or an LMA during the procedure to reduce the risk of the endoscope dislodging it during their manipulations.

Many techniques may be employed successfully to maintain adequate conditions for upper and lower gastrointestinal endoscopy. Although all anesthesia-delivery areas must meet ASA standards, scavenging and ventilation in endoscopy suites may not

always be effective in allowing the safe use of inhalational anesthetics. In these cases, total intravenous anesthesia can substitute for potent inhalation agents.<sup>98-100</sup> Over the last several years, various combinations of intravenous agents have been described for the delivery of sedation and anesthesia in the endoscopy suite for children. As a general rule, propofol is used either alone,<sup>101</sup> in combination with an opioid (fentanyl or remifentanyl),<sup>102,103</sup> or with ketamine.<sup>104</sup> Outcomes after deep sedation or anesthesia with propofol and inhalational anesthesia were similar.<sup>99</sup> However, the time to awakening was more rapid after the inhalational anesthetic, the incidence of agitation on emergence was less, and the time to hospital discharge earlier after propofol.

Access to the airway is obviously limited once a transoral endoscope is in place. The two most stimulating portions of the esophagogastroduodenoscopy are transoral and transpyloric passage of the endoscope. After endoscope insertion, the sedation or anesthesia can often be reduced without adverse effect on the procedure conditions. Smooth insertion of the endoscope can be aided by topical spray of local anesthesia to the oropharynx to reduce the discomfort of passing the endoscope and to prevent coughing and gagging. For older children, topicalization of the oropharynx can be accomplished before sedation and the child can position himself or herself for the gastroenterologist (lateral position). Sedation can be subsequently accomplished with the child prepositioned. For cases performed without tracheal intubation, a CO<sub>2</sub> sampling nasal cannula can be placed and used over the nose or near the mouth (for those who do not breath through the nose) to supplement O<sub>2</sub> and allow a monitor of respiration.

Upper endoscopies have the inherent risk of apnea, laryngospasm, bronchospasm, and airway obstruction. Most problems resolve after withdrawal of the endoscope and positive-pressure ventilation with a face mask.<sup>105</sup> In rare situations, tracheal intubation may be required to complete the procedure or resolve an airway issue. In young infants, abdominal distention secondary to air introduced into the stomach may impair diaphragmatic excursion, leading to hypoventilation. Little published evidence exists on which to base age-related practice in endoscopy sedation and analgesia, experience led several groups to select all infants up to 6 months of age as the age interval for which general anesthesia with tracheal intubation is required, because of a greater frequency of respiratory complications.<sup>95,96</sup> When extubating the tracheas in these infants, be wary that residual air in the stomach can impair effective ventilation and contribute to desaturation or O<sub>2</sub> dependence in the recovery room. Thus it is important to remind the endoscopist to suction any residual air from the stomach before removing the endoscope.

Few large studies have reported outcomes after pediatric gastrointestinal endoscopy. The Clinical Outcomes Research Initiative (CORI) is a national registry of endoscopic procedures that was started in 1995. The PEDS-CORI is the pediatric component that was started in 1999. A 2007 report collected the complications from pediatric upper endoscopy involving 10,236 encounters from 13 different institutions over 4 years.<sup>106</sup> Overall, there was a 2.3% incidence of complications (of any kind). Of these, 79.9% were cardiopulmonary, 18% were gastrointestinal complications, and 5.9% were other complications, including prolonged sedation, drug reactions, or rash. Not surprisingly, children who developed complications were younger and had a greater ASA physical status. General anesthesia was associated with a reduced overall complication rate (1.2%) compared with that in the IV

sedation group (3.7%). Although these data were not controlled or randomized, it does shed some insight into the complication rates associated with pediatric sedation outside the OR.

## Summary

As the need for anesthesia services for children outside the OR continues to expand, anesthesiologists will be more frequently called on to provide anesthesia services for this venue. It is in our patients' interests and our own professional interest to accept this responsibility and provide the most effective, efficient, and safe anesthesia and sedation and anesthesia outside of the OR. Each site and procedure may pose particular anesthetic implications and challenges. It remains important that a core group of anesthesiologists become familiar with these challenges and that they communicate amongst each other and with the proceduralists with whom they work. The anesthetic configuration and equipment demands may be unique at each center. Emergency situations should be role-played in advance so that all personnel are familiar with the location of code equipment and emergency airway equipment. All morbid conditions and untoward events should be reviewed regularly to make improvements and implement any changes in practice. Working in the areas outside the OR can be rewarding and challenging and should be approached with a commitment to ensure that children will receive a standard of care that is equal to the care provided in the OR.

## ACKNOWLEDGMENT

We wish to thank Leira P. Mason and Babu V. Koka for their prior contributions to this chapter.

**CHILDREN'S RECOVERY FROM ANESTHESIA** is substantively different from that of adults. Although both age groups share the key elements of regaining consciousness, controlling pain, and maintaining a patent airway, the nature and timing of these elements are different. In young children, emergence from inhalational agents can be quite rapid because of the increased minute ventilation, increased blood flow to the vessel-rich group (see Chapter 6), and decreased total body muscle and fat stores, whereas emergence from intravenous agents in infants may be delayed because of decreased clearance as a result of reduced liver blood flow and enzyme activity. The quality of the emergence is different in children and adults because agitation (i.e., emergence delirium) after sevoflurane and desflurane is more common in young children than in adults. The criteria used to evaluate emergence from anesthesia or sedation must be consistent with the developmental level of the child. The nature and rapidity of complications that can occur during emergence require careful planning and anticipation of problems. Parents should be considered partners and active participants in effective postoperative management.

The environment in the pediatric postanesthesia care unit (PACU) is unique and challenging. The staff and facility of any institution in which children recover after surgery must understand these challenges and be prepared to manage children through the difficult process of emerging from the anesthetized state to the new reality of postoperative consciousness. Early admission of parents to PACU and use of rocking chairs to permit parents to comfort their children is a common means of facilitating recovery.

## Perioperative Environment

The ideal perioperative environment is one that combines aspects of safety, ergonomics, and comfort for the child, family, and

caregivers. The environment should be child specific and staffed by experts in child care. This should start with the admission process and conclude with the discharge to home or the hospital ward. Ideally, a child should be under the care of the same team throughout his or her hospital stay. For example, the child can be admitted by the nurse who will later take care of the child and the family in the PACU. In some hospitals, this is achieved by creating an integrated perioperative environment, in which children are admitted, prepared, and allowed to recover in the same space, with the same nurses and child life specialist. Familiarity with personnel and surroundings is a great stress reliever for children and families; it also fosters trust and comfort.

Privacy and shelter from noise is an important aspect of the setup. The ability to spend time with the child without being disturbed is something that many families appreciate, and this helps the child to deal with the stress of a strange environment. Most modern PACUs have moved to individual patient rooms or cubicles for preoperative and postoperative care, similar to a typical pediatric intensive care unit (PICU).

Equipment (Table 46-1) and available medications (Tables 46-2 and 46-3) should be standardized throughout the unit and be compatible with transport monitors and other devices used in corresponding high care facilities (e.g., PICU). An important safety precaution is the use of preprinted weight-based emergency drug doses for each child; these rapid reference sheets can be attached to each child's bed or chart on admission so that a quick dose recommendation is readily available. Alternatively, the electronic record should have precalculated emergency drug doses for each child. This practice may also reduce the risk of drug errors in an emergency situation.

Nurses, residents, fellows, attending physicians, and other personnel working in the perioperative area should be competent in the provision of neonatal and pediatric advanced life support.

**TABLE 46-1 Suggested Essential Bedside Equipment**

Oxygen supply with regulated flows
Oxygen facemasks and face tents for spontaneous ventilation (various sizes)
Stethoscope
Resuscitation bags, self-inflating (Ambu)
Anesthesia facemasks for positive-pressure ventilation (pediatric sizes: 0, 1, 2, 3; adult sizes: small, medium, large)
Oral airways (sizes 00, 0, 1 to 5)
Nasal airways (sizes 12F to 36F)
Suction and appropriate suction catheters (sizes 6.5F to 14F); tonsil-type (Yankauer) attachment
Needles, syringes, alcohol wipes, Betadine solution, gauze pads
Arterial blood gas kit
Gloves (preferably nonlatex)
Pulse oximeter and sensors (size appropriate, stick-on type preferred to clip-on type)
Electrocardiograph, monitor and pads
Manual and automated blood pressure device
All sizes of blood pressure cuffs

**TABLE 46-2 Suggested Emergency Supplies for a Crash Cart or Central Location**

Laryngoscopes with blades: Miller 0, 1, 2, 3; Macintosh 2, 3, 4; extra laryngoscope bulbs and batteries
Endotracheal tubes, sizes 2.0-mm internal diameter (ID) through 8-mm ID; cuffed and uncuffed tubes for all sizes when available
Laryngeal mask airways, sizes 1, 1.5, 2, 2.5, 3, 4, 5
ProSeal laryngeal mask airway, sizes 1.5, 2, 2.5, 3, 3.5, 4, 5
Fast-track intubating laryngeal mask airway
Stylet appropriate for each endotracheal tube size
Syringe for endotracheal cuff inflation
Tape and liquid adhesive for endotracheal tube fixation
Intravenous catheter (14 gauge) with 3-mm ID endotracheal tube adapter for emergency cricothyroidotomy (see Fig. 12-25)
Cricothyrotomy kits appropriate for age (see Figs. 12-25 and 12-26; see also E-Figs. 12-5 through 12-10)
Backup resuscitation bags and masks and oral airways for each bedside
Nasogastric tubes
Intravenous infusion solutions, tubing, drip chambers
Supplies for intravenous cannulation, catheter sizes 24 to 14 gauge
Cutdown tray, tracheostomy, and suture sets
Central venous catheter insertion sets (3F to 7F single and multiple lumen)
Tube thoracotomy set and system for suction and underwater seal
Defibrillator (adult, child paddles)
Electrocardiograph
Pressure transducer system and oscilloscope monitor
Sterile gowns, gloves, masks, towels, drapes
Urinary catheters of appropriate pediatric size
Bed board for cardiopulmonary resuscitation

The team should participate in mock codes and simulations to train for an emergency. Patient sign outs should be standardized, include checklists, and follow an institution-specific protocol.<sup>1</sup> All personnel should be familiar with resuscitative equipment and be able to use it instantaneously. We recommend instituting

**TABLE 46-3 Suggested Recovery Room Medications****Suggested Emergency Medications on Crash Cart\***

Amiodarone
Atropine
Calcium chloride or gluconate
Dextrose
Diphenhydramine
Dopamine
Epinephrine
Etomidate
Flumazenil
Furosemide
Heparin
Hydrocortisone, dexamethasone, methylprednisolone
Lidocaine (intravenous and topical)
Mannitol
Naloxone
Neostigmine
Norepinephrine
Phenytoin or fosphenytoin
Physostigmine
Propranolol, atenolol, esmolol, labetalol
Sodium bicarbonate
Sodium nitroprusside
Succinylcholine and rocuronium
Thiopental and propofol
Verapamil
For inhalation: racemic epinephrine (2.2% at 0.05 mL/kg, common in the United States) or epinephrine 1:1000 (0.1%), 0.5 mL/kg, maximum of 5 mL

**Medications to Be Kept under Lock\***

Diazepam
Fentanyl
Ketamine
Meperidine
Midazolam (intravenous and oral)
Morphine
Phenobarbital
Potassium chloride

**Other Medications for Central Location\***

Acetaminophen (oral, rectal, and intravenous)
Antibiotics
Antiemetics (e.g., 5-HT <sub>3</sub> antagonist, promethazine, metoclopramide)
Dantrolene
Digoxin
Insulin
Pancuronium, rocuronium, vecuronium
Potassium chloride
Protamine

\*Alternative or additional medications may be needed.

equipment and policies according to the guidelines for the pediatric perioperative anesthesia environment published by the American Academy of Pediatrics.<sup>2</sup>

**TRANSPORT TO THE CARE UNIT**

Transport from the operating room to the PACU should be carried out under the direct supervision of a trained expert. The security and patency of the airway, intravenous and arterial lines, drains, and urinary catheters should be checked before transport. The security and patency of the tracheal tube (if the airway remains intubated) or laryngeal mask airway, all

intravenous lines, the arterial line, chest tubes, drains, and the urinary catheter should be checked before transport. Children should be in presentable condition (e.g., removal of blood and secretions) before and kept normothermic during transport to the PACU or PICU.

Unless children are awake, with protective airway reflexes intact, or unless there is a specific contraindication, it is sensible to transport extubated children in the lateral position (i.e., tonsillectomy recovery position) so that the tongue lies away from the larynx, and secretions and vomitus leave the mouth rather than enter the larynx, causing aspiration or airway obstruction. To assess ventilation and maintain a patent airway with the child in the decubitus position, we recommend applying the thumb to the forehead to extend the neck and holding the fingers (the finger tips are the most sensitive part of the hand) over the mouth (or nose) to feel for exhalation. A precordial stethoscope may also be used to auscultate respirations. If the child is breathing room air, a pulse oximeter can indicate oxygenation and serve as a crude measure of ventilation because desaturation will occur quickly if hypopnea develops. However, if oxygen is provided to the child, the oximeter can no longer serve as a guide to ventilation, because desaturation will not occur until a sustained apnea occurs. For sleepy children, the precordial stethoscope and portable oxygen saturation monitor can trend ventilation, oxygenation, and the heart rate within the previously described provisos. We recommend that children in a potentially unstable condition be transported with a pulse oximeter, capnogram, an electrocardiographic (ECG) monitor, and a blood pressure cuff or a transduced arterial line. The monitoring lines, intravenous drips, infusion pumps, and other equipment should be clearly labeled and simplified before transport. For sick children, those with intubated tracheas, and children with potentially difficult airways, an appropriate resuscitation bag, facemask, oral airway, oxygen tanks (oxygen levels should be checked), functioning laryngoscopes, tracheal tube, and medications (including atropine and succinylcholine) should be carried en route to the PACU or PICU. A tackle box containing all of this equipment is helpful, especially when children are transported to the PICU in an elevator. Children receiving vasoactive drugs require infusion pumps so that these agents can be continuously administered at precise titrated rates.

Transport to the PACU or PICU is a time of potential danger. Distance and duration of travel should be minimized. When designing pediatric perioperative areas or reallocating space, strong emphasis should be placed on ergonomics.

A child often appears awake after the stimulation of tracheal extubation and transfer to the stretcher but may subsequently become obtunded and obstruct the airway during transit to the PACU or PICU. Just as frequently, children may become restless during transit. Although restless behavior has many causes, hypoxia should never be overlooked. The guard rails on the stretcher should always be raised when the child is in it. Most importantly, the anesthesiologist must remain vigilant throughout the transfer.

#### ARRIVAL IN THE CARE UNIT

On arrival in the PACU, attention should first be directed to the airway, ensuring it is patent and not obstructed; to the color of the lips and mucous membranes; to the oxygen saturation; and to the adequacy of ventilation, perfusion, and central nervous system function. Admission heart rate, blood pressure, oxygen saturation, respiratory rate, and temperature should be recorded

on arrival. The nurse-to-patient ratio should be 1 to 1 for sick children and 1 to 2 or 1 to 3 for routine cases. Supplemental oxygen is administered as indicated, recognizing the limitations of the monitors to detect ventilation in such cases. Many children object to having an oxygen mask fixed to their faces; a funnel-type mask or open hose with large flow rates may be less objectionable (although less optimal). Thereafter, report should be given to the nurses and physicians in attendance. Ideally, the nurses taking care of the child postoperatively are already familiar with the child and family from the preoperative setting.

The standardized transfer of care report should include, at a minimum, the child's name, institutional identification code, age and gender, preoperative vital signs, and specific circumstances, such as a language barrier or developmental delay. The size and location of catheters, a description of the child's current problem, medical history, medications, allergies, operative procedure, and pertinent surgical problems should be outlined. The anesthetic should be summarized and include the premedication and anesthetic agents used at induction and for maintenance, techniques used, reversal of neuromuscular blockade (i.e., adequacy of the train-of-four response), estimated blood loss, fluid replacement (including amount and type of solution), urine output, and vasoactive drugs, bronchodilators, and intraoperative medications (e.g., antibiotics) used. Regional anesthesia issues, such as epidural use and location, drug choice and concentration, use of adjuvants, effective level of analgesia, and drug infusion rate should be clearly communicated. Administration of analgesics (time and dose), local blocks and wound infiltration with local anesthetics, problems with surgery or anesthesia (e.g., difficult intravenous access, difficult intubation, intraoperative hemodynamic instability, cardiac changes), and potential problems in the PACU should be listed.

The anesthesia team must remain with the child until he or she has stable vital signs and the PACU team is comfortable and ready to assume responsibility for the child. Physicians who will be in charge of taking care of the child in the PACU after the anesthesia team leaves must be clearly identified by name, and ways to reach them (e.g., pager number) must be given to surgeons, anesthesiologists, and regional block and pain services.

All children should be monitored continuously in the PACU. At the very least, this should include continuous pulse oximetry and intermittent noninvasive blood pressure and temperature monitoring. Most PACUs also monitor the electrocardiogram continuously, although some limit this to children with cardiac disease or complex multiple-organ disease. During emergence, many children are so active that it is impossible to maintain the monitoring devices in place. If the child is not hypoxic and is sufficiently awake to remove the monitors, he or she probably does not require the monitors any longer. If the child falls back to sleep, then a pulse oximeter probe should be reapplied, particularly for at-risk children such as those with obstructive sleep apnea. For a child who is physically or mentally challenged, it may be necessary to apply light restraints until he or she is oriented and awake.

## Central Nervous System

#### PHARMACODYNAMICS OF EMERGENCE

Emergence from anesthesia is faster after a relatively insoluble inhalational anesthetic agent such as sevoflurane or desflurane than it is after a more soluble agent such as halothane.<sup>3</sup> However, the clinical importance of these differences may be minimal and

vary with the duration of anesthesia and the coadministered medications. Differences in the times to discharge from the PACU and the hospital between inhalational agents are even more difficult to detect when specific comparisons are made because so many other factors, such as pain management, agitation, availability of hospital beds, and family circumstances, affect discharge readiness.

The age of the child exerts a minimal influence on the wash-out of inhalational anesthetic agents and has little impact on the rapidity of emergence, although age may be a factor for infants younger than 1 year of age.<sup>4</sup> However, the overall clinical implications of age-related differences in emergence are exceedingly difficult to detect.<sup>5</sup> The speed of emergence correlates more closely with the duration of anesthesia. The greater the duration of anesthesia, the more the tissue compartments become filled with these anesthetics and the more time it takes to eliminate these anesthetics and for the child to recover. For example, emergence from 30 minutes of sevoflurane anesthesia is significantly faster than emergence from 2 hours of anesthesia, which is more rapid than from 8 hours of anesthesia.<sup>6</sup> This relationship between emergence time and the duration of anesthesia has less relevance as inhalational anesthetics have become less soluble (e.g., desflurane).

Emergence from intravenous agents can vary significantly from that of inhalational agents. Several studies have evaluated the quality and rapidity of emergence after intravenous anesthetic agents compared with that after inhalational agents. For outpatient surgery, emergence after propofol anesthesia is as rapid as that after sevoflurane but with far less agitation and pain behaviors.<sup>7,8</sup> The recovery characteristics of propofol with remifentanyl total intravenous anesthesia have been compared with those after desflurane inhalational anesthesia. Recovery is as rapid as that after desflurane with nitrous oxide, with a similar incidence of nausea and vomiting but with much less agitation.<sup>9</sup>

Midazolam is rarely used for maintenance of anesthesia but is often used as an oral or intravenous premedication for anxiolysis and amnesia in the preinduction period. There is evidence that the addition of midazolam in the preinduction period to an inhalational or propofol anesthetic may delay early emergence after brief anesthesia. However, this effect of midazolam is attenuated after anesthesia of greater duration, or when considering late emergence, this effect is minimal.<sup>10</sup> Midazolam does not affect the incidence of postoperative agitation.<sup>11,12</sup>

## EMERGENCE AGITATION OR DELIRIUM

Emergence agitation (i.e., emergence delirium [Videos 46-1 and 46-2]) was first described in a large cohort of postsurgical patients

almost 40 years ago.<sup>13</sup> From a clinical perspective, it is often impossible to differentiate pure agitation from delirium. Delirium implies a specific set of thought disorders and hallucinations based on the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV). Despite numerous investigations, differentiating emergence delirium from postoperative pain has also proved difficult. Emergence delirium usually manifests as thrashing, disorientation, crying, and screaming. The child is unable to recognize parents, familiar objects, or surroundings; is inconsolable; and talks irrationally during early emergence from anesthesia. Emergence delirium occurs more often in children (rate of 10% to 20%) than in adults, particularly in those younger than 6 years of age.<sup>14,15</sup> It may in part reflect differences in clearance of insoluble inhalational agents from the central nervous system.

An emergence delirium scale has been developed and validated that may provide clinicians and investigators with a tool to differentiate emergence delirium from pain.<sup>16</sup> Tables 46-4 and 46-5 show two scoring systems used to evaluate emergence behaviors in children. In evaluating emergence delirium with the Pediatric Anesthesia Emergence Delirium (PAED) scale after anesthesia, preliminary evidence suggested that values greater than 10 were consistent with emergence delirium in 37% of patients,<sup>17</sup> although that cutoff value has not been useful for others.<sup>18</sup> Later evidence suggested that values greater than 12 provided greater sensitivity and specificity.<sup>17</sup> In the PICU, evidence suggests that a PAED score greater than 8 predicts emergence delirium.<sup>19</sup>

Our understanding of emergence delirium or agitation continues to evolve, but it is clear that it occurs after surgical procedures and after procedures that are free from pain, such as magnetic resonance imaging.<sup>14,20,21</sup> Emergence delirium appears to occur more frequently after use of less-soluble inhalational anesthetics such as sevoflurane and desflurane than after more-soluble inhalational anesthetics such as halothane and isoflurane,<sup>22,23</sup> even though some data suggest otherwise.<sup>24</sup> There may be a greater incidence of emergence delirium after painful procedures; emphasizing the difficulty separating agitation due to pain from agitation due to the direct effects of the inhalational agents on the sensorium.<sup>25</sup> Emergence delirium occurs more commonly in children younger than 6 years of age than in older children, usually lasts 5 to 15 minutes, and resolves spontaneously if the children are left undisturbed or they are held by their parents.<sup>14</sup>

Several strategies have been used to decrease the duration and intensity of emergence delirium. Effective regional analgesia, opioids, ketamine,  $\alpha_2$ -agonists, and propofol can prevent or treat

**TABLE 46-4 Pediatric Anesthesia Emergence Delirium Scale**

Scored Factor	SCORING				
	0	1	2	3	4
Child makes eye contact with caregiver	Extremely	Very much	Quite a bit	Just a little	Not at all
Child's actions are purposeful	Extremely	Very much	Quite a bit	Just a little	Not at all
Child is aware of surroundings	Extremely	Very much	Quite a bit	Just a little	Not at all
Child is restless	Not at all	Just a little	Quite a bit	Very much	Extremely
Child is inconsolable	Not at all	Just a little	Quite a bit	Very much	Extremely
Total score*					

Modified from Sikich N, Lerman J. Development and psychometric evaluation of the pediatric anesthesia emergence delirium scale. *Anesthesiology* 2004;100:1138-45.

\*Preliminary evidence suggested that a total pediatric anesthesia emergence delirium (PAED) score greater than 10 defined emergence delirium, but later evidence suggested that a total score greater than 12 might be more specific.

**TABLE 46-5 Postanesthesia Behavior Assessment Scale**

## Perceptual disturbances (maximal score 3)\*

- 0 None evident
- 1 Feelings of depersonalization (says that situation is not real, comments on "out of body" feelings)
- 2 Visual illusions or misperceptions (misidentifies objects, such as urinates in trash can)
- 3 Markedly confused about external reality (misidentifies self or surroundings, such as being at school)

## Hallucination type (maximal score 6)\*

- 0 None evident
- 1 Auditory hallucinations only (responds to questions not asked)
- 2 Visual hallucinations or misperceptions (responds to things only the child can see)
- 3 Tactile, olfactory (responds to sensations not obvious to others, such as a bug crawling on the leg)

## Psychomotor behavior (maximal score 3)\*

- 0 No significant agitation
- 1 Mild restlessness, tremulousness, or anxiety
- 2 Moderate agitation with pulling at intravenous lines
- 3 Severe agitation, needs to be restrained, combative

From Przybylo HJ, Martini DR, Mazurek AJ, et al. Assessing behavior in children emerging from anaesthesia: can we apply psychiatric diagnostic techniques? *Pediatr Anesth* 2003;13:609-16.

\*A higher postanesthesia behavior assessment (PABA) score is associated with a greater degree of postanesthetic distress.

emergence delirium. Low-dose fentanyl (2 µg/kg intranasally or 1 to 2 µg/kg intravenously) decreases the duration and intensity of emergence delirium,<sup>26</sup> even in the absence of significant painful stimuli.<sup>20</sup> Other adjunctive agents used to treat this phenomenon include ketorolac and acetaminophen (for myringotomy with ventilation tube placement) and midazolam; the effectiveness of midazolam, however, has been mixed.<sup>27,28</sup> Dexmedetomidine can decrease the incidence of emergence delirium,<sup>29,30</sup> but the cost-effectiveness of this treatment compared with others requires evaluation. Administration of propofol by continuous infusion or by bolus at the end of surgery appears to be preventative,<sup>31,32</sup> although these findings have not been consistent.<sup>18</sup> The induction dose of propofol administered at the start of the case does not appear to prevent postoperative emergence delirium.<sup>33</sup> Regional analgesia in the form of caudal blocks can reduce the incidence of emergence delirium, although this effect is probably related to improved pain control, which eliminates pain as a source of agitation.<sup>34,35</sup>

Although there is no evidence of long-term consequences, in the current era of fast-tracking anesthesia, emergence delirium can represent a significant time expenditure for nurses in the PACU. Discharge from the PACU may be delayed while waiting for the delirium to wane or for the effects of the interventional drugs to dissipate. Injury to the child who is extremely agitated is a concern. Parental satisfaction decreases when severe emergence delirium occurs. Although the impact of extreme delirium is not fully known, evidence suggests that the incidence of postoperative maladaptive behaviors increases among children who experience marked emergence delirium.<sup>36</sup>

## Respiratory System

### CRITERIA FOR EXTUBATION

In most cases, extubation may be safely performed in the operating room. However, a child's condition may necessitate delayed

extubation at a more appropriate time in the PACU or PICU. There is widespread agreement that children who have been anesthetized with a full stomach, children at risk for airway obstruction, those with difficult airways, premature infants, and other infants predisposed to apnea should be awake before extubation of the trachea is attempted. Beyond this, the timing of extubation is a matter of individual judgment. For example, the practice at some institutions is to extubate the trachea when a child is awake and demonstrating eye opening and other purposeful movements; the practice at others is to extubate while the child is under a deep plane of inhalational anesthesia. Clinicians report only rare problems with either approach. Most clinicians agree that either approach is preferable to extubating the trachea during a very light plane of anesthesia, when laryngospasm is more likely and vomiting may occur while protective reflexes are impaired.

### EXTUBATION IN THE OPERATING ROOM OR POSTANESTHESIA CARE UNIT

Immediately after extubation, oxygen should be administered, and the child should be observed for adequate ventilation, satisfactory oxygen saturation, color of the mucous membranes, and laryngospasm or vomiting. Transport of children should not be undertaken until the patency of the airway and the adequacy of oxygenation and ventilation have been confirmed in the form of stable and satisfactory oxygen saturation and adequate respiratory effort. Our criterion for transporting the child from the operating room to the PACU without oxygen is a stable oxygen saturation of 95% or greater while breathing room air. If the child cannot sustain this level of oxygen saturation, more time for recovery in the operating room is taken, or the child is transported with supplemental oxygen and a means for providing positive-pressure ventilation.

For children who are extubated in the PACU, respiratory insufficiency is the most worrisome and most frequent complication. It comprises approximately two thirds of critical perioperative events when it is associated with emergence from anesthesia.<sup>37</sup> Respiratory insufficiency may manifest in the form of difficulty breathing, or it may be more subtle as anxiety, unresponsiveness, tachycardia, bradycardia, hypertension, arrhythmia, or seizures. Cardiac arrest is a late manifestation. When any of these conditions are present, respiratory insufficiency must be considered as the root cause. Hypoxemia, hypoventilation, and upper airway obstruction are the three most common adverse respiratory events that occur in children in the PACU, and this is particularly true for children after tonsillectomy complicated by obesity and possible obstructive sleep apnea and for those who have undergone diagnostic bronchoscopy.

### HYPOXEMIA

Hypoxemia may result from hypoventilation, diffusion hypoxia, upper airway obstruction, bronchospasm, aspiration, pulmonary edema, pneumothorax, atelectasis, or rarely from postobstructive pulmonary edema or pulmonary embolism. Hypoxia occurs more rapidly and may be more profound during emergence from general anesthesia because general anesthesia inhibits the hypoxic and hypercapnic ventilatory drive, reduces functional residual capacity, and alters hypoxic pulmonary vasoconstriction. Shivering may further increase oxygen consumption by a factor of two to five<sup>38,39</sup> and exacerbate hemoglobin desaturation.

Postoperative hemoglobin desaturation is more common in children with or recovering from an active upper respiratory tract

infection due to increased airway reactivity, atelectasis, and increased secretions than in children without a history of upper respiratory tract infection.<sup>40,41</sup> In neonates, hypoxia *increases* ventilation for approximately 1 minute but then *depresses* the respiratory drive (i.e., respiratory rate and tidal volume).<sup>42</sup> The ventilatory response to hypoxia in formerly preterm infants with severe bronchopulmonary dysplasia who sustained an hypoxic injury is delayed for several months, placing them at particular risk for desaturation in the perioperative period.<sup>43</sup>

### HYPOVENTILATION

Minute ventilation is the product of tidal volume and respiratory rate. It decreases when tidal volume, respiratory rate, or both values decrease. Hypoventilation leads to hypercarbia and promotes alveolar collapse, known as *atelectasis*. Severe hypoventilation causes respiratory acidosis, hypoxemia, carbon dioxide narcosis, and apnea. The ventilatory response to carbon dioxide depends on the child's age. For example, during halothane anesthesia and spontaneous ventilation, 3.7% inspired carbon dioxide triggers no ventilatory response in infants younger than 6 months of age, but it triggers a 34% increase in minute ventilation in infants and children older than 6 months of age.<sup>44,45</sup>

Hypoventilation results from a decrease in ventilatory drive, insufficiency of the muscular system, or mechanical effects. Inhalational anesthetics, opioids, benzodiazepines, and other sedating medications decrease the ventilatory drive in children in a dose-dependent manner. At particular risk for postoperative hypoventilation are children with underlying disturbances in respiration, such as infants with apnea of prematurity (formerly preterm infants of less than 60 weeks postconceptual age [PCA]); those with central nervous system injury such as head injury, strokes, and intracranial surgery; and obese children, especially those with obstructive sleep apnea (OSA). Some of these children require prolonged observation in a setting with continuous monitoring capabilities.

Muscular weakness may contribute to respiratory insufficiency. Preexistent muscular disease (e.g., muscular dystrophy) and inadequate reversal of neuromuscular blockade, electrolyte abnormalities, neurologic disorders, drugs, infection, and endocrine disease may impair the respiratory effort sufficiently to cause hypoventilation and respiratory insufficiency.

Respiratory insufficiency may result from upper airway obstruction. Airway obstruction is a feature in children with known airway problems due to congenital anomalies of the face (particularly those with midfacial hypoplasia as in trisomy 21, achondroplasia, and Crouzon disease) and obese children with a history of OSA. Inadequate analgesia can lead to splinting and hypoventilation, which may depress oxygen saturation.

### AIRWAY OBSTRUCTION

Among the most common and serious problems in the PACU is an extrathoracic airway obstruction. Clinical hallmarks of airway obstruction include hemoglobin desaturation with inspiratory stridor, inspiratory retraction, and paradoxical chest wall motion. Common interventions include stimulating the child, repositioning, suctioning, performing a jaw thrust, insertion of an oral or nasal airway, and application of positive end-expiratory pressure (PEEP) (see Fig. 12-10). If these measures fail, patency of the upper and lower airways should be considered because gas exchange may be compromised by

laryngospasm, subglottic narrowing as the result of edema, bronchospasm, atelectasis, or tracheal secretions. Incomplete recovery from general anesthesia or neuromuscular blockade, wound hematoma, and vocal cord paralysis may also lead to upper airway obstruction.

If the airway is not cleared by any of the previously described maneuvers, placement of a tracheal tube preceded by administration of oxygen by mask with continuous positive airway pressure and indicated medications may be necessary. Post-obstructive pulmonary edema is a complication of acute upper airway obstruction and the relief of chronic airway obstruction after tonsillectomy. The mechanism appears to be generation of extreme negative intrathoracic pressure against a closed glottis or obstructed airway and its sudden release, resulting in a dramatic increase in pulmonary blood flow and causing noncardiogenic or neurogenic pulmonary edema. This complication should be suspected when significant hypoxia, persistent tachypnea, or tachycardia follows a prolonged episode of laryngospasm, airway obstruction, or tonsillectomy and the child has pink, frothy secretions. Treatment of noncardiogenic pulmonary edema includes tracheal intubation, positive-pressure ventilation with PEEP, 100% oxygen to maintain an adequate oxygen tension, furosemide, and morphine. Furosemide (1 to 2 mg/kg) should be given immediately intravenously because it is thought to act instantaneously by decreasing venous return to the heart by direct venodilation.<sup>46-48</sup>

Postintubation croup or subglottic edema has been associated with factors such as traumatic intubation, tight-fitting tracheal tubes, multiple intubation attempts, coughing with an in situ tracheal tube, a change in the child's position during surgery, prolonged duration of intubation, surgery of the head and neck, and a history of croup.<sup>49</sup> Treatment should be initiated with the inhalation of cool mist. If the symptoms do not abate, nebulized epinephrine should be administered, although its effects are temporary and its repeated use may be followed by rebound edema. The use of nebulized epinephrine indicates the need for a prolonged period of observation. Outpatients may have to be admitted to the hospital overnight or observed for an extended period.

### RESPIRATORY EFFORT

If the airway is patent, attention turns to the adequacy of ventilatory effort. Residual neuromuscular blockade can be diagnosed by observation (i.e., the patient's ability to lift extremities against gravity or perform a sustained head lift) and quantitatively by assessment with a peripheral nerve stimulator. Depending on the severity and the clinical situation, this condition may be treated with supplemental doses of reversal agents or ventilatory assistance. If the respiratory rate is slow, suggesting opioid-induced respiratory depression, titrated incremental doses of naloxone (0.01 to 0.1 µg/kg) reverses the respiratory depression without precipitating acute anxiety, pain, or pulmonary edema. If naloxone is effective, continuous monitoring of respiratory status is advised because naloxone has a short half-life of 20 minutes. The same effective total dose should be given intramuscularly to prevent recrudescence of the opioid-induced respiratory depression. Residual sedation after benzodiazepines may be antagonized with flumazenil.

Children who have an adequate airway and adequate muscular strength may experience difficulty breathing because of pain, restriction from bandages or casts, abdominal distention,

pneumothorax, atelectasis, aspiration pneumonitis, or cardiogenic or postobstructive pulmonary edema. In most cases, the history and physical examination focus the differential diagnosis, and when necessary, investigations that include a chest radiograph, blood gas analysis, and possibly invasive hemodynamic monitoring can identify the underlying cause and determine an effective treatment.

### DISCHARGE OF PRETERM INFANTS FROM THE POSTANESTHESIA CARE UNIT

Preterm infants (<37 weeks gestation at birth) are at risk for apnea after sedation and general anesthesia.<sup>50,51</sup> As the PCA (i.e., age since conception) increases, the risk for apnea decreases.<sup>52</sup> Guidelines are lacking because there are inadequate randomized, controlled trials and underpowered institutional studies, and apnea has been reported even after more modern anesthetic agents (i.e., desflurane and sevoflurane). However, it is recommended that formerly preterm infants who are 55 to 60 weeks PCA who are not anemic and not experiencing apnea be observed for an extended period and, if stable, later discharged. Infants younger than 55 weeks PCA, those who are anemic (hematocrit <30%), and those with ongoing apnea should be admitted for monitoring.<sup>53-59</sup> Prophylactic administration of caffeine (10 mg/kg intravenously) may reduce the risk of apnea after general anesthesia for infants at high risk,<sup>60,61</sup> although it should not supplant postoperative admission and monitoring. Administration should be discussed with neonatologists, because it does not change management (i.e., infants are monitored in the hospital), and the administration of caffeine resets the number of apnea or bradycardia-free days (i.e., used as a discharge criterion for preterm infants) to zero. Preterm infants younger than 55 weeks PCA, particularly those with anemia or those with major cardiorespiratory or neurologic disorders, should be admitted and monitored for at least 12 apnea-free hours after general or regional anesthesia or sedation (see Chapter 4).<sup>54,62</sup>

Although preterm infants who undergo surgery under spinal anesthesia have fewer respiratory and cardiovascular complications compared with those undergoing general anesthesia,<sup>54,55,58,61</sup> the infants remain at risk for apnea. It is unknown whether the risk is greater after a spinal anesthetic without supplemental sedation (with no other medication given) than the preoperative baseline risk. Similarly, caudal anesthesia has been reported as an effective alternative to spinal anesthesia in preterm infants undergoing herniotomy.<sup>62,63</sup> Infants who have received a spinal anesthetic supplemented with ketamine or midazolam are at greater risk for apnea than those who received no supplemental sedation. Despite evidence of a reduced risk of apnea after regional anesthesia<sup>61,64</sup> and no postdischarge complications on the day of surgery in some institutions,<sup>61,65</sup> there is insufficient evidence to make general recommendations regarding this practice. Our recommendation is to admit and monitor these infants.

Full-term neonates typically have a reduced risk of apnea and bradycardia after general anesthesia compared with preterm infants. Opinions vary on the minimum PCA for ambulatory surgery in infants 44 to 50 weeks PCA; many children's hospitals admit all full-term neonates (<28 days of age) for overnight monitoring after general anesthesia, although this is not evidence-based practice. All full-term infants with a history of apnea and bradycardia or those who have siblings with sudden infant death syndrome should be observed for an extended period or admitted for overnight monitoring after general anesthesia.

## Cardiovascular System

### BRADYCARDIA

Bradycardia is the most common dysrhythmia in children and requires immediate attention because of its association with decreased cardiac output. *Until proved otherwise, the most common cause of bradycardia in infants and children is hypoxemia.* Other possible causes for the bradycardia include vagal responses (e.g., passage of a nasogastric tube), medications (e.g., neostigmine,  $\beta$ -adrenergic blockade, high spinal blockade, opioids such as fentanyl), increased intracranial pressure, and high neuraxial anesthetic block. The definition of bradycardia depends on the age of the child; the incidence decreases with increasing age (see Chapter 2).

Treatment is directed at correcting the underlying cause, including the administration of oxygen and ensuring a patent airway. Bradycardia should be immediately treated with oxygen and, if necessary, with ventilation. If intervention with oxygen does not immediately restore the heart rate, atropine (0.02 mg/kg) should be administered; and if no response is observed within 30 seconds, administration of epinephrine (2 to 10  $\mu$ g/kg) is indicated. For symptomatic bradycardia (e.g., hypotension, decreased level of consciousness), immediate administration of epinephrine is indicated. If there is no response to epinephrine, chest compressions should be instituted and standard cardiopulmonary resuscitation algorithms followed (see Chapter 39).

### TACHYCARDIA

Tachycardia is an important postoperative sign that is a marker for one of several disorders, such as inadequate cardiac output or oxygen delivery, or it may be a response to pain or a direct drug effect (e.g., epinephrine, atropine). Tachycardia may occur in response to hypoxemia, hypercarbia, hypovolemia, hypervolemia, emergence delirium, anxiety, sepsis, fever, a full bladder, a previously unrecognized cardiac conduction abnormality (see Chapters 14 and 16), or heart failure. The threshold for diagnosing tachycardia varies with the age of the child, and the threshold decreases with age.

Treatment is directed at correcting the underlying cause. Occasionally, children present with a sustained tachycardia unrelated to the previously described conditions that is refractory to the usual therapy. A cardiac consultation is required to investigate and identify less common causes, such as an aberrant conduction system or ectopic foci as a source of supraventricular tachycardia (SVT). SVT, which is defined as more than 220 beats/min in infants and more than 180 beats/min in children, may be treated with adenosine when there are no other symptoms. However, SVT with accompanied hypotension or decreased level of consciousness may require cardioversion. Children who have had prior cardiac surgery are particularly at risk.

### OTHER ARRHYTHMIAS

With the exception of bradycardia and tachycardia, postoperative arrhythmias are rare in children. Isolated premature ventricular or atrial beats may be observed in the PACU and, unless they progress, are not important. Multifocal premature ventricular beats are uncommon in children. They may occur as a result of inadequately treated pain, cardiac conduction defects, or in rare instances, may be a harbinger of malignant hyperthermia (see Chapters 14, 16, and 40), acute rhabdomyolysis with hyperkalemia, inadequately treated pain, a congenital conduction defect, or a structural cardiac defect. Electrolyte and arterial

blood gas status should be checked. Children with known congenital heart disease should have continuous ECG monitoring in the PACU (see Chapters 14 and 16); all arrhythmias should be recorded and a cardiologist consulted because this may be the first manifestation of a developing ectopic focus.

## BLOOD PRESSURE CONTROL

### Hypotension

The anesthesiologist should be familiar with the normal blood pressure ranges of infants and children (see Chapter 2). The measurement should be obtained with an appropriately sized blood pressure cuff; the width of the cuff should be two thirds of the length of the upper arm. An improperly sized cuff produces spurious readings. Small cuffs may yield a false high reading, whereas large cuffs may yield a false low reading. Proper placement of the cuff is essential to avoid errors in interpretation.

*The most common cause of hypotension in children is hypovolemia from inadequate replacement of blood and fluids lost during the surgical procedure or ongoing blood loss. Clinical hallmarks of hypovolemia are tachycardia, urine output of less than 0.5 to 1 mL/kg/hr, slow capillary refill (>3 seconds), and narrowing of the pulse pressure. If the hematocrit is adequate, hypovolemia may be treated with an initial bolus of 10 to 20 mL/kg of isotonic crystalloid solution or albumin. This may be repeated until the blood pressure is normalized. If the hematocrit is inadequate, packed red blood cells (PRBCs) or whole blood should be administered. In this case, a rough guide for the volume of blood required is 4 mL/kg of packed cells or 6 mL/kg of whole blood to raise the hemoglobin 1 g/dL in children and adults (see Chapter 10). To achieve a desired hematocrit more precisely, the volume of PRBCs may be estimated as follows:*

$$\frac{(\text{Desired hematocrit} - \text{present hematocrit}) \times \text{estimated blood volume}}{\text{The hematocrit in the PRBCs}}$$

If the child does not respond to volume expansion, other causes for the hypotension need to be considered, such as occult blood loss (e.g., intraabdominal, retroperitoneal, intrathoracic [blocked chest tube], cardiac tamponade), sepsis, or other disorders. Any factor that interferes with venous return can cause hypotension, including positive-pressure ventilation, auto-PEEP, tension pneumothorax, pericardial tamponade, and compression of the inferior vena cava.

Large end-tidal concentrations of inhalational anesthetics, local anesthetics, or opioids and interactions between benzodiazepines and opioids may produce hypotension through vasodilation (i.e., relative hypovolemia) and direct myocardial depression. However, these factors are rarely important in the PACU. Uncommon causes include anaphylaxis (e.g., latex allergy, antibiotics), transfusion reaction, adrenal insufficiency, systemic inflammation, infection, severe liver failure, and administration of antihypertensive, antidysrhythmic, and anticonvulsant medications. Increased body temperature may cause vasodilation and a relative hypovolemia. The increased metabolic demands of fever may compromise an already stressed myocardium. If a child arrives in the PACU requiring vasopressors and subsequently develops hypotension, consider a disconnect or kink in the vasopressor infusion, disruption of the intravenous access, a disconnect from the pump, or pump failure.

Vasodilation caused by sympathetic blockade associated with regional anesthesia occasionally causes hypotension, especially

with a high-level blockade and restricted fluid intake. This typically is a problem only in children older than 6 years of age. Because of the developmental changes in the sympathetic nervous system, most children younger than 6 years of age are normally peripherally vasodilated and therefore have little response to further vasodilation with a regional block.

Decreased inotropy, dysrhythmia, cardiomyopathy, calcium channel blockers, sepsis, hypothyroidism, negative inotropic agents, and congestive heart failure are uncommon causes of hypotension in children. Treatment is directed at the underlying cause, such as correcting hypovolemia with volume loading, treating the allergic reaction, or treating the sepsis. Decreased cardiac contractility may be treated by diuresis and the administration of inotropic agents that also decrease the afterload (i.e., inodilators).

### Hypertension

Postoperative hypertension in children is less common than hypotension and most often reflects incorrect measurement or pain. A blood pressure cuff that is too small may yield a spuriously high blood pressure reading and should be one of the first considerations in the differential diagnosis, especially if the child has no other symptoms consistent with pain. Causative factors besides pain include hypervolemia, preexisting hypertension (e.g., renal disease with inadequate continuity of antihypertensive medications), distended bladder, hypercarbia, hypoxemia, agitation and delirium, increased intracranial pressure, and exogenous vasoactive drugs (e.g., epinephrine).

## Renal System

Complications related to the renal system are rare in the postoperative period. The most likely cause of low urine output (<0.5 to 1 mL/kg/hr) is hypovolemia as discussed previously (e.g., postoperative hypotension). Mechanical obstruction downstream from the kidneys may result from direct surgical interference or a misplaced or dysfunctional urinary catheter (i.e., blood clot or kink). If the child has regional (spinal or epidural) anesthesia that includes an opioid and there is no urinary catheter in place, placement of a Foley or straight catheter may be indicated. Renal failure is a rare possibility in children who have had major operations or have systemic inflammatory disease. If screening tests such as blood urea nitrogen, serum creatinine, and urine analysis suggest renal insufficiency, a pediatric nephrologist should be consulted (see also Chapter 26).

## Gastrointestinal System

### INCIDENCE OF POSTOPERATIVE NAUSEA AND VOMITING

Postoperative nausea and vomiting (PONV) is one of the most bothersome adverse effects of anesthesia and surgery. Unlike adults, most children are unfamiliar with and have never experienced nausea. It is unlikely that they will warn the PACU personnel that they are nauseated. In children, vomiting and complaining about a "sore tummy" are likely the first and only manifestations of gastrointestinal upset. Among children, PONV is inversely related to age.<sup>66</sup> The incidence of PONV is small in very young children, increases throughout childhood, and reaches a zenith in adolescents, for whom the incidence exceeds that for adults.<sup>66</sup>

The type of surgery influences the incidence of PONV. The incidence of PONV in children is greatest after tonsillectomy,

strabismus repair, hernia repair, orchiopexy, microtia, and middle ear procedures.<sup>67</sup> Before puberty, there are no gender-related differences in PONV; after puberty, girls experience much more PONV than boys. The medical complications of PONV include pulmonary aspiration, dehydration, electrolyte imbalance, fatigue, wound disruption, and esophageal tears. PONV can produce psychological effects that may produce anxiety in the children and parents and lead them to avoid further surgery. The cost implications of PONV can be major because of delayed recovery and discharge, increased medical care, and reoperation. Although these problems are seldom life-threatening, the cumulative costs in terms of prolonged PACU stays, unplanned admissions, and patient dissatisfaction are serious.<sup>68</sup>

### EVIDENCE-BASED CONSENSUS MANAGEMENT

Management of PONV is complex, and many treatment strategies have been formulated (Fig. 46-1). Most have been shown to be effective in one study or another. However, the superiority of some treatments over others has not been established, in part because of study design flaws such as inadequate dosing, small sample sizes, or various periods of observations and data collection; some studies monitored PONV only during the first few hours after surgery, whereas others monitored the children for 24 to 48 hours after surgery. To make sense of the conflicting data that exist, a consensus-based management strategy for the prevention and management of PONV has been devised.<sup>69</sup> These guidelines advise first identifying the children at significant risk for PONV as outlined earlier; prophylaxis for PONV is recommended for children in high-risk categories. Studies frequently focus on postoperative vomiting as the primary outcome because nausea may be difficult to identify in children.

The consensus guidelines recognize that the choice of anesthetic can influence the incidence of PONV in children. Propofol-based anesthesia during operations associated with a

large incidence of PONV dramatically reduces the incidence of PONV compared with isoflurane-based anesthesia, even when both groups are given prophylactic 5-hydroxytryptamine type 3 (5-HT<sub>3</sub>) receptor inhibitors.<sup>70</sup> Similarly, multimodal therapy that is a combination of PONV treatment strategies is more effective than a single-treatment strategy.<sup>71</sup> For instance, the combination of propofol anesthesia plus ondansetron has been shown to significantly reduce the incidence of PONV compared with the use of propofol alone (7% versus 22%).<sup>72</sup> The combination of dexamethasone and ondansetron is more effective than either intervention in isolation and permits the dose of ondansetron to be reduced by 50%.<sup>73</sup> A slightly more contentious effect has been the elimination of nitrous oxide, which decreases the incidence of PONV among those undergoing highly emetogenic surgery, with a number needed to treat of only five patients.<sup>74</sup> However, that meta-analysis also revealed a 2% incidence of awareness under anesthesia if nitrous oxide was omitted.<sup>74</sup>

Other strategies recommended to decrease the rate of PONV include the use of the smallest dose of opioids that still provides adequate pain control and the use of regional anesthesia if possible. The use of nonopioids such as acetaminophen, ketamine, and ketorolac should be considered. Adequate parenteral hydration and avoidance of early postoperative fluid ingestion can reduce the incidence of PONV (see Chapter 4).

### PROPHYLACTIC THERAPY

Ondansetron has been studied extensively and shown to decrease early and late PONV at doses of 50 to 100 µg/kg.<sup>75</sup> Because the 5-HT<sub>3</sub> receptor antagonists as a group have greater efficacy in the prevention of vomiting than nausea, they are the drugs of first choice for prophylaxis in children. Dexamethasone also is effective in decreasing PONV.<sup>76</sup> Administration of dexamethasone alone or in combination with other antiemetics can extend the period of effective treatment up to 24 hours. In a systematic review, Steward and associates demonstrated that children who

FIGURE 46-1 Treatment strategies for postoperative nausea and vomiting (PONV).

received a single dose of dexamethasone (0.15 to 1 mg/kg) were two times less likely to vomit after tonsillectomy and adenoidectomy than those who did not receive dexamethasone.<sup>77,78</sup> In a randomized, prospective dose-finding study of dexamethasone administered to children undergoing tonsillectomy, there was no difference in the incidence of vomiting after prophylactic doses of dexamethasone between 0.0625 and 1.0 mg/kg (see Fig. 31-5)<sup>79</sup>; a similar trial has not been conducted in the PACU for children who are already vomiting. Before the black box warning was added for droperidol, it was also recommended for prophylaxis of PONV in the United States,<sup>80</sup> but for medicolegal reasons alone, it is no longer a first-tier antiemetic. Droperidol is commonly used in low doses, which limit extrapyramidal and sedation side effects.

Adequate fluid resuscitation plays an important role in PONV prevention. Children given 10 mL/kg of lactated Ringer's solution during strabismus correction had more PONV than those given 30 mL/kg (54% versus 22%).<sup>81</sup>

The most effective prophylaxis strategy in children at moderate or high risk for PONV is to use combination therapy that includes hydration, a 5-HT<sub>3</sub> receptor antagonist, and a second drug such as dexamethasone. Antiemetic rescue therapy should be administered to children who vomit after surgery. An emetic episode more than 6 hours postoperatively can be treated with any of the drugs used for prophylaxis except dexamethasone and transdermal scopolamine.<sup>82</sup>

### Rescue Therapy

The consensus panel recommends that children who did not receive intraoperative prophylaxis or those who fail prophylaxis should receive a 5-HT<sub>3</sub> receptor antagonist at the first signs of PONV.<sup>69</sup> The recommended dose should be one fourth of that used for prophylaxis. For all other therapies, the data on efficacy for rescue are sparse, and doses are unknown. In adults, promethazine and droperidol have been as effective as ondansetron in the general surgical population, but comparable studies have not been conducted in children. The sedative properties of promethazine may last for many hours and may be a problem for patients with OSA.

### Alternative Treatments

Alternative methods for nausea and vomiting prophylaxis deserve consideration. Isopropyl alcohol reduces PONV, although the effect is transient.<sup>83</sup> In a meta-analysis of alternative antiemetic and vomiting techniques, acupuncture, electroacupuncture, transcutaneous electrical nerve stimulation, acupoint stimulation, and acupressure each exert antiemetic effects compared with placebo in adults, but not in children.<sup>84</sup>

## Postoperative Care and Discharge

### PAIN MANAGEMENT IN THE POSTANESTHESIA CARE UNIT

Acute postoperative pain management strategies are discussed in detail in Chapter 43. A child's level of pain (or the perception of pain) changes more rapidly in the PACU than in any other unit of the hospital. Frequent and consistent use of pain scores for children of all ages, including those with developmental disabilities, is essential. Many pain scales have been validated for use in children. More important than the specific

scale employed, the scale should be used consistently and follow simple principles. For instance, children who are verbal and developmentally appropriate should be encouraged to describe their pain using a self-report scale (e.g., Oucher scale). Young children or those without verbal skills should be assessed using an objective pain behavior scale (e.g., Face, Legs, Activity, Cry, Consolability [FLACC] scale).<sup>85,86</sup> Just as important is the consistent application of protocols to treat pain; treatment of a given pain level should not vary from shift to shift or from one nurse to another.<sup>87</sup>

As with other areas of pediatric pain control, a multimodal approach to postoperative pain is recommended. A plan for pain management should be discussed among the family, surgical team, and anesthesia team before surgery.<sup>88</sup> Depending on the surgery, the plan may include any or all of the following: acetaminophen, nonsteroidal agents, local anesthesia, nerve blocks, regional anesthesia, clonidine, opioids, patient-controlled analgesia, and patient-controlled epidural analgesia.

Acetaminophen and nonsteroidal drugs act through inhibition of prostaglandins and their metabolites. Most of these drugs are given orally and should be given preoperatively or intraoperatively to be effective in the PACU. Occasionally, they may be indicated in the PACU if they were not administered before arrival. Oral acetaminophen (15 mg/kg) or ibuprofen (10 mg/kg) has been shown to decrease opioid requirements by 20% to 30% after a variety of surgical procedures. Intravenous acetaminophen has become available in the United States for children 2 years of age or older, and it is likely to become a popular analgesic for mild to moderate pain in the PACU and as an opioid-sparing drug.<sup>89,90</sup> The U.S. Food and Drug Administration (FDA) has approved the use of intravenous acetaminophen for children 2 years or older for the treatment of mild to moderate pain or fever. The intravenous dose of 15 mg/kg every 6 hours is recommended for patients weighing less than 50 kg and should be administered over 15 minutes.<sup>91</sup> Studies on intravenous formulations of propacetamol and paracetamol have mostly been conducted in the European Union since drug approval in 2002. Several randomized, controlled studies and meta-analyses have demonstrated efficacy of intravenous administration in adults and children for the treatment of mild to moderate pain or fever.<sup>92,93</sup> It is effective as an adjuvant to other analgesic modalities for moderate to severe pain.<sup>94</sup>

Acetaminophen can also be given rectally in doses of 35 to 45 mg/kg; however, because absorption varies and is delayed (i.e., peak concentration at 60 to 180 minutes after rectal administration), this route is not recommended for use in the PACU.<sup>95</sup> Because of the pharmacokinetics of the rectal route, a greater interval (6 hours) between doses is recommended, and subsequent doses are reduced (20 mg/kg) so that the total dose per 24 hours does not exceed 100 mg/kg.<sup>96</sup> There are no data to provide guidance for rectal acetaminophen beyond 24 hours. If a child has received rectal acetaminophen, the first oral dose should be delayed until 6 hours after the rectal dose.

The nonsteroidal antiinflammatory drug ketorolac can decrease opioid requirements by approximately 30%. The recommended dosage is 0.2 to 0.5 mg/kg, which is given intravenously every 6 hours.<sup>97</sup> Caution is warranted in postoperative children with significant bleeding or a history of renal insufficiency. The manufacturer recommends limiting the total doses to 15 mg for children weighing less than 50 kg and to 30 mg for children weighing more than 50 kg.<sup>98</sup>

Opioids are indicated during the immediate postoperative period for any procedure in which moderate or severe pain is not being managed by other means. Morphine, fentanyl, and hydromorphone have a long history of safe use for infants and children in the PACU. Repeated doses of meperidine are not recommended for children because of the potential for seizures from epileptogenic metabolites (e.g., normeperidine).<sup>99</sup> Opioid dosing should be initiated according to body weight, physiologic development, underlying medical or surgical conditions, coadministered medications, and severity of pain. The goal should be effective and rapid pain relief. Subsequent dosing of the medications should be titrated based on response to the initial dose. Administration of multiple, small, ineffective doses results in prolongation of pain, stress, and anxiety without improving the safety of care provided. With this caveat in mind, patient-controlled analgesia and patient-controlled epidural analgesia (see Chapters 41 and 43) may be used in the PACU environment, but either intervention should be started only after acute pain has been adequately treated. The small doses administered by patient-controlled analgesia typically are not adequate to completely treat acute postoperative pain and may add to a sense that the method is not working for a given child.<sup>100</sup>

Regional analgesia is a common mode of intraoperative pain control in the child that extends into the PACU (see Chapters 41 to 43). The PACU personnel need to know how well it is working, and this assessment can be approached in a systematic manner.

The regional block should be placed in a manner that provides analgesia for the surgical incision site and visceral pain. Evidence that the regional block is effective should first be detected during surgery. If the regional block is effective, the anesthetic requirements are usually reduced. For instance, a caudal block is not effective for a midabdominal incision unless the catheter has been threaded to the region of the incision or relatively large volumes of local anesthetic have been administered. The addition of hydrophilic opioids or clonidine may extend the level of analgesia to some extent over the course of several hours; however, a block that is many dermatome segments away from the site of the surgical incision is unlikely to remain adequate for long. The addition of opioids to an epidural or spinal block increases the risk of pruritus, urinary retention, and emesis. Similarly, visceral pain such as bladder spasms (which have thoracic innervation) or the sore throat after intubation are not attenuated by a lumbar epidural catheter and must be managed by other measures.<sup>101</sup>

The anesthesiologist must verify that the catheter is in the epidural space. Older children can be questioned about their sensation level using ice or other cold sensation to determine the level of sympathectomy. Preverbal or developmentally disabled patients require some other objective form of confirmation. Previous reports have focused on electrical stimulation through the epidural catheter at the time of catheter placement to determine the level of insertion.<sup>102</sup> Ultrasound methods for detecting epidural catheter placement have been described.<sup>103</sup> Perhaps most practical in the PACU may be radiographic confirmation of the dermatome level of the tip of the catheter, often with the use of an appropriate contrast material (i.e., epidurogram) to ensure appropriate placement in the epidural space.<sup>104,105</sup> A small amount (<1 mL) of contrast (e.g., Omnipaque 180 or 240) can be infused into the catheter while one radiograph is taken to confirm placement (see Fig. 41-7).<sup>105</sup>

## TEMPERATURE MANAGEMENT

Intraoperative normothermia is key to maintaining a normal temperature postoperatively. Hypothermia is associated with discomfort, bleeding, infections, altered metabolism of drugs, delayed return of cognitive functions, and prolonged recovery.<sup>106-110</sup> Because about 90% of heat loss occurs through the skin, only heat exchange through the skin provides an adequate way of warming children. This method of warming is enhanced by the vasodilation properties of most anesthetic agents. Forced-air warming blankets are the most effective way of maintaining body temperature in children.<sup>111</sup> Given the vasoconstriction that occurs after anesthesia, attempts at warming are less effective postoperatively than intraoperatively, and most of the detrimental physiologic changes have already taken place. A growing body of literature documents the detrimental effects of hypothermia and shows that it is best when children arrive in the PACU with a normal body temperature.

Infants and children may suffer burns from overly aggressive rewarming measures. This is particularly true for nonverbal children, children who are somnolent, and children who have decreased sensation due to disease or use of regional anesthesia techniques. Recommendations from manufacturers and recent literature should be carefully reviewed before instituting routine use of warming devices.

## DISCHARGE CRITERIA

The recovery process and discharge criteria vary from institution to institution. Various criteria are used to determine readiness for discharge from the PACU. Some institutions require an assessment by a physician before discharge for all patients, but others require an evaluation only if routine discharge criteria are not met. The modified Aldrete scale is the most common system used to assess discharge readiness, but specific criteria depend on the particular situation or environment to which the child will be discharged. For example, a child with a slight degree of postextubation croup or stridor may be discharged for monitoring on a pediatric floor or ICU, but the same child is not discharged to parental care and a 2-hour drive home. The criteria for discharge of children to a general inpatient setting are summarized in Table 46-6. For outpatients, these criteria hold, and the additional criteria outlined in Table 46-7 usually must be met before discharge.

Traditionally, pediatric patients have been allowed to recover in a first-stage recovery unit until the airway was considered stable, consciousness is regained, baseline motor activity is

**TABLE 46-6 Discharge Criteria for Inpatients**

1. Recovery of airway and respiratory reflexes adequate to support gas exchange and to protect against aspiration of secretions, vomitus, or blood
2. Stability of circulation and control of any surgical bleeding
3. Absence of anticipated instability in criteria 1 and 2
4. Reasonable control of pain and vomiting
5. Appropriate duration of observation after opioid or naloxone flumazenil administration (minimum of 60 minutes after intravenous naloxone and up to 2 hours after flumazenil)
6. Return to baseline level of consciousness unless transfer is to an intensive care unit environment

**TABLE 46-7 Discharge Criteria for Outpatients**

<b>All criteria in Table 46-6, plus the following:</b>
1. Cardiovascular function and airway patency are satisfactory and stable.
2. The child is easily arousable, and protective reflexes are intact.
3. The child can talk (if age appropriate).
4. The child can sit up unaided (if age appropriate).
5. For a very young or handicapped child, incapable of the usually expected responses, the preanesthetic level of responsiveness or a level as close as possible to the normal level for that child should be achieved unless the child is to be transferred to another monitored location.
6. The state of hydration is adequate.
7. It may be permissible for parents to carry their children without full recovery of gait (parents must be advised that the child is at risk of injury if improperly supervised).
8. Control of pain should be achieved to permit adequate analgesia by the oral route thereafter.
9. Control of nausea and vomiting should be achieved to allow for oral hydration (see "Discharge Criteria" in text).

confirmed, vital signs are stable, and oxygen saturation values are stable in room air (or at baseline) without respiratory support (unless needed at baseline). Pain should be well controlled. Children then can be transferred to a second-stage recovery unit, where more complete recovery takes place with a reduced nurse-to-child ratio, until children have met criteria for adequate hydration, minimal emesis, appropriate wound status, good vital signs, and appropriate ambulation and mental status.

The requirements for children to eat, drink, and void before leaving the secondary recovery area significantly delay discharge. Efforts should be made to reinstate volume homeostasis during surgery, negating any physiologic imperative for oral intake in the immediate postoperative period. Postoperative maintenance fluids should consist of isotonic rather than hypotonic solutions for those expected to remain as inpatients to reduce the risk of hyponatremia (see also Chapter 8).<sup>112</sup> Other than children who are at high risk for urinary retention (e.g., history of urinary retention, urethral surgery), there is little evidence that discharge before voiding results in readmission for voiding problems, and this requirement is therefore no longer part of standard discharge criteria.<sup>113</sup> Children who have received a caudal block for surgery are likewise at low risk for urinary retention as long as opioids have not been added to the caudal medication.<sup>114</sup>

Although there are few data on the current status of recovery processes across the country, there appears to be a trend toward one-stage (fast-track) recovery for pediatric outpatients.<sup>115,116</sup> This process allows selected children to bypass the first-stage recovery and go directly to the second-stage unit based on appropriate level of consciousness, physical activity, vital signs, respiratory status, and pain control (Table 46-8). This approach has proved successful and quite safe, although appropriate attention to issues such as pain control must be addressed when initiating such a program.

#### ACKNOWLEDGMENT

The authors wish to thank A.J. de Armendi, MD, I.D. Todres, MD, and J.P. Cravero, MD, for their prior contributions to this chapter.

**TABLE 46-8 Discharge Criteria for Fast-Tracking**

Criteria	Score
<b>Level of Consciousness</b>	
Aware and oriented	2
Arousable with minimal stimulation	1
Responsive only to tactile stimulation	0
<b>Physical Activity</b>	
Able to move all extremities on command	2
Some weakness in movement of extremities	1
Unable to voluntarily move extremities	0
<b>Hemodynamic Stability</b>	
Blood pressure <15% of baseline MAP value	2
Blood pressure 15% to 30% of baseline MAP value	1
Blood pressure >30% of baseline MAP value	0
<b>Respiratory Stability</b>	
Able to breathe deeply	2
Tachypneic with good cough	1
Dyspneic with weak cough	0
<b>Oxygen Saturation Status</b>	
Maintains value >95% on room air	2
Requires supplemental oxygen (nasal prongs)	1
Saturation <90% with supplemental oxygen	0
<b>Postoperative Pain Assessment</b>	
None or mild discomfort	2
Moderate to severe pain controlled with intravenous analgesics	1
Persistent, severe pain	0
<b>Postoperative Emetic Symptoms</b>	
None or mild nausea with no active vomiting	2
Transient vomiting or retching	1

From White PF, Song D. New criteria for fast-tracking after outpatient anesthesia: a comparison with the modified Aldrete's scoring system. *Anesth Analg* 1998;88:1069-72.

MAP, Mean arterial pressure; PACU, postanesthesia care unit.

\*Pediatric patients must score 14 to bypass the phase 1 (PACU) recovery unit to be admitted directly to the step-down care unit.

#### ANNOTATED REFERENCES

- Anderson BJ, Woolard GA, Holford NH. Pharmacokinetics of rectal paracetamol after major surgery in children. *Paediatr Anaesth* 1995;5:237-42.
- The authors conducted a pharmacokinetic study in 20 children from 12 months to 17 years of age and demonstrated that paracetamol reached therapeutic plasma concentrations 1 to 2 hours after administration at a dose of 40 mg/kg. Anderson's research group subsequently defined the use paracetamol in various forms of administration (e.g., oral, rectal, intravenous) in children of all ages.
- Choong K, Arora S, Cheng J, et al. Hypotonic versus isotonic maintenance fluids after surgery for children: a randomized controlled trial. *Pediatrics* 2011;128:857-66.
- This important paper addresses the issue of postoperative hyponatremia in children. The authors randomized 258 children to two groups receiving isotonic or hypotonic maintenance solutions. Children in the isotonic group had hyponatremia at a rate of 22.7% (versus 40.8%), with no increased risk for hypernatremia.

Cravero JP, Beach M, Thyr B, Whalen K. The effect of small dose fentanyl on the emergence characteristics of pediatric patients after sevoflurane anesthesia without surgery. *Anesth Analg* 2003;97:364-7.

*The authors performed a prospective, randomized, blinded trial in which they studied patients undergoing magnetic resonance imaging with general inhaled sevoflurane anesthesia through a laryngeal mask airway. They concluded that small doses of opioids decrease emergence agitation without increasing unwanted side effects.*

Gan TJ, Meyer T, Apfel CC, et al. Consensus guidelines for managing postoperative nausea and vomiting. *Anesth Analg* 2003;97:62-71.

*The authors review the available literature concerning postoperative nausea and vomiting. They use strength of evidence criteria when possible and expert opinion when data are lacking.*

Hackel A, Badgwell JM, Binding RR, et al. Guidelines for the pediatric perioperative anesthesia environment. American Academy of Pediatrics. Section on Anesthesiology. *Pediatrics* 1999;103:512-5.

*The American Academy of Pediatrics guideline for the pediatric perioperative anesthesia environment addresses the facility- and personnel-based components of the postoperative care setting for children.*

Kain ZN, Caldwell-Andrews AA, Maranets I, et al. Preoperative anxiety and emergence delirium and postoperative maladaptive behaviors. *Anesth Analg* 2004;99:1648-54.

*This study is extremely unusual in its ability to correlate perioperative anxiety with the incidence of emergence agitation. Preoperative anxiety is significantly related to the incidence of emergence agitation, and the incidence of agitation is related to the rate of postoperative maladaptive behaviors. This study argues strongly for identifying children at risk for emergence agitation and gives some evidence for why it is worth the effort to prevent or ameliorate this phenomenon.*

McNicol ED, Tzortzopoulou A, Cepeda MS, et al. Single-dose intravenous paracetamol or propacetamol for prevention or treatment of postoperative pain: a systemic review and meta-analysis. *Br J Anaesth* 2011;106:764-75.

*The authors performed a meta-analysis of 36 randomized, controlled trials and 3896 patients to look at the effect of a single, intravenous dose of acetaminophen. They found that 37% of patients with acute postoperative pain had pain relief for about 4 hours.*

Barbiturates  
Opioids  
 $\alpha_2$ -Adrenoceptor Agonist: Dexmedetomidine  
General Anesthetics

**THE USE OF SEDATION** and analgesia for diagnostic and therapeutic procedures performed by anesthesiologists and nonanesthesiologists outside the operating room (OR) continues to dramatically increase. Millions of such procedures are performed each year throughout the world. Great progress has been made in understanding the need for and the risks associated with sedation and analgesia outside the OR; the mere restraint of a child for a frightening and/or painful procedure is difficult to justify.<sup>1-4</sup> Indeed, the time-honored techniques of immobilization by physical restraint or sedation with archaic medications, such as the “lytic cocktail” (meperidine, promethazine, and chlorpromazine), are unacceptable and were made possible only because children were easily overpowered, not routinely asked if they were in pain, and were unable to withdraw consent. Furthermore, many of these techniques were inefficient and failed to provide the conditions necessary to complete required procedures. Sedation/analgesia for painful procedures performed outside the OR (e.g., bone marrow aspiration, lumbar puncture, repair of minor surgical wounds, insertion of arterial or venous catheters, burn dressing changes, fracture reduction, bronchoscopy, and endoscopy) requires the same attention to detail as for procedures performed in the OR, because sedation levels needed often achieve the state of deep sedation or general anesthesia, particularly in children 6 years of age and younger. Nonpainful procedures often require sedation, immobility, and sometimes breath-holding. Children undergoing diagnostic studies (e.g., computed tomography [CT], magnetic resonance imaging [MRI], positron emission tomography, electroencephalography [EEG], electromyography), or who require high doses of ionizing radiation, also require deep levels of sedation or general anesthesia because they must remain absolutely motionless.<sup>5</sup> Given these requirements, a team approach is required to provide appropriate care for the child and to provide optimal conditions for the procedure.

Young and developmentally delayed children, are often unable to remain motionless for even short periods of time. Even some older children and adults may be unable to enter the confined space and often frightening environment of a diagnostic imaging scanner. The fear and anxiety associated with procedures are difficult to control and may be exacerbated by parental anxiety, separation from parents, and the pain (or anticipation of pain) from the procedure. Although distraction, guided imagery,

and the use of videos and music have clear and documented benefit, they are often not enough to efficiently and successfully complete procedures.<sup>6-10</sup>

The pharmacologic armamentarium for sedation for diagnostic and therapeutic procedures has greatly expanded to include drugs classified as sedatives, as well as those classified as general anesthetics. Who uses these drugs and what qualifications are needed by those who provide such sedation is controversial.<sup>11</sup> The demand for safe efficient sedation and analgesia outside the OR comes from many sources, including hospital administrators, insurance companies, and medical specialists. Failed sedations for diagnostic or therapeutic procedures are no longer acceptable, as this increases costs and frustrates parents<sup>12</sup>; however, this manpower need has far outstripped the available supply of anesthesiologists. This led to the demand to create sedation services for diagnostic or therapeutic procedures by nonanesthesiologists (i.e., nurse practitioners, pediatricians, emergency medicine physicians, intensivists, and dentists) who often use sedative agents, including general anesthetics. The development of pediatric sedation services has taken many directions. In a 2005 survey of pediatric sedation practice in 116 children’s hospitals in the United States and Canada,<sup>13</sup> only 50% of the hospitals had a formal pediatric sedation service. Anesthesiologists were the sole sedation providers in only 26% of institutions. A consortium of pediatric hospitals heavily involved in sedation noted that anesthesiologists were involved in 19% of sedation procedures.<sup>14</sup> Even when looking at the use of drugs such as propofol, which is considered a “general anesthetic,” this group noted anesthesiologists involvement only 10% of the time.<sup>15</sup> This chapter will focus on the current definitions of sedation for diagnostic and therapeutic procedures and the goals, risks, and guidelines for creation of safe conditions for children who require sedation for procedures outside the OR.

As anesthesiologists we need to ask—why should we care? We believe that we provide the best, most efficient, and safest conditions for procedures, whether they are painful or not and whether they are in the OR or not. However, there simply aren’t enough anesthesia care providers to meet the ever-increasing demand. Further, after years of training and the ability to provide anesthesia for “big” cases (e.g., liver transplants, craniofacial reconstruction, trauma, etc.), we need to ask ourselves whether we are

“overtrained” to care for children who require sedation or anesthesia for procedures outside of the OR, or whether it can be safely done by others with less training. Federal regulatory agencies, hospital administrations, and professional societies have recognized the expertise of anesthesiologists to provide sedation and have required us to lead, teach, and be responsible for oversight and credentialing of all sedation providers. We must “grab this tiger by its tail.”<sup>12,16</sup>

## Definition of Levels of Sedation

Several organizations have created guidelines and definitions of sedation for diagnostic and therapeutic procedures in children.<sup>17,20</sup>

The definitions of the American Academy of Pediatrics (AAP), the American Society of Anesthesiologists (ASA), The Joint Commission (previously called the Joint Commission on Accreditation of Healthcare Organizations), and the American Academy of Pediatric Dentistry (AAPD) are the most frequently cited and agreed-upon position statements.<sup>18,19,21-23</sup> These organizations defined sedation and analgesia for procedures as a continuum of consciousness to unconsciousness, ranging from minimal sedation (anxiolysis) to moderate sedation (previously, “conscious sedation”) to deep sedation and general anesthesia (Fig. 47-1). Note that a child’s depth of sedation may easily pass from a light level all the way to general anesthesia.<sup>24</sup>

A clear understanding of the definition of sedation is mandatory to recognize when the child has progressed to a deeper level of sedation than anticipated (i.e., from moderate sedation to deep sedation or from deep sedation to general anesthesia). Recognition of this transition allows escalation of monitoring and care to avoid complications. The AAP, ASA, and The Joint Commission formalized and defined the concepts of minimal sedation, moderate sedation, deep sedation, and general anesthesia. The definitions that follow are taken from The Joint Commission (2010)<sup>25,26</sup> and are in agreement with AAP, AAPD, and ASA definitions<sup>18,19,21</sup>:

- **Minimal sedation (anxiolysis):** A drug-induced state during which patients respond normally to verbal commands. Although cognitive function and coordination may be impaired, ventilatory and cardiovascular functions are unaffected (Video 47-1).
- **Moderate sedation** (previously called “conscious sedation” or sedation/analgesia): A drug-induced depression of consciousness during which patients respond purposefully to verbal

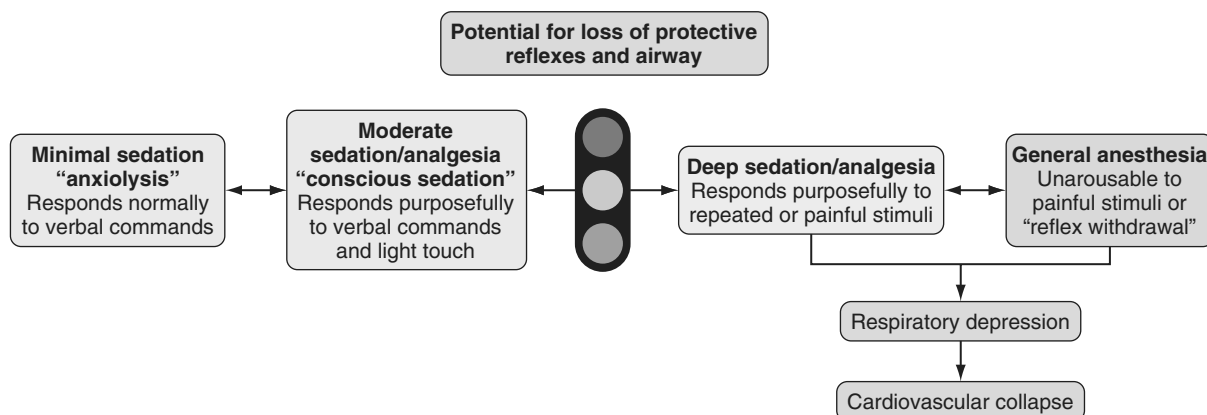

commands, either alone or accompanied by light tactile stimulation. No interventions are required to maintain a patent airway, and spontaneous ventilation is adequate. Cardiovascular function is usually maintained (Video 47-2).

- **Deep sedation:** A drug-induced depression of consciousness during which patients cannot be easily aroused but respond purposefully after repeated or painful stimuli (*note: reflex withdrawal from a painful stimulus is not considered a purposeful response*). The ability to independently maintain ventilatory function may be impaired. Patients may require assistance in maintaining a patent airway and spontaneous ventilation may be inadequate. Cardiovascular function is usually maintained (Video 47-3).

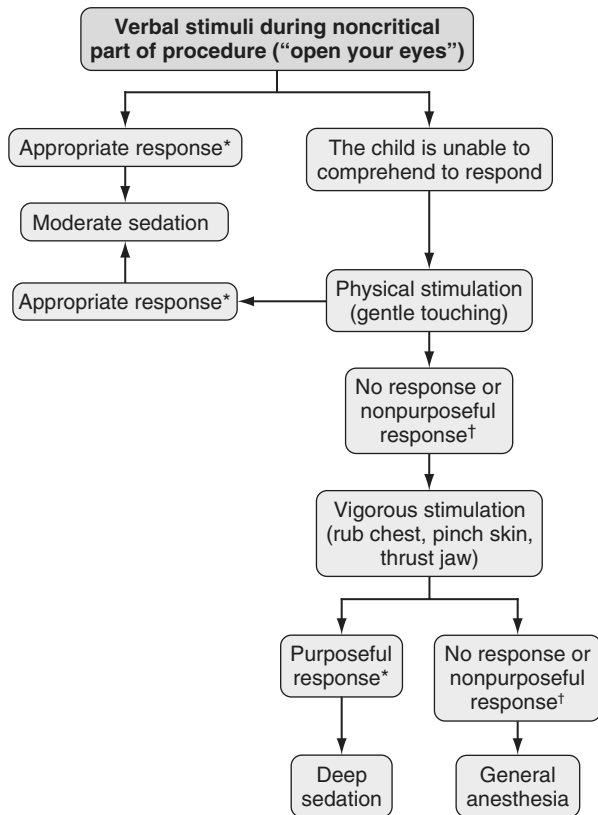

- **General anesthesia:** A drug-induced loss of consciousness during which patients are not arousable, even to painful stimuli. The ability to independently maintain ventilatory function is often impaired. Patients often require assistance in maintaining a patent airway, and positive-pressure ventilation may be required because of depressed spontaneous ventilation or drug-induced depression of neuromuscular function. Cardiovascular function may be impaired (Video 47-4).

Painful procedures or nonpainful procedures requiring complete immobility (e.g., diagnostic imaging or radiation therapy) cannot be performed in a child who is moderately (“consciously”) sedated. Most pediatric procedures require deep sedation. The myth that a state of moderate sedation in which children are conscious and simultaneously responsive to voice command while immobile in the face of pain is just that, a myth.<sup>27</sup>

Assessing the depth of sedation based on the child’s responses to stimulation is illustrated in Figure 47-2. This is a difficult challenge in children and depends on their verbal abilities, age, level of maturity, and underlying condition. A common problem with classifying a child as either moderately or deeply sedated is to misinterpret any movement in response to touch as “purposeful” and therefore a sign of “moderate sedation.” A child who is moderately sedated should respond to touch or firm rubbing by an appropriate response, such as saying “ouch,” pushing your hand away, and pulling up the covers. *An inappropriate response, such as nonpurposeful movement, is a sign that the child has progressed to a deeper sedation level, which should lead to an escalation of care because respiratory depression may occur.*<sup>28-31</sup> Similarly, children who are deeply sedated should respond purposefully to painful stimuli. *Reflex withdrawal, a nonpurposeful response or no response to painful stimuli, is a sign that the child has progressed to a level of*

**FIGURE 47-1** The sedation continuum. A patient may readily pass from a light level of sedation to deep sedation or general anesthesia. Health care providers must be prepared to increase vigilance and intensity of monitoring consistent with the depth of sedation.

**FIGURE 47-2** Sedated children must be continuously evaluated for depth of sedation and appropriateness of response. As diagrammed here, sedation is a continuum. Note that a purposeful response to voice or light touch is consistent with moderate sedation. A purposeful response to pain is consistent with deep sedation. A nonpurposeful response to pain is consistent with general anesthesia. However, such stimulation often defeats the purpose of the sedation, thus rendering these assessments less helpful unless patient movement is acceptable. None of the current sedation guidelines require such assessments.

\*Purposeful: opens eyes, talks back, pushes you out of the way.

†Nonpurposeful: winces, shrugs shoulders, nonspecific withdrawal to pain.

anesthesia and should be cared for using guidelines and personnel for general anesthesia. Children may quickly move from one level of sedation to another. A study in a large pediatric hospital showed that the goal of either moderate or deep sedation was only attained in 50% to 75% of patients. An awake state was noted in 12% to 28% of children, and a level consistent with general anesthesia was observed in up to 35% of children.<sup>32</sup> The need for accurate assessment of the sedated child has brought about several scoring systems.

The Ramsay scale was described by Ramsay and colleagues<sup>33</sup> in 1974 for the purpose of monitoring sedation with alphaxalone-alphadolone (Table 47-1). It continues to be the most widely used scale for assessing and monitoring sedation in daily practice, as well as in clinical research. It spans the continuum of sedation but does not clearly separate purposeful from nonpurposeful responses. The Ramsay scale has been modified to more clearly coincide with the AAP and Joint Commission guidelines (Table 47-2).<sup>34</sup> A score of 2 to 3 is anxiolysis, 4 to 5 is moderate sedation, 6 is deep sedation, and 7 to 8 is general anesthesia.

The Observer's Assessment of Alertness/Sedation (OAA/S) scale<sup>35</sup> is often cited as a scale for sedation. It is scored as follows: 1, no response to shaking; 2, responds to mild prodding; 3,

**TABLE 47-1** Ramsay Scale

Level	Characteristics
1	Patient awake, anxious, agitated, or restless
2	Patient awake, cooperative, orientated, and tranquil
3	Patient drowsy, with response to commands
4	Patient asleep, brisk response to glabella tap or loud auditory stimulus
5	Patient asleep, sluggish response to stimulus
6	Patient has no response to firm nail-bed pressure or other noxious stimuli

**TABLE 47-2** Modified Ramsay Sedation Scale

Score	Characteristics
1	Awake and alert, minimal or no cognitive impairment
2*	Awake but tranquil, purposeful responses to verbal commands at conversation level
3*	Appears asleep, purposeful responses to verbal commands at conversation level
4†	Appears asleep, purposeful responses to verbal commands but at louder than usual conversation level or requiring light glabellar tap
5†	Asleep, sluggish purposeful responses only to loud verbal commands or strong glabellar tap
6‡	Asleep, sluggish purposeful responses only to painful stimuli
7§	Asleep, reflex withdrawal to painful stimuli only (no purposeful responses)
8§	Unresponsive to external stimuli, including pain

\*Minimal sedation.

†Moderate sedation.

§General anesthesia.

responds to name called loudly; 4, lethargic response to name; and 5, readily responds to name. However, its inability to clearly categorize deep levels of sedation and lack of a clear differentiation between purposeful and nonpurposeful responses limit its usefulness. The University of Michigan Sedation Scale (UMSS)<sup>36</sup> is an assessment tool that has been shown to be valid when compared with the OAA/S scale and other scales of sedation (Table 47-3). It readily separates patients into the sedation categories defined by the AAP, ASA, and Joint Commission.

These subjective, responsiveness-based assessment tools all have the disadvantage of intermittently stimulating the child during the procedure and thereby undoing the very reason that sedation was given in the first place! Poking or prodding the child to determine their depth of sedation defeats the purpose of sedation in many situations, e.g., infants, developmentally delayed, or procedures requiring immobility. None of the guidelines require this type of assessment. These responsiveness-based definitions are meant to provide a roadmap for safety, with the understanding that a nonresponding child requires an increased level of vigilance and the provider must have the skills to rescue should an adverse respiratory or cardiac event occur.<sup>12</sup> Concerns regarding these types of assessment tools have led to a drive by some to revise the sedation continuum and to use other monitoring to assess level of sedation.<sup>37</sup>

To address the problem of defining the depth of sedation or anesthesia, a nonstimulating continuous-assessment tool using a

**TABLE 47-3** University of Michigan Sedation Scale (UMSS)

Score	Characteristics
0	Awake and alert
1	Minimally sedated: tired/sleepy, appropriate response to verbal conversation and/or sound
2	Moderately sedated: somnolent/sleeping, easily aroused with light tactile stimulation or a simple verbal command
3	Deeply sedated: deep sleep, arousable only with significant physical stimulation
4	Unarousable

processed EEG, as in the bispectral index (BIS) monitor, has been extensively explored. The BIS was derived from empirically estimating processed EEG parameters that best predicted OAA/S scale levels in adult volunteers receiving a wide variety of anesthetics, analgesics, and sedatives.<sup>38</sup> BIS values in adults range from 100 to 95, awake; 95 to 70, light to moderate sedation; 70 to 60, deep sedation with low probability of explicit recall; and 60 to 40, general anesthesia.<sup>39</sup> Unfortunately, the EEG in children varies markedly with age and drug, precluding accurate measures by the processed EEG.<sup>40,41</sup> Attempts to correlate BIS values with the depth of sedation in children have had varying success. In healthy children between 1 and 12 years of age who were sedated with chloral hydrate, meperidine and promethazine, midazolam, fentanyl, or pentobarbital, the BIS reading correlated well with the UMSS scores.<sup>42</sup> In a similar study with children between birth and 18 years of age who received inhalational anesthetics, chloral hydrate, midazolam, and fentanyl,<sup>43</sup> the BIS readings validated the sedation scores, although the data identified several important limitations when distinguishing moderate from deep sedation. For example, the researchers concluded that a BIS of 80 is the optimal cutoff for a diagnosis of deep sedation although this value is inconsistent with that found in the adult literature. In children recovering from propofol and remifentanyl anesthesia, there was a marked overlap between moderate and deep sedation using both the BIS and the composite A-line autoregressive index (auditory EEG).<sup>44,45</sup> From a safety perspective, it is worrisome that the BIS underestimates the depth of sedation with certain medications, such as chloral hydrate.<sup>45,46</sup> During pentobarbital sedation, the BIS had “limited ability to distinguish between moderate and deep sedation levels in children.”<sup>47</sup>

Furthermore BIS values are not age specific,<sup>48,49</sup> may differ from one side of the head to the other, are diminished in developmentally delayed children,<sup>50</sup> may increase with larger doses of ketamine because of ketamine-induced central excitation,<sup>51,52</sup> and are unaffected even by high-dose dexmedetomidine.<sup>53</sup> Therefore the overlap between levels of sedation, the few large well-controlled studies in children, the overall low quality of BIS data in some studies, as well as a lack of information for different age-groups and specific drugs, precludes validation of the BIS for use in sedated children.<sup>40</sup> In addition, the use of BIS-type monitoring is not feasible for many procedures, such as MRI, CT scans, or those involving the mouth and airway (endoscopy, dental, bronchoscopy), because the monitor is either not compatible, creates artifacts, is easily dislodged, or is in the way of the proceduralist.

The definitions and tools discussed previously attempt to assess sedation and decrease risk by quantitating the response

**TABLE 47-4** Examples of Sedative Drugs That Have Varying Effects on Response to Pain and Airway Protection

Response to Pain Does Not Predict Airway Maintenance  
All Drugs Are Different

	Response to Pain	Airway Maintenance
Fentanyl	↓↓	↓
Propofol	±	↓↓
Ketamine	↓↓	±
Dexmedetomidine	↓	+

to stimulation or EEG activity. These tools, however, do not directly measure the risk of loss of control of the airway, which is the primary cause of morbidity and mortality during sedation.<sup>54,55</sup> The implication is that there is a direct quantifiable correlation between response to touch or painful stimulation and the ability to control the airway. Thus a moderately sedated child who can respond to light touch can protect his or her airway and a deeply sedated child who can respond appropriately only to pain may not be able to protect his or her airway. *The important assessment of the child is not the response to stimulation, but the ability to protect the airway.* Furthermore, different sedative drugs have different effects on analgesia separate from obtundation of the airway. Propofol is not a profound analgesic but has profound effects on the airway.<sup>56</sup> Conversely, the sedative dexmedetomidine may provide profound sedation with little depression of respiratory function. Ketamine produces intense analgesia and most children maintain a patent airway and adequate respiratory effort (Table 47-4).<sup>57</sup>

Until recently, a quantifiable metric to assess control of the airway in sedated children was not available.<sup>58</sup> Studies on the changes of airway dimensions under different anesthetic and sedative agents, the effect of different positions on the upper airway,<sup>59-61</sup> and upper airway collapsibility with different concentrations of sedative drugs provide a more meaningful assessment of airway risk and protection. The profound effect of propofol-induced collapse of the upper airway can be partially mitigated by reducing the dose and including supplemental drugs, such as midazolam and nalbuphine.<sup>62,63</sup>

Assessing sedation must also focus on appropriate discharge readiness. Adverse effects, including death, have occurred after premature discharge following sedation for a procedure.<sup>55</sup> These events have occurred most often when a long-lasting (long half-life) sedative, such as chloral hydrate, has been given (Fig. 47-3). This can result in the child being unable to spontaneously clear his or her airway.<sup>54</sup> A simple modified “maintenance of wakefulness” score (infants had to stay awake for at least 20 minutes in a quiet environment before discharge) ensured that more than 90% of children had returned to baseline, compared with only 55% of children assessed as “street ready” according to usual hospital discharge criteria.<sup>44</sup>

## Goals of Sedation

The goals of pediatric sedation have not changed over the years and can be summarized as follows<sup>18,31</sup>:

- Guard the child’s safety and welfare. The individual who performs the procedure cannot safely monitor the child as

**FIGURE 47-3**  $\beta$ -Elimination half-life of the active metabolite of chloral hydrate, trichloroethanol, in preterm infants, term infants, and toddlers. Note the extremely prolonged half-lives and the large standard deviations in all age groups. Although often thought of as a short-acting sedative, chloral hydrate can have profoundly long sedative effects, with a real possibility of re-sedation after a procedure when the child is left undisturbed. It is for this reason that we recommend a longer period of observation in a step-down area before discharge.

well. A second individual must monitor the child, administer drugs, and record vital signs.

- Minimize physical discomfort and pain.
- Control anxiety, minimize psychological trauma, and maximize the potential for amnesia.
- Control behavior and/or movement, to allow the safe completion of the procedure.
- Rapidly return of the child to a state in which he or she is safe for discharge from medical supervision, as determined by recognized criteria.
- Create an optimal and efficient system that is not a burden to the health care providers

## Risks and Complications Associated with Sedation

The foremost goal is to optimize patient safety and thereby decrease the risk and associated complications. The assessment of risk for pediatric sedation must include age, type of procedure, underlying medical conditions and how these might influence the response to sedating medications, intended level of sedation, pharmacology (pharmacokinetics [PK] and pharmacodynamics [PD]) of the medications used, guidelines (i.e., training, equipment, personnel, monitoring), appropriate-for-age fasting, and strict discharge criteria.

A recent area of concern that was not previously recognized in providing safe sedation or anesthesia to small children is whether drugs used for sedation or anesthesia are neurotoxic to children<sup>64-71</sup>; this topic is covered in detail in Chapter 23. More important than the theoretical concern regarding potential neurotoxicity of sedating medications is the more practical risk assessment regarding both inadequate and excessive sedation. Sedation centers in the United States are less likely to offer sedation for painful procedures than similar centers in Europe. Thirty percent

of U.S. respondents to a mail survey reported performing bone marrow biopsies in children without significant sedation more than 50% of the time, as compared with 0% of European centers.<sup>72</sup> When 1140 children (mean age  $2.96 \pm 3.7$  years) were sedated by nonanesthesiologists who followed AAP guidelines for procedures,<sup>73</sup> approximately 13% received inadequate sedation.

The psychological consequences of inadequate sedation have not been specifically studied but can be inferred from children's responses to other stressful situations. Inadequate preoperative sedation is clearly linked to increased anxiety in children and their families. Of children undergoing a stressful anesthesia induction, 54% have postoperative maladaptive behaviors for up to 2 weeks after the experience.<sup>74</sup> The incidence of these behaviors decreases with the use of appropriate preoperative sedation. Similar sequelae have been reported after repeated invasive procedures in pediatric intensive care units (ICUs).<sup>75</sup> Although the number of children who developed posttraumatic stress syndrome because of no sedation or less than optimal sedation during diagnostic and therapeutic procedures is unknown, one can assume that it would be similar to that found in the study situations.

There have been many approaches to assess the risk involved in oversedation of children. One approach is to review sedation-related deaths and critical incidents to find common causes. In 2000, a now classic retrospective review was undertaken of 95 cases of sedation-related deaths and critical incidents derived from the U.S. Food and Drug Administration's (FDA) adverse drug event reporting system, the U.S. Pharmacopeia, and a survey of pediatric specialists.<sup>54</sup> Although a number of the incidents cited in this study occurred over 20 years ago, the findings remain applicable today. The analysis revealed that, rather than being related to a specific medication, the overwhelming majority of critical events were preventable and caused by operator error or lack of robust rescue systems. Drug interactions were the most common factor, followed by drug overdose, inadequate monitoring, inadequate cardiopulmonary resuscitation skills, inadequate evaluation before sedation, and premature discharge from medical supervision. The report emphasizes that most sedation complications are related to adverse respiratory events (80%); a majority progressed to cardiac arrest, indicating a lack of rescue skills of the practitioners. A disproportionately large number of severe complications and deaths occurred when sedation was performed in offices outside of hospitals, pointing to a lack of trained personnel available for rescue. There was no relationship with class of drug or route of administration, although there was a positive correlation when three or more sedating medications were administered.<sup>55</sup> Indeed, the combination of a sedative, hypnotic, and an opioid is well recognized as a precursor to significant respiratory depression.

There are many underpowered reports with relatively few patients ( $n < 200$ ) receiving a variety of sedative medications in a variety of settings declaring successful completion of the procedures and no fatalities.<sup>76-86</sup> Most studies describe adequate conditions and successful completion with no severe outcomes, but with varying frequencies of transient airway obstruction or desaturation. Conclusions often state that the particular technique and sedation providers are safe and effective. An example is a study that prospectively followed 1140 children (mean age  $2.96 \pm 3.7$  years) sedated for procedures by nonanesthesiologists following AAP guidelines and using a quality-assurance tool.<sup>73</sup> Neither death nor sedation-induced crises occurred, although they reported a 5.3% incidence of respiratory events, including one in

**TABLE 47-5** The Dartmouth Operative Conditions Scale (DOCS)

Patient State		Observed Behaviors		
Pain/stress	(0) Eyes closed or calm expression	(1) Grimace or frown	(2) Crying, sobbing, screaming	
Movement	(0) Still	(1) Random little movement	(2) Major purposeful movement	(3) Thrashing, kicking, biting
Consciousness	(0) Eyes open	(-1) Ptosis, uncoordinated, "drowsy"	(-2) Eyes closed	
Sedation side effects	(-1) SpO <sub>2</sub> < 92%	(-1) Noise with respiration	(-1) Respiratory pauses >10 seconds	(-1) BP decrease of > 50% from baseline

The Dartmouth Operative Conditions Score (DOCS). Patients are scored in four state categories at any one time during sedation for a procedure. The sum of the scores in all four categories is used to determine the DOCS score for any discrete point during a sedation encounter.

SpO<sub>2</sub>, Oxygen saturation as measured by pulse oximetry.

which a child developed apnea. Given that the expected incidence of a sedation-induced crisis should be on the order of one in tens of thousands, it is not surprising that the majority of similar studies are underpowered to report a critical event.<sup>87</sup>

Another approach to assessing safety is to carefully observe relatively small groups of children and track minute-to-minute changes in their level of sedation. This has been accomplished by the creation of the Dartmouth Operative Conditions Scale (DOCS) (Table 47-5).<sup>88</sup> This scale was derived from observing 110 videos of pediatric sedation outside the OR. The DOCS quantifies the child's "state" based on observable behavior. Continuously applying this scale allows for careful tracking of level of sedation, effectiveness of sedation, uncontrolled adverse effects, and the timing of induction of sedation and recovery without poking or prodding the child to determine their depth of sedation. These data can help to quantify the quality of sedation and best practices.

Simulations have been used to carefully examine rare adverse effects in pediatric sedation and ability to rescue.<sup>89,90</sup> In a simulated scenario of a sedation complication, a standard reproducible event was introduced in which physiologic variables degraded with inappropriate interventions and improved when effective treatment was introduced. The simulation was distributed throughout the hospital and used with different sedation provider teams (e.g., postanesthesia care unit, emergency department [ED], radiology, and sedation unit). The event was videotaped and scored based on deviations from best practice; it quantifies episodes of hypoventilation, apnea, hypoxia, and cardiovascular collapse. Hypoxia and hypotension lasted 90 seconds in the pediatric sedation unit and 360 seconds in the ED and radiology setting.<sup>91</sup> Such studies demonstrate that prospective and retrospective analysis of simulated but rare adverse events can identify areas within the hospital that are in need of improving their clinical skills, and have a positive impact on patient safety.

There has been a recent effort to capture information from the large numbers of pediatric sedation procedures necessary to understand the nature and frequency of adverse reactions to sedation. The Pediatric Sedation Research Consortium (PSRC) comprises a group of over 30 institutions in North America who share prospective data on pediatric sedation.<sup>14</sup> Analysis of the first 30,000 records identified demographics, procedures, sedation techniques, outcomes, and adverse events: (1) there were no deaths and only one cardiac arrest reported; (2) unanticipated admission occurred infrequently, 1 per 1500 sedations; (3) vomiting occurred 1 per 200 sedations, including one aspiration;

(4) stridor, laryngospasm, wheezing, and apnea occurred in 1 of 400 procedures; and (5) airway or ventilatory manipulations occurred in 1 time per 200 sedations.<sup>91</sup> Risk factors included age younger than 3 months, ASA physical status 3 or greater, and multiple drug combinations for sedation. The PSRC has also reviewed the incidence of adverse events in 49,386 propofol sedation and/or anesthesia encounters for procedures outside of the OR.<sup>15</sup> Propofol was delivered by multiple providers (anesthesiologists, intensivists, emergency medicine, pediatricians, and radiologists). No deaths were recorded. CPR was required in 2 children (anesthesiologists were not involved in their care) and aspiration occurred in 4 children. Desaturation of less than 90% for more than 30 seconds occurred 154 times per 10,000 sedations/anesthesias; central apnea or obstruction occurred 575 times per 10,000. Stridor, laryngospasm, excessive secretions, and vomiting occurred 50, 96, 341, and 49 times per 10,000, respectively. The most prominent type of complication was related to the airway and occurred 1 out of 65 sedations; 1 in 70 children required airway rescue. Unexpected admissions occurred 7.1 times per 10,000 sedations. When all possible adverse events are considered, anesthesiologists report fewer events than nonanesthesiologists, with an odds ratio of 1.38 (95% confidence interval [CI] of 1.21 to 1.57,  $P < 0.001$ ).<sup>15</sup> No difference, however, was noted when outcomes were limited only to major pulmonary complications. The authors concluded that propofol sedation and/or anesthesia when given under these strict organized conditions, i.e., following the AAP sedation guideline, with very well-trained providers, can result in effective sedation with a minimal incidence of severe adverse events. The safety of this practice is contingent on the ability to quickly and safely manage less serious events. In a prospective cohort study of 131,751 procedural sedations<sup>92</sup> in radiology (62%), hematology-oncology (11%), and minor medical or surgical procedures (16%), in which sedation included primarily propofol (60%), midazolam (25%), and others provided by anesthesiologists, emergency physicians, intensivists, pediatricians, and "other" (pediatric residents, radiologists, dentists, surgeons, and nurses), the rate of major complications per 10,000 sedations (and 95% CIs) were: anesthesiologist 7.6 (4.6 to 12.8), emergency physician 7.8 (5.5 to 11.2), intensivist 9.6 (7.3 to 12.6), pediatrician 12.4 (6.9 to 20.4) and "other" 10.2 (5.1 to 18.3). There were no statistical differences between any providers before or after potential confounding variables (age, ASA status, fasting status, propofol use). A significant limitation of the study was the selection bias that was introduced because not all sedation areas within each hospital

reported data and the providers were not randomized. The study did not track whether high-risk patients were referred to practitioners outside of their sedation practice (i.e., the anesthesia service). Only major complications and not minor but dangerous complications (i.e., desaturation, hypoventilation, and need for airway support) were monitored. The participants in these hospitals are highly motivated, and application of these data outside of the consortium requires rigorous evaluation of safeguards and training. The ASA thinks that anesthesiologist participation in all deep sedation is the best means to achieve the safest care. The ASA acknowledges that nonanesthesiologists administer or supervise the administration of deep sedation and has created guidelines to help anesthesiologists provide leadership in this area.<sup>93,94</sup>

## Guidelines

The first sedation guidelines were published in 1985 from the Committee on Drugs, Section on Anesthesiology, American Academy of Pediatrics.<sup>95</sup> These guidelines provided the first framework to improve safety for children requiring sedation for a procedure. The guidelines emphasized systems issues, such as the need for informed consent, appropriate fasting before sedation, frequent measurement and charting of vital signs, the availability of age- and size-appropriate equipment, the use of continuous physiologic monitoring, the need for basic life support skills, as well as proper recovery and discharge procedures. The guidelines stated that an independent observer whose only responsibility was to monitor the child was required for deep sedation. Advanced airway and resuscitation skills were encouraged but not required. In 1992, the guidelines were revised<sup>96</sup> emphasizing that a child could readily progress from one level of sedation to another and that the practitioner should be prepared to increase vigilance and monitoring as indicated. In 2002, the same Committee on Drugs of the AAP updated and amended the guidelines.<sup>97</sup> It eliminated the use of the confusing term *conscious sedation* and replaced it with the term *moderate sedation*. It also emphasized the application of these guidelines outside the hospital, in recognition of the relatively high complication rate in non-hospital-based settings. The ASA guidelines in use today were updated in 2002 and, in many respects, modeled after the AAP guideline.<sup>98</sup> These guidelines were systematically developed by a task force of 10 members. The task force reviewed the strength of evidence and made recommendations that include the following:

- **Patient Evaluation:** Clinicians should be familiar with the sedation-related aspects of the patient's medical history. These include (1) abnormalities of major organ systems, (2) previous adverse effects with sedation and general anesthesia, (3) drug allergies, current medications, and drug interactions, (4) time and nature of oral intake, and (5) history of tobacco, alcohol, or substance abuse. A focused physical examination, including vital signs, auscultation of the heart and lungs, and evaluation of the airway, is recommended.
- **Preprocedural Preparation:** Patients should be informed of and agree to sedation, including its risks, benefits, limitations, and alternatives. Sufficient time should elapse before a procedure to allow gastric emptying in elective patients. Minimum fasting periods of 2 hours (clear liquids), 4 hours (breast milk), and 6 hours (infant formula, nonhuman milk, and light meal), are recommended for healthy patients. If urgent, emergent, or other situations impair gastric emptying, the potential for pulmonary aspiration of gastric contents must be considered in determining the target level of sedation, delay, or intubation.
- **Monitoring Level of Consciousness:** Monitoring of verbal commands should be routine during moderate sedation, with the exception of young children and mentally impaired, uncooperative patients, or when the response would be detrimental. During deep sedation the response to a more profound stimulus should be sought to be sure the patient has not drifted into general anesthesia.
- **Physiologic Monitoring:** All patients undergoing sedation/analgesia should be monitored by pulse oximetry with appropriate alarms. In addition, ventilatory function should be continually monitored by observation or auscultation. Monitoring of end-tidal carbon dioxide (ETCO<sub>2</sub>) should be considered for all patients receiving deep sedation and for patients whose ventilation cannot be directly observed during moderate sedation. Multiple studies have confirmed the usefulness in ETCO<sub>2</sub> monitoring especially during deep sedation. Although not currently required, adverse events can be anticipated and corrected by using ETCO<sub>2</sub> monitoring.<sup>99</sup> It should be noted that ASA standards for basic monitoring have been amended to include ETCO<sub>2</sub> monitoring for all sedated patients beginning in 2012.<sup>99,100</sup> When possible, blood pressure (BP) should be determined before sedation/analgesia is initiated. Once sedation/analgesia is established, BP should be measured at regular intervals during the procedure, unless such monitoring interferes with the procedure (e.g., pediatric MRI, in which stimulation from the BP cuff could arouse an appropriately sedated child). Electrocardiographic (ECG) monitoring should be used in all children during deep sedation, and during moderate sedation in those with significant cardiovascular disease or those who are undergoing procedures in which dysrhythmias are anticipated.
- **Recording of Monitored Parameters:** For both moderate and deep sedation, the child's level of consciousness, ventilatory and oxygenation status, and hemodynamic variables should be assessed and recorded at a frequency that depends on the type and amount of medication administered, the length of the procedure, and the general condition of the patient. At a minimum, this should be (1) before the beginning of the procedure; (2) after administration of sedative/analgesic agents; (3) at regular intervals during the procedure; (4) during initial recovery; and (5) just before discharge. If recording is performed automatically, device alarms should be set to alert the care team to critical changes in patient status. (Children's National Medical Center [CNMC] hospital policy requires recording of vital signs every 15 minutes and every 5 minutes for moderate and deep sedation, respectively.)
- **Availability of an Individual Responsible for Patient Monitoring:** A designated individual, other than the practitioner performing the procedure should be present to monitor the child throughout procedures performed with sedation/analgesia. During deep sedation, this individual should have no other responsibilities. However, during moderate sedation, this individual may assist with minor, interruptible tasks once the patient's level of sedation/analgesia and vital signs have stabilized, provided that adequate monitoring for the child's level of sedation is maintained.
- **Training of Personnel:** Individuals responsible for children who receive sedation/analgesia should understand the pharmacology of the medications that are administered, as well as the

role of pharmacologic antagonists for opioids and benzodiazepines. Individuals who monitor children who receive sedation/analgesia should be able to recognize the associated complications. At least one individual capable of establishing a patent airway and positive-pressure ventilation, as well as a means for summoning additional assistance, should be present whenever sedation/analgesia is administered. It is recommended (although not specifically stated) that an individual with advanced life support skills be immediately available (within 5 minutes) for moderate sedation; such an individual must be within the procedure room for deep sedation.

- **Availability of Emergency Equipment:** Pharmacologic antagonists, as well as appropriately sized equipment for establishing a patent airway and providing positive-pressure ventilation with supplemental oxygen, should be present whenever sedation/analgesia is administered. Suction, advanced airway equipment, and resuscitation medications should be immediately available and in good working order. A functional defibrillator should be immediately available whenever deep sedation is administered and when moderate sedation is administered to those with mild or severe cardiovascular disease.
- **Use of Supplemental Oxygen:** Equipment to administer supplemental oxygen should be present when sedation/analgesia is administered. Supplemental oxygen should be considered for moderate sedation and should be administered during deep sedation unless specifically contraindicated for a particular child or procedure. If hypoxemia is anticipated or develops during sedation/analgesia, supplemental oxygen should be administered.
- **Combinations of Sedative/Analgesic Agents:** Combinations of sedative and analgesic agents may be administered as indicated for the procedure being performed and the condition of the child. Ideally, each component should be administered individually to achieve the desired effect (e.g., additional analgesic medication to relieve pain; additional sedative medication to decrease awareness or anxiety). The propensity for combinations of sedative and analgesic agents to cause respiratory depression and airway obstruction emphasizes the need to appropriately reduce the dose of each component, as well as the need to continually monitor respiratory function (Fig. 47-4).

**FIGURE 47-4** Relationship between ventilation and carbon dioxide is represented by a family of curves. Each curve has two parameters, an x-intercept and a slope. Sedatives and opioids increase the intercept and decrease the slope. The combination of sedatives and opioids produce the most profound effect. (From Yaster M, Nichols DG, Deshpande JK, Wetzel RC. Midazolam-fentanyl intravenous sedation in children: case report of respiratory arrest. *Pediatrics* 1990;86:463-7.)

- **Titration of Intravenous Sedative/Analgesic Medications:** Intravenous (IV) sedative/analgesic drugs should be given in small, incremental doses that are titrated to the desired end points of analgesia and sedation. Sufficient time must elapse between doses to allow the effect of each dose to be assessed before subsequent drug administration. When drugs are administered by non-IV routes (e.g., oral, rectal, intramuscular [IM], transmucosal), allowance should be made for the time required for drug absorption before supplementation is considered. Because absorption may be unpredictable, administration of repeat doses of oral medications to supplement sedation/analgesia is not recommended.
- **General Anesthetic Induction Agents Used for Sedation/Analgesia (Propofol, Methohexital, Ketamine):** Even if moderate sedation is intended, children who are sedated with either propofol or methohexital by any route should receive care consistent with that required for deep sedation. Accordingly, practitioners who administer these drugs should be qualified to rescue the children from any level of sedation, including general anesthesia. Children who are sedated with ketamine should be cared for in a manner consistent with the level of sedation that is achieved.
- **Recovery Care:** After sedation for diagnostic and therapeutic procedures, the children should be observed in an appropriately staffed and equipped area until they are near their baseline level of consciousness and are no longer at increased risk for cardiorespiratory depression. Oxygenation should be monitored periodically until they are no longer at risk for hypoxemia. Ventilation and circulation should be monitored at regular intervals until the children are suitable for discharge. Discharge criteria should be designed to minimize the risk of central nervous system (CNS) or cardiorespiratory depression after discharge from observation by trained personnel.
- **Consultation and Availability of an Anesthesiologist:** Whenever possible, appropriate medical specialists should be consulted before sedating children with significant underlying conditions. The choice of specialists depends on the nature of the underlying condition and the urgency of the situation. For severely compromised or medically unstable children (e.g., anticipated difficult airway, severe obstructive pulmonary disease, or congestive heart failure), or if it is likely that sedation to the point of unresponsiveness will be necessary to obtain adequate conditions, practitioners who are not trained in the administration of general anesthesia should consult an anesthesiologist (Table 47-6).

The above ASA guideline pertains to all age-groups. The AAP's most recent guideline update was published in 2006.<sup>18</sup> In general, their updated guideline reinforces the ASA guideline. The AAP updated revision retains the same definitions of the continuum of sedation that are identical to the ASA and Joint Commission definitions. The AAP guidelines emphasize a systematic approach to sedation that includes:

- No administration of sedative medications without the safety net of medical supervision (i.e., no sedative medications given at home)
- Careful presedation evaluation to include review of pertinent medical and surgical conditions
- Careful history for ingestion of nutraceuticals and other medications that may alter drug metabolism and prolong sedation
- A "time out" should be performed before sedation
- Appropriate fasting guidelines for elective and urgent procedures. There should be a balance between the depth of

**TABLE 47-6** Guidelines for the Consultation of an Anesthesiologist

1. Medical Problems
<ul style="list-style-type: none"> <li>• ASA Physical Status III or IV</li> <li>• Pulmonary: airway obstruction (tonsils/adenoids)—loud snoring, obstructive sleep apnea. Poorly controlled asthma, congenital or acquired anomalies of the airway or face (Trisomy 21, Pierre Robin syndrome, Treacher Collins syndrome, Crouzon disease, tracheomalacia)</li> <li>• Morbid obesity (<math>\geq 2</math> times ideal body weight, BMI <math>&gt; 30</math> kg/m<sup>2</sup>)</li> <li>• Cardiovascular: cyanosis, repaired or unrepaired congenital heart disease with significant symptoms of cyanosis or congestive heart failure</li> <li>• Prematurity: less than 60 weeks postconceptional age at time of sedation</li> <li>• Residual pulmonary, cardiovascular, gastrointestinal, neurologic problems</li> <li>• Neurologic: developmental disabilities, poorly controlled seizures, central apnea</li> <li>• Gastrointestinal: uncontrolled gastroesophageal reflux</li> <li>• Severe liver or renal disease</li> </ul>
2. Procedures requiring deep sedation in patients with a full stomach
<ul style="list-style-type: none"> <li>• Emergency Procedures</li> </ul>
3. Management problems
<ul style="list-style-type: none"> <li>• Severe developmental delay</li> <li>• Patients who are difficult to control</li> <li>• Severe attention deficit disorder (paradoxically, the child may develop increased agitation during or after the procedure)</li> </ul>
4. History of failed sedation
<ul style="list-style-type: none"> <li>• Oversedation (loss of airway reflexes)</li> <li>• Inability to adequately sedate</li> <li>• Hyperactive (paradoxical) response to sedatives</li> </ul>

ASA, American Society of Anesthesiologists; BMI, body mass index.

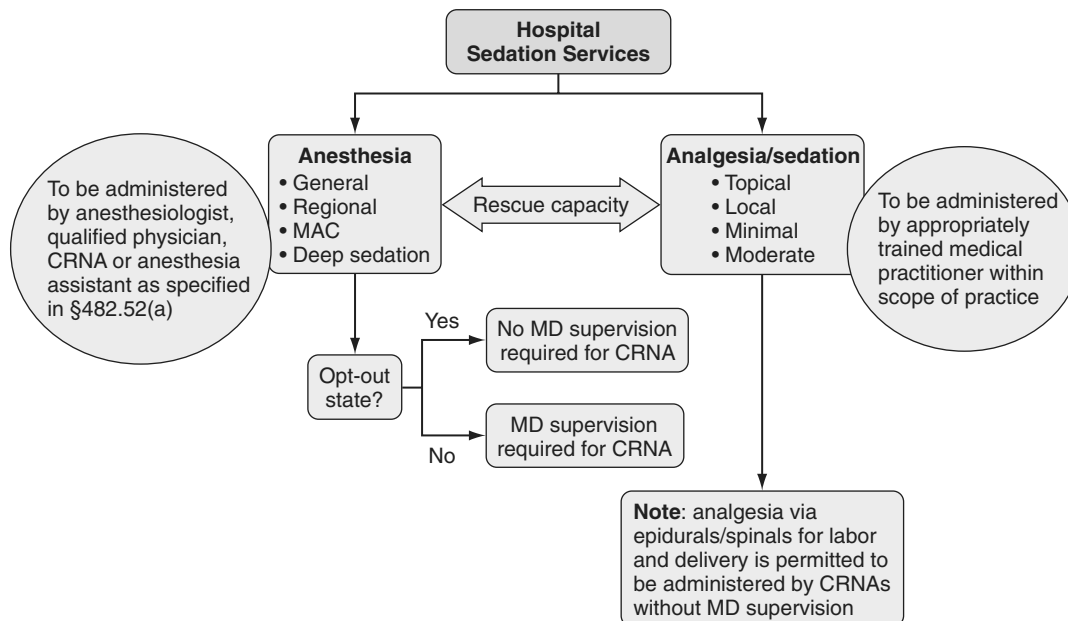

sedation and the risk for those who are unable to fast because of the urgent nature of the procedure

- Focused airway examination with particular attention to anatomic airway abnormalities and enlarged tonsils
- Understanding of the pharmacologic and PD effects of sedation medications and drug interactions
- Appropriate training and skills in airway management to allow for rescue. Deep sedation requires training in pediatric advanced life support
- Immediate availability of size- and age-appropriate airway, monitoring, and resuscitation equipment
- Appropriate medications and reversal agents
- Sufficient numbers of sedation providers to carry out the procedure and monitor the child
- Appropriate physiologic monitoring during and after the procedure; use of capnography is encouraged
- Appropriate recovery personnel, monitoring, and discharge criteria with return to baseline condition before discharge
- Prolonged observation in a step-down unit of children who have been sedated with drugs known to have a long half-life (e.g., chloral hydrate, “lytic cocktail” [see later discussion])
- Continuous quality improvement to track common markers of potential safety issues, such as desaturation events, airway obstructions, laryngospasm, unplanned hospital admission, unsatisfactory sedation, and medication errors
- Use of simulators to practice how to manage rare adverse events

- Assume all children younger than 6 years of age to be deeply sedated from the beginning of the sedation process

Other organizations, including the American College of Emergency Physicians (ACEP), published their own sedation guidelines.<sup>101-105</sup> The latter guidelines are distinguishable from the AAP and ASA guidelines in several respects, including the definition of the continuum of sedation. The ACEP guideline does not use the terms “moderate” or “deep” sedation but rather the term “procedural sedation.” It is defined “as a technique of administering sedatives, analgesics, dissociative agents, alone or in combination to induce a state that allows the child to tolerate unpleasant procedures while maintaining cardiopulmonary function.” It is intended to result in a depressed level of consciousness but one that allows the child to “independently and continuously” control their own airway. Unfortunately, the lack of uniform agreement on definitions and overlap of “procedural sedation” into “deep sedation” and “anesthesia” has led to considerable confusion and debate among practitioners. In 2006 the ASA asserted that “privileges to administer deep sedation should be granted only to practitioners who are qualified to administer general anesthesia.”<sup>93,94</sup> Intensivists and emergency room physicians took umbrage with the ASA “usurping” control over their sedation practice.<sup>11</sup> They pointed out that their specialties have been using drugs, such as propofol and ketamine, for procedural sedation with minimal complications at levels that are considered deep sedation or anesthesia for many years,<sup>106,107</sup> and that they resent an outside organization imposing guidelines on their practices. In 2010 the ASA acknowledged that Medicare regulations permit some non-anesthesia practitioners to administer deep sedation and created guidelines to help hospital directors of anesthesia services grant privileges to such individuals.<sup>93</sup> The guidelines include: formal training in administration of deep sedation during residency training (within 2 years) or an Accreditation Council for Graduate Medical Education accredited training program; experience and competency in managing sedated patients; clinical experience with more than 35 patients; knowledge of ASA guidelines; advanced cardiac life support training; and quality assurance tracking. Separate privileging is required for the care of children. The exact nature of these requirements are not specified, but are over and above baseline competencies and dependent on the hospital’s director of anesthesia services.

It is mandatory that sedation policies used in hospitals conform to Joint Commission standards that have been derived from the Department of Health & Human Services (DHHS) Centers for Medicare & Medicaid Services (CMS). In the 1990s, the Joint Commission recognized that there is considerable variation in the level of care provided to sedated children, depending on where the sedation is administered, even within one institution. They mandated that the standard of care for all sedated patients be uniform throughout any one institution. Thus institutionally standardized documentation (e.g., medical history, physical status, and record-keeping during the procedure and the recovery from the procedure), fasting guidelines, and informed consent procedures are mandatory for all patients undergoing sedation, regardless of the nature, duration, patient’s history, and location of the procedure. Similarly, the sedation personnel, monitoring equipment, and recovery facilities must be standardized or uniform within an institution. All of this must be part of an active quality improvement process. Hospitals risk losing federal funding if they fail to comply. In 2004, 18% of hospitals were found noncompliant in planning the administration of

**FIGURE 47-5** Centers for Medicare & Medicaid Services organizational chart showing deep sedation under the category of “Anesthesia” and supervised by “Hospital Sedation Services.” CRNA, Certified registered nurse anesthetist; MAC, monitored anesthesia care; MD, physician.

moderate or deep sedation.<sup>108</sup> In the most recent Joint Commission regulations, 2010,<sup>25</sup> the leadership and responsibilities for the delivery of deep sedation fall on the shoulders of the anesthesia department (Fig. 47-5).

*Deep sedation* is placed under Anesthesia and *subject to the anesthesia administration requirements at 42 CFR 482.52(a)*: whereas *minimal and moderate sedation* are placed under analgesia/sedation and therefore not subject to anesthesia administration requirements. CMS states that one anesthesia service has authority and responsibility of all anesthesia services throughout the institution. Anesthesia must be administered by a (1) qualified anesthesiologist; (2) CRNA (certified registered nurse anesthetist) or AA (anesthesiologist assistant) with appropriate supervision; (3) doctor of medicine or osteopathy (other than an anesthesiologist); and (4) dentist, oral surgeon, or podiatrist who is qualified to administer anesthesia under state regulations. Credentialing and privileging must be done per hospital policy and is the responsibility of the hospital’s director of anesthesia services. The appropriateness and quality of anesthesia, including sedation, must be reviewed and approved by the director of anesthesia services.

Specific standards for sedation are mentioned in Provision of Care, Treatment and Services (PC.03.01.01, .03, .05 .07), Improving Organization Performance (PI.01.01.01), and records (RC.02.01.03).<sup>23</sup> These standards address moderate and deep sedation, as well as anesthesia services. The standards require that each hospital develop specific appropriate protocols for patients receiving sedation. These protocols must be consistent with professional standards and address the following:

1. Qualified individuals in sufficient numbers to perform and monitor patients during and after the procedure. A registered nurse must supervise perioperative nursing care.
2. Competency-based education, training, and experience in evaluating patients. These must include the following:
  - a. Evaluating patients before the sedation

- b. Performing moderate and deep sedation, including rescuing patients who slip into a deeper than desired level of sedation. These include the following:

- i. Moderate sedation—are qualified to rescue patients from deep sedation and are competent to manage a compromised airway and to provide adequate oxygenation and ventilation
- ii. Deep sedation—are qualified to rescue patients from general anesthesia and are competent to manage an unstable cardiovascular system, as well as a compromised airway and inadequate oxygenation and ventilation

3. Appropriate equipment for care and resuscitation
4. The following must occur before moderate or deep sedation:
  - a. Appropriate needs of the patient are assessed
  - b. Preprocedural education is provided to the patient according to a plan of care
  - c. A “time out” is conducted immediately before starting, as described in universal protocol
  - d. A licensed independent practitioner plans or concurs with the planned procedure
5. Appropriate monitoring of vital signs during and after the procedure, including, but not limited to, heart rate and oxygenation using pulse oximetry, respiratory frequency and adequacy of pulmonary ventilation, monitoring of BP at regular levels, and cardiac monitoring (by ECG or use of a continuous cardiac monitoring device) in patients with significant cardiovascular disease or when dysrhythmias are anticipated or detected
6. Documentation of care before, during, and after the procedure
7. Monitoring of outcomes. In particular, analysis of data is performed on adverse events or patterns of adverse events during moderate or deep sedation.

#### IMPLEMENTATION OF SEDATION GUIDELINES

Institutions and health care organizations (e.g., offices or free-standing centers) may choose to provide a range of sedation

services to meet their particular needs. Large institutions, in which sedation is performed in multiple areas within the hospital at all hours, may choose to decentralize the approach, where individual departments have practitioners who perform sedation under strict guidelines and oversight. Other institutions may designate one area where most children who require sedation are prepared and a small team of sedation providers care for them. The latter is the organization model at Dartmouth Medical Center in New Hampshire. Other institutions may have teams of sedation nurses or hospitalists who go where sedation is required. CNMC has expanded sedation services to include non-operating room anesthesia locations on burn, hematology-oncology, and MRI units, where anesthesiologists provide deep sedation or anesthesia to these children; in all cases, institutional and anesthesia oversight is required.

The implementation of a successful institution-wide policy involves organization, education, record keeping, enforcement, and continuing quality improvement.<sup>109</sup> A sedation committee must be carefully organized and involves many departments, practitioners, and geographic areas within the institution. The goal of the committee is to create a sedation policy that can facilitate patient care without placing undue burden on practitioners. Ideally, the committee should be composed of representatives from at least one and preferably two to three sedation practitioner services (e.g., an endoscopist, intensivist, dentist, surgeon, or emergency medicine physician) and departments: anesthesiology, nursing, pharmacy, hospital administration, and—very importantly—risk management. The responsibilities of the sedation committee include the creation of hospital- or institution-wide sedation policies, determination of hospital- or institution-wide personnel and equipment needs, creation of educational programs, monitoring of sedation problems, modification of policies as needed, and granting sedation privileges.

The department of anesthesiology (chairperson or their designee) must play a central role in formulating policy, educating nonanesthesiology sedation practitioners, acting as consultants for potentially complex cases, particularly those patients with a difficult airway, and determining when sedation by a nonanesthesiologist is or is not appropriate. The department of anesthesiology should approve sedation flow sheets and records, and be involved, along with the committee and the institution's risk management department, in periodic review of the records and compliance with documentation and institutional policies and procedures. A member of the department of anesthesiology is responsible for the process of continuous quality improvement. Continuous quality improvement is needed to review complications, incident reports, and sedation flow sheets to ensure compliance with policy and recommend changes to the sedation committee. Finally, sedation and analgesia require a treatment plan. The department of anesthesiology must play a leading role in determining which sedatives, hypnotics, general anesthetics, and analgesics can be safely used alone and in combination in each institution. Several drugs in particular can easily produce deep sedation or general anesthesia, airway obstruction, an unprotected airway, and cardiorespiratory collapse, namely, methohexital, thiopental, nitrous oxide (when combined with other sedating medications), ketamine, propofol, and remifentanyl. Which drugs can be used and by whom should be made on an institution-by-institution basis. Education is vital to maintain safety. An institution-wide ongoing educational program on sedation, emphasizing physician (and dentist) responsibility, nursing responsibility, guidelines, and the pharmacology of drugs, should

be given frequently enough to train the staff and to accommodate staff turnover (usually one to two times a year). Teaching modules, videos, handouts, simulations, and hands-on supervision have been used to supplement such programs.<sup>87</sup> One institution (CNMC) uses a computerized teaching module that includes a review of hospital policy, equipment, personnel, pharmacology of drugs used, and rescue from deeper levels of sedation (see Children's Exchange [CHEX] course module). A quiz must be successfully completed at the end of the computerized teaching module. The module is part of the orientation and hospital privileging procedure for each physician and nurse, and must be successfully completed before they can administer sedation; the module must be reviewed and successfully completed every 2 years. Staff privileges also require training for Basic Life Support or equivalent for those providing moderate sedation and Pediatric Advanced Life Support or equivalent for those administering deep sedation. Each division chief or section supervisor must attest to the practitioner's competency to provide the desired level of sedation.

Specialty organizations are also becoming involved in training of sedation providers. The Society for Pediatric Sedation provides an extensive "primer" on pediatric sedation on its web site at [www.pedsedation.org](http://www.pedsedation.org). This organization also provides a credentialing course for pediatric sedation that uses a test of knowledge based on its written materials (see previous) and the completion of a full day "Sedation Provider Course," which includes lectures, interactive sessions, and human patient simulation sessions (developed from data relating to pediatric sedation adverse events) to teach and test core competencies.

Education should also emphasize the limits of sedation and appropriate referral to an anesthesiologist. Of particular concern is upper airway obstruction that would likely become worse with the administration of sedatives (Table 47-6).<sup>54</sup> Tonsil and adenoid hypertrophy is common in children aged 2 to 12 years, and is associated with loud snoring or obstructive sleep apnea. Obstructive sleep apnea occurs in 1% to 3% of all children, in up to 12% of adolescents, is threefold more frequent in African American children and fivefold more frequent in obese children.<sup>110</sup> Parents will frequently report that their child snores loudly and then "stops breathing." These children are at increased risk for airway obstruction and should be referred to an airway specialist (anesthesiologist, pediatric intensivist, pediatric emergency medicine specialist) if sedation will be required for their procedures. They may also require postsedation overnight admission and monitoring (see also Chapters 4 and 31).<sup>98,111-113</sup> Children with developmental disabilities should raise concern for sedation because they have a high incidence of airway obstruction during sedation and anesthesia.<sup>114</sup> Problems for which consultation with an anesthesiologist or other expert is suggested are listed in Table 47-6.

The importance of nursing in the provision of safe and effective sedation for children cannot be overemphasized. Nurses are the "front line" in sedation safety and frequently the part of the sedation team that identifies variation in policy compliance. Their support and education is mandatory. In addition, state nursing restrictions on nurses administering certain drugs (such as propofol and ketamine) must be taken into consideration.

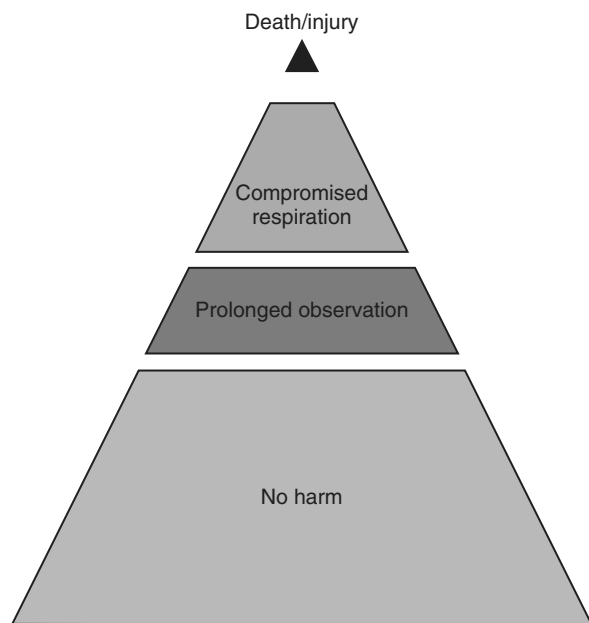

The performance improvement administrative part of sedation implementation is the final piece of the puzzle. Compliance can be monitored by the medical and dental staff office, the department of nursing, as well as a committee charged with the responsibility of continuing quality improvement. *This committee should fall under the purview of risk management.* Nursing

and medical staff offices should monitor compliance with educational certification for appropriate credentialing. The medical staff office should report to the department chairman and nursing office a list of individuals who need to be recertified in sedation. It is the responsibility of the department chairman and nursing supervisors to secure individual staff compliance. Finally, variance reports should be generated when sedation policy is not followed or when a critical incident occurs. The appropriate institutional committee reviews the incident and informs the sedation committee. Educational and corrective action should take place as quickly as possible. This committee should not be viewed as “sedation police,” but rather as a resource to objectively and unemotionally review critical sedation-related events. The committee can then determine where the “system” broke down, to define what went wrong and why (e.g., inadequate history taking combined with sedation, inadequate monitoring combined with delay in problem recognition, or inadequate recovery procedures combined with re-sedation at home). Tracking common problems, such as desaturation events, the need for bag-mask ventilation, apnea, unplanned hospital admissions, unsatisfactory sedation, and so on, can provide direction for developing changes in policy that will prevent more severe but much less frequent events from occurring (Fig. 47-6). This type of critical incident analysis allows recommendations to be made for future prevention.<sup>115-117</sup> An example of a successful hospital sedation policy is that of the CNMC (see Appendix 47-1).

## DOCUMENTATION

Although differing departmental procedures, practice requirements, patient needs, and location limitations produce unique

**FIGURE 47-6** The sedation accident pyramid. The majority of adverse sedation events result in no harm. A smaller number result in no harm but require prolonged observation. An even smaller number result in the need for some intervention, usually related to respirations (repositioning the head, a jaw thrust, bag or mask respirations or intubation). A very small number result in injury or death because the sentinel event was missed or inadequately treated. The latter cases are the types that occasionally are reported in newspapers, but in general go unreported. The reported cases likely represent just the tip of the pyramid in terms of events that could have indicated a developing problem.

problems, a unified systematic approach to sedation creates a safety net that will protect children while providing sedation/analgesia for procedures. A single sedation flow sheet that is used wherever sedation is given within the institution will allow for uniformity of care and compliance with sedation policy. The universal sedation flow sheet allows for nurses to rotate to different areas and feel familiar with sedation requirements in different locations. The sedation flow sheet should be organized such that the practitioners have a practical guide to the sedation policy. Following and completing the sedation flow sheet will ensure compliance with hospital policy (E-Fig 47-1). CNMC is in the process of converting to electronic records. As such we have an opportunity to move to an electronic paperless sedation document, which can “pull in” data from other databases and automatically add vital signs (Video 47-5). Our first draft will be available through this book. We still use the paper form when we are in areas that are remote or that do not have electronic record keeping (e.g., MRI, offsite locations) (see E-Fig 47-1). The flow sheet (both paper and electronic) is organized into Presedation, During Sedation, and Postsedation responsibilities of the registered nurse and licensed independent practitioner (physician or dentist) providing sedation. The electronic version has various dropdown menus which allows the practitioner to access rating scale information and automatically enter vital signs (see Video 47-5).

- **Presedation responsibilities:** During this time, the responsibilities of the registered nurse include evaluation of the child to include learning assessment, NPO (nothing by mouth) status, allergies, current medications, and review of medical problems. The licensed independent practitioner verifies this information with emphasis on airway assessment. A sedation plan is identified and informed consent is obtained. The licensed independent practitioner assigns an ASA physical status and reassesses the child immediately before the procedure.
- **Presedation pause:** A “time out” is performed immediately before sedation medications are given. The “time out” includes a process of verbal confirmation of the patient and procedure identification, verification of informed consent, as well as ASA physical status and confirmation of the procedure and site of the procedure. No medications will be administered without completion of the “time out.” One advantage of the electronic form is that it forces the licensed independent practitioner to verify “time out” before it allows further access to the rest of the sedation flow sheet.
- **During sedation:** The time-based flow sheet identifies the type of stimulation needed to elicit a response, as well as what monitors and how frequently vital signs should be recorded for both moderate and deep sedation. A summary of monitoring, documentation, personnel, and equipment during sedation is given in Table 47-7.
- **Postsedation:** The criteria for discharge from the sedation area, pain score, and disposition of the child, as well as discharge teaching are specified. This includes documentation and signature by the licensed independent practitioner and nurse. Space is given for additional documentation and medications given.

Most importantly, both the paper and electronic form have critical parts of the sedation policy for immediate bedside review. This includes pain assessment scales, NPO guideline variations, reassessment by the licensed independent practitioner before sedation, and the opioid medication order verification. A table that defines the levels of sedation, required monitors, and

# INPATIENT / OUTPATIENT MODERATE/DEEP SEDATION FLOWSHEET

Page 4 of 4

Label or Addressograph

OPS: OBJECTIVE PAIN SCALE - Operational Definitions - For a score $\geq 6$ , patient receives a narcotic analgesic		
BEHAVIOR	SCORE	DEFINITION
Blood Pressure (Systolic)	0	
	1	
	2	
Crying	0	Awake and not crying or asleep.
	1	Crying is controlled by being touched, reassured or held by nurse/parent.
	2	Crying uncontrollably. Measures to comfort child are unsuccessful.
Movement	0	Asleep or if patient is awake, lying or playing quietly.
	1	Child unable to sit or lie still. Frequent position changes. No threat of self harm.
	2	Child kicking and/or squirming. Potential for self harm. Has to be protected or restrained for safety.
Agitation	0	Asleep or awake and calm.
	1	Tense, voice quivering. Responds rationally to questions and/or responds to attempt to console.
	2	Does not appear rational, eyes wide. May be clinging to nurse/parent. Does not respond to attempts to console.
Verbal Evaluation or Body Language	0	
	1	Complains of general feeling of discomfort, but unable to describe location of pain or states pain is mild in nature. Legs drawn up. Arms may be folded across body.
	2	Complains of pain that is bothersome and is able to point to or describe location of pain. Holding, guarding, or touching location of pain. Infants with legs drawn up, fists clenched.

WONG-BAKER FACES PAIN RATING SCALE (recommended for persons age 3 years and older)	
	Explain to the person that each face is for a person who feels happy because he has no pain (hurt) or sad because he has some or a lot of pain.  Face 0 is very happy because he doesn't hurt at all. Face 2 hurts just a little bit. Face 4 hurts a little more. Face 6 hurts even more. Face 8 hurts a whole lot. Face 10 hurts worst.  Ask the person to choose the face that best describes how he is feeling.

NUMERIC PAIN RATING SCALE: (for older children and adolescents)	
	PAIN CHARACTER: S = Sharp T = Throbbing D = Dull  FREQUENCY: C = Constant I = Intermittent O = Occasional  INTERVENTIONS: PCA = Pump POS = Position change COM = Comfort Measure  TREATMENT OUTCOMES: N = No Relief MI = Minimal Relief (Relief for < 1hr) MO = Moderate Relief (Relief for 1-2 hrs) MA = Maximum Relief (Relief for 3-4 hrs)

## INPATIENT / OUTPATIENT MODERATE SEDATION

## FLOWSHEET INSTRUCTIONS

- The department performing the procedure initiates the Sedation Flowsheet.
- All required sections must be completed, including the signature, title and initials of those who provide documentation.
- NPO guidelines: If NPO guidelines cannot be met, the benefit of proceeding must be weighed against the risk of harm.
- The LIP must reassess the patient immediately prior to the administration of the sedation medications.
- All entries for medications and assessments must be timed and initialed with signature/title/initials written in the appropriate boxes below the "Medication" and "Assessment" sections.
- Medication orders for inpatients are written on an inpatient order sheet, transcribed onto the MAR and sent to the Pharmacy.
- Medication orders for Outpatient & EMTc patients are written on the Sedation Flowsheet.
- Narcotic Medication orders: LIP must write order per hospital policy. Before administration 2 RN's or an RN/LIP must separately verify patient weight, calculate dose in writing, and document amount/administration volume.
- Pre-sedation Procedural Pause: Verify informed consent, ASA-PS classification, assessment & reassessment has been completed prior to the administration of the sedating agent(s).
- The patient must receive continuous heart rate and SaO<sub>2</sub> monitoring until recovered and returned to pre-sedation level. Continuous respiratory rate and cardiac monitoring is required if deep sedation occurs.
- Each assessment box must be completed at the appropriate timed intervals (see table below).
- PCT's and Technicians may obtain and document vital signs per RN direction.
- The timed interval assessments (see table below) will continue until the patient is fully recovered from the sedation medication and has returned to the pre-sedation level.
- Assessments that cannot be obtained due to a need for the patient to remain undisturbed during the procedure will be documented as such (see "N" in the item keys).
- IF THE PATIENT ASSESSMENT INDICATES THAT DEEP SEDATION HAS OCCURRED, THE FOLLOWING MUST BE DONE:

One care provider must remain at bedside to continuously monitor patient as their sole responsibility. Appropriate interventions will be provided as needed (e.g., position airway, Administer oxygen if needed, etc.). Patient assessments must be performed and documented Q 5 minutes until patient transitions to the moderate sedation level, at which time the assessments may return to Q 15 minutes (see also table below).

SEDATION LEVEL	CHARACTERISTICS OF THE DRUG-INDUCED SEDATION LEVEL	REQUIRED CONTINUOUS MONITORING	REQUIRED FREQUENCY OF FULL ASSESSMENT
<b>Minimal (Anxiolysis)</b>	<ul style="list-style-type: none"> <li>State when pain &amp; anxiety is diminished / eliminated</li> <li>Cognitive function and coordination may be impaired</li> <li>Ventilatory and cardiovascular functions unaffected</li> <li>No significant risk of losing protective reflexes</li> </ul>	Patients who are not undergoing a diagnostic or therapeutic procedure & are receiving narcotics, sedatives or other medications that place them at risk for cardio/respiratory depression will be placed on cardiac/resp and/or pulse ox monitor	(see CH PC# TM#) *Cardiac/Respiratory and Pulse Oximetry Monitoring on Acute Care Units)
<b>Moderate (Conscious)</b> Chloral Hydrate > or equal to 50 mg/kg is considered moderate sedation	<ul style="list-style-type: none"> <li>Depression of consciousness</li> <li>Responds purposefully to verbal commands, either alone or accompanied by light tactile stimulation</li> <li>Able to maintain patient airway without interventions</li> <li>Spontaneous ventilation is adequate</li> <li>Cardiovascular function is usually maintained</li> </ul>	Heart rate, SaO <sub>2</sub> and ventilation monitored via direct visualization or capnography; Needs cardiac monitor if significant cardiovascular disease or when dysrhythmia anticipated or detected	<b>ASA I &amp; II:</b> Q 15 minutes (or more frequently if indicated) until returned to pre-sedation level <b>ASA III, IV:</b> Q 5 minutes until returned to pre-sedation level
<b>Deep</b>	<ul style="list-style-type: none"> <li>Depression of consciousness</li> <li>Patient cannot be easily aroused</li> <li>Responds only to repeated painful stimuli</li> <li>May require assistance in maintaining patient airway</li> <li>Spontaneous ventilation may be inadequate</li> <li>Cardiovascular function is usually maintained</li> </ul>	H R, RR, SaO <sub>2</sub> & Vent. Monitored via direct visualization or capnography; Cardiac Monitor if significant CV disease or when dysrhythmia anticipated or detected. Deep sedation is performed in cardiac cath, upper endoscopy, bronchoscopy, & anesthesia sed. service.	Q 5 minutes until returned to moderate sedation level
<b>Anesthesia</b>	<ul style="list-style-type: none"> <li>Loss of consciousness</li> <li>Not arousable, even by painful stimulation</li> <li>Often require assistance in maintaining patient airway</li> <li>Often has impaired ability to independently maintain ventilatory function due to depression of spontaneous ventilation or neuromuscular function</li> <li>May require positive pressure ventilation</li> <li>Cardiovascular function may be impaired</li> </ul>	Page anesthesia. (pager 6001)	As per anesthesia protocols.

- The patient must meet ALL "Discharge from Sedation Criteria" before monitoring/vital sign assessments cease.
- At the discretion of the LIP/RN, the sedated patient may be transferred to a patient care area within the Hospital. Appropriate monitoring and assessment will continue during and after transport until "Discharge from Sedation Criteria" is met. **The RN or Physician will continue appropriate monitoring & assessment during the transfer process.**
- The nurse/physician discharging the patient from sedation must sign the discharge section.
- The parent/legal guardian must sign the discharge section to indicate that instructions were received and understood.

18407 (Rev. 11/04)

**TABLE 47-7** Recommended Intensity of Monitoring, Documentation, Personnel, and Equipment for Different Levels of Sedation

	Moderate Sedation	Deep Sedation
Monitoring	Pulse oximetry continuous Heart rate continuous Respiratory rate every 15 minutes Level of consciousness every 15 minutes (if possible)	Pulse oximetry continuous Heart rate continuous Respiratory rate every 5 minutes Level of consciousness every 5 minutes (if possible)
Documentation	Pulse oximetry every 15 minutes Heart rate every 15 minutes Respiratory rate every 15 minutes Level of consciousness every 15 minutes, if possible	Pulse oximetry every 5 minutes Heart rate every 5 minutes Respiratory rate every 5 minutes Level of consciousness every 5 minutes, if possible ETCO <sub>2</sub> monitoring
Personnel	The same individual may observe the child and assist with procedure.	Dedicated independent observer—may not assist with procedure
Equipment	Pulse oximeter, blood pressure device, stethoscope Resuscitation equipment immediately available	Pulse oximeter, blood pressure device, stethoscope, ECG monitor Resuscitation equipment immediately available
Airway equipment	Age and size appropriate	Age and size appropriate (including a defibrillator)

ECG, Electrocardiography; ETCO<sub>2</sub>, end-tidal carbon dioxide.

frequency of monitoring is also present. This, in addition to the online availability of the hospital policy, ensures that sedation practitioners have all information available to be in compliance, to safely and successfully sedate children.

Individual departments may have special needs or situations that require addenda to the hospital sedation flow sheet. In addition, individual departments may find it helpful to create information sheets on presedation assessment, telephone interviews, and postsedation follow-up. The radiology–nursing database that consists of presedation telephone information, presedation instructions, NPO guidelines, health history, and postexamination telephone call information is shown in E-Figures 47-2 and 47-3. Samples of presedation and postsedation instruction sheets for pediatric dentistry are shown in E-Figures 47-4 and 47-5, respectively. These forms are available in Spanish and are explained via interpreters if necessary.

## Specific Sedation Techniques

A *sedation treatment plan* analyzing the requirements for analgesics, anxiolytics, or both is necessary for each child and will vary depending on the procedure and the anxiety of the child and family. Psychological techniques to allay anxiety (cuddling, parental support, warm blankets, a gentle reassuring voice, and hypnosis) are extraordinarily useful adjuncts to the sedation plan.<sup>6-10</sup>

Although the FDA is responsible for approval of the use of drugs, for a variety of reasons many of the drugs used for sedation and analgesia in children are not approved by the FDA for use in young children (e.g., fentanyl less than 2 years; morphine less than 12 years, bupivacaine less than 12 years, propofol less than 2 months, and dexmedetomidine less than 18 years of age). Although midazolam is approved even in preterm infants, the reversal agent flumazenil is not approved in children younger than 1 year of age! The lack of “approval” by the FDA does not imply that a drug should not be used; rather, it only means that the manufacturer never carried out the appropriate studies to gain FDA approval.<sup>28,118-121</sup> A number of legislative changes are intended to improve drug research in children and improve drug labeling; however, some of the drugs are no longer under patent

protection and there is no motivation for drug companies to study their use in children.<sup>122-124</sup> It is hoped that the continuing legislative efforts will improve drug labeling for children; see Chapter 6 for a more complete discussion of this issue.

It is important to review the child’s presedation medications. Particular note of the use of protease inhibitors (used by many patients with human immunodeficiency virus infection) must be sought. These protease inhibitors (e.g., nelfinavir, zidovudine, saquinavir) are potent inhibitors of the cytochrome P-450 CYP3A metabolic pathway. This pathway is responsible the metabolism of many sedatives, including midazolam, and may markedly prolong duration of action and may lead to life-threatening respiratory depression. Erythromycin and some calcium channel blockers may also inhibit the cytochrome system and delay metabolism of midazolam.<sup>125-127</sup> Dexmedetomidine should not be combined with digoxin in infants because severe bradycardia has been reported.<sup>128</sup> Another concern for the practitioner is the widespread use of herbal medicines that can enhance or shorten sedative medication activity.<sup>129-133</sup> Herbal medicines (e.g., St. John’s wort or echinacea) may alter drug PK through inhibition of the cytochrome P450 system, resulting in prolonged drug effect and altered (increased or decreased) blood drug concentrations. Kava may increase the effects of sedatives, and valerian may itself produce sedation (see also E-Table 4-4).<sup>134</sup>

The main classes of drugs used for sedation and analgesia for diagnostic and therapeutic procedures in children are:

- Local anesthetics
- Anxiolytics and sedatives
- Barbiturates
- Opioid analgesics
- General anesthetics

### LOCAL ANESTHETICS

*Local anesthetics* play a critical role in analgesia for painful procedures and greatly reduce requirements for systemic opioids. Unlike most drugs used in medicine, local anesthetics must be physically deposited at their site of action to produce their effect. Cessation of action often depends on the rapidity of removal of drug from this site. Systemic toxicity is related to how much and how rapidly local anesthetics are absorbed into the blood. Thus

## DEPARTMENT OF PEDIATRIC RADIOLOGY PRESEDATION PHONE CALL AND ASSESSMENT

## DIAGNOSTIC IMAGING & RADIOLOGY

### DISCHARGE TEACHING INFORMATION SHEET

The following medications were given to your child for sedation:

**Chloral Hydrate**\_\_\_\_\_ **Benadryl**\_\_\_\_\_ **Nembutal**\_\_\_\_\_

**Versed**\_\_\_\_\_ **Fentanyl**\_\_\_\_\_ **Propofol by Anesthesia MD**\_\_\_\_\_

Please review the following instructions with your nurse prior to discharge:

- 1) Your child will need assistance to walk, sit or crawl until the medication is worn off. Please hold onto your child's hand or carry your child at all times until the medication is worn off.
- 2) DO NOT allow your child to walk, sit, or crawl alone until your child is steady. Limit activity for the remainder of the day. Encourage quiet play. No toys with wheels, no swimming, no playing outside for the remainder of the day.
- 3) Please keep your child away from unsafe objects or areas of your home such as stairs, furniture, corners, bath tubs.
- 4) Increase your child's diet slowly from clear liquids to semi-solids to solids.
- 5) Do not feed unless child is fully awake.
- 6) If your child falls asleep on the way home be sure to position your child's head tilted back or to the side while sitting up in the car. Do not allow your child's head to fall forward while sleeping. If your child feels sick to his stomach at any time, place him on his side.

#### CONTACT CHILDREN'S HOSPITAL IF ANY OF THE FOLLOWING OCCUR:

**difficulty swallowing**                      **dizziness**                      **excessive vomiting**

**Radiology Nurses are available from 7 am to 7 pm at 000-000-0000**  
**After 7 pm you may call 000-000-0000 for assistance.**

**Thank you for choosing Children's National Medical Center. Please expect a follow-up call from our Nursing Staff during the next business day.**

**E-FIGURE 47-3** Sample diagnostic imaging and radiology discharge teaching information sheet for parents or guardians of treated children. (Courtesy Children's National Medical Center, Washington, D.C.)

## DEPARTMENT OF PEDIATRIC DENTISTRY

### PREOPERATIVE INSTRUCTIONS FOR DENTAL TREATMENT UNDER SEDATION

#### 1. WHAT IS SEDATION?

Your child needs to receive a mild sedative prior to receiving dental treatment. This sedative is given as a liquid by mouth or as a suppository one-half to one hour prior to the scheduled dental appointment.

#### 2. HISTORY AND PHYSICAL EXAM

Your child needs a complete physical examination within one month of the sedation appointment. The examination is performed by your primary care physician, who must fill out completely the Short Hospital Admission Form that we give you. You are responsible for bringing to us the completed Short Hospital Admission Form. WITHOUT THE COMPLETED FORM, THE SEDATION APPOINTMENT WILL BE CANCELED.

#### 3. NO SOLID FOOD BY MOUTH AFTER MIDNIGHT BEFORE THE SURGERY

Your child may drink clear liquids (apple juice, water, Kool-aid™) until 4 hours before the procedure.

#### 4. IF YOUR CHILD BECOMES ILL

If your child has any signs of a cold, such as a runny nose, cough or congestion, please call the clinic at 000-000-0000. Please also call us if your child is exposed to any communicable disease such as measles, mumps or chicken pox within 3 weeks of the sedation appointment.

#### 5. AFTER THE SEDATION APPOINTMENT

After the sedation appointment, please expect your child to be drowsy and require support. Someone should be available to drive the patient home. Plan on limited activity. You will need to give your child water, clear fluids and soft foods until he/she is able to tolerate a normal diet.

#### 6. PLEASE ARRIVE AT THE DENTAL CLINIC PROMPTLY AT \_\_\_\_\_ ON \_\_\_\_\_, \_\_\_\_\_.

You must plan on remaining in the Dental Clinic during your child's entire dental appointment.

**E-FIGURE 47-4** Sample preoperative instructions for parents or guardians of patients who will receive dental treatment under sedation. (Courtesy Children's National Medical Center, Washington, D.C.)

## POSTOPERATIVE INSTRUCTIONS FOLLOWING DENTAL TREATMENT UNDER SEDATION

### 1. OBSERVATION

Carefully observe your child until all sedative effects have disappeared. Watch your child closely for signs of breathing difficulty.

### 2. DIET

You may give your child small amounts of water and clear fluids (broths, soda or juices), or soft foods (Jell-O, sherbet) until he/she appears hungry and able to tolerate his/her regular diet. Remember that your child's lip and tongue will be numb—wait for the numbness to wear off before allowing your child to eat.

### 3. ACTIVITY

Your child should remain fairly quiet and rest for the remainder of today. Avoid any strenuous activity. He/she may resume regular activities tomorrow.

### 4. MEDICATION

Pain medication is usually not necessary but Tylenol may be given for minor discomfort.

### 5. CALL THE DENTAL CLINIC AT 000-000-0000 IF:

- a. temperature over 101 degrees
- b. persistent vomiting
- c. persistent drowsiness or dizziness
- d. difficulty with breathing
- e. unusual bleeding
- f. any other concern

YOUR CHILD'S FOLLOW-UP APPOINTMENT IS AT \_\_\_\_\_ ON \_\_\_\_\_

**E-FIGURE 47-5** Sample postoperative instructions after dental treatment under sedation for parents or guardians of treated children. (Courtesy Children's National Medical Center, Washington, D.C.)

**TABLE 47-8** Maximum Recommended Doses and Duration of Local Anesthetics

Local Anesthetic	Maximum Dose (mg/kg) without Epinephrine	Maximum Dose (mg/kg) with Epinephrine	Approximate Duration (minutes)
Procaine	7	10	60-90
2-chloroprocaine	15	20	30-60
Tetracaine	1	1.5	180-600
Lidocaine	5	7	90-200
Mepivacaine	5	7	120-240
Bupivacaine	2	3	180-600
Levobupivacaine	2	3	180-600
Ropivacaine	2	3	180-600
Articaine (dental procedures)		7	60-230

Modified from American Academy of Pediatrics; American Academy of Pediatric Dentistry; Coté CJ, Wilson S. Work Group on Sedation. Guidelines for monitoring and management of pediatric patients during and after sedation for diagnostic and therapeutic procedures: an update. *Pediatrics* 2006;118:2587-602.

small amounts of local anesthetics can be toxic if injected intra-arterially or IV. On the other hand very large amounts of local anesthetics can be safely administered in vascular-poor structures like fat. For most blocks and local skin infiltration, epinephrine (1:200,000 [5 µg/mL]) is used as a vasoconstrictor to lengthen the duration of blockade, decrease bleeding, and reduce systemic toxicity by decreasing vascular uptake. Local anesthetics should only be prepared in labeled syringes immediately before use. They should never be prepared before a procedure starts because of the possibility of inadvertent and catastrophic injection of the local anesthetic into an IV catheter or infusion. Finally, no more than the maximum allowable dose (mg/kg) should be prepared in the syringe to minimize the risk of an accidental overdose (Table 47-8). *Epinephrine-containing local anesthetics can cause tissue ischemia and are contraindicated in end-arterial areas (digits, ear, and penis), as well as in Bier blocks.* Local anesthetics can obtund airway reflexes when sprayed in the mouth for bronchoscopy or gastrointestinal endoscopy.

Specific blocks used in the sedated child include subcutaneous (SC) infiltration, field blocks, and IV regional anesthesia. A discussion of these topics and treatment of local anesthetic toxicity is found in Chapters 41 and 42. Topical administration of local anesthetics is useful in the sedated patient. EMLA cream is a eutectic mixture of local anesthetics (lidocaine 2.5% and prilocaine 2.5%) (AstraZeneca Pharmaceutical LP, Wilmington, Del.). When placed on the skin for 60 minutes,<sup>135,136</sup> it is useful for reducing the pain of skin incision, IV cannula insertions, lumbar punctures, and circumcision.<sup>137-139</sup> Absorption of large amounts of prilocaine can cause methemoglobinemia. It should be applied only to normal intact skin in appropriate doses<sup>31</sup> (i.e., for children weighing less than 10 kg, apply to a maximum of approximately 100 cm<sup>2</sup> surface area; for those 10 to 20 kg, apply to a maximum of approximately 600 cm<sup>2</sup> surface area; and for those more than 20 kg, apply to a maximum of approximately 2000 cm<sup>2</sup> surface area). The duration of action is 1 to 2 hours after the cream is removed. Adverse reactions include erythema, itching, rash, and methemoglobinemia. It also causes blanching of the skin, which can make IV access difficult. It is contraindicated in children younger than 1 month of age, in children with congenital

or idiopathic methemoglobinemia, or in infants receiving methemoglobinemia-inducing drugs (e.g., phenytoin, phenobarbital, acetaminophen, and sulfonamides).

ELA-Max and LMX4 (Ferndale Healthcare, Ferndale, Mich.) are topical 4% liposomal lidocaine solutions whose effects occur in 30 minutes.<sup>140</sup> The S-Caine patch (ZARS, Inc., Salt Lake City) is a eutectic mixture of 70 mg of lidocaine and 70 mg tetracaine in a bioadhesive layer that contains a heating element. The 20-minute application is effective in lessening pain from venipuncture procedures.<sup>141</sup>

## ANXIOLYTICS AND SEDATIVES

The most commonly used anxiolytics or sedatives in pediatric sedation are chloral hydrate, diazepam, and midazolam.

*Chloral hydrate* is one of the most widely used sedatives in neonates and children younger than 3 years of age (Table 47-9).<sup>142-145</sup> It is used as a sedative to facilitate nonpainful diagnostic procedures, such as EEG, CT, or MRI.<sup>144</sup> It is rapidly and completely absorbed when given orally. Rectal administration is erratically absorbed and therefore not recommended. The onset of sedation is 30 to 60 minutes, and the usual clinical duration is 1 hour. Although it has a long safety record, it can cause respiratory depression as a result of airway obstruction. Deaths have been associated with its use alone and when combined with other sedating medications.<sup>54,113,146-149</sup> One large series showed a 0.6% incidence of respiratory depression, especially at larger doses (75 to 100 mg/kg).<sup>150</sup> Its effect is primarily mediated by the active metabolite trichloroethanol, which is formed by the liver and erythrocytes.<sup>151</sup> Trichloroethanol has a half-life of 10 hours in toddlers, 18 hours in term infants, and 40 hours in preterm infants (see Fig. 47-3).<sup>152</sup> The prolonged effects of chloral hydrate warrant a longer period of postsedation observation; chloral hydrate can also cause adverse effects after discharge, which include motor imbalance (31%), gastrointestinal effects (23%), agitation (19%), and restlessness (14%). Agitation and restlessness lasted more than 6 hours in more than one-third of children who experienced these effects, 5% of whom did not return to baseline activity for 2 days after the procedure!<sup>144,153</sup> The unpredictable onset and active metabolites dictate that this drug (as well as all sedatives for sedation) is given only in facilities capable of resuscitation (AAP guidelines) and that discharge occurs when sedation is clearly lessening and the child meets discharge criteria. Airway obstruction and death occurred after chloral hydrate sedation in a child who was in a child's car seat in the back of a car.<sup>54</sup> Despite being restricted in some countries as a result of potential carcinogenicity, in the United States the AAP states that there is insufficient evidence to avoid single doses of chloral hydrate.<sup>154</sup>

The *benzodiazepines* are commonly used in pediatric sedation. They are anxiolytic, amnesic, sedative hypnotics with anticonvulsant activities but without analgesic properties. Their high lipid solubility at physiologic pH accounts for the rapid CNS effects. As opposed to diazepam, midazolam is delivered in a water-soluble form (pH 3.5), which markedly decreases the incidence of pain on injection and thrombophlebitis.<sup>151</sup> However, the resulting decrease in fat solubility markedly delays transport into the CNS (peak EEG effect 4.8 minutes for midazolam vs. 1.6 minutes for diazepam; Fig. 47-7).<sup>155,156</sup> Benzodiazepines exert their effects by occupying the benzodiazepine receptor that modulates  $\gamma$ -aminobutyric acid (GABA), the major inhibitory neurotransmitter in the brain. The clearance of benzodiazepines is decreased in neonates and also by liver enzyme inhibition that

**TABLE 47-9** Sedation Regimens for Children

Drug Regimen	Dose/Route	Onset (minutes)	Duration (minutes)	Comments
Pentobarbital	4-6 mg/kg IV or PO	IV: 2-5 PO: 20-60	IV: 15-45 PO: 60-240	Long history of safety. Slow onset. Prolonged emergence. May have paradoxical excitement. Half-life increased by valproic acid and MAO inhibitors. Contraindicated in porphyria.
Midazolam	0.25-0.75 mg/kg PO 0.025-0.05 mg/kg IV 0.2 mg/kg intranasal 0.1-0.15 mg/kg IM	15-30 1-3 10-15 10-15	60-90 45-60 60-90	Paradoxical response not infrequent. Intranasal route very irritating and should be avoided. Increased respiratory depression when used with opioids; reduce midazolam dose by 25%. Prolonged duration with protease inhibitors. Antagonist: flumazenil.
Chloral hydrate	50-100 mg/kg PO (maximum not to exceed 2 grams)	30-60	60-120	Very popular for nonpainful radiologic procedures in small children when IV not available. Effects unreliable over 1-2 years of age. Prolonged sedation and paradoxical responses noted. Respiratory depression and obstruction reported with tonsil hypertrophy and anatomic abnormalities. Moderate sedation guidelines required. Markedly prolonged half-life in neonates. Contraindicated in porphyria.
Etomidate	0.1-0.4 mg/kg IV	<1	5-15	No analgesic effect. Greater doses cause general anesthesia, respiratory depression, and loss of airway. Stable cardiovascular profile. Little data in children. Must be credentialed for deep sedation/anesthesia. No reversal drug. Causes adrenal suppression ~12 hours.
Methohexital	0.25-0.50 mg/kg IV 20-25 mg/kg rectal 10 mg/kg IM	<1 10-15 10-15	10-20 30-60 30-60	Avoid if temporal lobe epilepsy or porphyria. IV doses quickly lead to general anesthesia. Rectal doses cause high frequency of apnea and should be avoided. Deep sedation/anesthesia credentialing. Contraindicated in children younger than 3 months of age, psychosis, stimulation of oropharynx, increased intracranial pressure, head injury, glaucoma.
Dexmedetomidine	IV: 1-3 µg/kg bolus (over 10 minutes) Infusion: 0.5-3.0 µg/kg/hr	10	Clinical 30 minutes to 1 hour; half-life 1.5-3 hours	Mimics natural sleep. Rapid bolus may cause hypertension. Minimal respiratory depression. Dose-dependent hypotension and bradycardia. Use with caution with digitalis medications. Glycopyrrolate treatment of bradycardia may induce sustained hypertension of unknown mechanism.
Fentanyl with propofol	Fentanyl 1-2 µg/kg IV with propofol 50-150 mg/kg/min infusion IV	1-2	30-60	Child may rapidly become anesthetized with loss of airway. Advanced airway management skills required, with appropriate credentialing.
Midazolam with fentanyl	Midazolam 0.02 mg/kg IV with fentanyl 1-2 µg/kg IV	2-3	45-60	Commonly used for painful procedures. Careful titration needed to avoid deep sedation/anesthesia with apnea and hypoxia. Reduce dose of fentanyl when combined with benzodiazepine. Reduce dose with protease inhibitors.
Ketamine	3-4 mg/kg IM 1-2 mg/kg IV 4-6 mg/kg PO	5 1 10-20	30-60 30-60 30-90	Nausea and vomiting common after procedure. Laryngospasm, apnea, agitation, hallucinations reported but uncommon. Midazolam may not help emergence delirium. Anticholinergic to control secretions. Larger doses can produce state of general anesthesia. Usually causes tachycardia, hypertension, and bronchodilatation. Paradoxical hypotension in critically ill patients. No antagonist available. Advanced airway management skills required, with appropriate credentialing.
Propofol	Bolus 1-2 mg/kg Infusion 50-250 µg/kg/min	30 seconds	5-15 minutes after discontinuation	Profound, dose-related respiratory depressant. Assume deep sedation/anesthesia when using in children. Infusions > 5 hours may cause propofol infusion syndrome. Caution when used in mitochondrial myopathies. Pain on injection mitigated by IV lidocaine. Advanced airway management skills required, with appropriate credentialing.

TABLE 47-9 Sedation Regimens for Children—cont'd

Drug Regimen	Dose/Route	Onset (minutes)	Duration (minutes)	Comments
Remifentanyl	0.1-0.25 µg/kg/min	1	10-15	Difficulty in titration frequently leads to apnea and general anesthesia. Few studies in children. Exclusively used by anesthesiologists.
Nitrous oxide	50% in 50% oxygen for "minimal sedation"; up to 70% used by some for moderate sedation	<5	On discontinuing	Requires specialized equipment for delivery, monitoring, and scavenging. When used alone or with local anesthesia is considered "minimal sedation." Greater doses or addition of other sedatives/analgesics requires a minimum of "moderate sedation" guidelines. Contraindications include respiratory failure, altered mental status, otitis media, bowel obstruction, and pneumothorax. No antagonist available.
Opioid antagonist: naloxone	0.01-0.1 mg/kg IV or IM Max 2 mg/dose May repeat every 2 minutes	1-2	IV: 20-40 IM: 60-90	Specifically antagonizes opioid effects. Should not be used for routine reversal of opioid effect. Adverse reactions: nausea, vomiting, tachycardia, hypertension, delirium, pulmonary edema. Reversal after long-term opioid use may lead to acute withdrawal. Children may renarcotize 1 hour after IV dosing.
Benzodiazepine antagonist: flumazenil	IV 0.01-0.02 mg/kg May repeat every 1 minute to 1 mg	1-2	30-60	Specific benzodiazepine antagonist. Does not antagonize opioids or other sedatives. Re-sedation may occur in 1 hour. Prolonged observation (2 hours) required. Not for routine sedation reversal. Children using benzodiazepine to control seizures or drug dependency may have exacerbations with flumazenil.

Data modified from Cravero JP, Burke GT. A review of pediatric sedation. *Anesth Analg* 2004;99:1355-64; Krauss B, Green SM. Procedural sedation and analgesia in children. *Lancet* 2006;367:766-80; and Coté CJ, Stafford MA. The principle of pediatric sedation. Boston: Tufts University School of Medicine; 1998.  
IM, Intramuscularly; IV, intravenously; MAO, monoamine oxidase; PO, by mouth.

occurs during concomitant use of erythromycin, cimetidine, or protease inhibitors.<sup>126</sup>

The sedated child usually becomes compliant but does not lose consciousness. Children frequently move, and another agent, such as an opioid, may be necessary if the child must not move to successfully accomplish the procedure. Although many children initially act disinhibited and "drunk" after small doses of benzodiazepines, some have a true paradoxical response.<sup>157</sup> Paradoxical responses, such as combativeness, disorientation, hyperexcitability, and agitation may appear in 1% to 15% of treated children.<sup>158</sup> It is prudent to switch to a different sedative drug in these children, because increasing the dose of benzodiazepines may lead to severe agitation followed by unconsciousness and respiratory compromise. The benzodiazepines have the advantage of antegrade amnesia in a significant number of children.<sup>159,160</sup> The markedly prolonged and variable elimination half-life and active metabolite of diazepam (desmethyldiazepam) make midazolam a superior sedative drug in children, particularly infants.<sup>161-166</sup> The time to peak effect after IV administration of midazolam is 2 to 4 minutes, and its duration is 45 to 60 minutes. Midazolam can be given IV, intranasally, sublingually, orally, or rectally (see Table 47-9). It is the only drug in this class approved for neonates. A manufactured oral cherry-flavored form is available. The oral route has become very popular and is well tolerated. The oral route can lead to variable effects, dependent on gastric emptying and first-pass hepatic metabolism. Nasal administration causes nasopharyngeal burning and should be avoided.<sup>167,168</sup> Rectal administration is usually well tolerated in children who have not been toilet trained (younger than approximately 1 year of age), but absorption may be irregular owing to many factors, including superior versus inferior hemorrhoidal vein absorption within the

rectum. Benzodiazepines produce mild respiratory depression and upper airway obstruction.<sup>169-171</sup> Even small doses of oral midazolam (0.3 mg/kg) that cause minimal sedation were associated with a 6.5% decrease in functional residual capacity and a 7.4% increase in respiratory resistance.<sup>172,173</sup>

Respiratory depression may become severe in compromised children or in children with tonsil hypertrophy. Benzodiazepines must be given according to appropriate guidelines.<sup>18,56,74</sup> The combination of benzodiazepines and opioids is particularly troubling because they can produce a "super additive effect" on respiratory depression where the total depressant effect from the combination of drugs is much greater than the sum of their anticipated individual effects.<sup>173,174</sup>

*Flumazenil* is a specific benzodiazepine-receptor antagonist and will rapidly reverse the sedative and respiratory effects of benzodiazepines.<sup>175-179</sup> It is the first specific reversal agent for benzodiazepines and rapidly reverses CNS-induced unconsciousness, respiratory depression, sedation, amnesia, and psychomotor dysfunction. Children who take benzodiazepines for seizures or drug dependency may have those symptoms rapidly recur if flumazenil is given.<sup>180</sup> It should also be used with caution in children with benzodiazepine dependence, increased intracranial pressure, and in those taking drugs that decrease the seizure threshold (e.g., cyclosporine, theophylline, and lithium). The recommended dose of flumazenil is 10 µg/kg up to 0.2 mg every minute to a maximum cumulative dose of 1 mg IV. Antagonism begins within 1 to 2 minutes and lasts approximately 1 hour. Because re-sedation after 1 hour may occur, any child who receives flumazenil must be carefully monitored for at least 2 hours. Repeat flumazenil may be necessary. It should be noted that flumazenil will not antagonize respiratory depression caused

**FIGURE 47-7** Time to peak electroencephalographic (EEG) effect of diazepam vs. midazolam in adults. Note that it takes nearly three times longer to achieve a peak EEG effect after intravenous (IV) midazolam than after IV diazepam. This is likely caused by the difference in fat solubility; because midazolam is less fat-soluble than diazepam, midazolam does not cross biologic membranes as easily. The clinical importance of this observation is the need to wait 3 to 5 minutes between IV doses of midazolam to avoid stacking of doses and excessive drug effect. (Data from Buhner M, Maitre PO, Crevoisier C, Stanski DR. Electroencephalographic effects of benzodiazepines: II. Pharmacodynamic modeling of the electroencephalographic effects of midazolam and diazepam. *Clin Pharmacol Ther* 1990;48:555-67.)

by opioids.<sup>181</sup> Flumazenil should not be administered for the routine reversal of the sedative effects of benzodiazepines, but reserved for reversal of respiratory depression.

## BARBITURATES

*Pentobarbital* is the most commonly used intermediate-acting barbiturate for sedation. It has no analgesic effect and produces sedation, hypnosis, and amnesia. It has a long history of use during radiologic procedures. Sedation starts in 3 to 5 minutes and peaks in 10 minutes. Studies have shown a low incidence of respiratory obstruction and transient desaturation, as well as hypotension.<sup>182,183</sup> The barbiturates tend to make children more sensitive to pain and should be combined with analgesics when used during painful procedures. Pentobarbital's relatively long duration of action (1 to 2 hours or greater) and slow recovery sometimes leaves children in a prolonged disinhibited state that necessitates prolonged recovery and restraint<sup>143</sup>; pentobarbital "rage" occasionally occurs. The alkaline pH of barbiturates can lead to local erythema and thrombophlebitis if subcutaneous infiltration occurs. Newer, shorter-acting, faster recovery drugs are quickly replacing pentobarbital (see Table 47-9).

## OPIOIDS

*Opioid analgesics* are rarely used alone for diagnostic and therapeutic procedures in children. These potent analgesics are important during painful diagnostic and therapeutic procedures. They bind with four primary opioid receptor types ( $\mu$ ,  $\kappa$ ,  $\delta$ , and  $\sigma$ ) that are located in the brain, spinal cord, and periphery. Once opioids bind to the receptor, they trigger the production of signaling proteins (such as G proteins) whose end effects are modulation of pain neurotransmission.<sup>184</sup> The  $\mu_1$  subgroup is responsible for supraspinal analgesia and the development of dependence. The  $\mu_2$  and  $\kappa$  receptors are responsible for sedation. Although the opioids provide some sedation, the sedation produced is usually inadequate, therefore requiring combination with a sedative. The "super-additive" respiratory depressant effects of the combination of opioids and sedatives must be reemphasized (see Fig. 47-1).<sup>173,185</sup> This is especially true in infants and children with upper airway obstruction (e.g., tonsil and/or adenoid hypertrophy, trisomy 21, mucopolysaccharidosis). In addition, infants younger than 3 months of age and children who were born preterm have very large patient-to-patient drug metabolism variability.<sup>186</sup> Other serious effects of opioids include bradycardia, hypotension, seizures, and opioid-induced glottic and/or chest wall rigidity.

*Morphine* may be considered for painful procedures (lasting more than 1 hour) or when the child will also be in pain after the procedure. The duration of action is 3 to 5 hours after IV administration.<sup>186</sup> Morphine may be given orally (0.2 to 0.5 mg/kg), IV (0.05 to 0.1 mg/kg [maximum 0.3 mg/kg]), or IM (0.1 to 0.2 mg/kg). Rectal administration may cause delayed respiratory depression from erratic absorption and should be abandoned.<sup>187</sup> Time to peak effect for oral, IV, or IM administration is 60 minutes, 3 to 5 minutes, and 10 to 30 minutes, respectively. Its slow onset and prolonged duration have caused it to be replaced by shorter-acting opioids when used for sedation and analgesia for procedures.

*Meperidine* (Demerol) was also once used for sedation for procedures. Its clinical duration of action is 2 to 4 hours.<sup>31</sup> In addition to respiratory depression, the active metabolite of meperidine (normeperidine) may cause seizures, particularly after repeated doses of meperidine. Other adverse reactions include delirium, nausea, vomiting, urinary retention, pruritus, smooth muscle spasm, and hypotension (histamine induced). Special considerations include avoiding its use in children taking monoamine oxidase inhibitors (effects can include serotonin-induced hyperpyrexia and cardiovascular instability). CNS toxicity may occur in children taking tricyclic antidepressants and phenothiazines. Children taking phenytoin (Dilantin) may have a reduced analgesic effect. Reversal of meperidine-induced respiratory depression by antagonists may precipitate seizures caused by normeperidine. Because of these undesirable effects and prolonged duration, meperidine is not recommended for use as an analgesic or sedative in children.

*DPT "lytic cocktail"* is meperidine (Demerol [25 mg/mL]), promethazine (Phenergan [6.25 mg/mL]), and chlorpromazine (Thorazine [6.25 mg/mL]). Its long sedation duration (7 to 19 hours), hypotension, seizures, extrapyramidal reactions, and severe, prolonged, life-threatening respiratory depression<sup>143,188-191</sup> have caused its use to be abandoned.<sup>189-195</sup>

*Fentanyl* has replaced morphine and meperidine as the opioid of choice for sedation/analgesia for procedures in children. Fentanyl is available in parenteral form, in a transdermal patch delivery form (Duragesic), and in an oral transmucosal fentanyl

citrate (OTFC; Actiq) form. *Duragesic is not to be used for sedation/analgesia during procedures.* Similarly, OTFC is only approved for breakthrough cancer pain in children 16 years of age or older, and has a box warning that it should be used only in opioid-tolerant children.

IV fentanyl is a potent, pure opioid (i.e., approximately 50 to 100 times more potent than morphine) with no amnesic properties. Its high lipid solubility allows for onset within 30 seconds and a peak effect at 2 to 3 minutes. It has a brief clinical duration of 20 to 40 minutes when given in small doses, owing to its rapid redistribution to skeletal muscle, fat, and other inactive sites. Unlike morphine, it has no active metabolites. The clearance of fentanyl is decreased and its half-life increased in preterm and term infants compared with older infants.<sup>196</sup> It is fully antagonized by naloxone. Fentanyl is frequently used with a short-acting anxiolytic (midazolam). IV doses usually start at 0.5 to 1 µg/kg and are titrated every 5 minutes to effect but not to exceed 5 µg/kg.<sup>197</sup> Doses must be given in small aliquots and carefully titrated to avoid chest wall and glottic rigidity. When carefully titrated and appropriately monitored, fentanyl has few adverse effects. Chest wall rigidity is a centrally mediated idiosyncratic reaction that can interfere with respiratory function. The mechanism of action is partially modulated by GABA pathways at the spinal level. Chest wall rigidity can be reversed with either naloxone or muscle relaxants. The rigidity is quite rare and not described after these small doses were given in boluses for sedation in neonates.<sup>198-200</sup> Other adverse reactions from fentanyl include bradycardia, dysphoria, delirium, nausea, vomiting, pruritus, urinary retention, hypotension, and smooth muscle spasm. Close postprocedural observation is required because respiratory depression can outlast analgesia (see Table 47-9).

*Remifentanyl* an ultrashort-acting, rapid-acting, extremely potent, lipophilic opioid that is metabolized by plasma cholinesterase and must be administered as a continuous infusion. It has a context-sensitive half-life of 3 to 6 minutes that is independent of the duration of infusion. Remifentanyl, when used as a sole agent in adults in the ED, caused a 17% incidence of respiratory complications that required bag mask ventilation or the placement of an laryngeal mask airway.<sup>201</sup> This suggests a need to clearly understand the PK and PD when used outside of the OR.<sup>201</sup>

Remifentanyl has been used for intraoperative and procedural sedation by anesthesiologists and in intubated children in the ICU.<sup>202-207</sup> It has been suggested that children may develop opioid tolerance to this drug after several hours of infusion.<sup>208</sup> Remifentanyl is associated with a substantial incidence of apnea, hypoxemia, chest wall and glottic rigidity, and should not be used as a sole agent for pediatric sedation (see Table 47-9).<sup>204,206,209</sup>

*Opioid antagonists* specifically reverse the respiratory and analgesic effects of opioids, and should be readily available when opioids are used (see Table 47-9). Naloxone (Narcan) is the most commonly used antagonist.<sup>210</sup> Opioid antagonists should not be used to routinely reverse the sedative effects of opioids, but reserved for reversal of respiratory depression or respiratory arrest. Naloxone may be given IV, IM, or SC.<sup>211</sup> The initial dose for respiratory depression is 0.01 mg/kg titrated to effect every 2 to 3 minutes. A dose of 10 to 100 µg/kg up to 2 mg may be required for respiratory arrest. Adverse reactions from reversal of analgesia include nausea, vomiting, tachycardia, hypertension, delirium, and pulmonary edema.<sup>212-214</sup> Children on long-term opioid therapy should be given opioid reversal agents in low doses and with extreme caution, because withdrawal seizures and

delirium may occur. Children given naloxone may have recurrence of opioid effects after 1 hour. *If naloxone is used, the child should be observed for a minimum of 2 hours.* Repeat naloxone may be necessary. To avoid recrudescence of respiratory depression, some clinicians administer the same dose that was effective IV as an IM injection. Nalmefene (Revex) has a greater half-life (approximately 10 hours) than naloxone.<sup>215</sup> Although experience in children is limited, it has been shown to accelerate recovery from sedation.<sup>216</sup> Because of its relatively long half-life, it outlasts the effects of fentanyl and negates the treatment of pain with opioids for several hours.

## α<sub>2</sub>-ADRENOCEPTOR AGONIST: DEXMEDETOMIDINE

*Dexmedetomidine* is the most recent addition to the list of sedative drugs used in pediatrics. Unlike other sedatives, it is an imidazole α<sub>2</sub> agonist that is similar to clonidine but with an even greater α<sub>2</sub>- to α<sub>1</sub>-adrenoceptor specificity ratio of 1600 to 1. Clearance is predominantly by glucuronide conjugation, as well as by CYP2A6 action in the liver. The drug is highly lipid soluble and quickly crosses the blood-brain barrier. Its CNS effect is to stimulate receptors in the medullary vasomotor center, which decreases sympathetic tone. It also stimulates central parasympathetic outflow and decreases sympathetic outflow from the locus ceruleus of the brainstem. The decreased outflow from the locus ceruleus allows for increased activity of the inhibitory GABA neurons, which cause sedation and analgesia.<sup>217</sup> Dexmedetomidine is approved for sedation of ventilated adult patients in the ICU, and for procedural sedation, but as of 2012, it is not approved for use in children younger than 18 years of age. In addition to IV use, it has been administered via the buccal and IM routes in adults.<sup>218</sup> When administered in clinical doses, it causes limited effects on ventilation in adults and may mimic natural rapid-eye-movement sleep.<sup>219-221</sup> Because rapid IV boluses can cause transient systemic hypertension, the initial loading dose must be given over 10 minutes, followed by an infusion. When given in the recommended fashion, it decreases BP and heart rate in a dose-dependent manner. It should be used with caution in children with preexisting bradycardia, atrioventricular conduction defects, hypotension, and decreased cardiac output.<sup>222,223</sup> It has been associated with severe bradycardia in infants receiving digitalis.<sup>128</sup> The minimal effects on ventilation have led to a surge in its use in children.<sup>224-227</sup>

Sedation after IV administration has a relatively rapid onset of 10 min and a half-life of 1.5 to 3 hours. It is unique among sedatives in that it mimics natural sleep. Its minimal effect on respiration has led to its use alone in nonpainful procedures (e.g., EEG, CT, and MRI), in children with Down syndrome, and children with obstructive sleep apnea. It has also been used in combination with ketamine and propofol for painful procedures and syndromes (e.g., cardiac catheterizations and complex regional pain syndrome)<sup>228,229</sup>; however, caution is advised in children with known congenital heart disease, as it depresses sinus and atrioventricular node function and may pose an increased risk for children prone to bradycardia.<sup>228-232</sup> It has also been used as a novel approach to control the adverse effects of opioid and sedative withdrawal in children in the ICU.<sup>233-235</sup> The minimal respiratory effects of dexmedetomidine has been demonstrated both anatomically and physiologically in healthy children. Analyzed by MRI, the dose-response effects of dexmedetomidine (1 to 3 µg/kg/min) on upper airway morphology in children without obstructive sleep apnea<sup>236,237</sup> demonstrated minimal

changes in upper airway dimensions in several planes, with no clinical evidence of airway obstruction. Infants and children 5 months to 16 years of age who were sedated with dexmedetomidine for nonpainful procedures (e.g., MRI, MRI plus EEGs, and nuclear medicine procedures) showed minimal effects on respiration.<sup>57</sup> Boluses of 0.5 to 1.0 µg/kg dexmedetomidine were infused over 5 to 10 minutes, followed by an infusion of 0.5 to 1.0 µg/kg/hr. Heart rate, BP, and respiratory rate decreased but remained within normal limits for age. The ETCO<sub>2</sub> exceeded 50 mm Hg in only 7 of 404 measurements. Maximum ETCO<sub>2</sub> was 52 mm Hg; mean recovery time was 84 minutes. The minimal effect of dexmedetomidine on respirations has also been verified in children with obstructive sleep apnea.<sup>236,237</sup>

Initial studies demonstrated that standard doses of dexmedetomidine could not consistently provide optimal conditions for sedation for these procedures. Some clinicians increased the initial loading dose and maintenance infusion dose of dexmedetomidine, whereas others supplemented the original dosing regimen with midazolam 0.1 mg/kg, in search of a successful regimen for sedation for radiologic investigations. In the case of sedation for MRI,<sup>238</sup> a loading dose of 3 µg/kg administered over 10 minutes IV followed by an infusion of 2 µg/kg/hr minimized the need for rescue with pentobarbital (2.4%). Mean arterial pressure was maintained in all children and oxygen saturation remained greater than 95% in all children. However, most importantly, in 30 of the 747 (4%) children, the heart rate decreased to less than the 20th percentile for age. Heart rates in the 1- to 3-year-old and 3- to 6-year-old age-groups were as low as the 30 to 40 beats per minute, although no adverse effects were noted, nor were any treatments required. *Although not apparently harmful in this cohort, we do not recommend use of such large doses of dexmedetomidine, because heart rates of 30 to 40 beats per minute are well below the acceptable range of normal heart rates in children!* Caution should also be used when administering glycopyrrolate to treat the bradycardia from dexmedetomidine in children, because severe and sustained hypertension after traditional doses of 5 µg/kg have occurred (e.g., BP 161/113 in a 3-year-old); the mechanism of this unusual response remains elusive.<sup>239</sup> An alternative approach<sup>240</sup> included a loading dose of 1 µg/kg dexmedetomidine over 10 minutes followed by an infusion of 0.5 µg/kg/min plus a 0.1 mg/kg bolus of midazolam after a sevoflurane inhalational induction for IV placement. With this regimen, all MRI scans were completed successfully, with only small changes in ETCO<sub>2</sub> (maximum 57 mm Hg). Hemodynamically, systemic BP and heart rate were maintained, with the lowest systolic BP being 70 mm Hg and the lowest heart rate 64 beats per minute in 3 children. This regimen was compared with propofol at 300 µg/kg/min for 10 minutes and a dose of 250 µg/kg/min thereafter, with equivalent hemodynamic responses and no complications.

## GENERAL ANESTHETICS

General anesthetics traditionally have been used in the OR by anesthesiologists. With appropriate monitoring and skilled personnel, these agents are safely used outside the OR for diagnostic and therapeutic procedures. In the following discussion we will emphasize the use of IV drugs for sedation outside the OR when an anesthesiologist may not be directly involved.

*Ketamine* has been available since the 1960s. It is one of the few sedatives that produce both amnesia and analgesia. It is structurally similar to phencyclidine and exerts its dissociative properties by interacting with the limbic and thalamic systems. Additional mechanisms postulated are antagonism of

*N*-methyl-D-aspartate (NMDA) receptors and agonism of opioid subgroups.<sup>151</sup> The clinical appearance is that of a child who has open eyes (usually with horizontal nystagmus) but does not respond to pain, the so called “dissociative” state. Ketamine preserves cardiovascular function and exerts limited effects on respiratory mechanics, allowing spontaneous respirations in most children.<sup>241</sup> Although it is certainly not a new drug, ketamine has recently experienced a resurgence in popularity, particularly in the ED for procedural sedation. Some emergency medicine physicians suggest that ketamine not be considered an anesthetic, but rather a “dissociative sedation” drug with unique properties that warrant their own separate monitoring guidelines.<sup>242</sup> New clinical practice guidelines for EDs have been written which emphasize this position<sup>107</sup>; however, given the fact that airway obstruction, apnea, and laryngospasm occur with some regularity (approximately 1% to 2%), we strongly disagree with attempts to reclassify the drug as a means of side-stepping the AAP sedation guidelines.<sup>107,243-245</sup>

IM and IV ketamine (with and without midazolam) are frequently used for closed fracture reductions and other painful minor procedures in the ED (see Table 47-9).<sup>245-247</sup> In a review of 1022 children sedated with ketamine in the ED, there were no instances of aspiration, and airway reflexes were preserved, although complications included the need for airway management (0.7%), laryngospasm (0.4%), and apnea or respiratory depression (0.3%). Unpleasant reactions were rare and were not improved by prophylactic benzodiazepines.<sup>104</sup> In a more recent review of 4252 children, respiratory complications occurred in 2.4%, with serious airway events occurring more frequently: of this 2.4%, laryngospasm occurred in 28%, hypoxia in 79%, and apnea in 10%.<sup>99,248</sup> The risks in children younger than 2 years during ketamine with midazolam (62% of children) and morphine with midazolam (16% of children) showed a 6% incidence of complications in which all but one incident were related to ketamine with midazolam. Most were considered minor in severity, although one child required tracheal intubation.<sup>249</sup> Ketamine (1 to 3 mg/kg) has also been studied in children undergoing gastroendoscopy procedures, with transient laryngospasm occurring in 8.2%, emesis in 4.1%, emergence agitation in 2.4%, partial airway obstruction in 1.3%, apnea and respiratory depression in 0.5%, and excessive salivation in 0.3%.<sup>83</sup> The analgesic effects of ketamine make it very appealing for use during burn dressing changes. In one study, 4.9% of the sedations resulted in adverse outcomes, of which 2.9% required an intervention. Eight events were related to the airway.<sup>250</sup> Ketamine sedation/analgesia has a very long history of safety, perhaps having advantage over other sedation regimens, although these studies indicate that potentially life-threatening events can and do occur during ketamine sedation. Ketamine is also associated with nonpurposeful motion, which limits its usefulness when immobility is necessary (e.g., use during CT).

Ketamine is contraindicated in a number of clinical scenarios. It may increase cerebral blood flow and is contraindicated in children with increased intracranial pressure, particularly without controlled respirations. Similarly, it is contraindicated in those with head injury, open globe injury, hypertension, and psychosis. Ketamine decreases the ventilator response to hypercarbia, as well, it may cause laryngospasm, coughing, and apnea. No antagonist is available.

Typical starting doses<sup>251</sup> of ketamine are 1 to 2 mg/kg IM, 0.25 to 1.0 mg/kg IV, and 4 to 6 mg/kg orally.<sup>252-254</sup> The onset after IM injection is 2 to 5 minutes, with a peak at ~20 minutes;

duration can be 30 to 120 minutes. Onset after IV administration occurs in less than 1 minute, with a peak effect in several minutes and duration of action of approximately 15 minutes. Oral doses of 4 to 6 mg/kg are usually combined with atropine and have an effect in 30 minutes and last up to 120 minutes.<sup>31</sup> Larger doses or supplementation with other sedatives or opioids may produce deep sedation or general anesthesia. We advise that ketamine be administered with an anticholinergic (atropine, 0.02 mg/kg, or glycopyrrolate, 0.01 mg/kg) because copious secretions from ketamine alone may induce laryngospasm.<sup>255</sup>

*Etomidate* is a carboxylated imidazole that is primarily used as an induction agent for anesthesia. Its mechanism is thought to be potentiation of GABA inhibitory neurotransmission via alteration of chloride conductance. Loss of consciousness occurs in 15 to 20 seconds, and recovery results from redistribution and occurs in 5 to 10 minutes. It is hydrolyzed in the liver to inactive metabolites and excreted (90%) in the urine.<sup>151</sup> Etomidate produces sedation and anesthesia, anxiolysis, and amnesia similar to the barbiturates and propofol. Its major advantage is its lack of adverse cardiovascular effects. Etomidate has been used in adults and children for procedural sedation, although the end point of sedation is not well described and often is a state of general anesthesia.<sup>79</sup> Using data from the Pediatric Sedation Research Consortium, etomidate has been compared with pentobarbital for CT sedation. Adverse events were more common with pentobarbital (4.5%) than etomidate (0.9%); one child who received etomidate experienced apnea.<sup>256</sup> Etomidate with fentanyl has been compared to ketamine with midazolam for reduction of limb fractures in children in the ED. Etomidate with fentanyl had a quicker recovery time but was less effective in reducing observed patient distress.<sup>257</sup> Transient adrenal suppression can occur after multiple doses and has been described after single-dose administration in septic patients.<sup>258-262</sup>

*Propofol* is an anesthetic that is widely used for pediatric sedation and anesthesia. It is an isopropyl phenol derivative whose mechanism of action appears to be activation of the sodium channel of the  $\beta_1$  subunit of GABA receptors, thereby enhancing inhibitory transmission.<sup>263</sup> Its onset is within 30 seconds. It is highly lipid soluble and is provided in a lipid solution that is the same as the lipid component in total parenteral solutions. The lipid solubility makes the drug effect diminish extremely quickly (5 to 15 minutes).<sup>264</sup> It has no analgesic properties, but it does have antiemetic and antipruritic properties. Although small doses of propofol (25 to 50  $\mu\text{g/kg/min}$ ) can provide moderate sedation in adults, deep sedation and airway obstruction quickly occurs in some children at greater rates of administration. Dosing in adults for sedation is recommended at 25 to 200  $\mu\text{g/kg/min}$ , whereas children, particularly infants and those with cognitive impairment, require larger doses (150 to 250  $\mu\text{g/kg/min}$ ). Propofol is also a profound respiratory depressant and can cause apnea. Respiratory complications have been reported in 8% to 30% of children.<sup>265</sup> It is generally best administered by titration with an infusion pump. Other adverse reactions include increased salivary and tracheobronchial secretions, myoclonic movements, anaphylactic reactions, and bacterial contamination. Pain on injection can be lessened by several strategies, although the two most effective strategies are pretreatment with nitrous oxide by inhalation, or a mini-Bier block with 1 mg/kg lidocaine applied for 1 minute.<sup>266,267</sup> Hypotension is mild and usually not clinically significant. Cases of fatal metabolic acidosis, myocardial failure, and lipemic serum have been reported in children who received propofol infusions for more than 48 hours at doses exceeding

5 mg/kg/hr (83  $\mu\text{g/kg/min}$ ), with sporadic cases, which may have been exacerbated by an underlying mitochondrial disorder, of the syndrome appearing after only 5 to 6 hours in some cases.<sup>268-273</sup> Propofol should only be administered by practitioners with advanced sedation training and airway skills, because the propofol-sedated child will always be deeply sedated.

The use of all sedative drugs in children continues to grow. All providers must be aware of the potency and risks of sedative drugs. There are many anecdotes and reviews with small numbers of incidents that attest to the risks of propofol. This is especially true when sedatives with general anesthetic potential are used by health care providers who are not specifically trained to use them in children. Propofol sedation frequently causes anesthesia with an inability to maintain and protect the airway. In a study of propofol sedation (2.5 to 3 mg/kg IV loading dose with an infusion up to 200  $\mu\text{g/kg/min}$ ) in 105 painful procedures in the pediatric ICU, 21% of the children required airway repositioning, 17% had apnea, 5% had hypotension, and 45% had events that required intervention.<sup>86</sup> In the ED, propofol was administered to 113 children in a dose (4.5 mg/kg in addition to fentanyl 1 to 2  $\mu\text{g/kg}$ )<sup>274</sup> sufficient to ensure the children were motionless during the reduction of fractures. The net effect was an incidence of desaturation of 21%, laryngospasm in 1%, and a supplemental oxygen requirement in 25%. A study of sedation by nonanesthesiologists for bone marrow procedures, lumbar punctures, and esophagoscopies titrated propofol to a target of "not arousable"; 21 children 27 weeks to 18 years of age were studied. Only after a BIS score of 45 or less was 100% adequate sedation accomplished. Propofol total doses were 520  $\mu\text{g/kg/min}$  for these short procedures.<sup>275</sup> These responses to stimulation, effects on the airway, doses of propofol, and BIS levels are beyond the range of deep sedation, and more in keeping with the definition of general anesthesia, with the inherent risk of loss of the airway. More recent studies that reviewed the use of propofol by ED physicians specifically trained in sedation and performed in highly monitored environments, show that propofol can be used with much less severe adverse outcomes (and much smaller doses) than previously reported.<sup>15,92,106,276</sup> The debate about who is best to provide sedation with all drugs and especially propofol will continue. The key to safety is training and environment.

The risks associated with propofol were brought into the international spotlight with the death of Michael Jackson in 2009. Michael Jackson's physician who administered the propofol was tried for homicide and found guilty of involuntary manslaughter. This was not the first reported case of homicide using propofol.<sup>277</sup>

Sedatives also pose risks to providers. Propofol and all sedative drugs have severe abuse potential. The *New York Times* reported in August 2009 that 18% of anesthesia training programs reported propofol abuse. There is an effort to classify propofol as a "Class IV" drug by the U.S. Drug Enforcement Agency. This is the same category as benzodiazepines and this categorization will likely lead to tighter control of this drug.

*Fospropofol* (Lusedra) is a water-soluble prodrug of propofol. Fospropofol is hydrolyzed by plasma alkaline phosphatase to propofol, formaldehyde, and phosphate.<sup>278,279</sup> As fospropofol must first undergo dephosphorylation to propofol, time to onset of action is delayed (4 to 8 minutes).<sup>280,281</sup> Because of its slower onset, it was proposed as a safe alternative to propofol with fewer restrictions on its administration. In December 2008, the FDA qualified fospropofol to be administered only by persons trained in the administration of general anesthesia (i.e., the same wording

as propofol). Currently, there are no data on fospropofol use in children. The slow onset, adverse effect of perineal burning, and formaldehyde and formate byproducts may make this drug less appealing for sedation and only useful during general anesthesia.<sup>278,282</sup> One possible advantage for this preparation may be for long-term sedation because it is free of any fatty acids and thus may avoid possible propofol infusion syndrome. Further studies are needed, particularly because preliminary PK data were flawed.<sup>283</sup>

There has been increasing use of a combination of ketamine (10 mg/mL) with propofol (10 mg/mL), so called “ketofol,” for painful procedures in the ED and for oncology patients.<sup>284-289</sup> This combination is administered in incremental doses of 0.5 mg/kg of each drug at approximately 1-minute intervals. The limited number of prospective studies at this point preclude assessment of safety and efficacy. A literature review found insufficient evidence to recommend routine use of this combination.<sup>288</sup> A prospective study of adults found one patient in each group to require positive pressure ventilation.<sup>285</sup>

*Methohexital* is a short-acting oxybarbiturate that is rapidly metabolized and redistributed, and has a rapid recovery (see Table 47-9).<sup>290</sup> Induction of anesthesia occurs with IV doses of 1 to 2 mg/kg. Apnea, hiccups, and methohexital-induced seizures in children with temporal lobe epilepsy have been reported.<sup>291</sup> Methohexital has been used IM in doses of 8 to 10 mg/kg but has a slow onset<sup>292</sup> and is not generally recommended. Rectal methohexital (20 to 25 mg/kg [from a 100 mg/mL solution]) can induce deep sedation in 7 to 11 minutes<sup>293</sup> with a duration of action of about 30 to 45 minutes.<sup>294</sup> Absorption through the rectal route is erratic.<sup>295</sup> Children given methohexital (1 mg/kg) completed their head CT more quickly and needed less total sedation monitoring than those given pentobarbital (2 mg/kg).<sup>296</sup> The variability of absorption, tendency to deep sedation, and airway problems have decreased the use of methohexital in favor of newer drugs. This medication is rarely used and should be used only by individuals with advanced airway skills, because upper airway obstruction and apnea may readily occur.<sup>297</sup>

*Nitrous oxide* (N<sub>2</sub>O) is a potent inhalation analgesic with a peak effect in 3 to 5 minutes and very rapid return to baseline when discontinued (see Table 47-9). A premixed tank of no more than 50% N<sub>2</sub>O is available (Entonox). Administration of N<sub>2</sub>O can be used for “minimal sedation” under the following AAP guidelines: (1) only ASA physical status I or II patients; (2) only 50% nitrous oxide or less is used; (3) inhalation equipment must have the capacity to deliver 100% oxygen and never less than 25% oxygen; and (4) a calibrated oxygen analyzer must be used. The child is able to maintain verbal communication throughout

the procedure. Although N<sub>2</sub>O in 50% concentration with oxygen usually produces “minimal” sedation, the addition of any sedatives or hypnotic may rapidly produce a deeper level of sedation and require increased monitoring and vigilance.<sup>148,169</sup> Nitrous oxide is frequently used by dentists for sedation. A recent questionnaire showed that all respondents performed dental treatment as a trainee, to patients who were under sedation, and the majority used nitrous oxide inhalation sedation.<sup>298,299</sup> Extensive guidelines, following the ASA and AAP definitions and guidelines, have been written by the American Academy of Pediatric Dentistry that detail the accepted use of nitrous oxide.<sup>299</sup> Adverse reactions, drug interactions, and special concerns are listed in Table 47-9.

# Procedures for Vascular Access

SAMUEL H. WALD AND CHARLES J. COTÉ

## Venous Cannulation

Peripheral Intravenous Cannulation  
Central Venous Pressure Measurement  
Central Venous Catheterization  
Intraosseous Infusion  
Umbilical Vein Catheterization

## Arterial Cannulation

Umbilical Artery  
Radial Artery  
Temporal Artery  
Femoral Artery  
Dorsalis Pedis and Posterior Tibial Artery

**VASCULAR CANNULATION** is an important procedure in the anesthetic and perioperative management of children. Its routine use was introduced in the 1950s.<sup>1</sup> The indications are to provide routes for fluid, drug, and blood product administration, monitoring of cardiopulmonary function, and provision of access for blood sampling. Although the technique of insertion may be extremely difficult, especially in the very young or small child, no child should be denied an indicated procedure because of an operator's inexperience; appropriate consultation should be sought, if necessary. Regardless of the procedure, gloves should be worn to maintain clean or sterile technique and to protect health care professionals from exposure to blood.<sup>2-6</sup> An update from the Pediatric Perioperative Cardiac Arrest Registry suggests that lack of good vascular access may contribute to the underestimation of fluid or blood loss and inadequate replacement of fluid or blood in anesthetized children, emphasizing the importance of appropriate and adequate vascular access and monitoring.<sup>7,8</sup>

## Venous Cannulation

### PERIPHERAL INTRAVENOUS CANNULATION

#### Indications

Percutaneous intravenous cannulation should be used in almost all anesthetized children for the following purposes<sup>9,10</sup>:

- Provision of a route for postoperative pain relief
- Administration of drugs, fluids and electrolytes, glucose, and blood products, including resuscitation medications
- Indirect central venous pressure measurement; the accuracy of this method for central venous pressure measurement does not appear to vary by location of the catheter<sup>11</sup> but does depend on ensuring direct continuity between the central and peripheral circulation.<sup>12,13</sup> This can be assessed by providing a large, sustained inspiration or occluding the venous return of the extremity, which both cause an increase in the peripheral pressure.<sup>14-16</sup> Hypothermia may impair the accuracy of such measurement.<sup>17</sup>

#### Equipment

- Alcohol pads or chlorhexidine swabs
- Gloves
- Tourniquet

- Gauze
- Clear plastic dressing (Tegaderm, 3M Medical-Surgical Division, St. Paul, Minn., or OpSite, Smith + Nephew, Inc., Largo, Fla.)
- Tape
- Armboard

Consider the possible need for latex-free equipment. In cases of difficult access, the availability of a transillumination light source (Karl Storz, 485 B Type, Tutlingen, Germany) may improve the success rate of catheter placement.<sup>18</sup> Ultrasonography also may be used for obtaining peripheral venous access at the basilic, cephalic, or brachial veins.<sup>19,20</sup> Finally, new near-infrared and infrared technology is available to aid in the identification of peripheral veins (AccuVein, Accuvein, Huntington, N.Y.; Vein-Viewer, Christie Digital Systems, Cypress, Calif.).<sup>21</sup>

#### Practical Suggestions

1. Awake intravenous line placement can be facilitated by any combination of good patient rapport, EMLA cream (lidocaine 2.5% and prilocaine 2.5%), lidocaine and tetracaine patch, lidocaine by iontophoresis, lidocaine by topical cream, topical tetracaine (Ametop), ethyl chloride spray, and/or pre-medication.<sup>22-31</sup>
2. Prefilling the cannula with saline may reduce meniscus tension and allow a more rapid blood flash back.
3. A butterfly needle can be inserted for induction, followed by an appropriate-size catheter after anesthesia.
4. A T-connector (Abbott Hospitals, Inc., Chicago) may be used to minimize the fluids necessary to flush drugs administered through the intravenous line; this is particularly important for infants.<sup>32</sup>
5. A calibrated burette should be used to limit the total infusion and provide a means to titrate fluids accurately in infants and young children.
6. A flow-limiting infusion pump may be used for preterm and full-term neonates.
7. Flow rates may be significantly changed by catheter brand, tubing type, and addition of extensions and stopcocks.<sup>33</sup>
8. One-way valves in the intravenous tubing are useful in preventing back-flow of drugs or infusions.
9. Air filters also may be useful for children at risk for paradoxical gas embolization.

**TABLE 48-1** Comparison of Intravenous Safety Mechanisms

Safety Mechanism	Operator Activation Required	Syringe Attachment	Rapid Flash	Bulky	Advantages	Disadvantages	Devices (Manufacturers)
Retractable needle	Yes	No	Yes	Yes	Unobstructed and rapid blood flash Similarity in use to nonsafety devices	Bulky Requires operator activation No syringe attachment	Angiocath Autoguard (BD Medical, Franklin Lakes, N.J.), Secure IV (Span America Medical Systems, Inc., Greenville, S.C.)
Blunted needle	No	Yes	No	No	Passive action requiring no operator activation Syringe attachment possible	Slow blood flash if needle has been partially withdrawn	Introcan Safety IV (B. Braun, Bethlehem, Pa.), Protectiv Acuvance (Smiths Medical, U.K.)

### Complications

Hematoma from a failed vascular cannulation is usually of no serious consequence. Infection or thrombosis may be limited by aseptic technique.<sup>34-36</sup> One study of 642 Teflon catheters in 525 patients showed that the risk of catheter complications in children was extremely small and would not be reduced significantly by routine replacement of the catheters.<sup>37</sup> Catheter life span has been found to be unrelated to insertion site, cannula size, or brand in infants younger than 12 months of age.<sup>38,39</sup>

Skin sloughing is usually caused by subcutaneous infiltration of calcium, potassium, or hypertonic solutions; it may be avoided by frequent inspection of the intravenous line before injecting medications.<sup>40</sup> The risk of subcutaneous infiltration increases with the administration of medications versus no medications and with parenteral nutrition solutions compared with 5% or 10% dextrose solutions, but the risk of infiltration is no different with solutions that contain potassium ( $\leq 20$  mEq/L vs.  $>20$  mEq/L). In addition, there is no difference between gravity-controlled versus infusion delivery devices.<sup>41</sup>

There are insufficient data to support the routine use of heparin to prolong the patency of peripheral intravenous catheters in neonates and children.<sup>42</sup>

### CENTRAL VENOUS PRESSURE MEASUREMENT

Some studies in children and adults describe a reasonable correlation between peripheral intravenous catheters and central venous catheters, even in critically ill children. Hypothermia (peripheral vasoconstriction) decreases the accuracy of such measurements, but it is useful to understand that transducing the pressure of a peripheral vein may provide valuable information regarding right-sided cardiac filling pressures.<sup>9,10,43-46</sup>

### Establishing a Large Intravenous Catheter in Small Patients

#### Indications

The following procedure is used for any child in whom there is the potential for massive, rapid hemorrhage:

1. Prepare and drape the appropriate area using standard sterile techniques.
2. Perform a standard intravenous cannulation of an antecubital, saphenous, or external jugular vein with a small (22-gauge) intravenous catheter.
3. Pass a small, flexible guidewire (0.018 inch) through the intravenous catheter, remove the catheter, and with a number 11 blade make a small incision at the entry point of the wire at the skin.

4. Pass the next larger size intravenous catheter over the wire to dilate the vein and leave in place; stiff intravenous catheters are more effective. An alternative is to use a small dilator from a pulmonary artery catheter introducer and leave the sheath in place. The wire is removed, and the next larger size wire is inserted (0.025 inch). The catheter (or sheath) is removed, leaving this larger wire within the vein. This process may be repeated with larger catheters and wires until the desired size cannula or sheath is reached. An alternative is to leave progressively larger pulmonary artery introducer sheaths in the vein; both techniques provide a reasonably rapid method of establishing a large-bore intravenous infusion site.

### Rapid Infusion Catheters and Introducer Sheaths

Special rapid volume catheters (6F and larger, Arrow International, Reading, Pa.) allow venipuncture with a needle or small intravenous catheter, passage of a guidewire, and then introduction of a dilator and sheath, with fewer steps required (see E-Fig. 10-1).

### Intravenous Cutdown

#### Indications

- Percutaneous cannulation is unsuccessful.
- Percutaneous cannulation is tenuous.
- The catheter in place is inadequate for the planned surgical procedure.

The most common sites for insertion are the saphenous vein at the medial malleolus and the brachiocephalic vein at the antecubital fossa. This procedure may require considerable time to perform and has limited utility for emergent access.<sup>47</sup>

#### Complications

Intravenous cutdown has a high incidence of infection and therefore should be used only on a short-term basis.

### Saphenous Vein Cannulation

The saphenous vein is often a reliable point for intravenous access in infants and children that may be directly visualized or cannulated with a "blind" technique (Fig. 48-1). It is consistently found lateral to the medial malleolus of the ankle one-half to one finger breadth over the anterior quadrant.

1. Cleanse the area in the standard fashion after a tourniquet is applied to the lower extremity below the knee.

FIGURE 48-1 Saphenous vein cannulation.

2. The saphenous vein may or may not be palpated, and visualization may not be possible.
3. Enter the skin at a 30-degree angle at the expected site of the saphenous vein at the level of the medial malleolus, with the tip of the needle directed toward the upper two thirds of the calf. If no evidence of venipuncture is seen on insertion, slowly withdraw the needle because the flash of blood may occur while exiting the vein.
4. If unsuccessful on the first attempt, fan medially and then laterally from the same insertion point, slowly advancing and withdrawing the catheter until blood return is obtained.
5. Once a flashback is seen, gently advance the entire unit 2 to 3 mm into the lumen before advancing the catheter off the needle.

### Safety Intravenous Catheters

In the United States, federal law requires that retractable or sheathed needles designed to reduce the potential for needlestick injury are available for use by health care personnel (see Table 48-1).<sup>48</sup> A study that compared traditional intravenous catheters to safety devices found that a larger proportion of children younger than 3 years of age required more than one catheter to successfully gain intravenous access. The retractable intravenous catheter was associated with a nearly fourfold greater incidence of splattering and spilling of blood compared with traditional catheters.<sup>49</sup> Retractable needles require activation of a button to trigger the safety device; therefore sheathed catheters are regarded as inherently safer because they require no action on the part of the operator to protect the needle tip. Note that the U.S. federal legislation requires that these devices be available but the ultimate decision to use them rests with the physician. *Therefore the*

*type of catheter should not be dictated by the hospital but rather by the individuals who place the catheters.*

## CENTRAL VENOUS CATHETERIZATION

### Indications

- Provision of a secure means for administration of fluid and blood when major shifts in intravascular volume are anticipated (e.g., multiple trauma, intestinal obstruction, burns)
- Monitoring of cardiac filling pressures
- Infusion of drugs and fluids that are sclerosing to peripheral veins (e.g., antibiotics, vasopressors, and hyperalimentation fluids)
- Need for blood sampling
- Measurement of mixed venous acid-base balance, estimation of cardiac output (Fick principle) or measurement of cardiac output (dye dilution)
- Route for aspiration of air emboli

The common sites for central venous cannulation are the external and internal jugular veins, the subclavian and brachiocephalic veins, the femoral vein in infants and children, and the umbilical vein in neonates. Approaches such as the internal jugular and subclavian veins should be used with extreme caution in the presence of a bleeding diathesis as stopping bleeding may be difficult. The percutaneous approach to central venous cannulation is often successful using a modified Seldinger technique (Fig. 48-2).<sup>50,51</sup> The advantages of this technique are that it avoids the need for a cutdown, only one venipuncture is made with a thin-walled small-gauge needle, a guidewire directs the catheter within the blood vessel, introducing a large catheter through the small venipuncture site minimizes the chances of significant hematoma formation even after systemic heparinization, and the procedure often can be accomplished when access is required emergently. Whenever a central line is inserted into the heart from above, care must be taken to ensure that the catheter tip is positioned at the junction of the superior vena cava and the right atrium, because positions within the heart have been associated with perforation of large vessels and the myocardium (Fig. 48-3) with triggering of ventricular arrhythmias.<sup>52</sup>

Ultrasound guidance, pressure waveform analysis, or electrocardiographic guidance may help prevent complications related to central catheter placement.<sup>53,54</sup> Ultrasound-guided access assists successful cannulation of the internal jugular vein,<sup>53</sup> the infraclavicular axillary vein,<sup>54</sup> and the subclavian vein.<sup>55,56</sup> A meta-analysis of 18 trials with 1646 participants, including infants, children, and adults, showed a benefit from the use of two-dimensional ultrasound guidance compared with the landmark method. The greatest benefit was for internal jugular vein cannulation rather than subclavian or femoral veins.<sup>57</sup> See Chapter 42 and Video 48-1 for ultrasound-guided techniques.

### Complications

Pneumothorax, arrhythmia, hematoma, bleeding, infection, thrombosis, inadvertent arterial puncture, cardiac tamponade, air embolus, thoracic duct injury, and malposition are all possible complications associated with central venous cannulation. Data in adults suggest that the smallest catheter and placement from the left subclavian approach may have the least complication rate; similar studies have not been conducted in children.<sup>58</sup> The infection rate reported after 1056 central venous catheters were inserted into 289 children with burn injury varied from 2.0% to 7.3% for catheters in place for 11 or fewer days, but that the rate

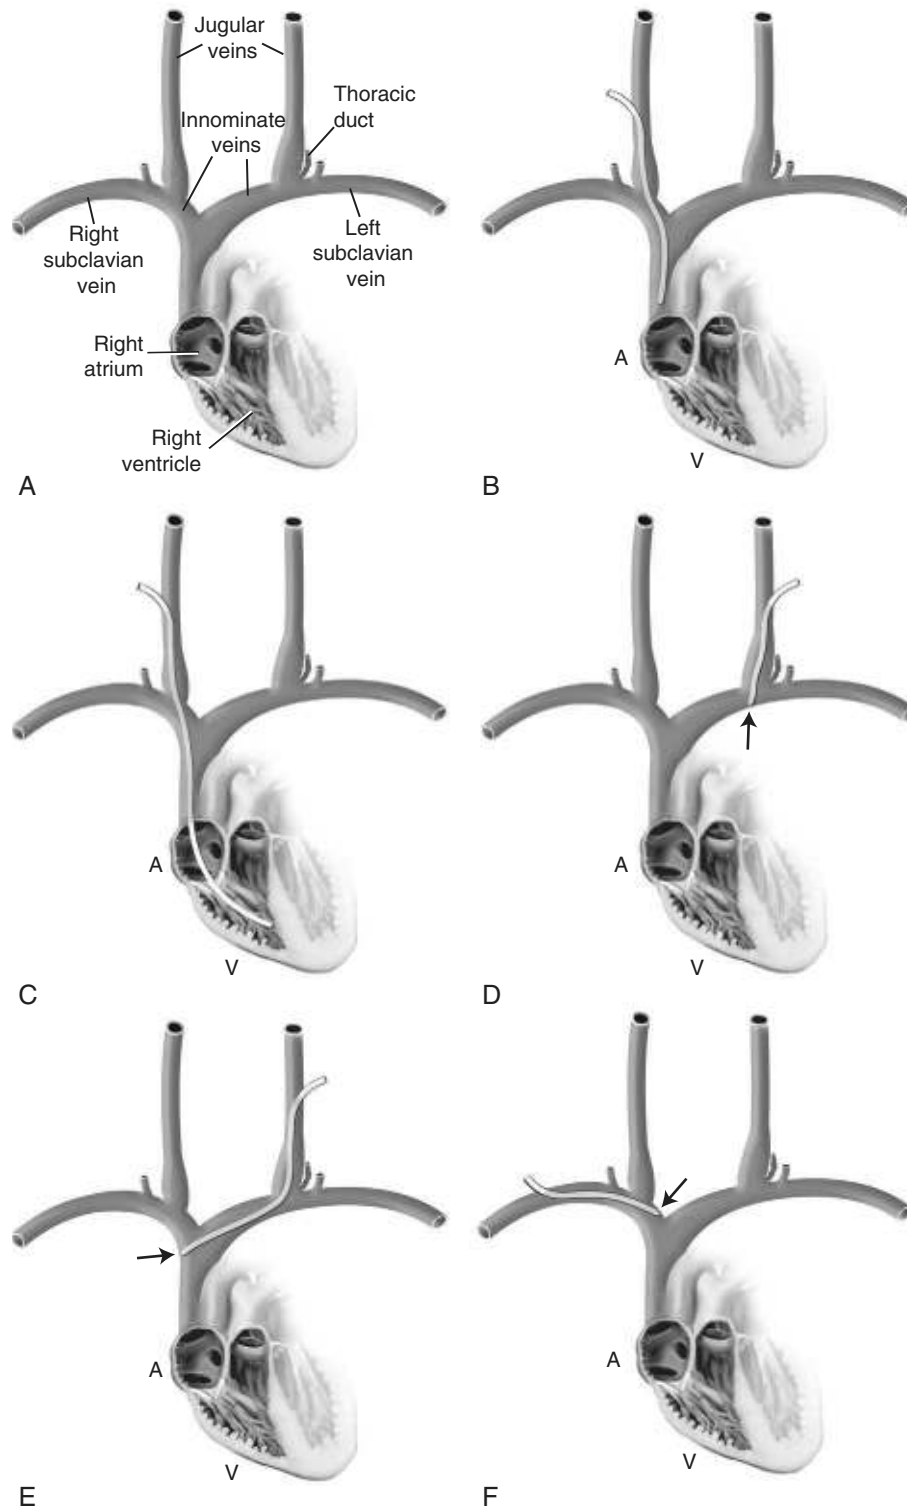

**FIGURE 48-2** A, Seldinger technique for catheter placement. The needle is inserted into the target vessel, and the flexible end of the guidewire is passed freely into the vessel. B, The needle is then removed, leaving the guidewire in place. C, The catheter is advanced with a twisting motion into the vessel. D, The wire is removed, and the catheter is connected to an appropriate infusion or monitoring device. (Redrawn with permission from Schwartz AJ, Coté CJ, Jobes DR, et al. Central venous catheterization in pediatrics. Scientific exhibit, American Society of Anesthesiologists, New Orleans, 1977.)

increased dramatically to 15.8% to 37.5% for catheters left in place for 12 to 14 days.<sup>59</sup>

#### **Aseptic Technique**

Contamination of catheters during insertion may result in catheter colonization or bacterial infection. Evidence suggests that the use of maximum barrier precautions during placement, including the use of sterile gloves, long-sleeved gowns, full-size drape, and a nonsterile mask and cap, decrease the risk of

catheter-related infection.<sup>34,36,60,61</sup> The efficacy of chlorhexidine versus povidone-iodine for preventing bacteremia remains unclear, and the safety of chlorhexidine in infants and children has not been fully established.<sup>62</sup> For older infants and children, chlorhexidine may be safe and effective, but it can cause severe local contact dermatitis in low-birth-weight infants.<sup>63,64</sup> In a case-controlled, prospective, active surveillance study in a pediatric intensive care unit (ICU), independent risk factors for central line-associated bloodstream infection were the duration of central

**FIGURE 48-3** Proper and improper central venous pressure catheter placement. **A**, Normal vascular anatomy. **B**, Proper location for right internal jugular catheter (i.e., high right atrium or superior vena cava). **C**, Ventricular location of any catheter is dangerous and contraindicated. **D**, A short left-sided internal jugular catheter may erode through the innominate vein (*arrow*). **E**, A left-sided internal jugular catheter striking the lateral wall of the superior vena cava (*arrow*) may erode through it and must be partially withdrawn or advanced. **F**, A short right subclavian catheter may strike the lateral wall of the innominate vein (*arrow*) and erode through it; this catheter should be advanced or withdrawn.

venous catheterization in the ICU, nonoperative cardiovascular disease, gastrostomy tube, parenteral nutrition, central line placement in the ICU, and red blood cell transfusion.<sup>65</sup>

#### External Jugular Vein Catheterization

1. Place the child in the Trendelenburg position with the head turned 45 degrees away from the side of cannulation.
2. Place a pillow or rolled sheet under the shoulders to extend the head and allow complete access to the neck.
3. Under aseptic conditions, venipuncture and catheter insertion are completed according to the techniques shown in Figure 48-2. A J-wire is usually more useful to circumvent the plexus of veins at the clavicle.<sup>66,67</sup>
4. Suture or tape appropriately and cover with an occlusive dressing. Many catheters will not pass beyond the clavicle or will pass into the axillary vein; success is generally more often attained on the right side.<sup>68,69</sup> If a shorter catheter is used, infusion and pressure monitoring are very dependent on the position of the head.<sup>70</sup> Continuous free-flowing infusion is best maintained when the head is turned away from the side of catheter insertion. This vein is particularly valuable in children with difficult peripheral venous access and in an emergent situation that suddenly develops intraoperatively that requires establishment of additional intravenous access.

#### Internal Jugular Vein Catheterization

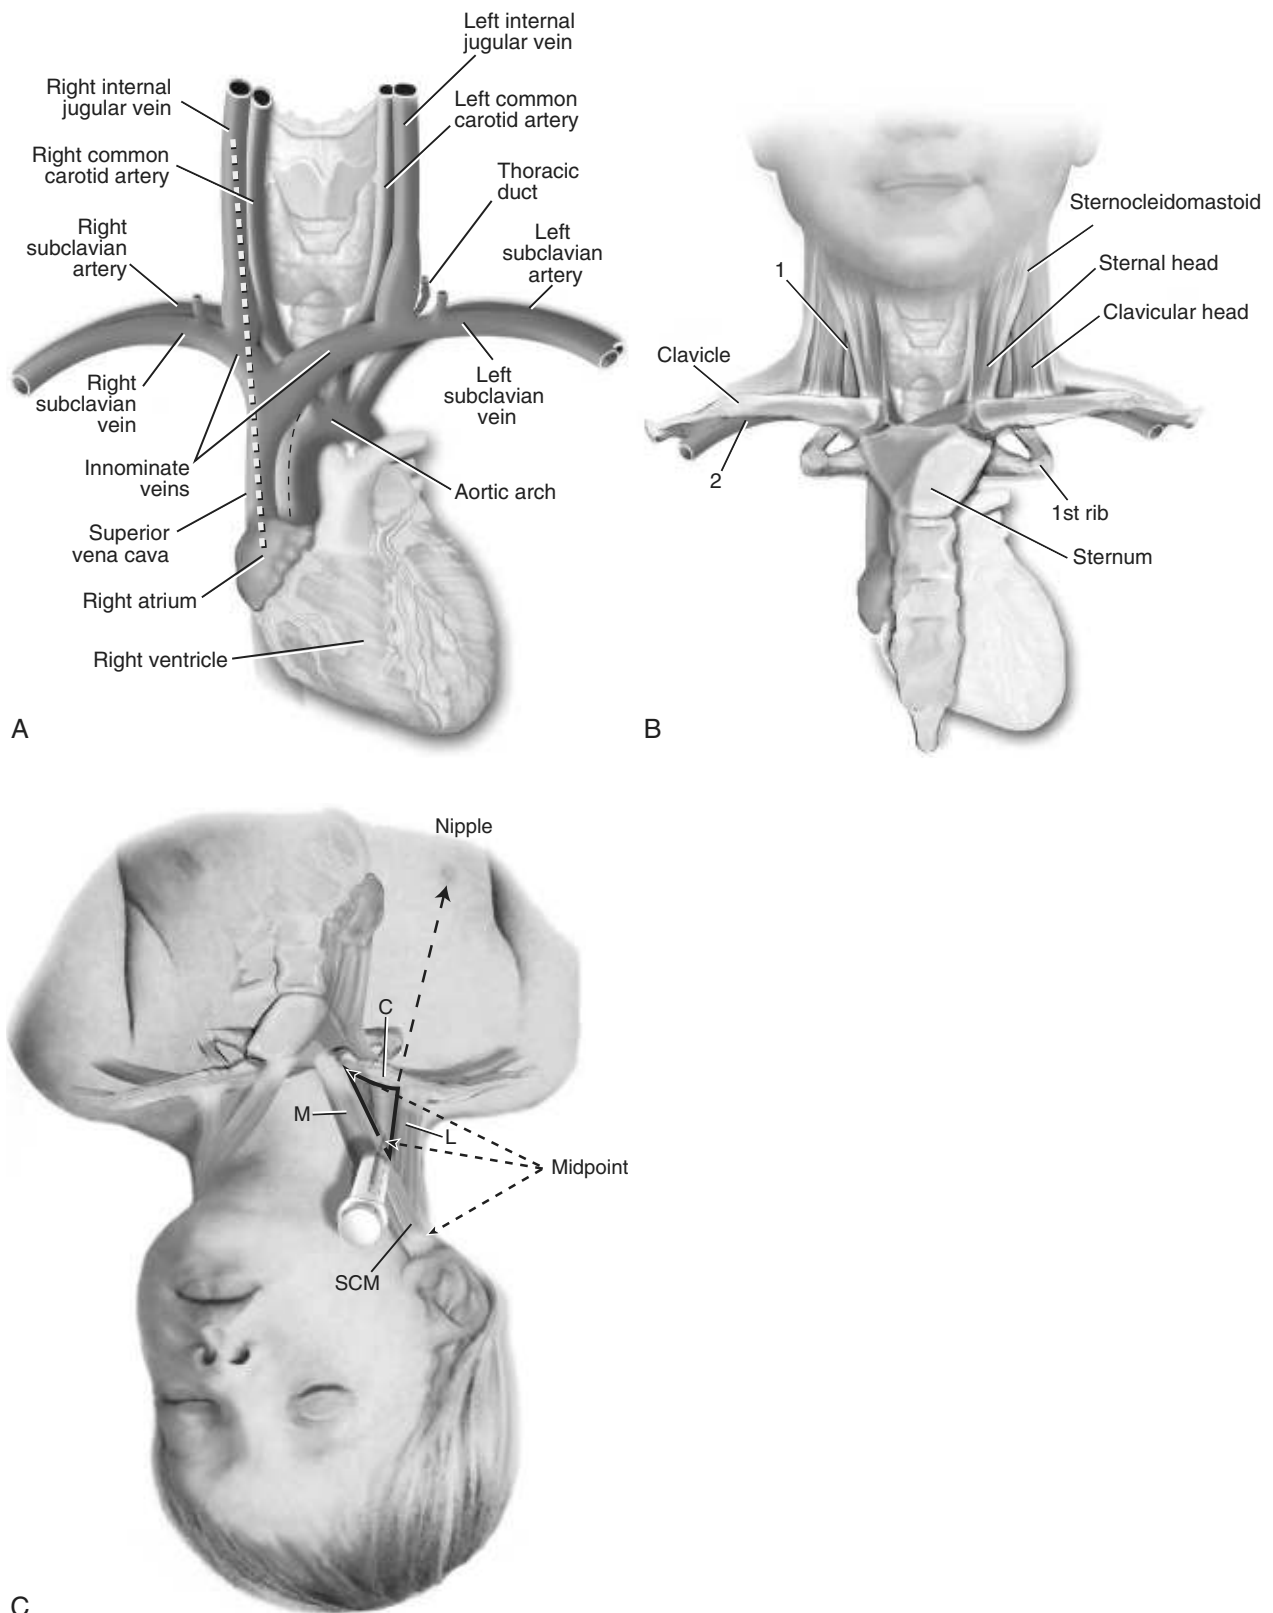

Numerous approaches and techniques are used for internal jugular vein cannulation.<sup>71-74</sup> A high approach using the apex of a triangle formed by the two bellies of the sternocleidomastoid muscle and the clavicle may be used as a landmark for insertion (Fig. 48-4). With the use of the Seldinger technique, the success rate, even in neonates, approaches 75% on the first attempt and 90% to 95% on the second attempt.<sup>50</sup> Cannulation of the right side virtually ensures a central location because the internal jugular vein, the superior vena cava, and the right atrium are in a straight line (see Fig. 48-4). Left-sided cannulation risks injury to the thoracic duct and possible pneumothorax because the apex of the lung is more cephalad on the left. In addition, if the catheter inserted on the left is too short, it is not unusual for the tip to rest against the wall of the superior vena cava, be position dependent, and possibly erode through the wall of the vessel.

Figure 48-3 illustrates less desirable sites for catheter tips that may result in perforation. The principal advantage of the high approach is that the most common complication (arterial puncture, approximately 10%) is easily recognized and usually treated uneventfully. In one study, the effect individually and in combination of the simulated Valsalva maneuver (positive inspiratory pressure of 25 mm Hg for 10 seconds), liver compression, and Trendelenburg position to increase the cross-sectional area of the right internal jugular vein was investigated.<sup>75</sup> A maximal mean increase in cross-sectional area of the right internal jugular vein was  $17.4 \pm 16.1\%$  from baseline when all three maneuvers were combined. This effect was most pronounced in children 1 to 6 years of age and was clinically negligible in infants younger than 12 months of age. The effect on ease of catheter placement was not investigated.<sup>75</sup> For neonates, a study using skin traction in infants less than 5 kg showed that a technique using tape for skin traction combined with ultrasound guidance increased internal jugular cross-sectional area and decreased the time for catheter placement.<sup>76-78</sup>

#### Technique

1. Position the child as for external jugular vein cannulation but with a rolled towel under the center of the back to allow the head to be slightly extended (see Fig. 48-3 and Video 48-1 for positioning and the use of ultrasound to guide insertion). The head is turned slightly away from the side of insertion; *turning the head too far to the side may result in compression of the vein and moving the vein in closer proximity to the carotid artery.*
2. Locate the apex of a triangle formed by the two bellies of the sternocleidomastoid muscle. This point is usually where the external jugular vein crosses the sternocleidomastoid muscle or the midpoint between the mastoid process and the sternal notch.
3. Palpate the carotid artery. Introduce the needle just lateral to this artery at an angle of 30 degrees to the skin surface. If the internal jugular vein is superficial, a less acute angle may be indicated. While continuously aspirating, advance the needle toward the ipsilateral nipple a distance of no more than 2.5 cm. If no blood is freely obtained, slowly withdraw the needle while maintaining aspiration. The

**FIGURE 48-4** **A**, The anatomic relationships of major chest and neck structures. Note how the internal jugular vein is in close proximity to the carotid artery. Also note that a nearly straight line is formed by the internal jugular vein, innominate vein, superior vena cava, and right atrium (*yellow hatched line*); thus it is rare for a right internal jugular catheter to migrate anywhere but to the right atrium. **B**, The relationship of external anatomic landmarks to the anatomy illustrated in **A**. Note the triangle formed by the two bellies of the sternocleidomastoid muscle and the clavicle. 1, The preferred point of needle insertion at the apex of this triangle for internal jugular vein puncture. 2, The point of needle insertion for subclavian vein puncture. **C**, The anatomic landmarks as they would appear to an anesthetologist. The needle is introduced at the apex of the triangle outlined in **C** and is directed at an angle of 30 degrees to the skin toward the ipsilateral nipple. This point of entry is generally half the distance between the mastoid process and the sternal notch. C, Clavicle; M and L, medial and lateral bellies of the sternocleidomastoid muscle (SCM).

needle can compress the vessel on entry, and it straightens during withdrawal, allowing free aspiration of blood.

4. Once venipuncture is accomplished, carefully remove the syringe and occlude the end of the needle (to prevent entraining air if the child is breathing spontaneously) until a flexible guidewire is inserted (see Fig. 48-2).<sup>51</sup> The wire should advance easily. However, if the wire cannot be advanced, the needle has passed out of the vessel lumen or its tip rests against the vessel wall. In this situation, the wire and needle should be withdrawn simultaneously to avoid shearing the wire. If the wire passes without difficulty, then cannulation proceeds as demonstrated in Figures 48-2 and 48-4. Catheter tip location should be confirmed with a radiologic study and repositioned as necessary (see Fig. 48-3).
5. Suture the catheter in place, and protect the area with an occlusive dressing.

#### Contraindications

- A bleeding diathesis (relative contraindication); in life-threatening emergencies, the benefit may outweigh the risk.
- Contralateral pneumothorax
- Raised intracranial pressure (Trendelenburg position and venous occlusion by the catheter may increase intracranial pressure); this is a relative contraindication and ultrasound-guided insertion may provide a great advantage because Trendelenburg position may not be required.
- Aberrant vessels (e.g., cervical aortic arch)

#### Subclavian Vein Catheterization

The subclavian vein is a site frequently used for central vein cannulation.<sup>79,80</sup> Success rates of over 80% have been reported even in infants younger than 4 weeks of age.<sup>81-83</sup> The advantages include fixed landmarks, ease of securing the line to children for long-term management, and patient comfort. Disadvantages include pneumothorax and hemothorax.<sup>84,85</sup> If this site is chosen, we suggest obtaining a chest radiograph after the catheter is inserted and before surgery begins to preclude an unrecognized intraoperative tension pneumothorax. The use of the Seldinger technique (our preference) may reduce the incidence of damage to intrathoracic structures compared with other techniques. As with left-sided internal jugular vein cannulation, if a left subclavian catheter tip rests against the wall of the superior vena cava, it can erode through, resulting in hemothorax or hydrothorax (see Fig. 48-3, *H*). In a comparison of neutral versus lowered shoulder position in 361 adult patients, neutral position significantly reduced the incidence of misplacement of the catheter tip (ipsilateral internal jugular or brachiocephalic vein) with no difference in the rate of arterial puncture or pneumothorax.<sup>86</sup> This maneuver remains to be tested in children.

#### Technique

1. Prepare and position the child as previously described for external jugular vein puncture.
2. Insert a needle immediately inferior to the clavicle at a point one-half to two-thirds its length from the sternoclavicular junction; while “hugging” the undersurface of the clavicle, the needle is directed toward the suprasternal notch while continuously aspirating.
3. As soon as free blood flow is obtained, proceed as in Figure 48-2. If the Seldinger technique is not used, then first

locating the subclavian vein with a small-gauge finder needle is recommended.

4. Suture the catheter in place, and apply an occlusive dressing.

If the child's ventilation is controlled, the risk of pneumothorax may be decreased by momentarily ceasing ventilation so that the apex of the lung is away from the needle tip. While probing for the subclavian vein, once successful venipuncture has been achieved, maintaining positive end-expiratory pressure reduces the possibility of air embolism. Optimal depths for right subclavian catheterization have been studied in infants 2 to 5 kg using transesophageal echocardiography and found to be 40 to 55 mm for catheter tip placement at the junction of the superior vena cava and the right atrium.<sup>87</sup> Contraindications are the same as for internal jugular vein catheterization (see Video 48-1 for illustration of technique).

#### Brachiocephalic Vein Catheterization

The brachiocephalic vein offers the advantage of being far removed from the intrathoracic structures.<sup>88</sup> The main disadvantage is that a significant number of catheters introduced at this site do not pass centrally, that is, they are caught in the axilla or pass up the jugular vein (internal or external).<sup>89-91</sup> Other disadvantages include significant catheter migration with movement of the arm and possibly an increased incidence of infection. This approach is commonly used by radiologists and pediatric nurses for placement of peripherally inserted central catheters (PICCs), which can be used on a long-term basis.<sup>92-94</sup> These catheters often markedly improve patient care and the quality of life for the child because of the reduced need for peripheral venous access and the reduced number of venipunctures for blood testing. The routine use of heparin to prevent catheter thrombosis and occlusion is not supported by published studies, but the data are inadequate to reach a conclusion one way or the other.<sup>95</sup>

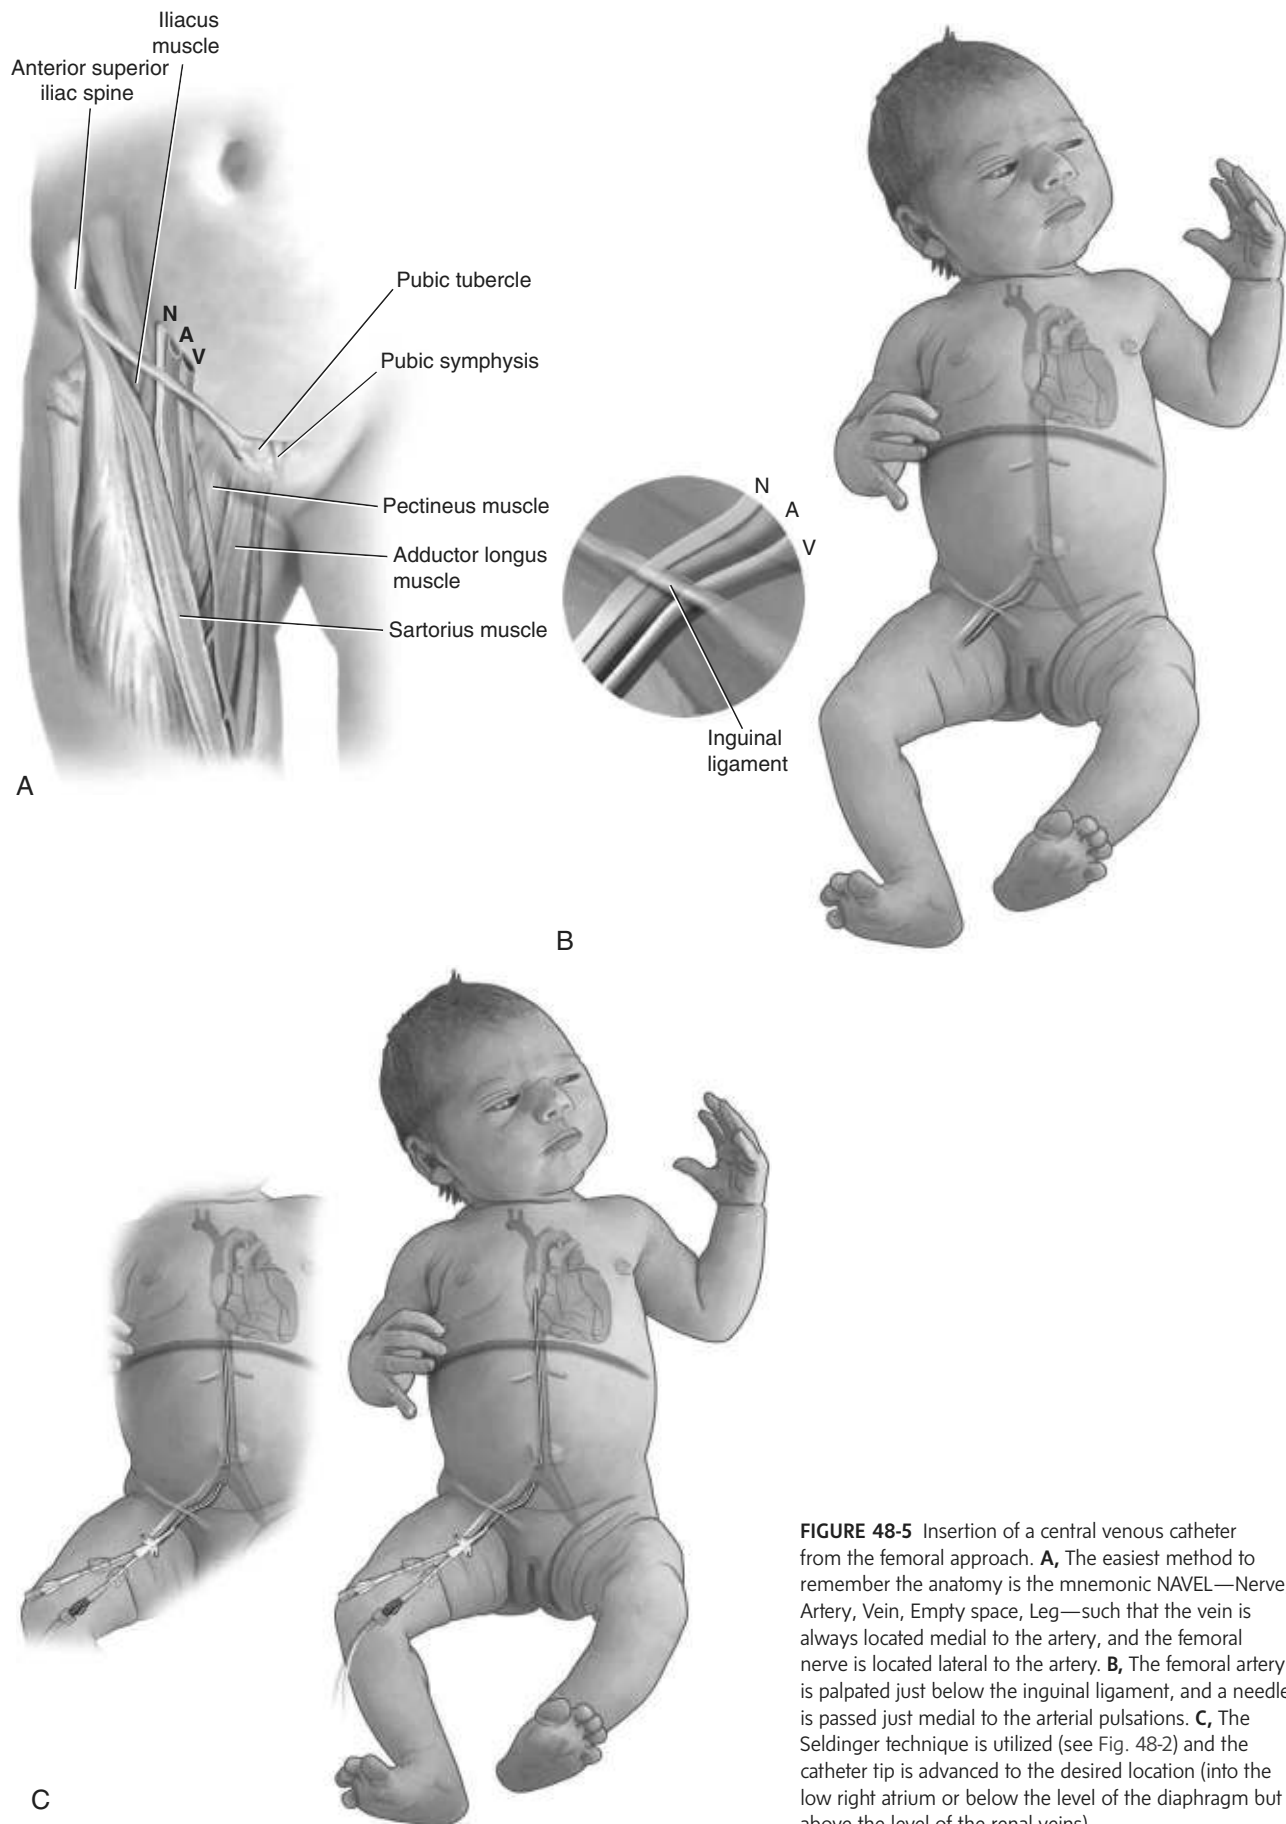

#### Technique

1. Prepare and drape the arm with aseptic technique.
2. Cannulate the brachiocephalic vein either by using the modified Seldinger technique (special long catheters and wires for this purpose) or by passing a catheter through a needle (Intra Cath, New Delhi, India). If the catheter cannot be threaded once the vein is entered, initiating rapid intravenous fluid administration, cephalad positioning of the arm, and anterior displacement of the shoulder may assist advancement. If percutaneous techniques are not possible, direct venous cutdown may be performed.

#### Femoral Vein Catheterization

The femoral vein may also be used for access to the central circulation.<sup>96</sup> The catheter must pass into the thorax to provide accurate cardiac filling pressure measurements, although there seems to be a reasonable correlation with central filling pressures even when the catheter tip is within the abdomen.<sup>97</sup> One advantage of this route is that the vein is large and presents easy access distant from the vital intrathoracic structures (Fig. 48-5). Disadvantages include difficulty in securing the catheter to the child, kinking of the catheter with leg flexion, and problems in maintaining insertion site sterility. Short-term catheterization can provide large-bore venous access for the duration of a procedure with expected large and rapid blood loss if other veins are not accessible. Surprisingly, this site is not associated with a greater

**FIGURE 48-5** Insertion of a central venous catheter from the femoral approach. **A**, The easiest method to remember the anatomy is the mnemonic NAVEL—Nerve, Artery, Vein, Empty space, Leg—such that the vein is always located medial to the artery, and the femoral nerve is located lateral to the artery. **B**, The femoral artery is palpated just below the inguinal ligament, and a needle is passed just medial to the arterial pulsations. **C**, The Seldinger technique is utilized (see Fig. 48-2) and the catheter tip is advanced to the desired location (into the low right atrium or below the level of the diaphragm but above the level of the renal veins).

incidence of catheter-related sepsis compared with other insertion sites.<sup>59,98</sup> This site is not appropriate if disruption of inferior vena cava blood flow is possible (e.g., Wilms tumor resection with invasion of the inferior vena cava, abdominal trauma). The tip of the catheter should be located either low in the atrium or inferior to the level of the diaphragm but superior to the level of the renal veins to reduce the potential for renal vein thrombosis. Use of this technique also has been reported to be safe in infants weighing less than 1000 g with the caution of careful catheter advancement to avoid cardiac perforation.<sup>99</sup>

#### Technique

1. Prepare and drape the groin using an aseptic technique with the legs at 90-degree angles ("frog-leg position") (see Fig. 48-5, *B*). A roll under the hips also may provide optimal conditions by slightly elevating the hips.
2. Palpate the femoral artery at a point midway between the pubic tubercle and the anterior superior iliac spine (see Fig. 48-5, *A*).
3. Using the Seldinger technique, enter the vein at a point just medial to the femoral artery and 1 to 2 cm below the inguinal ligament. A catheter is inserted as in Figure 48-2. As for the brachiocephalic vein, special long catheters and wires are needed to achieve a central location (see Video 48-1). As with many vascular access methods, ultrasound guidance can be quite useful.<sup>100-102</sup>
4. Protect the catheter insertion site as previously described (see discussion of internal jugular vein catheterization). If an alternative technique is used (e.g., catheter through the needle), maintain compression of the cannulation site until hemostasis is ensured. The saphenous vein may be cannulated by direct venous cutdown at its junction with the femoral vein if percutaneous techniques are unsuccessful.

#### INTRAOSSEOUS INFUSION

The administration of intravenous fluid into the medullary cavity of long bones is a proven method for volume resuscitation in a hypovolemic child and even in teenagers.<sup>103-109</sup> This method can effectively deliver drugs to the central circulation as quickly as using peripheral intravenous infusion sites.<sup>110</sup> It is a particularly valuable emergency route of drug administration, even in the hands of emergency medical technicians<sup>111-113</sup> and as part of emergency department resuscitation of pediatric trauma patients.<sup>107</sup> Complications such as cellulitis, abscess, fractures, and osteomyelitis have been reported in less than 1% of cases, and this technique does not appear to affect later growth of the tibia with proper insertion technique.<sup>114-116</sup> These complications relate in part to duration of infusion, underlying medical conditions, and aseptic technique. The major difficulties with this technique are due to failure to adhere to proper landmarks<sup>117</sup> and bending and clotting of the needle. This technique is used in an emergency situation if several attempts at peripheral or central venous cannulation have failed (suggested "if you cannot achieve reliable access quickly," which generally means after three attempts or 90 seconds).<sup>118,119</sup> Sites for insertion include the upper medial tibia just below the tibial tuberosity, the lower medial tibia just superior to the medial malleolus (to avoid growth plates), the lower femur and the anterior iliac crest. Intraosseous infusions are discontinued once an alternative intravenous infusion site has been secured. This technique has been successfully used for

resuscitation of burn victims.<sup>120,121</sup> Intraosseous devices should not be used in a fractured leg. For the most recent, complete information, please refer to a review directed to the anesthesiologist caring for pediatric patients.<sup>122</sup>

#### Technique

1. Palpate the tibial tuberosity.
2. Locate a point on the medial surface of the tibia at least 1 to 2 cm below and medial to the tibial tuberosity for the site of needle puncture, because the mantle of the tibia is thin at this location (Fig. 48-6, *A*).
3. Use a special short needle with a stylet to puncture the mantle of the tibia at a 75-degree angle directed toward the feet to avoid the epiphyseal plate (see Fig. 48-6, *B* and *C*). A styleted spinal needle also may be used.
4. The appropriate position is readily achieved with the loss of resistance; take care to avoid advancing the needle too far (i.e., out the opposite side or against the opposite mantle of the tibia). The needle is usually quite stable if properly positioned.
5. Attach standard intravenous infusion equipment. Fluid should flow freely without extravasation (see Fig. 48-6, *D*). A new device for intraosseous access is the EZ-IO (Vida-Care, San Antonio, Tex.), which is a handheld battery-powered device that works much like an electric drill (E-Fig. 48-1). This device should be immediately available in all operating rooms and prenatal intensive care units because this is the simplest and easiest means for establishing emergent intraosseous access even in out of hospital venues.<sup>123-127</sup>

#### UMBILICAL VEIN CATHETERIZATION

##### Indications

The umbilical vein provides convenient access to the central circulation of a neonate for restoration of blood volume and for administration of glucose and drugs. This procedure is often carried out blindly with later radiographic confirmation of correct position. A large fraction of catheters are initially malpositioned, which if unrecognized, can lead to life-threatening complications.<sup>128-132</sup> A change in the configuration of the electrocardiogram (ECG) suggests that a small QRS complex reflects catheter position below the diaphragm; a normal-sized QRS complex with a small P wave was associated with location within the inferior vena cava at the thoracic level; and the appearance of a tall P wave indicated positioning within the right atrium.<sup>128</sup> Umbilical vein catheterization also provides a route for the procedure of exchange transfusion and for measuring central venous pressure.

##### Equipment

- Umbilical artery catheter sizes 3.5 and 5F
- Scalpel and blade
- Fine-curved forceps
- Mosquito hemostats
- Umbilical tape
- Scissors
- Sutures with needle (3-0 silk)
- Antiseptic solutions (povidone-iodine and alcohol)
- Three-way stopcocks
- 10-mL syringe
- Sterile drapes

**E-FIGURE 48-1** **A**, The EZ-IO (Vidacare, Shavano Park, Tex.) is a battery-powered intraosseous needle insertion device that works much like an electric drill. **B**, After appropriate preparation of the skin, at a point 1 to 2 cm below and medial to the tibial tuberosity, the intraosseous needle is directed down and away from the epiphyseal plate. **C**, After successful insertion of the needle and its sheath, the needle is removed, leaving the tip of the metal sheath lodged within the bone marrow cavity. **D**, The intraosseous system is ready for connection and use. **E**, The specially designed intravenous fluid adapter (already primed with intravenous fluid) is then attached to the sheath, providing clear access for drugs, fluid, or blood administration. (Courtesy Charles J. Coté, MD.)

**FIGURE 48-6** **A**, The intraosseous needle may be inserted in either of two locations: at a point 1 to 2 cm below and medial to the tibial tuberosity or at the medial malleolus (arrows). **B** and **C**, The leg is prepared, and the intraosseous needle punctures the skin (note the X mark connecting the tibial tuberosity with the point of needle insertion); the needle is advanced with a twisting motion in a caudal direction. **D**, The stylet is removed, and the selected solution is infused.

- Infusion solution of 10% dextrose in water, with 1 to 2 units of heparin per milliliter at 1 mL/hour
- Calibrated transducer/monitoring system if used for central venous pressure measurement

#### Technique

1. Prepare and drape the umbilicus with sterile technique; cut the cord approximately 1 cm above the umbilicus. The umbilical vein orifice is more patulous and thin walled than the two umbilical arteries (Fig. 48-7).
2. Holding the catheter filled with heparinized solution 2 cm from the tip, gently introduce it into the vein. In some situations, forceps can aid in directing the catheter. Traction of the umbilical stump *caudad* may facilitate the catheter's advancement (see Fig. 48-7). The catheter is passed a distance that approximates the length between the umbilical stump and the right atrium. Blood should freely aspirate into a syringe. Inability to withdraw blood may occur if the tip of the catheter is resting against a vessel wall or if a clot is present within the catheter lumen. *It is important that the tip of the catheter be placed in the proper position, that is, at the junction of the inferior vena cava and right atrium.* A radiograph confirms proper catheter position. Monitoring changes in the configuration of the ECG during insertion may allow for a more accurate placement within the right atrium but is limited to neonates with a

normal tracing.<sup>128</sup> At times, the catheter may fail to traverse the ductus venosus and become wedged in the liver. This position is potentially dangerous because portal necrosis and subsequent cirrhosis may result should hyperosmolar or sclerosing solutions be injected (calcium, sodium bicarbonate, 25% to 50% glucose).<sup>132,133</sup> A low position might be acceptable for short-term use if it is not possible to pass the catheter centrally, but the distance of insertion should be no more than 3 to 4 cm or just until blood is freely aspirated.

3. Suture the catheter in place, cover the insertion site with antibiotic ointment, and tape it to the abdominal wall. The catheter is then connected to a constant-infusion system and should be removed as soon as the indications for its insertion have passed. Complications appear to relate in part to the duration of insertion.<sup>130,132,134</sup>

#### Complications

- Thrombosis of portal or mesenteric veins<sup>132,135</sup>
- Infection (septicemia)<sup>130</sup>
- Endocarditis
- Pulmonary infarction (misplacement of the catheter into the pulmonary vein through a patent foramen ovale)
- Portal cirrhosis and esophageal varices later in life<sup>136-139</sup>
- Cardiac tamponade<sup>140</sup>
- Liver abscess and subcapsular hematoma<sup>129,133</sup>

**FIGURE 48-7** Umbilical vein catheterization. The umbilical vein is thin walled and patulous, whereas umbilical arteries are thicker walled and of smaller diameter. Caudal traction on the umbilical stump may facilitate catheter advancement. The catheter should be advanced through the liver into the central circulation within the low right atrium (RA) before administration of any medications. IVC, Inferior vena cava; RV, right ventricle.

## Arterial Cannulation

### UMBILICAL ARTERY

The umbilical artery in a neonate is a convenient site for monitoring arterial blood pressure, blood gases, and pH. It provides emergency access to an infant's circulation for restoration of blood volume and administration of glucose and drugs.<sup>141-144</sup> Continuous monitoring of arterial O<sub>2</sub> saturation is also possible.<sup>145</sup>

### Equipment

The materials used for cannulation are identical to those described for umbilical venous catheterization. Equipment is required for continuous monitoring of blood pressure. *End-hole rather than side-hole catheters may have a lower incidence of thrombosis or associated ischemic events.*<sup>146</sup>

### Technique

1. Prepare and drape the area with sterile technique; cut the umbilical cord approximately 1 cm above the umbilicus. The two umbilical arteries are identified (Fig. 48-8). The cut vessel ends have thicker walls, are smaller than the vein, and are usually in spasm. The artery is entered in the manner described for umbilical vein catheterization, except that *cephalad* traction is applied to the umbilical stump (see Fig. 48-6, A) to encourage *caudal* direction

of the catheter. The catheter should course through the umbilical artery into the iliohypogastric artery and then into the descending aorta. Proper positioning of the catheter tip is crucial. If the catheter is advanced too far up the aorta, it may pass through the ductus arteriosus and into the pulmonary artery. If this situation is not recognized, blood pressure and blood gas measurements may be misleading. Care should be taken to ensure the placement of the catheter tip in the descending aorta (at T7 to T9). Early reports suggested that a cephalad position, at or above the level of the diaphragm, is easier to maintain but predisposes infants to increased risk of embolization to renal or mesenteric vessels (see Fig. 48-8, B).<sup>147-150</sup> However, positioning just above the bifurcation of the descending aorta, that is, at L3 to L5 (see Fig. 48-8, A) (below the origin of the renal arteries and visceral branches of the aorta) has not been supported by a Cochrane review; a cephalad position is recommended.<sup>151</sup> The caudad position is difficult to maintain, and the catheter tip may slip into one of the iliac arteries, resulting in tissue ischemia (see Fig. 48-8, C).

2. Confirm the position radiographically. Once the catheter is properly positioned, the system is connected to a constant-infusion pump and heparinized fluids (10% dextrose in water or normal saline) are infused. Suture and tape the catheter and apply antibiotic ointment as for umbilical vein catheters. A Cochrane review of the use of heparin suggested that low-dose heparinization of the infusate (0.25 unit/mL) has been shown to reduce the likelihood of catheter occlusion compared with intermittent flushing with heparinized solutions.<sup>152</sup>

### Complications

Using the umbilical artery as a source for blood pressure monitoring and blood gas analysis only and reserving alternative sites for glucose and drug administration may minimize complications. Changes in cerebral blood flow are associated with intraventricular hemorrhage and have been documented to occur with umbilical artery blood sampling; fewer changes in cerebral blood flow occur with low-positioned catheters.<sup>153</sup> The incidence of documented intraventricular hemorrhage appears to have a stronger relation with age than with catheter position and is not associated with the use of low-dose heparin.<sup>152,154</sup> Other complications are as follows:

- Accidental disconnection of stopcocks and catheters can lead to potentially dangerous exsanguination.
- Blood clots may embolize retrograde or, more likely, distally, leading to ischemia or infarction of the infant's gut, kidneys, or lower limbs (see Fig. 48-8, C).<sup>155</sup>
- Vascular spasm is usually transitory and may be resolved by withdrawal of the catheter. Several cases of flaccid paraplegia have been reported resulting from spasm or embolic phenomena.<sup>156</sup>
- The infant is always at risk for sepsis; therefore clear indications for the insertion of this catheter are mandatory. The catheter should be removed at the earliest possible time. A Cochrane review failed to establish a role for prophylactic antibiotics in reducing catheter-related infections.<sup>157</sup>
- Hypertension as a result of renal artery emboli may cause ischemia and infarction of the kidney.<sup>150,158</sup>
- Aortic thrombosis may occur.

**FIGURE 48-8** Umbilical artery catheterization. *Cephalad* traction on the umbilical stump may facilitate catheter advancement. **A**, The catheter tip at L3-4 just above the aortic bifurcation and below the renal arteries is one acceptable location (arrow to yellow line). **B**, An alternative acceptable location is in the descending aorta between T7 to T9 (arrow to yellow line). **C**, An area of necrosis in the left buttock that resulted from a catheter migrating into the internal iliac vessel, occluding one of its branches.

### RADIAL ARTERY

Radial artery cannulation is a reasonable alternative to umbilical artery cannulation in a neonate and is the primary site of arterial cannulation in infants and children in most pediatric institutions. Percutaneous radial artery cannulation is widely practiced, with minimal morbidity.<sup>130,159-164</sup> Failure to cannulate the artery percutaneously may be followed successfully by direct arterial cutdown. Of children with Down syndrome (trisomy 21), 16% to 19% have abnormal radial vessels (both size and location), which can make arterial cannulation particularly difficult; some children with Down syndrome have a single median artery.<sup>166,167</sup> The ulnar artery also has been used as an alternative site for arterial catheterization when attempts at insertion in other locations have been unsuccessful; to ensure adequate perfusion of the hand, this site

should not be used if previous attempts at cannulation of the ipsilateral radial artery had been attempted.<sup>165</sup>

### Indications

Indications for radial artery cannulation include monitoring of arterial blood pressure, arterial blood gases, and pH. The right radial artery is preferred in neonates because it is representative of preductal blood flow.

### Technique

1. Confirm the adequacy of ulnar artery collateral flow by the modified Allen test (Fig. 48-9, *A*). The color of the hand is noted. The hand is passively clenched, and the radial and ulnar arteries are simultaneously compressed at

**FIGURE 48-9** Modified Allen test. **A**, Color and perfusion of the hand are noted. **B**, The hand is first passively clenched, and then both radial and ulnar vessels are occluded. **C**, The ulnar artery is released while the radial artery remains occluded. If flow through the ulnar artery and collateral arch in the hand is adequate, the color and perfusion should rapidly return.

the wrist (see Fig. 48-9, **B**). The ulnar artery is then released, and flushing (reperfusion) of the blanched hand is noted (see Fig. 48-9, **C**). If the entire hand is well perfused while the radial artery remains occluded, indicating adequate collateral flow, catheterization of the radial artery is performed. Note that the sensitivity of the Allen test is approximately 73%, with a specificity of 97%.<sup>168</sup>

2. Secure the hand using an arm board with slight extension of the wrist to avoid excessive median nerve stretching. The fingertips should be left exposed when the hand is taped down so that any peripheral ischemic changes from spasm, clot, or air can be observed.

3. Observe the course of the radial artery in a neonate with the aid of a fiberoptic light source directed toward the lateral side or dorsal aspect of the wrist. Use of a Doppler device may also be of great value.<sup>169,170</sup>
4. Use a 20-gauge needle to make a small skin puncture over the maximal pulsation of the radial artery, usually at the second proximal wrist crease. This step eases passage of the cannula by reducing resistance offered by the skin and prevents a burr from forming on the catheter tip as it passes through the dermis. A method to avoid accidental puncture of the artery is to pull the overlying skin laterally to make the skin nick.
5. Perform cannulation with a 24- or 22-gauge catheter either on direct entry of the artery at an angle of 15 to 20 degrees or on withdrawing the cannula after transfixion of the artery (Fig. 48-10, **A** to **C**). A wire (0.018 inch) may be used as an aid to advance 22-gauge and nontapered 24-gauge catheters.
6. Attach the catheter firmly to a T-connector to permit continuous infusion of isotonic saline (1 unit/mL) at the rate of 1 to 2 mL/hr via a constant-infusion pump (see Fig. 48-10, **D**). The catheter is securely taped in place. A pressure transducer is connected to allow continuous arterial pressure monitoring. To ensure accurate blood pressure measurement, it is essential that the transducer be calibrated to the neonate's or child's heart level, that all air bubbles be removed from the system, and that no more than 3 feet of tubing be used between the neonate or child and the transducer to minimize artifacts caused by the monitoring tubing.<sup>171</sup>
7. Obtain blood samples by clamping off the distal end of the T-connector, cleaning the injection port of the T-connector with povidone-iodine, introducing a 22-gauge needle, and withdrawing 1 mL of blood. A sample of blood is obtained by heparinized syringe, with minimal blood loss and minimal manipulation of the system.<sup>159,172</sup> An alternative is the use of a 3-mL syringe on a three-way stopcock: aspirate 2 to 3 mL, clamp the system, and then take the sample of blood from the T-connector as just described. After sampling, the clamp is released, the aspirated blood is readministered, and continuous infusion is resumed or flush is run into the 3-mL syringe and then the system is gently manually flushed intermittently with the syringe but the flush syringe is changed just once per 24 hours. This method of sampling maintains a closed system with reduced potential for sources of infection. Bolus flushes are avoided, which is an important consideration because bolus flushing has been associated with retrograde blood flow to the brain. Disastrous results may occur if an air bubble or blood clot should accompany a bolus flush.<sup>173-177</sup> *All arterial lines must be clearly identified (red tape) to avoid accidental infusion of hypertonic solutions and sclerosing medications.*

#### Complications

- Infection at the site of the catheter insertion, with possible septicemia.
- Arterial thrombus formation. This depends on the size of catheter inserted, the material of which it is constructed, the technique of insertion, and the duration of cannulation.
- Emboli. A blood clot or air may embolize to the digits, resulting in arteriolar spasm or more serious ischemic necrosis.

**FIGURE 48-10** **A**, After adequate collateral circulation has been ensured, the radial artery is palpated and the appropriate catheter is advanced into the vessel. **B**, After blood return is noted, the catheter is threaded over the needle and into the artery. **C**, Pulsatile backbleeding confirms intraarterial position. **D**, A T-connector with appropriate flush solution is connected; the catheter is aspirated to clear air bubbles and then gently flushed. Antibiotic ointment and benzoin are applied. The injection port should be clearly marked as “arterial” so as to minimize accidental drug administration into the artery. A Luer-Lok connection is preferred to prevent accidental disconnection.

- Disconnection of the catheter from the infusion system. Blood loss may be life-threatening, especially in an infant.
- Ischemia. The radial artery cannula should be withdrawn if ischemic changes develop.
- Vasospasm. Usually transient but requires careful observation.

The method just described is the traditional percutaneous radial artery cannulation at the ventral aspect of the wrist. The radial artery on the dorsal aspect of the wrist within the anatomic snuff box may be used as an alternative site.<sup>178</sup> Once an attempt at cannulation of the radial artery is made, the ipsilateral ulnar artery should not be instrumented to ensure adequate perfusion of the entire hand. Strict indications for inserting radial artery catheters are necessary, and their removal must be considered at the earliest possible time.<sup>147-150</sup>

#### TEMPORAL ARTERY

When the radial artery has been previously cannulated or is inaccessible, the temporal artery may be used.<sup>179</sup> Cerebral infarction has been described as a complication of this technique. It appears to be related to retrograde embolization of air or a blood clot.<sup>180</sup>

An advantage of this sampling site is that it provides preductal blood gas values. However, in our experience, the tortuous course of the artery and the resultant apposition of the distal tip of the

catheter and the arterial wall have caused difficulties in freely drawing blood samples.

#### FEMORAL ARTERY

Femoral catheterization in infants and children includes a greater risk of vascular injury or thrombosis resulting in ischemia<sup>181</sup> and is not recommended if other peripheral sites are available. In situations in which peripheral arterial cannulation is impossible (e.g., in burned patients or children with poor peripheral perfusion), the femoral artery should be used rather than not having any invasive arterial monitoring; the remote possibility of a complication must be balanced versus a greater likelihood of life-threatening complications owing to less than ideal monitoring.<sup>182</sup>

#### Technique

1. Locate the femoral artery by palpation at the groin; this can be confirmed with ultrasonic guidance. Anatomically, it is situated midway between the anterior superior iliac spine and the pubic tubercle.
2. After sterile preparation of the skin, insert a catheter of appropriate size into the femoral artery using the Seldinger technique. The artery is entered at the point of maximal pulsation, approximately 1 cm below the line joining the anterior superior iliac spine and the pubic tubercle.
3. After cannulation, connect the catheter to a continuous-flow system and pressure transducer. The catheter is

sutured in place, the insertion site is covered, and an occlusive dressing is applied. The likelihood of fecal and urinary contamination makes this last step particularly important.

### *Complications*

- Infection
- Emboli of clot and air, leading to ischemic necrosis of the lower limb
- Poor arterial puncture technique, leading to osteoarthritis of the hip joint; severe trauma to the femoral artery has resulted in gangrene of the lower limb, retroperitoneal hemorrhage, and arteriovenous fistula formation.<sup>183-185</sup> A late complication can be partial arrest of bone growth likely as a result of thrombus formation.<sup>186</sup>
- Vasospasm. Usually transient but requires careful observation.

### **DORSALIS PEDIS AND POSTERIOR TIBIAL ARTERY**

The dorsalis pedis and posterior tibial arteries are additional sites for arterial cannulation in children when more desirable locations

are inaccessible. Collateral circulation should always be checked. If cannulation is attempted or performed in one artery in the foot, the ipsilateral artery should not be instrumented, to ensure adequate collateral blood flow.

### *Technique*

The artery is cannulated in the same manner as for the radial artery at a point of maximal pulsation. An understanding of the anatomy of the dorsalis pedis and posterior tibial arteries before attempting this procedure is important. If percutaneous cannulation is impossible, the cutdown technique may be performed. The complications are similar to other arterial line sites of insertion.

# Infectious Disease Considerations for the Operating Room

ANDRE L. JAICHENCO

49

Causative Agent	Measures for Prevention of Infection
Host	Transmission in the Operating Room
Methods of Transmission	Prevention of Airborne
Air Transmission	Pathogen Transmission
Contact Transmission	Standard Precautions
Accidents with Cutting or Piercing Devices	Antimicrobial Prophylaxis
Strategy for Preventing Infection Transmission in Health Care Institutions	

THE TRANSMISSION OF INFECTION depends on the presence of three interconnected elements: a causative agent, a source, and a mode of transmission (Fig. 49-1). Understanding the characteristics of each element provides the practicing anesthesiologist with a methodologic aid to protect susceptible patients and health care workers and to avoid spreading infection.

There has always been concern about the transmission of infectious agents both to the patient from the anesthesiologist as well as from the anesthesiologist to the patient.<sup>1</sup> In addition, there are many sites within the hospital environment where moist or desiccated organic material with the ability to host potentially pathogenic microbes may survive for extended periods of time (Table 49-1)<sup>2,3</sup>; some may even resist the usual cleaning and disinfection techniques.<sup>4</sup> Their transmission from the source to the host may occur via indirect nonapparent mechanisms (e.g., most commonly through hand contact).

## Causative Agent

The infectious vector may be any microorganism capable of causing infection. The pathogenicity is the ability to induce disease, which is characterized by its *virulence* (infection severity, determined by the germ morbidity and mortality rates) and the level of *invasiveness* (capacity to invade tissues). No microorganism is completely avirulent. An organism may have a very low level of virulence, but if the host (i.e., patient or health care provider) is highly susceptible, infection by the organism may cause disease. The risk of infection increases with the *infecting dose* (the number of organisms available to induce disease), the *reservoir* (the site where the organisms reside and multiply), and the *infection source* (the site from where it is transmitted to a susceptible host either directly or indirectly through an intermediary object). The infection source may be a human (e.g., health care providers, children, visitors, housekeeping personnel) with a symptomatic or an asymptomatic infection during the incubation period. The source may also be temporarily or permanently colonized (the most frequently colonized tissues are the skin and digestive and respiratory tracts).

## Host

The presence of a susceptible host is an increasingly important element in the chain of infection that paradoxically results from advances in current medical therapies and technology (e.g., children undergoing organ transplantation, chemotherapy, or extremely premature neonates) and the presence of children with diseases that compromise their immune systems (e.g., acquired immunodeficiency syndrome [AIDS], tuberculosis, malnutrition, or burns). The organism may enter the host through the skin, mucous membranes, lungs, gastrointestinal tract, genitourinary tract, or the bloodstream via intravenous (IV) solutions, after laryngoscopy, or from surgical wounds. Organisms may also infect the individual as a result of work accidents with cutting or piercing devices. The development of infection is influenced by the host defense mechanisms that may be classified as either nonspecific or specific:

- *Nonspecific defense mechanisms* include the skin, mucous membranes, secretions, excretions, enzymes, inflammatory responses, genetic factors, hormonal responses, nutritional status, behavior patterns, and the presence of other diseases.
- *Specific defense mechanisms or immunity* may occur as a result of exposure to an infectious agent (antibody formation) or through placental transfer of antibodies; artificial defenses may be acquired through vaccines, toxoids, or exogenously administered immunoglobulins.

## Methods of Transmission

Microorganisms are transmitted in the hospital environment through a number of different routes; the same microorganism may also be transmitted via more than one route. In the operating room (OR), three main routes of transmission are possible: air, direct, and indirect contact.

### AIR TRANSMISSION

Airborne infections that may infect susceptible hosts are transmitted via two mechanisms: droplets and droplet nuclei.

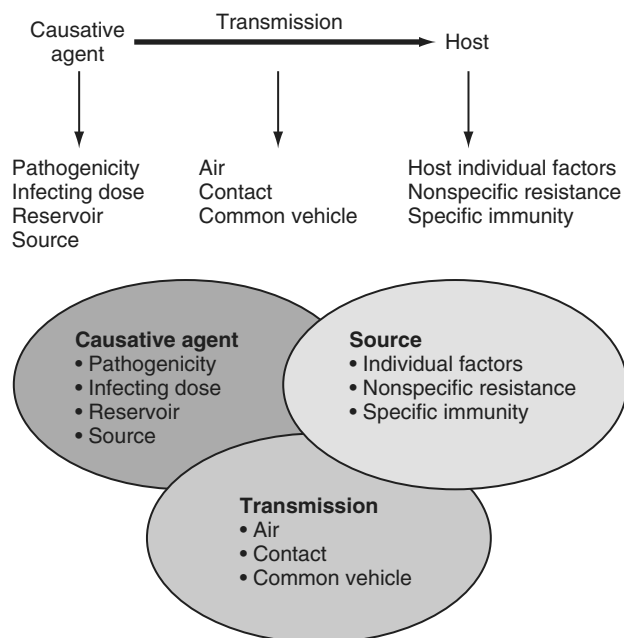

FIGURE 49-1 Elements of the chain of infection.

### Droplets

Droplet contamination is considered a direct transmission of organisms because there is a direct transfer of microorganisms from the colonized or infected person to the host. This generally occurs with particles whose diameters are greater than 5  $\mu\text{m}$  that are expelled from an individual's mouth or nose, mainly during sneezing, coughing, talking or during procedures such as suction, laryngoscopy, and bronchoscopy (Fig. 49-2). Transmission occurs when the microorganism-containing droplets, expelled or shed by the infected person (source), are propelled a short distance (usually not exceeding 60 cm or about 2 feet through the air) and deposited on the host's conjunctivae or oral or nasal mucous membranes. When a person coughs, the exhaled air may reach a speed of up to 965 km/hr (600 mph).<sup>5</sup> However, because the droplets are relatively large, they tend to descend quickly and remain suspended in the air for a very brief period, thus obviating the need for special handling procedures for the OR air. Examples of droplet-borne diseases include influenza, respiratory syncytial virus, severe acute respiratory syndrome (SARS), and others commonly found in droplets from the respiratory tract.

### Droplet Nuclei

Droplet nuclei result from the evaporation of droplets while suspended in the air. Unlike droplets, the nuclei have an outer layer of desiccated organic material and a very small diameter (1 to 5  $\mu\text{m}$ ) and remain suspended in air indefinitely. The microorganisms contained within these nuclei may be spread by air drafts over great distances, depending on the environmental conditions (dry and cold atmosphere, with limited or no exposure to sunlight favoring the spread).<sup>6</sup> In contrast to droplets, which are deposited on mucous membranes, droplet nuclei may enter the susceptible host by inhalation; examples of droplet nuclei-borne diseases include tuberculosis, varicella, and measles.

### CONTACT TRANSMISSION

Direct and indirect contacts are the most significant and frequent methods of hospital infection transmission.

FIGURE 49-2 Droplets expelled during sneezing. (From [www.vaccineinformation.org/flu/photos.asp](http://www.vaccineinformation.org/flu/photos.asp).)

TABLE 49-1 Nosocomial Pathogens and Environmental Contamination

Pathogen	Types of Environmental Contamination	Organism Survival Time
Influenza virus	Aerosolization after cleaning; fomites	24-48 hours on nonporous surfaces
Parainfluenza virus	Clothes and nonporous surfaces	10 hours on nonporous surfaces; 6 hours on clothes
Norovirus	Extensive environmental contamination, possible aerosolization	≤14 days on fecal specimens, ≤12 days on carpets
Hepatitis B virus	Environmental contamination with blood	7 days
Coronavirus-SARS	Possible results from emergency department specimens; super-spreading events	24-72 hours on fomites and fecal specimens
<i>Candida</i>	Fomite contamination	3 days for <i>Candida albicans</i> and 14 days for <i>Candida parapsilosis</i>
<i>Clostridium difficile</i>	Extensive environmental contamination	5 months on hospital floors
<i>Pseudomonas aeruginosa</i>	Drain sink contamination	7 hours on glass slides
<i>Acinetobacter baumannii</i>	Extensive environmental contamination	33 hours on laminated plastic surfaces
MRSA	Extensively contaminated burn units	≤9 weeks after drying; 2 days on laminated plastic surfaces
VRE	Extensive environmental contamination	≤58 days on working surfaces

Modified from Hota B. Contamination, disinfection, and cross-colonization: are hospital surfaces reservoirs for nosocomial infection? Clin Infect Dis 2004;39: 1182-9.

MRSA, Methicillin-resistant *Staphylococcus aureus*; VRE, vancomycin-resistant enterococci.

### Direct Contact

This type of disease transmission involves direct physical contact between two individuals. The physical transfer of microorganisms from an infected or colonized person to a susceptible host may occur from child to health care provider or from health care provider to child during professional practice (e.g., venous cannulation, laryngoscopy, burn care, or suction of secretions). Health care providers working in the OR may be exposed to skin contamination by body fluids. This is an issue of grave concern because of the potential exposure of health care providers to patients with unrecognized infections, especially hepatitis B virus (HBV), hepatitis C virus (HCV), and human immunodeficiency virus (HIV). Hepatitis B is a highly infectious virus that requires a small amount of blood ( $10^{-7}$  to  $10^{-9}$  mL) to transmit the disease. The incidence of skin contamination of anesthesiologists and related personnel by blood and saliva is substantial. One study examined 270 anesthetic procedures during 7 consecutive days. The blood of 35 patients (14%) contaminated the skin of 65 anesthesiologists in 46 incidents. Of these contamination events, 28 (61%) occurred during venous cannulation. Of anesthesiologists who had been contaminated by blood, 5 of 65 (8%) had cuts in the skin of their hands.<sup>7</sup> The importance of this observation is that seroconversion of health care providers has been reported after skin contamination by infected blood from HIV carriers<sup>8</sup> and HBV infection after blood splashing into health care workers' eyes.<sup>9</sup> Scabies, pediculosis, and herpes simplex are among the diseases most frequently transmitted by direct contact.<sup>10-17</sup> These studies explain why meticulous hand washing and routine use of barriers such as gloves and eye protection are such an important part of protecting ourselves even during routine procedures such as starting an IV line or performing laryngoscopy.<sup>18</sup>

### Indirect Contact

Indirect contact involves the transmission of microorganisms from a source (animate or inanimate) to a susceptible host by means of a vehicle (e.g., an intermediary object) contaminated by body fluids. Tables 49-2 and 49-3 provide examples of diseases associated with bodily fluids to which health care workers may be exposed. The vehicle for transmission may be the hands of a health care provider who is not wearing gloves or a provider who fails to wash his or her hands after providing care to a child.<sup>19-22</sup>

**TABLE 49-2 Body Fluids and Diseases They May Transmit**

Body Fluid	Disease Transmitted
Blood	HBV, HIV, HCV, CMV, EBV, NANBH
Seminal fluid	HIV, HBV, CMV
Vaginal discharge	HIV, HBV, CMV
Saliva and sputum	HSV, TB, CMV, respiratory diseases
Cerebrospinal fluid	Encephalopathic organisms (see Table 49-5), HIV
Breast milk	HIV, HBV, CMV
Urine	CMV, EBV, HBV
Feces and intestinal fluid	HAV, gastrointestinal diseases (see Table 49-5)

Modified with permission from Browne RA, Chenesky MA. Infectious diseases and the anaesthetist. Can J Anesth 1988;35:655-65.

CMV, Cytomegalovirus; EBV, Epstein-Barr virus; HAV, hepatitis A virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus; HSV, herpes simplex types I and II; NANBH, non-A, non-B hepatitis; TB, tuberculosis.

**TABLE 49-3 Infectious Agents That May Be Found in the Operating Room**

Viral Hepatitis	Viruses
Hepatitis A virus	Rhinovirus
Hepatitis B virus	Influenza
Hepatitis C virus	Parainfluenza
Delta hepatitis virus	Adenovirus
Non-A, non-B hepatitis	Respiratory syncytial virus
Human immunodeficiency virus	Measles
Cytomegalovirus	Rubella
Epstein-Barr virus	Cytomegalovirus*
Herpes simplex virus	
Respiratory Bacteria	Gastrointestinal
Streptococcus	Viruses: hepatitis A virus, rotavirus, adenovirus, enterovirus
Pneumococcus	Bacteria: <i>Giardia</i> ,*
Meningococcus	<i>Cryptosporidium</i> , <i>Isospora</i> *
Diphtheria	Fungi: <i>Candida</i> *
Mycobacterium*	
Legionella*	
Fungi	Central Nervous System
Candida*	Viruses: Human immunodeficiency virus,*
Nocardia*	herpes simplex virus,*
Cryptococcus*	Epstein-Barr virus*
Parasites	Parasites: <i>Toxoplasma</i> *
Pneumocystis*	Fungi: <i>Cryptococcus</i>

Modified with permission from Browne RA, Chenesky MA. Infectious diseases and the anaesthetist. Can J Anesth 1988;35:655-65.

\*Opportunistic infections in immunocompromised patients, especially those with acquired immunodeficiency.

This type of contact can also come from health care providers who touch (with or without gloves) contaminated monitoring or other patient care devices (e.g., blood pressure cuffs, stethoscopes, electrocardiographic cables, or ventilation systems [respirators, corrugated tubes, Y pieces, valves]), which are used with several children without proper cleaning or disinfection between each use.<sup>23-25</sup>

There are also reports of equipment, fomites, and drugs (mainly propofol) that have resulted in hospital-acquired infections.<sup>14,26-44</sup> However, many of the following situations could potentially cause an infection:

- Up to 40% of the anesthetic equipment in the OR that was in direct or indirect contact with the child (blood pressure cuffs, cables, oximeters, laryngoscopes, monitors, respirator settings, and horizontal and vertical surfaces) may be contaminated with blood because of inadequate cleansing procedures between uses.<sup>2,3,23,45,46</sup>
- In some institutions, up to 8% of the Bain circuits that were reused without previous sterilization were contaminated.<sup>47</sup>
- Contamination of syringe contents has occurred with glass particles during ampule opening, which in turn may compromise the sterility of the contents, presumably because of the passage of bacteria contained on glass particles into the solution.<sup>48-50</sup>
- IV tubing has a significant blood contamination rate as well as contamination by blood from syringes used to inject medications. This can occur with the absence of visible blood reflux in the tubing or syringe. Simply replacing the needle on a syringe that will be reused is ineffective in preventing

cross-infection. The only certain strategy to prevent infection is to not use the same syringe in multiple patients.<sup>51</sup>

- Refilling both glass and plastic syringes several times has been shown to result in contamination of the contents; single use is therefore recommended.<sup>51,52</sup>
- Some drug formulations, especially propofol, can sustain bacterial growth under certain conditions. Thus great care should be given to aseptic technique when transferring drugs from the vial to a syringe and to use the contents of the syringe within 4 hours.<sup>53-57</sup>
- Needles that had been used for spinal or epidural anesthesia were found to be contaminated with coagulase-negative staphylococci (15.7%), yeasts (1.5%), enterococci (0.8%), pneumococci (0.8%), and micrococci (0.8%), suggesting that despite standard skin preparation and cleansing there may be a significant rate of needle contamination.<sup>58</sup> It is unclear whether these skin organisms can be transmitted and cause an infection during administration of a neuraxial block.
- Blood and saliva frequently contaminate the skin of anesthetic personnel during routine anesthetic practice.<sup>7</sup>
- Violations of contemporary guidelines for preventing infections (e.g., hand-washing, wearing gloves, surgical masks, ocular protection, scrubs, or syringe reuse) by anesthesiologists are frequent.<sup>18</sup> Anesthesia staff are aware that they work in a potentially infectious environment, but whether they adopt the protective measures to prevent infections in both themselves and their patients is quite variable (11% to 99%).<sup>23,59-61</sup>

#### ACCIDENTS WITH CUTTING OR PIERCING DEVICES

Percutaneous contamination as a result of a cutting or piercing accident is the most effective means to transmit bloodborne pathogens. Evidence suggests that this is the main route of HIV, HBV, and HCV infection,<sup>62-64</sup> especially if the injury is caused by hollow-bore needles that were used to draw blood or establish IV access.<sup>65,66</sup> Over 20 other bloodborne pathogens have been transmitted by this means, including those causing herpes, malaria, and tuberculosis.<sup>67</sup> The infectious risk after a percutaneous exposure to blood or body fluids from an HIV positive person is approximately 0.3%. Among health care providers lacking protective antibodies, the risk of HBV infection after an injury with a cutting or piercing device contaminated with hepatitis B antigen is approximately 37%; in the case of HCV it is approximately 1.8% (range 0% to 7%). Anesthesia staff lacking HBV protective antibodies are at great risk for acquiring the disease.<sup>68,69</sup> These infection rates underscore the need for the use of “safe” needles and the need to advocate the use of “needleless” systems even though they are significantly more expensive. This also emphasizes the need for meticulous handling and disposal of needles and other sharp instruments as well as the use of special “sharps boxes” designed to minimize accidental needle sticks (e.g., “mail box” type boxes that do not allow the hand to enter the disposal area).<sup>70-85</sup> The U.S. Centers for Disease Control and Prevention (CDC) has estimated that in the United States there are approximately 385,000 cutting and piercing accidents annually among health care providers in hospitals; 25% of these occur in the OR.<sup>67</sup> However, the actual prevalence is thought to be much greater, because many of these events are unreported. The distribution of these accidents among anesthesiologists is shown in Figure 49-3, *A*; the distribution of the items most frequently associated with cutting and piercing injuries in health care providers is shown in Figure 49-3, *B*. Should such an accident occur

**FIGURE 49-3** **A**, Percentage distribution of percutaneous injury to anesthesiologists caused by contaminated cutting or piercing devices. **B**, Percentage distribution of items associated with percutaneous injuries in health care work.

(e.g., needle puncture, exposure to nonintact skin, or mucous membrane exposure) there are now specific recommendations regarding immediate assessment of risk, assessment of the exposure source (chart review, inform the patient that an accident has occurred and ask permission to determine HBV, HCV, and HIV serologic status) and initiation of appropriate treatment of the health care worker. It is advised to obtain as much information regarding the patient as possible, if the patient is known, to obtain a sample of blood from the patient for determination of potential carrier state (Table 49-4), and to report to the health service for immediate institution of prophylaxis and follow-up (Table 49-5), especially for HIV exposure (Tables 49-6 and 49-7).

## Strategy for Preventing Infection Transmission in Health Care Institutions

Institutional administrative measures aimed at developing, implementing, and monitoring specifically designed accident prevention policies and procedures are key factors in reducing and preventing transmission of infectious agents in health care centers. To this end, the center must take the following actions<sup>67,86,87</sup>:

- Include infection control as a major goal in the organizational mission statement and implement safety programs, both for patients and health care workers.
- Provide sufficient administrative and financial support to carry out this mission.

**TABLE 49-4** Recommendations for the Contents of the Occupational Exposure Report

- Date and time of exposure
- Details of the procedure being performed, including where and how the exposure occurred; if related to a sharp device, the type and brand of device; and how and when in the course of handling the device the exposure occurred
- Details of the exposure, including the type and amount of fluid or material and the severity of the exposure; for example, for a percutaneous exposure, depth of injury and whether fluid was injected and for a skin or mucous membrane exposure, the estimated volume of material and the condition of the skin (e.g., chapped, abraded, intact)
- Details about the exposure source (e.g., whether the source material contained hepatitis B virus, hepatitis C virus, or human immunodeficiency virus; if the source is infected with human immunodeficiency virus, the stage of disease, history of antiretroviral therapy, viral load, and antiretroviral resistance information, if known)
- Details about the exposed person (e.g., hepatitis B vaccination and vaccine-response status)
- Details about counseling, postexposure management, and follow-up

Modified with permission from Updated U.S. Public Health Service guidelines for the management of occupational exposures to HBV, HCV, and HIV and recommendations for postexposure prophylaxis. MMWR Recomm Rep 2001;50:1-52. Available at [www.cdc.gov/mmwr/PDF/rr/rr5011.pdf](http://www.cdc.gov/mmwr/PDF/rr/rr5011.pdf)

**TABLE 49-5** Factors to Consider in Assessing the Need for Follow-up of Occupational Exposures

<b>Type of Exposure</b>
Percutaneous injury
Mucous membrane exposure
Nonintact skin exposure
Bites resulting in blood exposure to either person involved
<b>Type and Amount of Fluid/Tissue</b>
Blood
Fluids containing blood
Potentially infectious fluid or tissue (semen; vaginal secretions; and cerebrospinal, synovial, pleural, peritoneal, pericardial, and amniotic fluids)
Direct contact with concentrated virus
<b>Infectious Status of Source</b>
Presence of HBsAg
Presence of HCV antibody
Presence of HIV antibody
<b>Susceptibility of Exposed Person</b>
Hepatitis B vaccine and vaccine response status
HBV, HCV, and HIV immune status

From Updated U.S. Public Health Service guidelines for the management of occupational exposures to HBV, HCV, and HIV and recommendations for postexposure prophylaxis. MMWR Recomm Rep 2001;50:1-52. Available at [www.cdc.gov/mmwr/PDF/rr/rr5011.pdf](http://www.cdc.gov/mmwr/PDF/rr/rr5011.pdf)

HBsAg, Hepatitis B virus surface antigen; HBV, hepatitis B virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus.

**TABLE 49-6** Recommended HIV Postexposure Prophylaxis for Percutaneous Injuries

Exposure Type	INFECTION STATUS OF SOURCE				
	HIV-Positive Class 1*	HIV-Positive Class 2*	Source of Unknown HIV Status <sup>†</sup>	Unknown Source <sup>‡</sup>	HIV-Negative
Less severe <sup>§</sup>	Recommend basic 2-drug PEP	Recommend expanded ≥3-drug PEP	In general, no PEP warranted; however, consider basic 2-drug PEP <sup>  </sup> for source with HIV risk factors <sup>¶</sup>	In general, no PEP warranted; however, consider basic 2-drug PEP <sup>  </sup> in settings in which exposure to HIV-infected persons is likely	No PEP warranted
More severe**	Recommend expanded 3-drug PEP	Recommend expanded ≥3-drug PEP	In general, no PEP warranted; however, consider basic 2-drug PEP <sup>  </sup> for source with HIV risk factors <sup>¶</sup>	In general, no PEP warranted; however, consider basic 2-drug PEP <sup>  </sup> in settings in which exposure to HIV-infected persons is likely	No PEP warranted

Updated U.S. Public Health Service guidelines for the management of occupational exposures to HBV, HCV, and HIV and recommendations for postexposure prophylaxis. MMWR Recomm Rep 2001;50:1-52. Available at [www.cdc.gov/mmwr/PDF/rr/rr5011.pdf](http://www.cdc.gov/mmwr/PDF/rr/rr5011.pdf)

HIV, Human immunodeficiency virus; PEP, postexposure prophylaxis.

\*HIV-positive class 1: asymptomatic HIV infection or known low viral load (e.g., <1500 ribonucleic acid copies/mL). HIV-positive class 2: symptomatic HIV infection, acquired immunodeficiency syndrome, acute seroconversion, or known high viral load. If drug resistance is a concern, obtain expert consultation. Initiation of PEP should be delayed pending expert consultation, and because expert consultation alone cannot substitute for face-to-face counseling, resources should be available to provide immediate evaluation and follow-up care for all exposures.

<sup>†</sup>For example, deceased source person with no samples available for HIV testing.

<sup>‡</sup>For example, a needle from a sharps disposal container.

<sup>§</sup>For example, solid needle or superficial injury.

<sup>||</sup>The recommendation "consider PEP" indicates that PEP is optional; a decision to initiate PEP should be based on a discussion between the exposed person and the treating clinician regarding the risks versus benefits of PEP.

<sup>¶</sup>If PEP is offered and administered and the source is later determined to be HIV-negative, PEP should be discontinued.

\*\*For example, large-bore hollow needle, deep puncture, visible blood on device, or needle used in patient's artery or vein.

**TABLE 49-7** Recommended HIV Postexposure Prophylaxis for Mucous Membrane Exposures and Nonintact Skin\* Exposures

Exposure Type	INFECTION STATUS OF SOURCE				
	HIV-Positive Class 1 <sup>†</sup>	HIV-Positive Class 2 <sup>‡</sup>	Source of Unknown HIV Status <sup>‡</sup>	Unknown Source <sup>§</sup>	HIV-Negative
Small volume <sup>  </sup>	Consider basic 2-drug PEP <sup>¶</sup>	Recommend basic 2-drug PEP	In general, no PEP warranted**	In general, no PEP warranted	No PEP warranted
Large volume <sup>††</sup>	Recommend basic 2-drug PEP	Recommend expanded ≥3-drug PEP	In general, no PEP warranted; however, consider basic 2-drug PEP <sup>¶</sup> for source with HIV risk factors**	In general, no PEP warranted; however, consider basic 2-drug PEP <sup>¶</sup> in settings in which exposure to HIV-infected persons is likely	No PEP warranted

Updated U.S. Public Health Service guidelines for the management of occupational exposures to HBV, HCV, and HIV and recommendations for postexposure prophylaxis. MMWR Recomm Rep 2001;50:1-52. Available at [www.cdc.gov/mmwr/PDF/rr/rr5011.pdf](http://www.cdc.gov/mmwr/PDF/rr/rr5011.pdf)

PEP, Postexposure prophylaxis.

\*For skin exposures, follow-up is indicated only if evidence exists of compromised skin integrity (e.g., dermatitis, abrasion, or open wound).

<sup>†</sup>HIV-positive class 1: asymptomatic HIV infection or known low viral load (e.g., <1500 ribonucleic acid copies/mL). HIV-positive class 2: symptomatic HIV infection, acquired immunodeficiency syndrome, acute seroconversion, or known high viral load. If drug resistance is a concern, obtain expert consultation. Initiation of PEP should be delayed pending expert consultation, and because expert consultation alone cannot substitute for face-to-face counseling, resources should be available to provide immediate evaluation and follow-up care for all exposures.

<sup>‡</sup>For example, deceased source person with no samples available for HIV testing.

<sup>§</sup>For example, splash from inappropriately disposed blood.

<sup>||</sup>For example, a few drops.

<sup>¶</sup>The recommendation "consider PEP" indicates that PEP is optional; a decision to initiate PEP should be based on a discussion between the exposed person and the treating clinician regarding the risks versus benefits of PEP.

\*\*If PEP is offered and administered and the source is later determined to be HIV-negative, PEP should be discontinued.

<sup>††</sup>For example, a major blood splash.

- Provide sufficient administrative and financial support for the microbiology laboratory and implement an infection surveillance plan, especially for postsurgical infections.
- Establish a multi-discipline cross-functional team (e.g., a team manager, an epidemiologist, a representative from industrial health, and a person trained in quality control) to identify health and safety issues within the institution, analyze trends, assess outcomes, implement interventions, and make recommendations to other members of the organization.
- Provide sufficient administrative and financial support to develop and implement education programs for health care providers, patients, and their families. One positive example of such education is that anesthesiologists who have read the CDC's Universal Precaution Guidelines for the Prevention of Occupational Transmission of HIV and HBV develop better hygienic practices.<sup>59</sup>
- Provide health care workers with hepatitis B vaccine and document that an appropriate immunologic response was achieved. Provide hepatitis B immune globulin (HBIG) for those exposed who do not have established immunity.<sup>4</sup>
- Provide a health care service for employees for counseling and postexposure prophylaxis should an exposure to HIV occur.<sup>88</sup>
- Provide regular surveillance of health care workers to determine established immunity to infectious diseases such as tuberculosis, measles, mumps, rubella, and chickenpox. Lack of immunity may require immunization; several studies have demonstrated the cost-effectiveness of immunization (for prevention of disease) versus the cost of replacement of health care workers who have become infected.<sup>63,89-94</sup>

## Measures for Prevention of Infection Transmission in the Operating Room

### PREVENTION OF AIRBORNE PATHOGEN TRANSMISSION

Airborne pathogens may be transmitted through the OR heating, ventilation, and air conditioning systems. Thus it is vital to have

**TABLE 49-8** Ventilation System Specifications for the Operating Room

- Minimize the circulation of people during surgeries. It has been proved that the level of microbes in the operating room air is directly proportional to the number of people moving inside the room.
- Maintain humidity under 68% and temperature control to prevent environmental conditions that favor the development of germs.
- Maintain positive pressure compared with corridors and surrounding areas to prevent microorganisms from entering the operating room.
- Provide at least 15 air changes per hour in the operating room, 20% of which should be fresh air. Air should be recirculated through a high-efficiency particulate air (HEPA) filter.
- Air should be introduced at ceiling level and disposed of at ground level.

From Guidelines for environmental infection control in healthcare facilities: recommendations of CDC and the Healthcare Infection Control Practices Advisory Committee (HICPAC). 2003. <http://www.cdc.gov/mmwr/preview/mmwrhtml/rr5210a1.htm>

in place proper systems to (1) remove contaminated air, (2) facilitate air management requirements to protect susceptible health care providers and children against hospital-related airborne pathogens, and (3) minimize the risk of airborne pathogens being transmitted by children. Table 49-8 shows the 2003 HICPAC's (Healthcare Infection Control Practices Advisory Committee) and CDC's general recommendations for ventilation system specifications for the OR.<sup>95</sup> Children with tuberculosis require special consideration because of the high risk of occupational transmission of *Mycobacterium tuberculosis*,<sup>96,97</sup> especially after the emergence of multidrug-resistant strains (Table 49-9). An easy preventive measure is to screen all children before coming to the OR to determine recent exposure to infectious disease such as measles, mumps, rubella, and chickenpox because these infections can pose a significant risk to health care providers and patients, especially those who are immunocompromised.<sup>63,93</sup> Another potential source for airborne spread of pathogens is through the anesthesia circuit; this may be reduced

**TABLE 49-9** Summary of Recommended Tuberculosis Control Guidelines

Early diagnosis  
 Availability and access to diagnostic tests  
 Improved tests and reporting of results  
 Source controls  
 Containment of infectious nuclei from coughs and sneezes  
 Patient isolation  
 Personal respirators  
 Engineering controls

\*Negative-pressure rooms are to prevent the escape of contaminated air to the outside.

by the use of circuit filters. However, at present there are no regulatory requirements to use such devices, and performance characteristics vary widely.<sup>24,25,98-102</sup>

## STANDARD PRECAUTIONS

*Standard precautions*<sup>103</sup> assume that any person or patient is potentially infected or colonized by microorganisms that could be transmitted and cause an infectious process. Standard precautions must be implemented with all patients and include:

- *Universal precautions—blood and body fluid precautions*, developed to reduce bloodborne pathogen transmission
- *Body substance isolation*, designed to reduce the risk of pathogen transmission by moist body substances

Standard precautions are used to reduce the transmission of all infectious agents from one person to another, thus protecting health care providers and children against exposure to the most common microorganisms. Standard precautions are implemented for any contact with blood and body fluids, secretions, and excretions (except sweat), whether or not they contain visible blood, as well as for any contact with nonintact skin, mucous membranes, and intact skin that is visibly soiled with blood and/or body fluids. Summaries of standard precautions, droplet precautions, airborne precautions, and contact precautions are available on line.<sup>87,104-107</sup>

## Hand Washing

Hand washing is considered the most important and cost-effective individual intervention in the prevention of hospital-acquired infections in children and health care providers.<sup>108</sup> Its significance in medical practice had not been universally accepted, despite the pioneering work by Oliver Wendell Holmes<sup>109</sup> (1843) and Ignaz Semmelweis<sup>110</sup> (1846), who separately recognized that the contaminated hands of physicians performing autopsies were the vectors responsible for the spread of puerperal fever caused by streptococci, and how by washing their hands before delivering a baby, they could reduce the risk of infectious transmission and maternal mortality, the latter by 90%! Unfortunately, the

**TABLE 49-10** Indications for Hand Washing and Antisepsis

*Hand washing* is defined as a process for removal of soil and transient microorganisms from the hands. Hands should be washed with soap and water or disinfected.

1. When hands are visibly dirty or contaminated with proteinaceous material or are visibly soiled with blood or other body fluids, wash hands with either a non-antimicrobial soap and water or with an antimicrobial soap and water.
2. If hands are not visibly soiled, use an alcohol-based hand rub for routinely decontaminating hands in all other clinical situations described in items 3 to 10. Alternatively, wash hands with an antimicrobial soap and water in all clinical situations described in items 3 to 10.
3. Decontaminate hands before having direct contact with patients.
4. Decontaminate hands before donning sterile gloves when inserting a central intravascular catheter.
5. Decontaminate hands before inserting indwelling urinary catheters, peripheral vascular catheters, or other invasive devices that do not require a surgical procedure.
6. Decontaminate hands after contact with a patient's intact skin (e.g., when taking a pulse or blood pressure and lifting a patient).
7. Decontaminate hands after contact with body fluids or excretions, mucous membranes, nonintact skin, and wound dressings if hands are not visibly soiled.
8. Decontaminate hands if moving from a contaminated body site to a clean body site during patient care. Decontaminate hands after contact with inanimate objects (including medical equipment) in the immediate vicinity of the patient.
9. Decontaminate hands after removing gloves.
10. Before eating and after using a rest room, wash hands with a non-antimicrobial soap and water or with an antimicrobial soap and water.
11. Antimicrobial agent-impregnated wipes (i.e., towelettes) may be considered as an alternative to washing hands with non-antimicrobial soap and water. Because they are not as effective as alcohol-based hand rubs or washing hands with an antimicrobial soap and water for reducing bacterial counts on the hands of health care workers, they are not a substitute for using an alcohol-based hand rub or antimicrobial soap.
12. Wash hands with non-antimicrobial soap and water or with antimicrobial soap and water if exposure to *Bacillus anthracis* is suspected or proven. The physical action of washing and rinsing hands under such circumstances is recommended because alcohols, chlorhexidine, iodophors, and other antiseptic agents have poor activity against spores.

Modified from Boyce JM, Pittet D. Guideline for hand hygiene in health-care settings. Recommendations of the Healthcare Infection Control Practices Advisory Committee and the HIPAC/SHEA/APIC/IDSA Hand Hygiene Task Force. *Am J Infect Control* 2002;30:51-46.

scientific basis for hand washing was not established until the introduction of the germ theory of disease by Louis Pasteur<sup>111</sup> and the discovery of the microorganism that caused anthrax (*Bacillus anthracis*) by Robert Koch<sup>112</sup> in the late 19th century. More than one-and-a-half centuries later, and with strong evidence that health care providers are a leading source of hospital acquired infections,<sup>19,20,113</sup> health care providers' compliance with hand hygiene protocols in the hospital environment is generally poor (5%-48%) and difficult to change,<sup>114-120</sup> especially in intensive care areas, ORs, and postanesthesia care units. The risk of pathogen transmission via the hands is proportional to the power of the number of times a child is touched.<sup>121</sup> Table 49-10 presents

a summary of the indications for hand washing and antisepsis. Compared with soap and water, alcohol-based hand rubs are more effective in reducing microbial colonization of hands.<sup>122,123</sup> The use of alcohol-based hand rubs prompted some authors to change the term *hand washing* to *hand hygiene*. An important addition to the 2002 CDC Hand Washing Guide<sup>120</sup> is to use alcohol-based hand rubs, because they work more rapidly (10 to 20 seconds compared with 90 to 120 seconds for hand washing) and can be used while ambulating. These advantages preclude the usual objections of health care workers to hand washing that include a lack of time, absence of sinks, and skin damage.<sup>18,124</sup> Furthermore, the scarcity of water in developing countries no longer needs to be a constraint against hand hygiene.

After hand washing, it is very important to dry the hands properly with appropriate paper towels, hot air flow, or both, because the level of pathogen transmission from a health care worker's hands to a patient is greatly increased if the hands are wet.<sup>125</sup> Transmission may also occur from patients' wet sites, such as groins or armpits, or when a health care worker gets his or her hands wet when opening parenteral solutions. It is critical for health institutions to establish written procedures and protocols to support adherence to the recommended hand hygiene practices.

### Gloves

Wearing clean or sterile gloves while caring for children is an effective means of reducing hospital-acquired infections. Gloves remain a supplementary barrier to infection that should not replace proper hand hygiene. Gloves protect patients by reducing health care provider hand contamination and the subsequent transmission of pathogens to other children, provided the gloves are changed after providing care to each child. Additionally, when the use of gloves is combined with CDC standard precautions, they protect the health care provider against exposure to blood-borne infections or infections transmitted by any other body fluids, such as excretions, secretions (except sweat), mucous membranes, and nonintact skin.

Recommendations for the use of gloves include<sup>126-128</sup>:

- Wear gloves in case of contact with blood or any other potentially infecting body fluid such as excretions, secretions (except sweat), mucous membranes, and nonintact skin.
- Remove the gloves immediately after providing care to a child. Staff should not wear the same pair of gloves to take care of more than one child, nor should they touch the surfaces of any equipment, monitoring devices, or even light switches. Contaminated gloves can pass blood or other body fluids to working surfaces and are vectors for hepatitis transmission.<sup>62</sup>
- Change gloves when taking care of a child if you must move from a contaminated to a clean body site.
- Apply hand hygiene measures immediately after removing the gloves because, despite the use of gloves, hands may get contaminated through small (microscopic) holes in the gloves.<sup>113,129,130</sup> Microbial contamination of hands and possible infection transmission have been reported even with the use of gloves.<sup>131</sup>
- Remove the gloves by using an appropriate technique (so as not to contaminate your hands with the contaminated surface of the gloves).
- Alcohol-based hand rub dispensers and clean glove boxes (at least two sizes) should be in place near every patient care site (e.g., on top of every anesthesia cart, medication cart, or in the nursing station).

- Disposable gloves should not be washed, re-sterilized, or disinfected. If gloves are reused, appropriate reprocessing methods should be in place to ensure the physical integrity of the gloves and their full decontamination.
- Sterile gloves are much more expensive than clean, disposable gloves and should be used only for certain procedures, such as when hands are in contact with normally sterile body areas or when inserting intravascular or urinary catheters. Clean gloves should be used during any other procedure, including wound dressing.
- Latex-free gloves should be worn when caring for children at risk for latex allergy.

### ANTIMICROBIAL PROPHYLAXIS

Surgical antimicrobial prophylaxis is an essential tool to reduce the risk of postoperative infections, and the anesthesia team plays a central role in ensuring the proper timing of drug administration.<sup>132,133</sup> The aim of the perioperative administration of antibiotics is to obtain plasma and tissue drug concentrations exceeding the minimal inhibitory concentration of those organisms most likely to cause an infection. This will reduce the microbial load of the intraoperative contamination to a level not exceeding the host defenses; it is not the intent to cover all possible pathogens, because this can lead to the selection of drug-resistant bacteria.

#### Selection of the Antimicrobial Agent

Several antimicrobial prophylaxis guidelines have been published (Table 49-11). For most surgical procedures that do not involve chronically colonized organs, the most common pathogens are the skin flora, *Streptococcus* and *Staphylococcus*. A first-generation cephalosporin (i.e., cefazolin) can provide cost-effective coverage for these organisms. Surgical procedures that involve contamination from the bowel require antibiotic treatment against gram-negative and anaerobic pathogens. For these procedures, cefoxitin, cefotetan, or a second-generation cephalosporin is appropriate.<sup>134</sup> The selection of antibiotics requires consideration of resistance patterns as determined by local microbiology or health center infectious disease departments. The newer-generation broad-spectrum antibiotics should not be used for routine antibiotic prophylaxis but should be reserved for the treatment of resistant organisms. Moreover, the dose of antibiotic selected should be based on the child's weight or body mass index; administration should be repeated intraoperatively if surgery exceeds more than two half-lives after the first antibiotic administration (see Table 49-11), if the duration of surgery exceeds 4 to 8 hours, if blood loss is extreme, or if the drug has a particularly short half-life (e.g., penicillin or cefoxitin) to ensure appropriate tissue concentrations of antibiotic until wound closure.<sup>135</sup>

#### The Timing of Antibiotic Prophylaxis

A key element in the prevention of surgical site infection is the timely administration of prophylactic antibiotics. For most surgical procedures, a single prophylactic dose of antibiotics should be administered 30 to 60 minutes before the skin incision. This should provide appropriate plasma concentrations of the antibiotic.<sup>136,137</sup> However, in the case of children, IV access is often established after induction of anesthesia. With a brief time interval between establishing IV access and skin incision, it is important to administer the antibiotics as soon as possible after IV access is established and before surgical incision. If vancomycin must be used for prophylaxis, it should be infused slowly over 60 minutes (to minimize the risk of severe hypotension, ["red

**TABLE 49-11** Suggested Initial Dose and Time to Redosing for Antimicrobials Commonly Used for Surgical Prophylaxis

Antimicrobial	Half-Life Normal Renal Function (hours)	Half-Life End-Stage Renal Disease (hours)	Recommended Infusion Time (minutes)	Standard Intravenous Dose (g)	Weight-Based Dose Recommendation* (mg)	Recommended Dosing Interval <sup>†</sup> (hours)

Vancomycin	4-6	44.1-406.4 (CLcr <10 mL/min)	1 g: ≥60 minutes (use extended infusion times if dose <1 g)	1.0	10-15 mg/kg (adult)	6-12

CLcr, Creatinine clearance; NA, not applicable.

\*Weight-based doses are primarily from published pediatric recommendations.

<sup>†</sup>For procedures of long duration, antimicrobials should be redosed at intervals of 1 to 2 times the half-life of the drug. The intervals in the table were calculated for patients with normal renal function.

<sup>‡</sup>Dose injected directly into vein or running intravenous fluids.

<sup>§</sup>Intermittent intravenous infusion.

<sup>||</sup>In patients with a serum creatinine value of 5 to 9 mg/dL.

<sup>¶</sup>The half-life of clindamycin is the same or slightly increased in patients with end-stage renal disease compared with patients with normal renal function.

<sup>\*</sup>If the patient's weight is 30% above the ideal body weight, dosing weight can be determined as follows: Dosing weight = ideal body weight + 0.4 (total body weight – ideal body weight).

<sup>\*\*</sup>Gentamicin may also be given as a single daily dose 5 to 8 mg/kg. Dose is dependent on postmenstrual age, renal function, and subsequent therapeutic drug monitoring.

man" syndrome]) beginning within 2 hours of skin incision. If a tourniquet is required, the full antibiotic dose should be administered before the tourniquet is pressurized.<sup>138</sup> Postsurgical prophylactic antibiotics are not necessary for most procedures and should generally be stopped within 24 hours after the surgical procedure.<sup>138</sup>

### Allergy to $\beta$ -Lactams

Several studies have shown that the true incidence of allergy to antibiotics is less than that reflected in medical charts.<sup>139</sup> For surgical procedures where cephalosporins are the prophylaxis of choice, alternative antibiotics should be administered to those children at risk of anaphylaxis to  $\beta$ -lactams, based on their history or diagnostic tests (e.g., skin testing). However, the incidence of severe allergic reactions to first-generation cephalosporins in children with reported allergy to penicillin is rare (but not zero)<sup>140,141</sup>; furthermore, skin testing does not reliably predict the likelihood of adverse reactions to cephalosporins in those with reported

allergy to penicillin.<sup>142-144</sup> There is no evidence of any risk of cross-reactivity between penicillin and second- and third-generation cephalosporins. For the most part, "allergies" to oral antibiotics that appear on children's charts (rash, vomiting, gastrointestinal disturbances) are most likely reactions to the additives in the antibiotic formulation, including food dyes, fillers, and other compounds, or a manifestation of the underlying infection. IV administration of small test doses of the pure antibiotics in a fully monitored (and anesthetized) child with a so-called allergy will determine whether the child is at risk for an allergic reaction to the antibiotic. In the case of surgical procedures where antibiotic prophylaxis is mainly directed at gram-positive cocci, children who are truly allergic to  $\beta$ -lactams (cephalosporins) should receive either vancomycin or clindamycin.<sup>134</sup>

### Indications for Prophylactic Antibiotics

Surgical wounds are classified in four categories (Table 49-12). The use of antibiotic prophylaxis for postoperative infections is

**TABLE 49-12 Wound Classification System**

Wound Category	Description
Class I/clean	Uninfected wound with no inflammation and the respiratory, alimentary, genital, or uninfected urinary tract is not entered. Clean wounds primarily are closed and drained, when necessary, with closed drainage. Operative wounds after blunt trauma may be included in this category if they meet criteria.
Class II/clean contaminated	Operative wound in which the respiratory, alimentary, genital, or urinary tract is entered under controlled conditions and without unusual contamination. Specifically, operations involving the biliary tract, appendix, vagina, and oropharynx are included in the category, provided no evidence of infection or major break in technique is encountered.
Class III/contaminated	Open, fresh, accidental wounds; operations with major breaks in sterile technique (e.g., open cardiac massage) or gross spillage from the gastrointestinal tract; and incisions in which acute, nonpurulent inflammation is encountered
Class IV/dirty-infected	Old traumatic wounds with retained devitalized tissue and those that involve existing clinical infection or perforated viscera, suggesting that the organisms causing postoperative infection were present in the operative field before operation.

From Neville HL, Lally KP. Pediatric surgical wound infections. *Semin Pediatr Infect Dis* 2001;12:124-9.

well established for clean-contaminated procedures. Within the clean category, prophylaxis has been traditionally reserved for surgical procedures involving a foreign body implantation or for any surgical procedure where a surgical site infection would be catastrophic (e.g., cardiac surgery or neurosurgical procedures). However, there is evidence that postoperative infections resulting from procedures not involving prosthetic elements are underreported; estimates show that over 50% of all complications occur after the patient is discharged and are thus unrecognized by the surgical team. Therefore, antibiotic prophylaxis is also recommended for certain procedures, such as herniorrhaphy.<sup>145,146</sup> The direct and indirect costs of these complications may not affect the hospital budget; however, they represent a substantial cost for the community at large. In the case of contaminated or dirty procedures, bacterial contamination or infection is established before the procedure begins. Accordingly, the perioperative

administration of antibiotics is a therapeutic, not a prophylactic, measure. The use of antibiotics in children has implications not only for the response to the current treatment, but also to future treatments. Thus all medical professionals are jointly responsible for the rational use of antibiotics.

Protocols, although effective, require continuous feedback on their acceptance and surgical-site infection results.<sup>147</sup> No surgical protocol can replace the judgment of the medical professional; clinical reasoning must be tailored to the individual circumstances. Finally, children with congenital heart disease and a subgroup of those with repaired congenital heart disease may require bacterial endocarditis prophylaxis (see also Tables 14-2 and 14-3).<sup>148</sup>

## ANNOTATED REFERENCES

- Hota B. Contamination, disinfection, and cross-colonization: are hospital surfaces reservoirs for nosocomial infection? *Clin Infect Dis* 2004;39:1182-9.
- Although much about the spread of nosocomial infection remains unknown, several facts have been established by existing data: (1) inanimate environmental surfaces can become durably contaminated after exposure to colonized patients; (2) although an organism may be endemic within an institution, specific isolates may predominate in the inanimate environment (e.g., vancomycin-resistant enterococci); and (3) contaminated rooms may be a risk factor for the acquisition of nosocomial pathogens by unaffected patients. This author elaborates on the need for improved infection control measures for preventing nosocomial infections.*
- Rizzo M. Striving to eliminate catheter-related bloodstream infections: a literature review of evidence-based strategies. *Semin Anesth Perioper Med Pain* 2005;24:214-25.
- This paper reviews and emphasizes the need for preventive measures that could help to avoid or reduce most nosocomial catheter-related infections. The use of evidence-based standardized protocols will result in "best practices" and markedly reduce such infections.*
- Sagoe-Moses CH, Pearson R, Perry J, Jagger J. Risks to health care workers in developing countries. *N Engl J Med* 2001;345:538-41.
- Protecting health care workers in developing countries from exposure to bloodborne pathogens will involve some cost. Health care workers are a crucial resource in the health care systems of developing nations. In many countries, including those in sub-Saharan Africa, workers are at high risk for preventable, life-threatening occupational infections. This paper expands on the need for improved support of health care workers throughout the world with appropriate supplies of gloves, barriers, sharps disposal, and the need for accident education programs.*

## Conclusions

THE POPULATION IN THE DEVELOPING WORLD CONTINUES TO GROW while world demographics trend toward an aging population in an urbanized, developed world. Children, many orphaned by the ravages of war, human immunodeficiency virus (HIV) infection,<sup>1</sup> and famine, constitute more than one half of the population in many of these countries.<sup>2</sup> Eighty-five percent of them will require surgery before their 15th birthday.<sup>3</sup> The burden of surgical disease requires safe anesthesia,<sup>4,5</sup> but provision of safe pediatric anesthesia<sup>6</sup> and intensive care<sup>7-9</sup> in the developing world presents serious challenges.<sup>10-12</sup> Poverty, poor educational standards, and limited health resources characterize the developing world.<sup>5,6,13</sup> Debt repayment, housing, education, social service, and health care provision are near-impossible tasks for most governments of these countries. Of the world's poorest countries, 70% are in sub-Saharan Africa, and they are ravaged by HIV, malaria, and tuberculosis and are desperately short of health care providers.<sup>4,5</sup>

Pediatric anesthesia in these low-income countries has not kept pace with the advances made in the developed countries.<sup>4</sup> International standards for the safe practice of anesthesia, adopted by the World Federation of Societies of Anaesthesiologists (WFSA) in 1992, are seldom met in developing countries.<sup>14-16</sup> In one survey, only 13% of anesthesiologists were able to provide safe anesthesia for children.<sup>3</sup> Consequently, perioperative mortality and morbidity rates in these countries are high by developed world standards<sup>5,17-21</sup> although local expectations are commensurate with the facilities and quality of the available care.

This chapter outlines some of the many challenges that anesthesiologists face when providing anesthesia for children in a developing country. Different countries have different problems requiring different solutions. The problems faced in many tropical countries,<sup>8,13</sup> for example, are completely different from those on a tropical island in the South Pacific<sup>22</sup> or West Indies,<sup>23,24</sup> at altitude in Nepal<sup>25</sup> and Afghanistan,<sup>26</sup> or in the humidity of sub-Saharan Africa.<sup>2,3,19,21,27-30</sup> These diverse situations necessitate that generalizations be made. The main differences among the sites, however, are related to the personnel, the spectrum and nature of the pathology, the facilities and equipment available, and a tenuous supply of cheap, generic, and perhaps outmoded drugs.<sup>10,31</sup>

## The Child

Children of the developing world are for the most part victims of circumstance; natural disasters, war, social unrest,<sup>32</sup> and economic crises. For many, medical care or timely access to care is a remote or nonexistent possibility.<sup>10,25,30,33,34</sup> Fear, poor understanding, and poor education often result in delayed presentation. Frequently, prior visits to well-meaning traditional healers expose the child to additional risks caused by potions that may be hepatic-renal toxic or enemas that may perforate the bowel.<sup>35</sup> Further delays occur when patients have to undertake long journeys to the hospital, and if the initial diagnosis is wrong, tertiary referral is made only when complications arise (Fig. 50-1).<sup>10,30,36,37</sup>

A typical example is acute appendicitis, a relatively uncommon condition in the developing world, where many other causes for a change in bowel habit are initially suspected.<sup>37,38</sup> Most patients present for surgery with generalized peritonitis, and perforation is common. In the developing world, the prospect of providing anesthesia for a toxic, acidotic, and dehydrated child is daunting.

Another example is infantile hypertrophic pyloric stenosis, also uncommon in developing countries, where symptoms other than the classic triad of bile-free vomiting, visible peristalsis, and a palpable tumor are more likely. The unsuspecting anesthesiologist, who may have no access to a laboratory<sup>2,13-15</sup> and is limited in the choice of fluid for resuscitation, would be challenged to manage the extreme metabolic derangements in these infants.

Superstition plays a role in compounding the anesthesia risk. For example, rural Vietnamese believe that it is not good to die with an empty stomach. Parents consider surgery to be an enormous risk so they feed their children beforehand. In these circumstances, passage of a nasogastric tube before induction is routine, although it is quite likely that the stomach cannot be completely emptied of solids despite the tube.<sup>24</sup>

Perinatal mortality in some parts of the developing world is ten times greater than those in developed countries.<sup>5,39-41</sup> The common denominators are early childbearing, poor maternal health, and lack of appropriate and quality medical services. Although lifesaving practices for most infants have been known

**FIGURE 50-1** Peripheral gangrene of the hand. Severe dehydration in this infant was caused by severe gastroenteritis. Dehydration associated with delayed presentation, hypernatremia, herbal medications, and pneumonia are common contributors to this disastrous outcome.

for decades, one third of pregnant women still have no access to medical services during pregnancy, and almost 50% do not have access to medical services for childbirth.<sup>30,34,41</sup> Most parturients give birth at home or in rural health centers,<sup>34</sup> where basic neonatal resuscitation equipment is deficient or nonexistent.<sup>30</sup> Those who require surgery may need to be transferred, but specialized transport teams rarely exist.

In some hospitals, neonates are not candidates for surgery because “they always die,”<sup>42</sup> whereas in others, they undergo surgery without anesthesia<sup>23</sup> because “it’s safer” and because some still believe that neonates do not feel pain. When surgery is performed on neonates, there are additional challenges, particularly in emergency situations.<sup>23</sup> Appropriately sized equipment is lacking,<sup>36</sup> and it may be extremely difficult to maintain normothermia even in relatively warm climates without improvisation. Regional anesthesia can play a significant role in neonatal anesthesia<sup>30,36,43</sup> and in some centers may be the only choice for anesthesia.<sup>34,44</sup> Apart from providing analgesia without respiratory depression, the need for postoperative ventilatory support for conditions such as esophageal atresia,<sup>45</sup> congenital diaphragmatic hernia,<sup>46</sup> and abdominal wall defects is reduced by continuous epidural analgesia (Fig. 50-2).

Regrettably, even neonates who have skillful anesthesia and surgery may die because of inadequate postoperative care.<sup>44</sup> Overwhelming infection, sepsis, respiratory insufficiency, and surgical complications are the main causes of morbidity and mortality.<sup>30,34</sup> The development of highly specialized neonatal anesthesia and surgical services,<sup>7,40-42</sup> essential for a good outcome after neonatal surgery,<sup>30,34,36</sup> is a low priority.

Although the burden of disease is dominated by infections and malnutrition,<sup>4,5</sup> pediatric trauma has a low level of advocacy and is given scant attention.<sup>30,36,47</sup> Socioeconomic advances in some countries have introduced a new danger in the form of faster, more powerful vehicles without the necessary maintenance culture or road discipline. Road traffic accidents are inevitable, and effective systems to handle the polytrauma victims that result are hard to find.<sup>36</sup>

Road traffic accidents are common. Even simple bone fractures have disastrous outcomes. Inappropriate management by

**FIGURE 50-2** Gastroschisis is a major problem in the developing world. The outcome is poor because of a paucity of facilities for neonates. This defect was not diagnosed antenatally, and the patient presented late for closure, which proved difficult. Ventilatory support was not available, and a silo was fashioned. Unfortunately, the child died of overwhelming sepsis a week later.

traditional bonesetters frequently results in compartment syndromes or gangrene.<sup>47</sup> Trauma prevention strategies are given low priority despite the acknowledged impact trauma has on the economy of any country. Many developing countries are at war, and this has led to massive trauma and injuries to children who are participants in the fighting or innocent bystanders.

### CHILDREN AND WAR

Children may be victims of all aspects of violence. They face an intense struggle for survival as a consequence of displacement, separation from or loss of parents, poverty, hunger, and disease. They are vulnerable to the abuse of abandonment, abduction, rape, and forced soldiering. An estimated 300,000 children are used as child soldiers in more than 30 countries.<sup>48</sup> Many sustain physical injuries and permanent disabilities, and a large number acquire sexually transmitted disease, including HIV infection and acquired immunodeficiency syndrome (AIDS). These HIV-positive child soldiers then become vectors in communities where they are deployed.<sup>49</sup>

For many of these children, acts of violence become their form of normality, and the former victims become the perpetrators.<sup>32</sup> Survivors are subjected to the total collapse of economic, health, social, and educational infrastructures. Lost and abandoned children sleep on the streets and are forced to beg for food while trying to find their families. Many become child laborers or turn to crime or prostitution for survival.<sup>50</sup>

Children in war-torn areas sustain bullet, machete, or shrapnel wounds, and others are burned. They often sustain mutilating injuries (Figs. 50-3 and 50-4) that are not commonly seen in civilians.<sup>51</sup> Land mines are responsible for killing or maiming an estimated 12,000 civilians per annum. In Angola, a country with

**FIGURE 50-3** Facial burn injuries are common in the developing world, and these children may require multiple episodes of anesthesia. **A**, Flame burns of the face are invariably associated with inhalation injuries that may necessitate ventilatory support in intensive care facilities, which are not readily available. **B**, Pain management and pain assessment are challenging. The pained expression on this child's face is one of fear (and possible indignation about having the photograph taken) rather than actual pain.

the highest rate of amputees in the world, there were an estimated 5.5 land mines for every child. Continuing land mine explosions remain a legacy of this conflict.<sup>51</sup> These blast injuries leave children without feet or lower limbs and with genital injuries, blindness, and deafness—a pattern of injury that has become a post-civil war syndrome encountered by surgeons worldwide.<sup>51</sup> Although the war in Angola is essentially over, the cost of mine removal is beyond the means of local governments. Ironically, artificial limb manufacture has become a developing industry.<sup>51</sup> Tragedies such as these are likely to be repeated in the ongoing conflicts in Afghanistan, Iraq, and Somalia.

**FIGURE 50-4** Children fare poorly in war. This 8-year-boy bit a detonator he found while playing. Endotracheal intubation proved a major challenge without a fiberoptic laryngoscope, which is a luxury in the developing world.

The terrible psychological effects of war persist even though the armed conflict may be over. Mental and psychiatric disorders with all the ramifications of posttraumatic stress disorder are common among child survivors.

## PAIN

Pain management modalities for children in a First World environment are vastly different from those available to practitioners working with limited resources.<sup>52</sup> Attempting to apply similar standards is fraught with difficulty. Illiteracy, malnutrition, poor cognitive development, different coping strategies, altitude (e.g., chronic hypoxia),<sup>53</sup> and pharmacogenetic, cultural, and language differences all contribute to the complexity of the problem.<sup>54</sup>

Children of the developing world learn to cope with vastly different problems. They may be victims of poverty, malnutrition, violence (e.g., war, trauma, abuse), and their attitudes about pain and pain tolerance are diverse. Children from an impoverished background seem more stoic and indifferent to even severe pain. After cardiac surgery, for example, some appear to need very little pain relief and are easily soothed by lollipops (A. Davis, personal communication) or play therapy.<sup>33</sup> Many walk from the intensive care unit to the general ward on the first postoperative day (A. Davis and R. Ing, personal communication).

Pain assessment of children from an impoverished background is difficult<sup>55</sup> (see Fig. 50-3, B). Many children in acute pain do not show facial expressions. Is this stoicism or simply a reflection of malnutrition, lack of social stimulation, severity of illness, or even cultural attitude? Language difficulties, cultural barriers, willingness to share information, emotional expressiveness, and outdated attitudes of the caregiver may endorse this quandary. Some societies convey pain readily, but others teach that expression of pain is inappropriate. Although many pain assessment instruments are available, few have been validated in the developing world.<sup>55-57</sup>

There is an urgent need to develop pain treatment strategies that can be applied to the children of the developing world. Local conditions dictate their use and applicability. Simple pain management strategies may produce the most benefit with the least risk, whereas more complex techniques, which offer the most benefit, require a minimum standard of monitoring and regular reassessment to allow individualized titration of analgesia. These devices and personnel are seldom available to children of the developing world. The final choice of analgesia is therefore dictated by economic pressures or by the facilities available rather than what would be considered best for the child.

## Human Resources

Anesthesia does not enjoy a high profile and lacks the voice to demand access to resources in developing countries. The critical shortage of manpower is a barrier to progress.<sup>5,8</sup> Anesthesia is frequently delivered by nonphysicians,<sup>3,6,58</sup> a reality that has remained constant over many decades. Most anesthetics are administered by nurses or unqualified personnel who have little medical background and are “trained on the job.”<sup>3,36</sup> In many African<sup>5,59</sup> and Asian countries,<sup>5,60</sup> the ratio of doctors to patients often is so small that the ideal of employing a physician specifically to provide routine anesthesia is out of the question.<sup>5,61,62</sup> Salaries are insufficient to attract suitably trained and qualified practitioners for more than short periods. Emigration of scarce trained personnel to developed countries in search of better salaries and improved lifestyles exacerbates these human resource difficulties.<sup>3,5,10,58,61-64</sup>

Anesthesia is not perceived as an attractive career for many undergraduates,<sup>63</sup> who receive little or no exposure to the specialty.<sup>64</sup> In some countries, surgery is performed without the “luxury” of anesthesia.<sup>65</sup> Few developing countries can afford specialist anesthesiologists, except possibly in the principal hospitals. Supervision of “nonphysician anesthesiologists” is invariably inadequate,<sup>66</sup> and access to textbooks, journals, or other medical literature is limited. Internet access depends on a reliable electrical supply, telecommunications network, and a computer, luxuries that are considered the norm in the developed world.<sup>67,68</sup>

Despite these problems, many individuals provide high-quality anesthesia for a limited range of surgical procedures, but few receive formal training in pediatric or neonatal anesthesia. Inadequately trained anesthesiologists tend to shy away from children, particularly neonates and infants, because of the perceived difficulty and fear. This is understandable in view of the lack of supervision, the severity of the child’s condition, and the equipment that is more suited for adults. Invariably, the “pediatric anesthesiologist” is someone who may have a special interest in or affinity for children or who has been allocated to pediatric anesthesia for the day because there is no one else. A genuine pediatric anesthesiologist is a luxury.

On a more positive note, the World Health Organization (WHO) has recognized that surgery is a public health issue and has launched the Safe Surgery Saves Lives program.<sup>5,16,17,62,69</sup> The WHO has emphasized that safe surgery does not exist without safe anesthesia.<sup>10,11,16,17</sup> Training anesthesiologists in the skills required for pediatric anesthesia is a slow process. It is hoped that the WFSA program<sup>69-78</sup> will snowball so that children undergoing surgery in developing countries will reap the benefit.

## Pathology

Many pathologic conditions that are seldom seen in industrialized countries are more prevalent in developing countries because of poor health education, malnutrition, proximity of livestock to humans, earth-floored homes, poor sanitation, and contaminated water supplies (Fig. 50-5). Some conditions that are prevalent worldwide and relevant to the anesthesiologist are considered in the following sections.

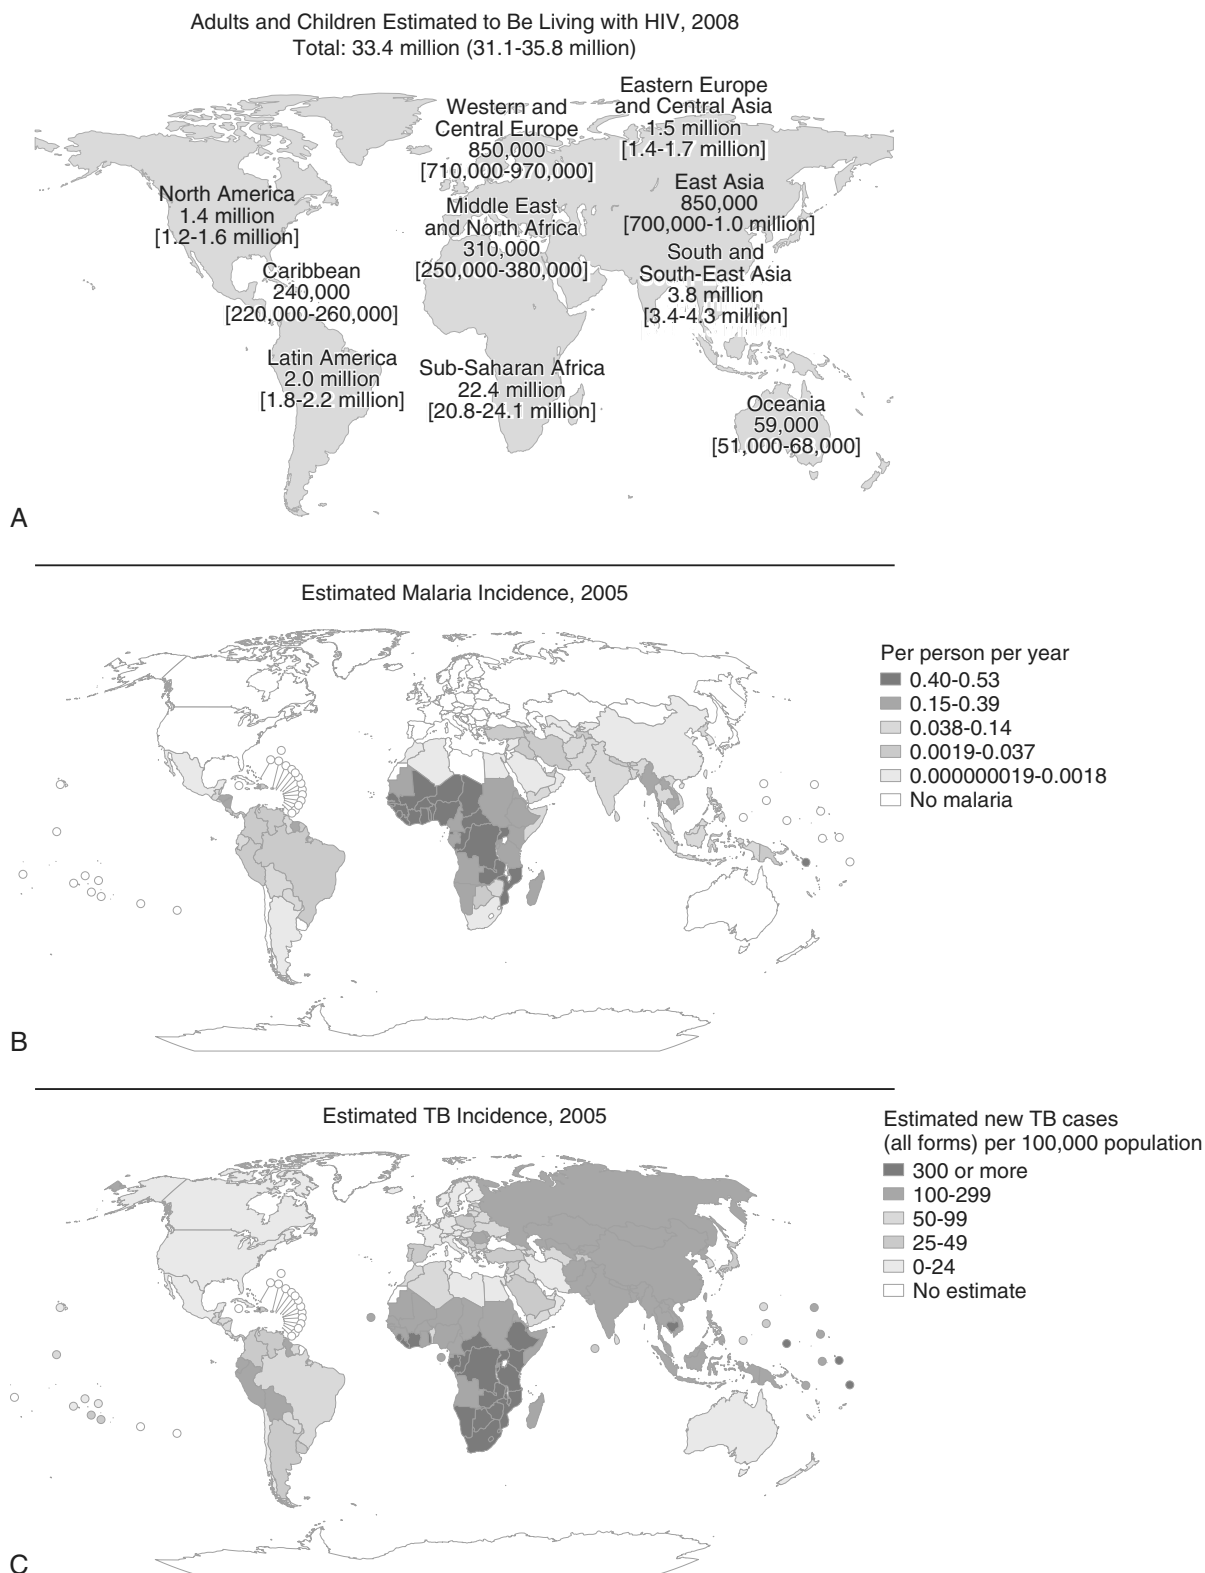

### HUMAN IMMUNODEFICIENCY VIRUS INFECTION AND ACQUIRED IMMUNODEFICIENCY SYNDROME

An estimated 33.4 million people are living with HIV. Most cases occur in the developing world (90%), with sub-Saharan Africa (22.4 million) and Southeast Asia (3.8 million) making up two thirds of the global total; approximately 6% are children (see Fig. 50-5, A).<sup>79</sup> More than 25 million have died of HIV-related diseases since 1981, and as a consequence, there are an estimated 14 million orphans in sub-Saharan Africa alone.<sup>79</sup> Worldwide, more than 1000 children are newly infected with HIV each day; most of these children are in sub-Saharan Africa.<sup>80</sup> The prevalence of HIV seropositivity varies from one country to another. In this environment, it is prudent for the anesthesiologist and surgeon<sup>81</sup> to assume a positive status for every patient until proved otherwise.<sup>36</sup>

Although some success has been achieved in slowing the transmission of HIV in developed countries,<sup>81-87</sup> there are numerous barriers to the treatment of HIV-infected children in the developing world. Only 4 million people in low- to middle-income countries have access to treatment.<sup>79</sup> Treatment of children has lagged behind that of adults, in part because of the expense and the lack of pediatric antiretroviral drug formulations<sup>84</sup> but mainly due to poor human resources and infrastructure for administration of treatment.<sup>88</sup> Only an estimated 38% children infected with HIV receive treatment.<sup>79</sup>

Children can be infected by vertical transmission from the mother (>90%) or when sexually abused (≈2%) by an infected adult.<sup>89</sup> Transmission through blood products remains a risk, but with the global trend toward volunteer donors and more sophisticated testing of blood, this risk is expected to diminish. Vertical transmission can occur in utero, during labor and delivery, or postnatally. Risk factors include maternal plasma viral load and breastfeeding.<sup>80,86</sup> Data indicate that mixed feeding (i.e., breastfeeding with other oral foods and liquids) is associated with the greatest risk of transmission.<sup>90</sup> Perinatal transmission rates have been dramatically reduced by universal HIV testing of pregnant women, provision of antiretroviral therapy (when needed for maternal health) or prophylaxis, elective cesarean delivery, and avoidance of breastfeeding.<sup>80,86</sup> Highly active antiretroviral therapy (HAART), the triple antiretroviral therapy, has changed HIV from a fatal illness to a chronic disease with decreased mortality rates and improved quality of life<sup>86</sup>; however, these strategies require resources.

In practical terms, it is difficult to differentiate infants who are infected by vertical transmission from those who are not infected because differentiating between actively or passively acquired antibodies is virtually impossible in low-income countries. All children born to HIV-positive mothers have acquired HIV antibodies for the first 6 to 18 months. Only 30% to 40% of the infants who are infected may go on to develop AIDS. The presence of HIV antibody is therefore not a reliable indicator of infection. More sophisticated and expensive tests have been

**FIGURE 50-5** **A**, Global distribution of human immunodeficiency virus infection and acquired immunodeficiency syndrome (HIV/AIDS). Developing countries, particularly sub-Saharan Africa, carry the greatest health burden with the poor resources. **B**, The global distribution of malaria is remarkably similar to that of HIV/AIDS. Blood products in these regions carry an enormous risk, even if family members act as donors. **C**, Global distribution of tuberculosis (TB) in 2005. (**A**, From AIDS Epidemic Update, p. 66. Available at [http://data.unaids.org/pub/EpiReport/2006/2006\\_EpiUpdate\\_en.pdf](http://data.unaids.org/pub/EpiReport/2006/2006_EpiUpdate_en.pdf), page 66 [accessed July 2012]; **B**, from World Malaria Report. Available at <http://www.rbm.who.int/wmr2005/html/map3.htm> [accessed July 2012]; **C**, from World Health Report, 2006. Available at <http://www.who.int/whr/2006/en/> [accessed July 2012].)

developed but are not widely available. All children born to HIV-positive mothers should be considered infected; if antibody persists beyond 15 months, infection should be assumed.

Progression of the disease depends on the mode of transmission; vertically acquired infection is more aggressive than other forms. Between 20% and 30% of untreated HIV-infected children will develop profound immunodeficiency and AIDS-defining illnesses within a year, whereas two thirds will have a slowly progressive disease. The course of the disease depends on a variety of factors, including timing of infection in utero, the viral load, the mother's stage of the disease, and whether the mother is receiving antiretroviral therapy. Treatment of children depends on clinical category, CD4 T-cell cell count, viral load, and age at the time of diagnosis. According to the current state of knowledge, after HAART is started, it must be carried on lifelong. This implies great challenges in adherence to avoid development of resistance and to evade long-term adverse effects of HIV therapy. Emerging drug resistance in children in low- and middle-income countries has necessitated new treatment strategies.<sup>84,87</sup>

The clinical manifestation of HIV in infants and children depends on whether they have been managed with antiretrovirals.<sup>81,84,87</sup> Most have asymptomatic infections, and the presentation may be subtle, such as failure to thrive, lymphadenopathy, hepatosplenomegaly, interstitial pneumonia, chronic diarrhea, or persistent oral thrush. Some present for the first time with life-threatening disease. Chronic diarrhea, wasting, and severe malnutrition predominate in Africa, whereas systemic and pulmonary pathologies are more common in the United States and Europe. Recurrent bacterial infections, chronic parotid swelling, lymphocytic interstitial pneumonitis (LIP), and early onset of progressive neurologic deterioration are characteristic of children with AIDS.

Pulmonary disease remains the leading cause of morbidity and mortality.<sup>91-93</sup> Bacterial pneumonia, viral pneumonia, and pulmonary tuberculosis are common in children throughout the developing world. The course of these infections is more fulminant when associated with HIV infection.<sup>94</sup> Acute opportunistic infections occur when the CD4 T-cell count falls; they include *Pneumocystis (carinii) jiroveci* pneumonia (PCP or PJP), cytomegalovirus infection, and the more typical *Haemophilus influenzae*, *Streptococcus pneumoniae*, and respiratory syncytial virus infections.<sup>91,92,94</sup> The classic presentation of PCP is fever, tachypnea, dyspnea, and marked hypoxemia, but in some children, the presentation is more indolent, with hypoxemia preceding clinical or radiologic changes.<sup>95</sup>

LIP is a slowly progressive, chronic form of lung disease seen in older children. It can lead to an insidious onset of dyspnea, cough, and chronic hypoxia with normal auscultatory findings and can cause pulmonary lymphoid hyperplasia in AIDS patients. In contrast to adults, LIP in children may cause acute respiratory failure, which is treated with steroids and bronchodilators. The clinical manifestations affecting otolaryngologists<sup>96</sup> and dental surgeons<sup>97</sup> have been outlined. Management of the upper airway may be difficult in the presence of stomatitis and gingival disease. Intubation may be difficult in the presence of acute (i.e., candidal infection) or chronic epiglottitis (i.e., lymphoid hyperplasia), necrotizing laryngotracheitis, Kaposi sarcoma (Fig. 50-6), or laryngeal papillomas (Fig. 50-7). These comorbid respiratory disorders can challenge even the most experienced pediatric anesthesiologist (Fig. 50-8).

Cardiac disease is being recognized with increasing frequency in HIV-infected children. The pathogenesis of cardiomyopathy is multifactorial and includes pulmonary insufficiency, anemia,

**FIGURE 50-6** Human immunodeficiency virus infection and acquired immunodeficiency syndrome (HIV/AIDS) are an increasing problem in developing countries, particularly in sub-Saharan Africa. The skin manifestations in this 8-year-old boy indicate Kaposi sarcoma, an AIDS-defining tumor.

**FIGURE 50-7** Laryngeal papilloma. Papillomas, caused by the human papillomavirus, are prevalent in low socioeconomic groups and have the highest incidence in the 2- to 5-year-old age-group. This age distribution is changing in the human immunodeficiency virus-exposed population. Even in well-equipped institutions, anesthesia for these patients can be challenging.

nutritional deficiencies, specific viral infections, and drug therapy. Left and right ventricular dysfunction, arrhythmias, and pericardial effusions occur, but pulmonary hypertension is rare.<sup>98</sup> HIV may directly infect the myocardium, leading to early electrocardiographic (ECG) changes and abnormal echocardiograms showing hyperdynamic left ventricular dysfunction or evidence of diminished contractility (e.g., dilated cardiomyopathy, myocarditis).

The gastrointestinal tract is commonly involved,<sup>99</sup> particularly in those living in tropical countries, and affected children show evidence of malabsorption (i.e., slim), chronic recurrent diarrhea,

**FIGURE 50-8** Kaposi sarcoma is a marker for acquired immunodeficiency syndrome (AIDS). **A**, AIDS was previously considered to be rare in children, but it may affect the airway at different levels, as shown in this 12-year-old girl. She is clearly fatigued from the respiratory distress caused by Kaposi sarcoma at three levels: base of the tongue, tonsil, and trachea. She also has an underlying pneumonia. Significant supraclavicular recession suggests upper airway obstruction. **B**, The Kaposi sarcoma of the base of the tongue, tonsil, and trachea is shown on a poor-quality, lateral neck radiograph, which illustrates one of the many difficulties faced in remote areas, high quality imaging. **C**, Laryngoscopic view of the Kaposi sarcoma at the base of the tongue and the tonsil. **D**, Computed tomography shows a large retropharyngeal Kaposi sarcoma (arrows) obstructing the upper airway. The poor quality of the scan reflects inexperienced radiographers using the poor-quality equipment commonly found in developing countries.

dysphagia, failure to thrive, or enteric infection. They may require endoscopy for diagnostic studies. From the point of view of the anesthesiologist, there is an increased risk of reflux due to esophagitis, which may be caused by infection (e.g., *Candida*, cytomegalovirus) or drugs (e.g., zidovudine). Pseudobulbar palsy, a manifestation of central neurologic involvement, or esophageal strictures may occur.

Nausea and vomiting may have a neurologic, infectious, or drug-related cause. Pancreatitis, lymphomas, or smooth muscle tumors may delay gastric emptying. Hepatomegaly is invariably

present, but severe hepatocellular dysfunction is seldom a major problem unless the patient has chronic hepatitis (e.g., hepatitis B or C, cytomegalovirus). Cholestasis and fluctuating transaminase levels may be caused by HIV infection, poor nutrition, or drugs. In theory, hepatic enzyme dysfunction caused by antiretroviral therapy should affect the metabolism and pharmacokinetics of some anesthetic agents, but little research has been done on this subject.

Medications used to manage HIV are involved in drug interactions on several levels.<sup>100</sup> The reverse transcriptase inhibitors

(e.g., zidovudine) are excreted by the kidney, and drugs affecting renal clearance reduce excretion. Reverse transcriptase inhibitors may induce CYP3A4 (e.g., nevirapine) or inhibit CYP3A4 (e.g., delavirdine) and affect other drugs (e.g., midazolam, levobupivacaine, ketamine, methadone) cleared by this enzyme. Protease inhibitors are inhibitors of CYP3A enzyme systems and are substrates and inhibitors of P-glycoprotein transporters. Coagulation status with the concomitant use of warfarin (which is metabolized by CYP2C9) may be altered by enzyme induction (e.g., ritonavir) or competition for clearance pathways (e.g., efavirenz, nelfinavir).<sup>101</sup>

Protease inhibitors also can inhibit specific uridine 5-diphosphoglucuronosyltransferase (UGT) pathways. This accounts for the increase in bilirubin concentration (i.e., UGT1A1 glucuronidates bilirubin) observed in some patients. UGT1A6 (i.e., acetaminophen glucuronidation) and UGT2B7 (i.e., morphine glucuronidation) are unaffected.<sup>102</sup> Gastric motility changes due to opioids (e.g., methadone) reduces absorption of some reverse transcriptase inhibitors.

HIV, a neurotrophic virus, can have a devastating effect on the immature brain, which is further compounded by the opportunistic infections and neoplasms that occur as a consequence of the associated immunosuppression.<sup>103</sup> Neurologic impairment is seen in most symptomatic HIV-infected children, commonly as a progressive encephalopathy with developmental delay, progressive motor dysfunction, and behavioral changes. Craniofacial dysmorphic features have been described. Hematologic abnormalities can reflect depression of all cell lines. Anemia may be caused by primary marrow failure, malnutrition, or drugs, whereas thrombocytopenia may reflect an autoimmune disorder.

Universal precautions should be strictly applied for all anesthesia procedures. Extra care should be taken when anesthetizing an HIV-infected child. Precautions should also be taken to prevent contamination of the anesthetic circuits. Disposable equipment, bacterial filters, and disposable circuits are recommended. The prohibitive cost for most institutions in developing countries limits the use of disposables. Reusable equipment should be cleaned, sterilized, and decontaminated according to the manufacturer's instructions. Fortunately, HIV is sensitive to a wide range of disinfectants.<sup>104</sup>

## TUBERCULOSIS

Tuberculosis remains an important cause of morbidity and mortality.<sup>36,105-110</sup> The epidemiology of pediatric tuberculosis is shaped by risk factors such as age, race, immigration, poverty, overcrowding, and prevalence of HIV/AIDS (see Fig. 50-5, C).<sup>109,110</sup> HIV and tuberculosis form a dangerous synergy that is difficult to manage in view of drug interactions between the antituberculosis and antiretroviral agents.<sup>79,106</sup> Even bacillus Calmette-Guérin (BCG) vaccinations can cause significant complications in immunocompromised HIV patients.<sup>106</sup> The emergence of drug-resistant tuberculosis adds to the burden and is a constant danger to health care workers in general and anesthesiologists in particular.

Primary tuberculosis infection usually does not produce clinical illness in well-nourished, immunized children, whereas reactivated pulmonary tuberculosis is a chronic or subacute disease that may present a variety of challenges for the anesthesiologist, including preventing transmission by contamination of the anesthetic circuits and the risks associated with pleural effusions, pulmonary cavitation, or bronchiectasis.<sup>93,95</sup> Mediastinal and hilar lymphadenopathy may severely compromise the airway.

Primary tuberculosis and its complications are more common in children than in adults. After young children are infected, they

are at increased risk for progression to extrapulmonary disease.<sup>109,110</sup> *Mycobacterium tuberculosis* infection can cause symptomatic disease in any organ of the body and is usually a reactivation of a latent site of infection. The most common sites of reactivation are lymph nodes, bones, joints, and the genitourinary tract. Less frequently, the disease may involve the gastrointestinal tract, peritoneum, pericardium, or skin. Tuberculosis meningitis and miliary tuberculosis, both more common in children, carry a high mortality rate.<sup>109</sup> In view of the high prevalence of HIV infection among tuberculous children, HIV testing should be performed on all children with tuberculosis; conversely, tuberculosis should be sought in all HIV-positive children. Tuberculosis is, however, difficult to diagnose in young children, and the search for more sensitive tests continues.<sup>105</sup>

## MALARIA

Malaria (see Fig. 50-5, B) is a febrile, flulike illness caused by one of four species of malaria parasites: *Plasmodium falciparum*, *P. vivax*, *P. ovale*, and *P. malariae*. Effective and safe prophylaxis against malaria has become increasingly difficult because the species that causes the most severe illness, *P. falciparum*, has become widely resistant to chloroquine and to other antimalarial drugs in some areas.<sup>110</sup> Severe malaria, even when optimally treated, carries a mortality rate of 10% to 25%.<sup>110-112</sup>

Prompt diagnosis and early treatment is an important determinant of outcome. Uncomplicated malaria usually manifests as fever, headache, dizziness, and arthralgia. Gastrointestinal symptoms may predominate and include anorexia, nausea, vomiting, and abdominal discomfort or pain that may mimic appendicitis. In children, malaria can manifest with an acute, life-threatening disease or run a chronic course with acute exacerbations. The acute manifestations include three overlapping syndromes: respiratory distress due to a severe underlying metabolic acidosis (pH <7.3), usually a lactic acidemia; severe anemia (hemoglobin <5 g/dL) with hypovolemia<sup>113</sup> and thrombocytopenia; or neurologic impairment as a manifestation of cerebral malaria.<sup>111-114</sup> Seizures are an important presenting feature in 60% to 80% of cases. Prolonged seizures refractory to treatment and those that occur on antimalarial treatment are ominous signs and are usually associated with neurologic sequelae or death.<sup>113</sup> Cerebral malaria can also manifest as a prolonged postictal state, status epilepticus, severe metabolic derangement (i.e., hypoglycemia and metabolic acidosis), or a primary neurologic syndrome, ranging from diffuse cortical involvement to brainstem abnormalities.

Children with chronic malaria adjust physiologically to low hemoglobin levels but may decompensate rapidly when challenged with a febrile illness or surgery. The characteristic physical findings in children with severe anemia are respiratory distress and a hyperdynamic circulation. Blood transfusion may be administered rapidly in children with metabolic acidosis because most have a depleted intravascular volume.

Although controversial, exchange transfusion has been advocated for severe malaria, particularly for those with cardiorespiratory compromise, hyperparasitemia, or cerebral malaria. The rationale is to remove harmful metabolites, toxins, and cytokines; decrease the parasite load; remove deformed red cells; and restore normal red cell mass, platelets, and other clotting factors.<sup>113</sup> Unfortunately, many malaria-endemic areas also have a high prevalence of HIV, adding significantly to the risk of blood transfusions.

Chronic recurrent malarial infections may manifest with splenic enlargement. This may cause delayed gastric emptying

and pose an aspiration risk on induction of anesthesia. The spleen may enlarge acutely or rupture spontaneously during coughing, vomiting, or defecation. Rupture during external cardiac massage has also been described. Malaria may cause bloody diarrhea with massive fluid loss of fluid resembling dysentery in children.

### CARDIAC DISEASE

Pediatric cardiac services typically are too expensive for most developing countries, and the increasing economic divide threatens those services that do exist.<sup>115,116</sup> In North America, each cardiac center serves 120,000 people; by contrast, one center serves 16 million people in Asia and 33 million in Africa.<sup>61</sup> Despite the need, few third world units can treat the required volume of cases. Unless families have the financial means to travel to a developed country, the options for diagnostic or therapeutic cardiac procedures are poor.<sup>33,115-117</sup> Medical missions may provide immediate help, but their impact on a developing country is short term and potentially disruptive. These visiting teams ultimately have little effect on the complex socioeconomic and sociopolitical problems that exist.<sup>116</sup>

Rheumatic heart disease is more common than congenital heart disease in many developing countries,<sup>115-117</sup> reflecting the socioeconomic problems of poverty, overcrowding, malnutrition, and lack of antibiotics. Children often present late with life-threatening symptoms due to repeated infections and superimposed endocarditis. The acute deterioration precipitated by endocarditis may be the factor that prompts the search for medical attention. Valve replacement can be lifesaving, but long-term follow-up of anticoagulant therapy is often not feasible.

Congenital heart disease is an additional challenge, and it is common to see congenital heart defects in adults in developing countries. Those who have survived without the benefit of palliative or corrective surgery may present with pulmonary hypertension or endocarditis. Total correction of these defects usually is not feasible, and palliative surgery may be the more effective alternative. Excellent palliation with reasonable quality of life can be achieved relatively cheaply.<sup>116</sup>

### TETANUS

Tetanus is a disease characterized by painful tonic muscle spasms, hyperreflexia, and autonomic instability.<sup>118</sup> It is caused by the exotoxin of *Clostridium tetani*, an organism that is ever present in the soil and contaminated wounds. Although rarely seen in developed countries, tetanus is prevalent in countries where children are not routinely immunized. Tetanus neonatorum carries a high mortality rate and is still encountered in areas where it is customary to apply feces to the umbilical cord to stop bleeding.

The clinical manifestations of the disease are not the result of invasive tissue injury but are caused by production of a potent neurotoxin, tetanospasmin, at the site of the injury. The injury may be trivial and may not even be detectable at the time of presentation. The incubation period is inversely proportional to the distance between the site of the injury and the central nervous system. This usually occurs within 14 days of the injury in children.

Trismus is the presenting sign in most cases, and sustained trismus produces a characteristic sardonic smile (i.e., risus sardonicus). Persistent contractions of the chest and back muscles result in opisthotonos. Restlessness and irritability may be followed by tetanic seizures, which are often precipitated by trivial

stimuli (e.g., touch, noise). Glottic or laryngeal spasm can cause sudden death. Late deaths may be caused by nosocomial infection, renal failure, sudden cardiac arrest, or cerebral hemorrhage as result of the autonomic instability.<sup>118</sup>

Treatment consists of surgical débridement of the wound, administration of human tetanus immunoglobulin, antibiotic therapy, and intensive supportive medical care. Ventilatory support is invariably necessary because the frequent spasms impair ventilation already compromised by sedative therapy. Benzodiazepines and opioids are the mainstay of treatment, but numerous protocols have been studied.<sup>118</sup> Magnesium sulfate has been successfully used to reduce spasms and has been shown to reduce circulating catecholamines,<sup>119</sup> whereas clonidine does not.<sup>120</sup> Pain management should also be considered, and I have been encouraged by the use of continuous epidural analgesia for these children. Further advantages of epidural analgesia include good control of autonomic instability, earlier weaning from ventilatory support, and possible reduction in the complication rate.<sup>118</sup> From the anesthesiologist's point of view, trismus is overcome by muscle relaxants and does not pose a significant intubation problem.

### Drugs

The supply of anesthetic gases and drugs for rural medical facilities is erratic and unreliable.<sup>3,8</sup> The cost of many drugs, particularly the modern anesthetics, has increased alarmingly beyond the reach of most health care budgets. Anesthesiologists in developing countries therefore must be resigned to using less expensive anesthetics or generic medications.

Ether and halothane remain the only inhalational anesthetics available in many countries and are the mainstay of anesthesia in many institutions.<sup>2,3,10,31,121</sup> Ether is cheaper and probably safer than halothane, although its use is limited by its flammability. This extreme flammability limits its transportability and therefore its availability in remote areas.

Ether and halothane have virtually disappeared from the operating rooms in the developed world and have been replaced by isoflurane, sevoflurane, and desflurane. As demand for the less-expensive agents has waned, some manufacturers claim a lack of profitability for them and have threatened their withdrawal. Although this may make commercial business sense, these agents sustain the anesthesia services for millions of patients in the developing world,<sup>2</sup> and their loss would be tragic.

Ketamine is probably the most commonly used intravenous anesthetic.<sup>3,65,121</sup> Ketamine is simple to use, effective, and relatively safe when used as a sole agent for short procedures, used in combination with muscle relaxants, or used to supplement general anesthesia for major surgery. It should be used with midazolam to reduce the hallucinatory side effects and nightmares after ketamine use. Benzodiazepines, however, are not always available. Morphine and other opioids may not be permitted in some cultures or even available in some institutions. It is sobering to realize that only 6% of the morphine consumption worldwide is used in the low- and middle-income countries that are home to 80% of the world's population.<sup>52</sup>

The choice of neuromuscular blocking drugs is limited. Suxamethonium, gallamine, curare, alcuronium, or pancuronium are the usual options, and the choice is dictated by their availability or the availability of reversal agents. For this reason, neuromuscular blocking drugs are not commonly used.

The cost of nitrous oxide is prohibitive in terms of storage, erratic delivery, and budgetary constraints.<sup>122,123</sup> Closed or semi-closed anesthetic systems are considered dangerous in an environment where the oxygen supply is erratic,<sup>123</sup> agent monitors are seldom available,<sup>25</sup> and the supply of soda lime and compressed gas cylinders is erratic. Consequently, the potential benefits and cost savings of low-flow anesthesia are lost.<sup>123,124</sup>

Regional anesthesia has many benefits in terms of safety, cost savings, and immediate postoperative analgesia.\* Children in developing countries usually are very accepting of this form of analgesia. However there seems to be a general reluctance to perform regional anesthesia in children,<sup>29,36</sup> even in some institutions in the developed world. Possible reasons include lack of training or expertise, fear of failure, and the unavailability of drugs, disposables, and other ancillary equipment such as ultrasound.

Improvisation may be the key. In the absence of appropriate equipment, access to the epidural space can be achieved by using a technique first described before the introduction of pediatric epidural needles into clinical practice. A catheter can be threaded through an intravenous cannula into the epidural space through the sacral hiatus in neonates and small infants.<sup>127</sup> Cheap, uninsulated needles can be used for peripheral nerve blocks when more expensive, insulated needles are not available.<sup>128</sup>

## Blood Safety

An estimated 70% of all blood transfusions in Africa are given to children with severe anemia caused by malaria. Blood transfusion services, when they exist, aim to provide a lifesaving service by ensuring an adequate supply of safe blood.<sup>129-131</sup> Patients, particularly children, in developing countries face the greatest risks from unsafe blood and blood products.<sup>130-133</sup>

Less than 30% of developing countries have a nationally coordinated blood transfusion service. Many do not perform the most rudimentary tests for diseases such as HIV or hepatitis B and C because of economic constraints.<sup>133</sup> Even limited testing doubles the basic cost of a unit of blood. It is estimated that about 6 million tests that should be done globally to check for infections are not done annually.

Many countries still rely on paid donors or family members to donate blood before surgery.<sup>133</sup> In Argentina, for example, up to 92% of the blood supply is derived from family members. Although voluntary, unpaid blood donation has increased to 20% in the past 5 years in Pakistan, family donors comprised 70% and paid donors 10% of the blood donors in 2004.<sup>131</sup> Public education about the value of blood transfusion is vital to improve supply.<sup>129,130</sup> Through concerted efforts by the World Health Organization to improve blood safety worldwide over the past decade, the number of voluntary, unpaid donors has increased considerably. For example, voluntary blood donation in China increased from 45% of donations in 2000 to 90% in 2004. Similarly, the rate of voluntary, unpaid donations in Bolivia increased from 10% in 2002 to 50% in 2005. Malaysia, China, and India reached 100% screening of donated blood for HIV by the year 2000.<sup>132</sup>

There are risks in any system.<sup>129,130</sup> Family and paid donors may hide aspects of their health and lifestyle that could make the blood unsafe for different reasons. Family members may feel pressured to donate, whereas paid donors are driven by need and avoid important details about their health status that would

negate the transaction. The commercial plasma industry and blood trade can fuel the transmission of HIV. In 1999, 26 million liters of plasma were fractionated for global use,<sup>133</sup> and the major source was paid donors from developing countries. Voluntary, unpaid donors have a greater sense of responsibility to their community and keep themselves healthy to be able to keep giving safe blood. South Africa has had 100% voluntary, unpaid donations since it established a national blood service. With HIV prevalence approaching 30% among the adult population of Africa, only 0.02% of its regular blood donors in South Africa have contracted HIV.

Storage of blood is difficult considering the unreliable and unpredictable electricity supply in many developing countries. To obviate the risk of transmission of malaria, HIV, and other infectious diseases, blood should be transfused only when absolutely necessary. In sophisticated blood transfusion units, the use of predonated autologous blood is an option.<sup>134-135</sup> In poorer countries, this is not practical because malnutrition and chronic anemia are common. There is often a lack of appropriate equipment, and cost is prohibitive. Similarly, intraoperative blood salvage and cell savers appropriate for use in children are not available. Recombinant factor VII, which is being used increasingly to reduce blood use by those who can afford it,<sup>134</sup> is beyond the scope (and cost) of practice in many countries.<sup>135</sup>

## Equipment

Electricity is unreliable in many hospitals in the developing world. In some, particularly in rural areas, neither power-line electricity nor a reliable functional generator is available.<sup>3,4</sup> General facilities for infection control, such as running water, disinfectants, or gloves, are also unreliable, even though recycling disposable equipment such as endotracheal tubes is considered normal practice in many countries.<sup>2</sup>

Essential equipment to provide safe anesthesia for children and particularly for neonates is lacking.<sup>3,25,30,36</sup> Neonatal or pediatric ventilators are virtually nonexistent outside the main centers.<sup>30</sup> Small intravenous cannulae are a precious commodity, and butterfly needles are still used and sometimes reused. Syringe pumps and other control devices are impractical in environments that have an erratic electricity supply. Metal and plastic laryngoscopes usually are available but not well maintained. Batteries may be in short supply and light bulbs unreliable. A full range pediatric tracheal tubes is considered a luxury. Laryngeal mask airways in pediatric sizes are usually unavailable. Intravenous fluids are very expensive if not manufactured locally, and many developing countries do not have local production facilities.<sup>10</sup> The choice of intravenous fluid is therefore limited and in short supply.

Monitoring is very basic: a precordial stethoscope and a finger on the pulse.<sup>2,11</sup> ECG monitoring is used when available, but it depends on a continuous electricity supply and proper maintenance. Appropriately sized blood pressure cuffs are scarce. Pulse oximetry has been the most useful monitor and should be available in all centers where pediatric surgery is performed.<sup>2,25</sup> Unfortunately, this ideal is far from reality, but it is hoped that the global pulse oximetry project will be rewarded with universal quality improvement.<sup>17</sup>

Anesthetic machines in developing countries fall into two categories: modern, sophisticated machines and simple, low-maintenance equipment. The electronic machines provided by well-meaning donors have a poor track record in austere

\*References 2, 23, 30, 34, 36, 43, 125-127

environments. Sophisticated equipment needs to be understood, but operating manuals printed in foreign languages are not helpful. Sophisticated machines require ongoing maintenance, but individuals trained to repair such equipment are seldom available. Service contracts are not considered viable. Unfortunately, these machines are invariably discarded when the first fault occurs, because guarantees are unlikely to be honored and faults are considered too expensive to repair. Poorly maintained equipment becomes hazardous and even life-threatening in untrained hands.

Simplicity and safety has long been the key to anesthetic equipment in developing countries.<sup>2-4,136</sup> Ideally, a suitable anesthetic machine should be inexpensive, versatile, robust, and able to withstand extreme climatic conditions; able to function even if the supply of cylinders or electricity is interrupted; easy to understand and operate by those with limited training, economical to use; and easily maintained by locally available skills.<sup>136-138</sup> The cheapest, most practical, and most widely used method is inhalational anesthesia administered through an Epstein

Macintosh Oxford drawover vaporizer (EMO, Penlon Ltd., Oxford, United Kingdom) or Oxford Miniature Vaporizer (OMV, Penlon Ltd.). Oxygen concentrators supplement oxygen delivery and eliminate the need for expensive oxygen cylinders, whose reducing valves are often faulty or destroyed in these situations. The most appropriate ventilator is the Manley Multivent Ventilator, which essentially functions like a mechanical version of the Oxford Inflating Bellows (OIB) and can be used with a drawover system.<sup>138</sup>

A general scheme for inhalational anesthesia, which was first proposed by Ezi Ashi and colleagues in 1983,<sup>124</sup> for use in developing countries is shown in Figure 50-9.<sup>136</sup> Applying this scheme, four different modes can be used and modified according to the available supplies and services. The basic mode A is used when there is no electricity and no supply of compressed gases. The apparatus consists of a low-resistance vaporizer linked by valves to the child to act as a drawover system with room air as the carrier gas. The self-inflating bag or hand bellows makes it possible to provide artificial ventilation while the

**FIGURE 50-9** The schematic diagram shows the use of anesthetic systems, depending on available resources. **Mode A** provides basic inhalational anesthesia with air, spontaneous ventilation, or self-inflating bags. Drawover vaporizers are required. **Mode B** provides oxygen enrichment but requires the availability of oxygen cylinders. Plenum vaporizers can be used. **Mode C** requires electricity to power the oxygen concentrator, air compressor, and ventilator. A mechanical ventilator (e.g., Manley) does not require electrical power. **Mode D** requires a Boyle's machine and nitrous oxide cylinders. 1, T-piece with reservoir tube and facemask; 2, Ambu Pedi valve; 3, self-inflating bag (Ambu); 4, Oxford Inflating Bellows (OIB); 5, Oxford Miniature Vaporizer (OMV) with halothane; 6, OMV with trichloroethylene; 7, Epstein, Macintosh, Oxford (EMO) vaporizer with ether. These circuits and manual ventilators are interchangeable, and ether, halothane, and trichloroethylene can be used on their own or in series. Farman entrainer (8) with an oxygen cylinder (9) can be used to supplement oxygen, or an electrical power source (10) with an oxygen concentrator (11), air compressor (12), or Manley ventilator (13). Nitrous oxide (14) and Boyle's apparatus (15) allow anesthesia practice equivalent to that of developed countries.

vaporizer remains as a drawover device. The addition of low-flow oxygen to the inspired gas in mode B depends on the availability of an oxygen cylinder. The addition of a length of reservoir tubing to the circuit enables oxygen to be stored on expiration and to be used on the next inspiration, substantially improving its economy.

When electricity is available (mode C), operation of the anesthetic apparatus can be extended by permitting the use of an air compressor to provide continuous gas flow (allowing use of a Boyles apparatus and plenum vaporizer), an oxygen concentrator, and ventilators. When nitrous oxide is available (mode D), all types of inhalational anesthesia available in developed countries can be practiced. When services and supplies are interrupted even briefly, it is possible to change from one mode to another without requiring other anesthetic apparatuses.

These techniques may be of little interest to the anesthesiologist working comfortably in the well-maintained, sophisticated environment of developed nations. Their roles, however, are essential in field situations (e.g., war, natural disasters), and all anesthesiologists should be acquainted with their functioning in this unpredictable world (Videos 50-1 and 50-2).

### DRAWOVER ANESTHESIA

Drawover anesthesia enables inhalational anesthesia to be administered using atmospheric air as the carrier gas. The essential features of this system consist of a calibrated vaporizer with sufficiently low resistance (i.e., EMO and OMV) to allow the negative pressure created by the child's inspiratory effort to draw room air through the vaporizer during spontaneous ventilation. Positive-pressure ventilation can be provided by means of a self-inflating bag or bellows (OIB), using a valve to prevent the gas mixture from reentering the vaporizer and a unidirectional valve at the child's airway to direct expired gases to the atmosphere, preventing rebreathing (see mode A, Fig. 50-9). In this way, an anesthetic can be administered in the absence of compressed gases. The vaporizer has an inlet for supplementary oxygen that can be attached to the oxygen output tube of an oxygen concentrator or oxygen cylinder when available (see modes B and C, Fig. 50-9).

The EMO and OMV are the more commonly used low-resistance vaporizers. The EMO is calibrated only for ether, but its performance is linear for other agents. The OMV is calibrated for a variety of agents;<sup>42,137-139</sup> despite the lack of temperature compensation, its performance is stable under most conditions. Both vaporizers have been used successfully in pediatric anesthetic practice,<sup>33</sup> but it is recommended that they be converted to form a T-piece for greater safety.

The OMV has been evaluated as a simple drawover system for pediatric anesthesia. Wilson and Bem<sup>42</sup> showed that when a self-inflation bag is used in a drawover mode, more efficient vaporization occurs despite vaporizer cooling. However, the respiratory efforts of neonates or weak infants are insufficient to operate the valve mechanisms of the self-inflating bag (e.g., Ambu bag), necessitating continuous assisted ventilation even in the presence of ether, which stimulates ventilation.

### OXYGEN CONCENTRATORS

Improved oxygen availability, independent of compressed gas and electrical power supply, can be provided by linking oxygen concentrators<sup>140,141</sup> to a drawover anesthetic apparatus as first described by Fenton.<sup>121</sup> Maintenance requirements are low, and servicing is recommended only after approximately 10,000 hours

of usage. The benefits are enormous, but a reliable electricity supply is critical.

The concentrator functions by using a compressor to pump ambient air alternately through one of two canisters containing a molecular sieve of zeolite granules that reversibly absorbs nitrogen from compressed air.<sup>121,136,140</sup> The controls are simple and comprise an on/off switch for the compressor and a flow-control knob to deliver 0 to 5 L/min. Flow of oxygen continues uninterrupted as the canisters are alternated automatically so that oxygen from one canister is available while the other regenerates. A warning light on a built-in oxygen analyzer illuminates if the oxygen concentration is less than 85%, and the concentrator switches off automatically when the oxygen concentration is less than 70%. This action is heralded by visual and audible alarms. Air is then delivered as the effluent gas. Modern machines are relatively silent.

The oxygen output of the concentrator depends on the size of the unit, the inflow of oxygen, the minute volume, and pattern of ventilation. The addition of dead space (or oxygen economizer tube) at the outlet improves the performance, and predictable concentrations of more than 90% oxygen can be obtained with flows between 1 and 5 L/min, independent of the pattern of ventilation. Much lower concentrations and less predictability were observed when the dead space tubing was omitted.<sup>142</sup>

The possible hazards of oxygen concentrators are few if they are positioned in the operating room so that the in-draw area is free from pollutants. Failure of the power supply or failure of the zeolite canisters results in the delivery of ambient air. A bacterial filter at the outlet combined with the use of dust-free zeolite should prevent contamination of the delivered gas. Dirty internal air filters may produce lower oxygen concentrations and must be checked. An oxygen storage tank and booster pumps afford protection against the vagaries in electrical supply.

## The Visitor

Personality traits compatible with survival have been suggested as a prerequisite for working in the developing world. These traits include an almost pathologic desire for work, a willingness to merge or at least sympathize with different cultures, patience in relating to and teaching people sometimes far removed educationally, the ability to withstand prolonged periods of cultural isolation, and mostly a never-failing ability to improvise and make the best of a bad situation.<sup>143-147</sup> There is no place for risk-taking "cowboy anesthesiologists."<sup>139,147</sup>

International travel, particularly visits to many parts of the developing world, needs careful preparation and planning, whether the anesthesiologist is part of a volunteer organization<sup>33,145-148</sup> or traveling as an individual.<sup>146</sup> Detailed advice<sup>144-149</sup> is beyond the scope of this chapter, but some generalizations are made based on personal experience and that of colleagues. Changing political climates and international health guidelines dictate visa and vaccination requirements. Expert advice should be sought to tailor the traveler's needs according to the individual's medical and immunization history, the duration of stay, and proposed itinerary.

Physical acclimatization to jet lag, altitude sickness, and heat or sun exposure is necessary, as is adjustment to the local culture and cuisine. Social graces acceptable in a Western culture may be deemed offensive in some other cultures. An interpreter is an important ally. However, the inability to understand a language or the local dialect places a visiting anesthesiologist at a serious

disadvantage, particularly when dealing with children. Children often use subtle ways to describe their feelings that even a skilled interpreter may fail to convey.

The hospital environment may be disconcerting for some. In contrast to the familiar comforts of a clean, child-friendly hospital, the visitor may be struck by the relatively shabby, bland appearance of many hospitals in developing countries. The buildings may not have received a coat of paint since they were built, and broken windowpanes provide the only air conditioning. Children are usually cared for in adult wards.

In the operating room, the visitor may be faced with anesthetic equipment barely recognizable from its original manufacture or in a state of disrepair with nonstandard improvisations in attempts to make it functional. The choice of drugs may be limited, and the names of locally manufactured generic drugs and the presentation of intravenous solutions may add to the perplexity. Surgical safety may be the next issue. Informed consent as we know it is unlikely, and identification of the child in the absence of parents may not be obvious to the newcomer. A local or itinerant surgeon may suggest an extensive procedure on a malnourished child without consideration for monitoring, blood transfusion, or availability of intensive care or postoperative analgesia in an unmonitored environment. The anesthesiologist is obligated to consider the risks and benefits carefully in such circumstances.

## Conclusions

The practice of anesthesia in a developing country will always be challenging, particularly for those who provide anesthesia for children. The challenges vary, and it is wise to expect the unexpected and have the flexibility to improvise in the face of an ever-changing world racked by famine, violence, natural disasters, and political unrest.

Attracting trained anesthesiologists to work in the developing world is difficult.<sup>5,62,70-74,146-150</sup> Temporary sojourns with volunteer medical groups are for the most part stimulating, but volunteers are unlikely to return for longer periods, let alone permanently.

Can anything be done to improve the lot of children who undergo anesthesia in the developing world? The Pediatric Anesthesia Fellowship Program established through the WFSA is commendable, but it produces only a small number of trainees each year.<sup>70,73,74</sup> Audits of morbidity and mortality are the first steps toward improvement if action is taken to address the problems uncovered. Publications reflecting outcomes in developing countries have increased over the past decade.<sup>19-21</sup> Purchasing equipment without ensuring subsequent maintenance is wasteful. Disposables are short-lived items even if they are recycled. Human resources are needed.

Different standards may emerge from different parts of the world. These standards need not necessarily be considered inferior but may open the way for the assimilation of new ideas.<sup>149</sup> The nuances of practice in different communities inevitably vary and may challenge some fondly held beliefs in pediatric anesthesia. A safe anesthetic is not necessarily the most expensive one. It is usually not the agents that we use but the skill with which we use them that determines outcome. It should never be necessary to depart from the dictum *primum non nocere*. Simplicity may be the key, but there is no place for double standards. Guidelines that have evolved over time in the United Kingdom, United States, and Australasia may be untenable in many parts of the world,<sup>147</sup> but every attempt should be made to exercise the same standard of care as expected in developed countries. Our children deserve no less.

- Walker IA, Merry AF, Wilson IH, et al. Global oximetry: an international anaesthesia quality improvement project. *Anaesthesia* 2009;64:1051-60.
- This paper describes the initial quality assurance program for pulse oximetry in four pilot studies of pulse oximetry in Uganda, Vietnam, India, and the Philippines. The studies determined that formal training in pulse oximetry needed to be a central part of the WHO Safe Surgery Saves Lives project.*
- Walker IA, Newton M, Bosenberg AT. Improving surgical safety globally: pulse oximetry and the WHO Guidelines for Safe Surgery. *Paediatr Anaesth* 2011;21:825-8.
- This paper describes the fact that approximately 78,000 operating rooms lack pulse oximetry. It discusses the WHO Safe Surgery Saves Lives Program as well as the Global Pulse Oximetry Program.*
- Zoumenou E, Gbenou S, Assouto P, et al. Pediatric anesthesia in developing countries: experience in the two main university hospitals of Benin in West Africa. *Paediatr Anaesth* 2010;20:741-7.
- This article describes anesthesia in Benin. Cardiac arrests occurred at a rate of 156 per 10,000 cases with a mortality rate of approximately 60%, even in two University Hospitals. The authors are to be congratulated for studying this issue to gain more financial support from their government for better equipment and monitoring.*

## Heating and Cooling Systems

The operating room (OR), which is comparable to a large infant incubator, provides the physical environment for the conduct of anesthesia. Readily controlled heating and cooling systems are crucial for thermal stability of the child, that is, control of the external environment. Neonates and small infants require a warmer room temperature than adults; they should be considered poikilothermic, particularly if they are preterm, critically ill, or stressed. With approximately 40% of heat loss by radiation and 35% by convection, heating the OR temperature warms the walls, which decreases radiation heat loss and warms the air, which decreases convection heat loss (see Chapters 35 and 36). Exposure to a cool room temperature during induction of anesthesia and surgical preparation may cause significant thermal stress,

particularly in the neonate and young infant. Mild to moderate hypothermia may cause acidosis and apnea in infants, alter the pharmacokinetics of medications, cause difficulty in antagonizing the neuromuscular blockade, and increase oxygen ( $O_2$ ) consumption with shivering.<sup>1</sup> Once the child is prepared and draped, the OR temperature may be reduced to a more comfortable level.

## Warming Devices

### RADIANT WARMERS

Overhead radiant heating units with servomechanism temperature control were useful to maintain the temperature of small neonates and infants in the past, but these have been replaced with other strategies. Given the risk of skin burn, the servomechanism control sensor must be applied to the warmed skin and

should not measure body core temperature.<sup>1</sup> A maximum skin temperature of 98.6° F (37° C) should preclude surface burns, although the risk persists in poorly perfused skin. The radiant warmer may be used during induction and surgical preparation; it may be used again as the drapes are removed. If infrared light bulbs are used, care must be taken to ensure that the heat lamp is an appropriate distance from the child to avoid thermal injury<sup>2</sup>; note that the red cast from the light may make evaluation of a child's color difficult.

### WARMING BLANKETS

Circulating water mattresses help maintain normothermia in children with body surface areas of 0.5 m<sup>2</sup> or less (approximately 10 kg).<sup>3</sup> For most children, conductive heat loss accounts for less than 5% of total body heat loss; therefore these devices have limited usefulness in maintaining thermal homeostasis and virtually no benefit for children weighing more than 10 kg. To avoid surface burns, the fluid temperature should never exceed 102.2° F (39° C) and must be monitored<sup>4</sup>; several layers of material should be interposed between the child and the warming blanket to avoid direct contact. In many institutions these have been replaced by forced air warming mattresses.

### FORCED WARM AIR DEVICES

The most useful device for maintaining thermal homeostasis is the warm air mattress that can be wrapped around the head and upper or lower torso.<sup>5-9</sup> These devices rely on the combination of convection with warm air and plastic wrap that also serves to reduce evaporative heat losses. They are the single most effective means for warming children, even when only a portion of the body is covered.<sup>5,10</sup> One report suggests that simple delivery of warm air beneath bed sheets without the use of a plastic blanket can be effective,<sup>10</sup> but significant thermal injuries have been reported without the use of a licensed blanket or when used in children with poor skin perfusion.<sup>6</sup> Therefore unlicensed use of these devices is *not* recommended. In extreme cases of hypothermia (cardiac surgery or liver transplant), a blanket can be placed both beneath and on top of the child to speed the warming process. Two concerns have been raised regarding these devices. First, concern has been expressed that these devices may incubate infections and distribute them into the OR. The standard design and design changes in the hardware may, unbeknownst to the operator, increase the infectious risk from some warmers.<sup>7,9</sup> Concern also exists that under laminar airflow conditions for joint replacement, these devices increase the infectious risk.<sup>11</sup> Also, the cost of these disposable air mattresses may be a considerable expense.

### PASSIVE HEAT AND MOISTURIZER EXCHANGERS, "ARTIFICIAL NOSE"

Heat moisture exchangers are effective in preserving body heat, but ineffective to raise the child's body temperature.<sup>12-14</sup> In infants and children, these devices add humidity to the circuit<sup>15</sup> and may also function as filters for infectious pathogens and reduce the transmission of infectious agents between children.<sup>16,17</sup> These devices may increase the resistance to breathing during spontaneous ventilation and completely obstruct the circuit with prolonged use.<sup>18-20</sup>

### FLUID AND BLOOD WARMERS

The effectiveness of standard fluid warmers depends on the time that the intravenous fluids or blood products are in contact with

the warmer. Excessive heating may cause hemolysis of red blood cells.<sup>21</sup> With slow intravenous fluid therapy, the fluid warmer does not contribute significant heat transfer because heat is lost along the intravenous tubing between the warmer and the child, before the fluid enters the child's body. Warming intravenous fluid during maintenance therapy is virtually useless for temperature regulation.

Blood warmers vary from simple coiled tubing in a warming bath to the more sophisticated rapid transfusion devices. Rapid transfusion systems are vitally important in any institution that manages trauma patients or performs major surgical procedures. The new generation of warming devices is far superior to water-bath warmers. They use countercurrent heat exchange or microwave technology as a means of rapidly warming fluid along the length of the column of fluid. The choice of device depends on the size of the child, the anticipated rate of blood loss, and cost. The length of the intravenous tubing and the diameter of the intravenous catheter also limit the rate of rapid infusion. An example of these devices with the lowest capacity is the Hot Line (Smiths Medical ASD, Rockland, Mass.), which is extremely effective at rates up to 75 mL/min.<sup>22</sup> The manufacturer's data suggest that approximately 90 mL/min of refrigerated blood products can be warmed to 95° F (35° C) with this device. Another device that has a low volume (6 mL priming volume) and is inserted within the intravenous system just before the intravenous catheter is the Belmont Buddy fluid warmer (Belmont Instrument Corp., Billerica, Mass.). The manufacturer claims a warming capacity of cold fluids to 100.4° F (38° C) at flow rates as low as "keep vein open" (KVO) and as great as 100 mL/min.<sup>23</sup> This device should be inserted close to the intravenous catheter because it may help maintain the child's temperature by minimizing heat loss along the length of the intravenous tubing. A more complex and larger capacity system is the Level 1 System 1000 (Smiths Medical ASD, Rockland, Mass.), which uses countercurrent warming technology combined with the capacity to infuse fluid, blood, or plasma in bags under pressure. *Because this device infuses bags of fluid under pressure, it is important to eliminate all air from the bags to avoid the possibility of air embolization.* This system is capable of warming fluids at rates up to approximately 500 mL/min.<sup>24</sup> The Level 1 device is capable of warming blood starting at 41° F (5° C) to 42.8° F (6° C) to at least 91.4° F (33° C) at rates as high as 250 mL/min.<sup>25</sup> The manufacturer's data suggest that up to 600 mL/min of red cells diluted to a hematocrit of 60% can be delivered through a 14-gauge intravenous catheter and 750 mL/min through an 8.5F introducer sheath. The addition of an air detection device with automatic flow interruption has improved safety.<sup>26</sup> Another high-capacity system is the Belmont FMS warmer (Belmont Instrument Corp., Billerica, Mass.) uses microwave warming and is capable of fluid delivery at rates of 10 to 750 mL/min; this device has two air detectors and an in-line pressure detector. One study compared the flow rates and warming capabilities of the Level 1 system with the Rapid Infusion System (no longer manufactured but equivalent to two Belmont FMS systems); both devices were comparable when used with 18- or 20-gauge intravenous catheters in terms of warming and flow rates. However, for any catheter larger than 18 gauge, the Rapid Infusion System was superior for both flow and fluid warming, particularly for flows greater than 200 mL/min (Figs. 51-1 and 51-2).<sup>27,28</sup> A similar comparison has been made with the Level 1 and the Belmont FMS systems, with a similar difference in terms of better warming capacity during high flows.<sup>29</sup>

**FIGURE 51-1** This figure plots the mean temperature of the fluid at the end of two 2-liter infusions of crystalloid for the Level 1 versus the Rapid Infusion System. Note that both devices have equivalent warming capacities with flow rates 200 mL or less per minute but that there is markedly less warming capacity with the Level 1 system at higher flow rates. (From Barcelona SL, Vilich F, Coté CJ. A comparison of flow rates and warming capabilities of the Level 1 and Rapid Infusion System with various-size intravenous catheters. *Anesth Analg* 2003;97:358-63.)

**FIGURE 51-2** Percent differences in flow rates for the Rapid Infusion System versus the Level 1 for various catheter sizes. Note that the Rapid Infusion System produced greater incremental changes in flow with progressively larger catheters (16 gauge or larger). The Belmont FMS system should have performance characteristics similar to those of the Rapid Infusion System. (From Barcelona SL, Vilich F, Coté CJ. A comparison of flow rates and warming capabilities of the Level 1 and Rapid Infusion System with various-size intravenous catheters. *Anesth Analg* 2003;97:358-63.)

In general, the Level 1 Hotline (Smiths Medical) or the Belmont Buddy appear most suited for low-volume, relatively slow blood loss. The Level 1 system seems most appropriate for children weighing 40 kg or less with expected rapid blood loss and the Belmont FMS for larger children with expected massive and rapid blood loss. The advantages and disadvantages of these warming devices are compared in Table 51-1.<sup>30</sup>

### HEATED HUMIDIFIERS

Airstream warming and humidification devices are useful for maintaining body temperature.<sup>31-33</sup> If a humidifier is used, the

anesthesiologist should be familiar with the potential hazards: overheating, leaks, “rain out,” changes in compression volume, and obstruction if connected in reverse. Humidifiers with servomechanism-controlled temperature regulation may prevent overheating and overhydration of infants. Anesthesia breathing circuits with internal heating elements may further reduce the rainout problem and minimize the risk of overheating; these advantages must be weighed against the additional expense. However, with the advent of warm air mattresses and more common use of circle systems in children of all sizes, there appears to be less of a need for in-line humidification as a means of warming children. The main indication for in-line humidification is to prevent secretions from drying when nonrebreathing circuits are used.

### WRAPPING

Any form of wrapping can reduce radiant and convective heat losses; plastic wrap used for food is particularly effective and inexpensive. Covering an infant’s head is of greatest value because the head represents such a large proportion of the body surface area. As with any warming device, there are hazards; the plastic drapes reduce conductive losses but also eliminate sweating as a mechanism of thermal regulation, so that hyperthermia may result.<sup>34</sup> “Space” blankets with reflective aluminized Mylar layers have been very effective in preventing heat loss in the past.<sup>35</sup> With effective room temperature control and forced air heating mattresses, the importance of wrapping the child has diminished.

### Intravenous Therapy

It is necessary to have the appropriate range of intravenous equipment for the patient population being anesthetized. In general, it is safest to establish intravenous access in all anesthetized children. The only exception to this practice may be a brief, noninvasive procedure such as myringotomy and tube insertion or suture removal; in this situation, an infusion set is primed and ready for use should it be needed.

The volume of the infusion fluid container should not exceed the child’s estimated fluid deficit unless a volume-limiting device is interposed between the intravenous container and the child. Generally, an intravenous set with a microdrop outlet (60 drops/mL) is most practical for children weighing less than 50 kg. Infusion sets that include a one-way valve to prevent retrograde flow in the intravenous administration set are most useful. The infusion setup should include easily accessible injection ports; intravenous extension tubing may be required if the access is in the lower extremities. A three-way stopcock within the system is also helpful should an “adult” intravenous line be needed to give a rapid bolus of intravenous fluid. Recent practice has shifted from needle injection ports to needleless. Both the needleless ports and stopcocks are reservoirs for small volumes of air that may be injected into the intravenous tubing if the air is not cleared during the initial setup or aspirated into the medication syringe before delivering the syringe contents. It is best to purge infusion sets of all air bubbles, especially at each injection port, before use with infants and children.<sup>36</sup> In children with known cardiac defects with shunts or arteriovenous malformations, and in infants with patent foramen ovale, the potential for paradoxical air emboli is always present (up to 27% of adults).<sup>37</sup> In these circumstances, intravenous air traps may reduce this risk, but caution is advised because blood cannot pass through such

**TABLE 51-1** Comparison of Three Blood and Fluid Warming Devices

	WARMING DEVICE		
	Level-1	FMS2000	Buddy
Manufacturer	Level-1 Technologies, Rockland, Mass.	Belmont Instrument Corp., Billerica, Mass.	Belmont Instrument Corp., Billerica, Mass.
Cost*	Without air detector, ~\$5500 With air detector, ~\$8950	~\$20,000	~\$1600
Footprint	Medium	Medium	Small
Setup	Stand-alone system mounted on its own IV pole	Mounted on IV pole	Power module mounted on IV pole, warming unit mounted on IV tubing
Weight (kg)	~32 with IV pole	~12	~4.4 (unit on IV tubing only 105 g)
Air detection	Single detector (optional)	Two detectors	Pressure-regulating valve and venting membrane
Ease of fluid loading	Requires venting of air from IV bags to prevent air embolization	No air venting required	No air venting required but not designed to deliver fluid under pressure
Ease of setup	Easy	Relatively easy	Very easy
Other	No reservoir for blood mixing	Does not heat at flows <10 mL/min	Unclear effectiveness with rapid blood transfusion

Modified from Barcelona SL, Thompson AA, Coté CJ. Intraoperative pediatric blood transfusion therapy: a review of common issues: I. Hematologic and physiologic differences from adults; metabolic and infectious risks. *Paediatr Anaesth* 2005;15:716-26.

IV, Intravenous.

\*In U.S. dollars; cost may vary from country to country and with multiple purchases.

devices.<sup>38</sup> In the smallest patients, a T-connector placed at the hub of the intravenous catheter allows direct injection of drugs with minimal fluid dead space. It should also be noted that stopcocks and injection ports may act as a reservoir for administered drugs; it is thus important to always flush through any medications administered with these systems. With standard injection ports, long needles will bypass the injection port and deliver drug into the main body of the intravenous tubing (see later).

When carefully metered transfusion of colloid or blood is necessary, a multiple-stopcock manifold, preferably with Luer-Loks to avoid disconnections, added to the infusion line allows the main line to continue infusing maintenance fluid except during the actual administration of either blood or colloid. This arrangement provides an outlet for blood administration, another for colloid administration, and a third for a metering syringe. Careful titration of intravenous fluid and medication infusion rates may be facilitated by the use of electronic pumps or intravenous rate controllers. The infusion pump chosen for a child must suit the circumstances. In most situations, a device with precise volume limits and air bubble and pressure alarms is the safest. Multiple stop-cock manifolds allow the administration of several medications (e.g., vasopressors) simultaneously; special narrow-bore tubing also reduces the dead space of such a setup, thus minimizing delays in response to changes in the vasopressors because of the reduced dead space of the system (see later).

The flow of crystalloid is not a simple linear function of perfusion pressure; the relationship deviates substantially from linearity. Additionally, elements of the intravenous system have isolated effects on one factor or another. For example, a 5- $\mu$ m filter increases resistance and reduces flow at all pressures. A check valve significantly increases resistance but reduces flow primarily at high flow rates.<sup>39</sup> A similar nonlinear function describes the pressure and flow relationship of intravenous cannulas.<sup>40</sup> Studies of crystalloid solutions demonstrate steep increases in resistance with increasing pressure in a nonlinear manner with smaller-gauge cannulas (E-Fig. 51-1). The effects of the tubing set add to the effects of the cannula; connecting

large-diameter tubing to a smaller-diameter catheter limits flow according to the diameter of the catheter. In situations in which massive and rapid blood loss is anticipated, insertion of extra-large peripheral intravenous catheters such as 5, 6, 7 or 8F pulmonary artery flow catheter introducers or specially designed rapid infusion catheters will provide the most efficient method for rapid volume administration. Special placement kits are available that allow the dilation of small veins by the placement of a guidewire through either a small needle (Seldinger technique) or a small-gauge intravenous line followed by dilation of the vein and placement of a larger-diameter cannula (see Chapter 48).

Accelerating flow through an intravenous line is a concern in emergency situations. Rapid transfusion devices are the best method for increasing flow rates (see earlier).<sup>22,24,25</sup> For bags of crystalloid, colloid, or blood components a pressure infusion cuff is a relatively fast, readily available, and the least expensive method for rapidly administering large volumes.<sup>41</sup> *It is important to remove air from these bags so as to avoid air embolization because an air detector is not used with this technique.* Next in order of efficacy are in-line blood pumps or a stopcock and syringe arrangement; gravity is the slowest method of infusion. The syringe technique is often used in infants and children (primarily for accurate measurement in infants); it is similar in efficiency to the in-line blood pump. Intravenous tubing designed for administering blood has better flow characteristics than standard intravenous tubing.<sup>42</sup> Large-bore "resuscitation" tubing provides the best flow characteristics; however, the final common pathway, the lumen of the intravenous catheter itself, is the major limitation of flow capacity.<sup>25,39-44</sup> Larger-diameter, short catheters allow greater flow than long narrow-diameter catheters.<sup>44</sup> This factor is particularly important when rapid volume administration is required but the only intravenous access is through a central venous catheter. This problem is greatly magnified when multilumen catheters are used.<sup>44-45</sup> *If rapid volume resuscitation is a significant potential problem, then one single-lumen, large-bore peripheral intravenous line is of much greater value than a multilumen central venous catheter. Peripherally inserted central catheters (PICC) lines are a potential problem as well because of their very large resistance they cannot be relied on for rapid*

**E-FIGURE 51-1** The pressure-flow relationship of intravenous catheters. Note that the pressure-flow relationship is nonlinear; the smaller the catheter diameter, the greater the resistance. (These data appeared, in part, in Philip BK, Philip JH. Characteristics of flow in intravenous catheters. IEEE Trans Biomed Eng 1986;33:529-31.)

*volume administration* (see further discussion of laminar and turbulent flow).

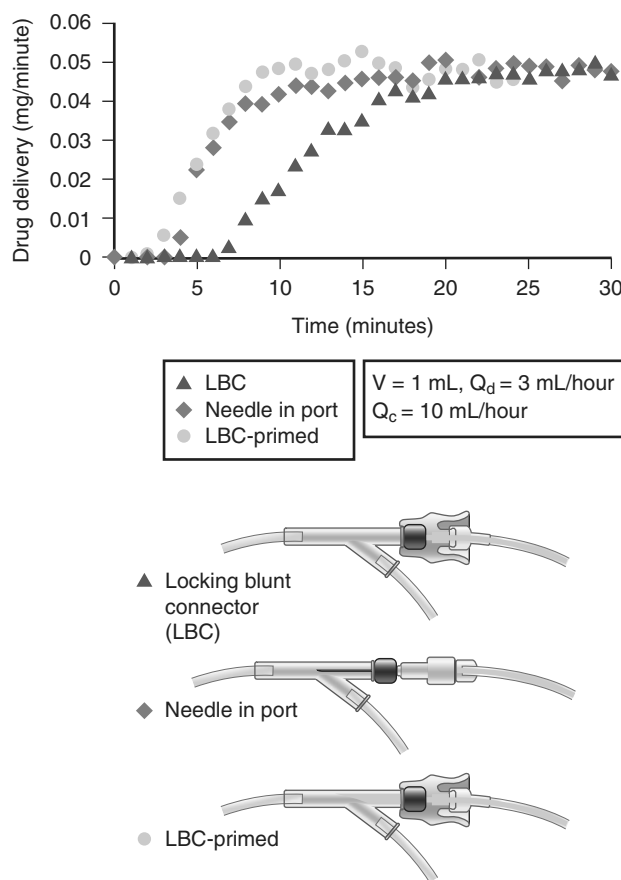

The choice of fluid and its temperature also have effects on the rate of infusion, primarily because of differences in viscosity. Crystalloid passes most readily, followed by colloid, whole blood, and packed red blood cells. Dilution of packed red blood cells with normal saline markedly improves the flow rate and decreases hemolysis during rapid infusion.<sup>46</sup> Hemolysis and associated hyperkalemia of packed red blood cells transfused through short or long catheters under high pressure appears to not be clinically important when the rate of transfusion is moderate. However, rapid transfusion may be associated with hyperkalemia, particularly in infants.<sup>47-51</sup>

One further concern that has very important clinical implications is the interaction among intravenous tubing design, infusion pumps, and carrier flow rates regarding timing of actual drug delivery to the child. This is an even greater issue in infants and neonates in whom the volumes of drugs and the carrier infusion rates are small. Several studies of adult equipment have examined the interactions of dead space volumes and carrier rates on the time lag to initial drug delivery, time to steady-state drug delivery, and then offset once the infusion is stopped. These interactions also vary whenever a change in carrier flow rate occurs (e.g., when a slow carrier infusion is suddenly increased, this will result in a bolus of drug). Conversely, when a rapid carrier rate is suddenly reduced, this will result in a marked reduction in drug delivery. The importance of these interactions increases the further upstream in the system that a drug is administered; for example, the administration of a drug directly into the T-connector will be the least susceptible to these variables than a drug administered into a side port of an intravenous line 10 to 30 cm away from the intravenous catheter. Thus, when life-support medications are being administered, it is vital to avoid fluctuations or interruptions in carrier rate and to reduce as much as possible the dead space in the system between the child's bloodstream and the point of drug entering the intravenous system. This is true for the OR, during transit to the intensive care unit (ICU), and at the time of transfer of care. This is particularly an issue when OR pumps and intravenous equipment are switched over to new tubing and pumps in the ICU. Figure 51-3 illustrates the time delay in drug delivery comparing the dead space of an injection port with and without a needle that bypasses the dead space of the injection port and how this time delay can be minimized by "priming" the dead space of the injection port.<sup>52,53</sup> Figure 51-4 illustrates several multidrug administration manifolds that allow administration of many medications simultaneously, each with differing dead space characteristics that could cause considerable delay in drug delivery if the dead space within each is inadequately primed. The best way to avoid this problem is to flush each drug through the system from entry to exit point, shut off the infusion, flush the carrier through the system to remove any medications from the carrier portion of the manifold, then attach the system to the patient, so that all infusions will immediately be discharged into the carrier intravenous fluid when turned on, rather than having a delay while the dead space at the connection is filled.

## Airway Apparatus

### MASKS

The importance of elimination of mechanical dead space increases with decreasing size of the child. Rendell-Baker/Soucek masks,

**FIGURE 51-3** The time delay in onset of drug delivery to steady-state drug delivery as affected by a needle in an injection port, a blunt locking connector or "priming" of the dead space of the injection port are illustrated. Note that the time to initiate drug delivery is delayed by several minutes and the time to achieve a steady-state rate of drug administration may be delayed by 10 minutes or longer when the dead space is not primed or a needle is not used to bypass the dead space of the injection port (in this example, the parameters were: carrier rate [ $Q_c$ ] 10 mL/hr, drug flow rate [ $Q_d$ ] 3 mL/hr, dead space volume [ $V$ ] 1 mL). This concept has important implications regarding drug delivery to all patients, but this is particularly important in infants and neonates in whom small volumes of drug may be administered into a relatively large dead space that must be filled before any drug enters the flow of the intravenous fluid and the hourly rate of the carrier is low. (From Lovich MA, Doles J, Peterfreund RA. The impact of carrier flow rate and infusion set dead-volume on the dynamics of intravenous drug delivery. *Anesth Analg* 2005;100:1048-55.)

developed from molds of the facial contours of Caucasian children, were designed to minimize mechanical dead space without the inflatable cuff or high dome of adult masks. Transparent disposable plastic models are preferable to the classic black conductive rubber because they allow observation of a child's color and condensate from exhaled humidity with respirations. Plastic disposable masks with soft inflatable cuffs around the periphery of the mask are particularly well suited for children with anatomic or mechanical problems that interfere with normal mask application. An especially useful mask has a built-in port, which allows passage of an endotracheal tube over a fiberoptic scope, thus providing excellent fiberoptic intubation conditions while maintaining spontaneous respiration, oxygenation, and depth of anesthesia (see E-Fig. 12-13).<sup>54</sup>

**FIGURE 51-4** Several multiple-drug and fluid administration systems are illustrated. Note the wide variation in dead space volume among the screw-in connectors (A), simple stopcocks (B), screw-in connectors with one-way valves (C), and multiple short tubing connections (D). To avoid variations in rate of drug delivery, it is advised to use a dedicated carrier on a pump. To ensure that the initiation of drug delivery is timely, the following steps are necessary: (1) each dead space port must be flushed and primed with the desired infusion as it is attached to the delivery manifolds; (2) after priming, the stopcock is turned to the off position or the tubing clamped; (3) the carrier portion of the system is then run through or flushed with the carrier intravenous fluid; and (4) the system is attached to the patient with just the carrier ensuring a constant flow to the patient. When the drug infusion is initiated, the stopcock is turned to the on position or the tubing unclamped and each drug infusion pump turned on at the desired rate. This ensures that no drug is accidentally administered and reduces the time to initial drug delivery by priming the dead space of the system for each drug infusion. It should be borne in mind that this system should be connected as closely as possible to the intravenous catheter to avoid further delay in drug delivery because of the need to fill the dead space between the multiple drug manifolds and the entry into a vein. The use of a pump for the carrier solution also prevents retrograde drug infusion.

## ORAL AIRWAYS

A complete selection of oral airways must be readily available. Infants have a relatively large tongue, which easily obstructs the airway once they lose consciousness. If too large an airway is inserted, damage to laryngeal structures (traumatic epiglottitis, uvular swelling) may result in postoperative airway obstruction (see Fig. 12-13).<sup>55</sup> Improperly inserted airways, by obstructing venous and lymphatic drainage, also may result in airway obstruction secondary to swelling of the tongue.<sup>56,57</sup> A tongue blade is useful to help insert the airway without kinking the tongue or catching the tongue or lips between the airway and the teeth.

## NASOPHARYNGEAL AIRWAYS

Nasopharyngeal airways are not as frequently used in children because the internal diameter is often small, resulting in increased work of breathing and increased chance of blockage by sections or blood. In addition, adenoid hypertrophy makes a child susceptible to bleeding after nasopharyngeal airway insertion. Despite its limitations, it can help provide a patent airway in spontaneously breathing infants and children (particularly after pharyngoplasty or cleft palate repair) and is better tolerated in awake children. Nasopharyngeal airways range in sizes to accommodate neonates through to adolescents and may have a movable ring to set the length or a flange on the end to prevent loss in the nasal cavity. If a stiffer airway is necessary, a well-lubricated tracheal tube, cut to the appropriate length (to reach the nasopharynx only), may be used; however, it must be safely secured because it may accidentally pass into the nasopharynx.

## LARYNGEAL MASK AIRWAY

The laryngeal mask airway (LMA) has proved to be a great addition to the airway management of children. Minimal practice is required to develop the skills for insertion. In some circumstances the LMA can be lifesaving (see Chapter 12).<sup>58-64</sup> This device generally provides a clear airway for maintaining spontaneous respirations; however, it cannot be relied on if controlled ventilation is required. Controlled ventilation has been described but holds the risk of gastric dilation.<sup>65</sup> We think that this device should be used primarily for spontaneous ventilation and with great caution with controlled ventilation in infants and children. Modern anesthesia ventilators provide the alternative and likely safer pressure-assisted mode of ventilation.<sup>66</sup> The LMA is particularly useful in children with anatomic airway abnormalities, because it provides a clear airway while other measures are planned for successful tracheal intubation or a tracheotomy.<sup>64,67</sup> Fiberoptic intubation through the LMA is possible in children with midfacial hypoplasia syndromes and in those with redundant airway tissue such as mucopolysaccharidoses (see also E-Fig. 12-22, A through C). Fiberoptic intubation is easier through the LMA because the child can be well oxygenated while using the fiberoptic scope to find the laryngeal inlet. Emergency placement of this device can also be lifesaving in children who are difficult to ventilate with bag and mask with or without a nasal or oral airway.<sup>68</sup>

Variations to the classic LMA include disposable LMAs of all sizes, intubating LMAs in larger sizes, LMAs with reinforced tubing, and the ProSeal LMA (LMA, La Jolla, Calif.) with a distal opening that provides the ability to pass an orogastric tube (see

Fig. 12-18, *A* and *B*). This variation to the classic LMA produces a better laryngeal seal and provides the ability to ventilate the lungs without a significant leak at greater peak inflation pressures.<sup>69</sup> This variation would seem to offer the greatest advantage in the child with a known difficult airway or in the emergency management of the child with a difficult airway who also has a full stomach. Many other LMA variants are available, each with claimed advantages. Each practitioner should assess which device is most effective in the practice environment<sup>70</sup> (see also Chapter 12 for a more in-depth discussion).

## TRACHEAL TUBES

A variety of tracheal tubes must be available with appropriate sizes of stylets. There may be considerable variations from one manufacturer to another in wall thickness, external diameter, kink resistance, and direction and angle of bevel, as well as differences in tracheal tube cuff length and thickness of cuffed tracheal tubes.<sup>71</sup> All tracheal tubes should be implantation tested and manufactured in accordance with the Z79 international agreement for safe products. Tracheal tubes are sized by the internal diameter (ID) in millimeters. Despite differences in endotracheal tube wall thickness among manufacturers, a first approximation for the correct tracheal tube size for an average child older than 2 years of age is<sup>72</sup>:

$$4 + \frac{\text{age in years}}{4}$$

Preterm infants weighing less than 1500 g generally require a 2.5-mm ID tracheal tube, whereas preterm infants of more than 1500 g require a 3.0-mm ID tube, full-term neonates require a 3.0- to 3.5-mm ID tube, a 1-year-old requires a 4.0-mm ID, and a 2-year-old requires a 4.5- to 5.0-mm ID. Although it has been suggested that the correct diameter of the tracheal tube may be determined by examining the diameter of the distal phalanx of the child's first or fifth digit, evidence suggests that this is unreliable.<sup>69</sup> Tracheal tubes at least one half-size larger and smaller than estimated should be immediately available to accommodate airway size variability. The only true test for appropriate size selection is that the tube passes through the subglottis easily and has an appropriate leak (e.g., between 10 and 40 cm H<sub>2</sub>O peak inflation pressure). The leak may be easily assessed by closing the circuit pop-off valve and slowly increasing the pressure by gently squeezing the anesthesia bag while listening over the larynx with a stethoscope. This technique has been demonstrated to be a sensitive and accurate measure of fit between the tracheal lumen and the endotracheal tube.<sup>73</sup> It should be borne in mind that a leak is dependent in part, upon the child's head position and degree of paralysis.<sup>74</sup> For example, if the neck is flexed or the head is turned from side to side, a leak may become worse or decrease. If the trachea was intubated without the use of muscle relaxants, the child must be well anesthetized to assess the leak properly. If a child is coughing, it is difficult to make this assessment. Conversely, if the child has laryngospasm around the tube, then it will appear to be too large because a leak may not be present. On the other hand, too large a leak may prevent adequate ventilation should positive-pressure ventilation be required, pollute the OR excessively, and dilute the inspired gases during spontaneous respirations. In this circumstance, the tracheal tube should be replaced with the next larger size and the leak reassessed. The relationship of age, tracheal tube sizes and inhalation pressure leak is commonly used to estimate laryngeal size (see Fig. 31-13).

The past decade has seen a transition from the routine use of uncuffed tubes in children during general anesthesia to the

routine use of cuffed tubes. Uncuffed tubes are available for use from 2.0-mm ID to 6-mm ID and have been used as a standard in children up to 8 years of age. Indeed, traditional teaching suggests that the use of uncuffed tubes is the most appropriate practice<sup>75</sup>; however, this is not evidence-based. The use of cuffed tracheal tubes has been demonstrated to reduce costs of inhalation agents use because of the ability to use lower fresh gas flows.<sup>76</sup> With the introduction of the MICROCUFF (Kimberly-Clark Health Care, Roswell, Ga.) tube and publication of several clinical studies, practice has shifted from the routine use of uncuffed to cuffed tracheal tubes. The external diameter of cuffed tracheal tubes is approximately 0.5 mm larger than uncuffed because of the cuff, so one must use a smaller-ID tube for a given tracheal size. Cuffed tracheal tubes as small as 3.0 mm ID are available for use in elective and emergency surgery in infants and children. Some have proposed that the advantages of a cuffed tracheal tube for children include reduced number of reintubations, decreased leak around the tracheal tube leading to less contamination of the operating room, greater ease and consistency of ventilation, reduced cost if low-flow anesthesia is used, and a theoretical attenuated incidence of aspiration.<sup>76-82</sup> If a cuffed endotracheal tube is used, the cuff is generally inflated just enough to provide a leak between 20 and 30 cm H<sub>2</sub>O peak inflation pressure or cuff pressure can be monitored using a device that continually monitors cuff pressure.<sup>83</sup> It must be recognized that the endotracheal tube cuff pressure will increase during a nitrous oxide (N<sub>2</sub>O)-supplemented anesthetic because of diffusion of N<sub>2</sub>O into the cuff,<sup>84</sup> unless saline is used to fill the cuff.<sup>85</sup> However, because the MICROCUFF tube seals the airway at a reduced pressure compared with polyurethane cuffed tubes, the time until the pressure within the cuff becomes excessive with the MICROCUFF tube is greater than with traditional tracheal tubes.<sup>86</sup> Excessive cuff pressures may present a special additional hazard to children, in whom swelling of the pseudostratified columnar epithelium that lines the inside of the cricoid ring may critically reduce the diameter of the upper airway. To date, studies have not investigated long-term complications such as subglottic stenosis that might occur in the intensive care unit. Tracheal tubes used in the OR remain in the trachea for only a brief time; thus it is unlikely that such use could result in long-term complications. An important advantage of the MICROCUFF tube is that the cuff is located closer to the tip of the tube (thereby reducing the potential for cuff pressure on the vocal cords or the cricoid cartilage, but eliminating the Murphy eye), lower cuff sealing pressure (again potentially reducing injury to the mucosa of the trachea), and less leakage around the cuff (less microaspiration) (see Fig. 12-15).<sup>87-92</sup> However, the marked nearly fivefold difference in cost will likely prohibit the routine use of this tracheal tube for short term intubation. Additionally, reports of easy kinking in the smaller size tubes resulted in a product recall.<sup>93</sup> The authors' practice has increased the use of the Mallinckrodt Lo-Pro Endotracheal Tubes (Nelcor, Pleasanton, Calif.), which is not a new product but anecdotally provides a low-pressure cuff that has a lower contour, aiding the view during tracheal intubation, and has a smaller effect on the size of the outer diameter of the tracheal tube. No specific studies have demonstrated any differences in complications when comparing different low-pressure endotracheal tubes. The original Khine formula (4 + age [years]/4)<sup>79</sup> has been critically evaluated, and a new formula with greater tracheal tube size accuracy has been proposed (3.5 + age [years]/4).<sup>79,94</sup> However, these studies did not adequately examine the infants in the lowest age range, nor did they examine these specific brands of tracheal tubes. The argument could be made

that long-term follow-up data for complications has not been adequately investigated.<sup>95</sup> *Currently, we do not recommend the routine use of 3.0-mm ID cuffed tracheal tubes in neonates because the potential for laryngeal/tracheal damage far outweighs the advantage of avoiding an extra laryngoscopy and intubation.*

Molded preformed tracheal tubes are especially useful for head and neck surgery because they remove the anesthesia circuit connections from the surgical field.<sup>96</sup> When excessive external pressure may be applied to the tracheal tube or when extreme flexion of the neck is likely to kink a standard endotracheal tube, a tracheal tube with Tovell spiral wire reinforcement may be used. Its kink resistance is well-known, but the additional wall thickness limits its applicability in younger children. The spiral springlike construction has caused the tube to pop out of the airway; in addition, repeated improper sterilization of nondisposable models may lead to bubble formation within the rubber, leading to airway obstruction when used with N<sub>2</sub>O.<sup>97</sup>

The carbon dioxide (CO<sub>2</sub>) laser for treatment of laryngeal polyposis and other airway lesions has introduced the problem of ignition of the tracheal tube or other material in the airway. Avoiding high levels of O<sub>2</sub> and N<sub>2</sub>O, which both support combustion, diminishes the risk of fire. Special stainless steel and metal implanted tracheal tubes are available but are quite expensive. Protecting the tube surface with aluminum or copper foil or wet sponges and red rubber tracheal tubes, which have a much reduced ignition potential, may offer the greatest protection (see Chapter 31).<sup>98-102</sup> Electrocautery can ignite standard tracheal tubes, esophageal stethoscopes, oral airways, feeding tubes, tissue, and packs if the correct circumstances combine.<sup>103-105</sup> Rubber tracheal tubes may soon no longer be manufactured because they are made of latex rubber but are still being advocated by some practitioners for laser surgery.

The tracheal tube itself creates significant resistance to airflow, and this phenomenon is described in the physics of resistance to flow for all gases and fluids. Flow of gases and fluids through airways and blood vessels and at branching points may be described as either laminar or turbulent. Reynolds number, a dimensionless value, is calculated as the ratio of inertial to viscous forces in the following equation:

$$NRe = DV\rho/\mu$$

where  $NRe$  is the Reynolds number,  $D$  is the diameter of the airway or blood vessel, and  $V$  is the velocity,  $\rho$  is the density, and  $\mu$  is the viscosity of the gas or fluid. An  $NRe$  less than 2100 denotes flow that is laminar, whereas an  $NRe$  of 3000 or greater denotes turbulent flow. Flows that have  $NRe$  between 2100 and 3000 may be either laminar or turbulent. Conceptually, laminar flow is organized flow in which each plate of fluid, air, or gas moves in parallel at the same speed, with zero velocity at the interface between the wall of the airway or blood vessel and the gas or fluid. Laminar flow occurs in blood beyond the aortic arch and in airways beyond the fifth bronchial division. In contrast, turbulent flow is chaotic, unpredictable flow in which the fluid, air, or gas does not flow in parallel plates but rather develop eddies and lateral as well as forward flow, thus dissipating large amounts of energy. Turbulent flow occurs in the aortic arch and in the large airways of the tracheobronchial tree down to the fifth bronchial division.

Laminar flow is characterized by the Hagen-Poiseuille equation:

$$\Delta P = 8Q\eta l/\pi r^4$$

Where  $\Delta P$  is the pressure drop,  $Q$  is the flow rate,  $\eta$  is the viscosity of the fluid (air or gas),  $l$  is the length of the airway or blood vessel, and  $r$  is the radius of the airway or blood vessel. Thus pressure drop is proportional to the flow rate and viscosity of the fluid and inversely proportional to the radius to the *fourth power*.

Turbulent flow is not easily characterized by an equation. Unpredictable losses such as friction are difficult to quantify. Hence, no single equation exists for turbulent flow as in the case of laminar flow. However, for large  $NRe$ , we know that:

$$\Delta P \propto Q^2 \rho / r^5$$

Where  $\Delta P$  is the pressure drop,  $Q$  is the flow rate,  $\rho$  is the density and  $r$  is the radius of the airway or blood vessel. Note that in contrast to laminar flow, pressure drop is proportional to the square of the flow rate and inversely related to the *fifth power* of the radius.

Therefore the resistance to gas or fluid flow is greater in relation to the longer and narrower tracheal tube (or intravenous catheter) used; anything that increases turbulence may proportionally increase the resistance to gas or fluid flow. In practical terms, this means that with a tracheal tube, when the respiratory rate is increased, turbulent flow results (meaning that resistance changes with radius to the fifth power, not the fourth power), decreasing the size of the delivered tidal volume.<sup>106</sup> In addition, flow may vary from laminar to turbulent at different portions of the respiratory cycle. Studies with in vivo models have shown that this effect is less pronounced with progressively larger tracheal tubes; however, larger tubes may result in reductions in delivered tidal volume when the respiratory rate is increased in children who require a smaller than normal endotracheal tube; that is, an increase in respiratory rate from 10 to 20/min does not double the delivered minute ventilation.<sup>106-108</sup> Data suggest that in children with poorly compliant lungs, lung compliance seems to be the most important factor, even with very small tracheal tubes.<sup>106</sup> The implications of these observations are that accurate measurement of end-expired CO<sub>2</sub> or arterial blood gases are the only way to be certain of the effectiveness of ventilation. In patients with severe pulmonary disease with ventilation-perfusion mismatch, only arterial blood gases or transcutaneous CO<sub>2</sub> monitoring will provide the needed information.

## Intubation Equipment

### ROUTINE EQUIPMENT

Intubation equipment must suit pediatric children of all sizes. Laryngoscopes are available with lightweight small handles and a full range of blades (see Chapter 12). An Oxyscope (Foregger, Inc. Langhorne, Pa.), which incorporates a small-bore O<sub>2</sub> delivery tube, reduces the incidence of cyanosis and bradycardia in spontaneously breathing neonates should laryngoscopy be prolonged (see E-Fig. 12-12, *A* and *B*).<sup>109</sup> Magill forceps are available in several sizes for children of different ages.

### SPECIAL AIRWAY EQUIPMENT

Difficult airways require special intubation equipment; flexible and rigid fiberoptic laryngoscopes and bronchoscopes are available for infants and children. Flexible fiberoptic laryngoscopes are available as small as 1.8 mm external diameter; these are suitable for passage of 2.5-mm ID endotracheal tube.<sup>110</sup> The small scope is limited because it does not provide suction. Fiberoptic endoscopic skills should be developed during routine elective cases and in training exercises using airway or full manikin

simulators to acquire these skills before encountering emergency cases or children with abnormal airway anatomy (see Chapter 12).<sup>110</sup> Fiberoptic intubation through the LMA in infants and neonates with midfacial hypoplasia allows the maintenance of a clear airway, delivery of O<sub>2</sub> with or without inhalation anesthetic and provides optimal conditions for successful placement of the tracheal tube.<sup>61,62,111-114</sup>

Lighted stylets provide an alternative technique for management of a difficult airway.<sup>115-118</sup> Other airway devices such as the Bonfils fiberscope (Karl Storz, Tuttlingen, Germany), the Airtraq disposable optical laryngoscope (Prodol Meditec, Vizcaya, Spain), the GlideScope video laryngoscope (Verathon, Bothell Wash.), the Storz DCI video laryngoscope (Karl Storz, Tuttlingen, Germany), and the Trueview PCD Infant (Truphatek, Netanya, Israel) can optimize the management of difficult pediatric airways<sup>119-125</sup> (see Chapter 12 for a more in-depth discussion).

## Suction Apparatus

A functioning suction apparatus must be available before beginning any anesthetic administration. The device should be capable of regulated pressures; suctioning the oropharynx requires a greater vacuum level than suctioning the tracheal tube. Special circumstances (e.g., a full stomach and arterial bleeding in the oropharynx) may require a second suction device. A separate vacuum system is needed to scavenge waste anesthetic gases. Several sizes of suction catheters are helpful, depending on the indication—tracheal, gastric, or oropharyngeal suction. A 6 or 8F suction catheter with a thumb-controlled side port is useful for suctioning through small tracheal tubes, whereas 10, 12, and 14F catheters are useful for larger tracheal tubes. Routine suction of stomach contents after induction of anesthesia may reduce the potential for gastric fluid regurgitation and serious pulmonary aspiration of gastric contents. In larger patients, vented catheters (e.g., Salem Sump; Sherwood Medical, St. Louis) may be more efficacious than unvented catheters. Suctioning the stomach with the child in the supine position and in left and right lateral decubitus positions has been shown to be most efficient in evacuation of stomach contents.<sup>126</sup>

Yankauer suction devices are commonly used for oropharyngeal suctioning. When purchasing Yankauer suction devices, it is best to choose a plastic model rather than metal to minimize the risk of damage to the teeth. These suction devices are more efficient at removing large fluid volumes (e.g., during regurgitation) than suction catheters.

## The Anesthesia Machine and Its Appendages

### ANESTHESIA MACHINE

All children can be anesthetized with standard adult machinery as long as the anesthesiologist is aware of the pitfalls and limitations. No anesthesia machines are currently marketed solely for pediatric use; however, anesthesia machines that have the ability to be customized for pediatric use may be of value, but not necessary. If one wishes to use special circuits, a Mapleson D system may be permanently mounted, allowing the choice of either a circle or open system. Modifying the anesthesia machine has inherent danger, especially for inexperienced users; the circuit or other components could be assembled incorrectly and potentially be unsafe. In addition, air should be available from a central

pipeline or a cylinder with an appropriate yoke and flow meter. This is particularly advantageous in circumstances in which N<sub>2</sub>O or a high inspired O<sub>2</sub> concentration is contraindicated (avoiding hyperoxia in a premature infant, N<sub>2</sub>O in a patient with bowel distention, or laser airway surgery).<sup>127-129</sup> Even though machines are designed not to allow the delivery of a hypoxic gas mixture, an in-line O<sub>2</sub> analyzer and pulse oximetry are indicated to use an air-oxygen blend safely. The anesthesia machine should also be equipped with an alternative means of providing O<sub>2</sub> and positive-pressure ventilation (self-inflating bag) in case of a machine failure or malfunction.

### SCAVENGER

The scavenging of anesthetic waste gases to limit exposure of anesthetic gases to health care providers is important. However, during pediatric anesthesia, exposure to anesthetic gases occurs during inhalational inductions by mask where high fresh gas flows are used and a poor mask seal exists because of patient anxiety or movement. The use of uncuffed tracheal tubes with large leaks also increases exposure. Modern scavenging systems are designed to avoid applying either negative or positive pressure to a patient circuit by using an *open system*, in which a reservoir is used to collect the waste gases and active (suction) or passive pressures are used to remove waste gases from the OR.<sup>130</sup> In a *closed scavenging system*, positive or negative relief values are used in the reservoir or waste gas exhaust hose to ensure that positive pressure does not build up in the system or if the system is blocked so negative pressure is not applied to the patient circuit.<sup>131,132</sup> In addition to scavenging systems, exposure to anesthetic gases is also related to adequate ventilation of the OR.<sup>133</sup>

### CIRCUITS

A full spectrum of anesthetic circuits have been used in infants and children.<sup>134</sup> Adolescents and older children may be anesthetized with a standard adult semiclosed circle absorber system, perhaps with the substitution of a smaller rebreathing bag. Younger children may be anesthetized with the circuit modified by replacing the hoses with small-diameter pediatric tubing and by substituting a smaller reservoir bag. In the past, most infants and neonates (10 kg or less) were anesthetized with nonrebreathing open systems, such as the Mapleson D or F variety. These circuits are used infrequently today and may soon be of historical interest only because the increasing pressure for cost containment and the expense of the newer anesthetic agents has forced most children's hospitals to convert to circle systems. In our institutions, we use only circle systems; this has simplified teaching and markedly reduced anesthetic agent costs. However, because Mapleson D systems are still being used, the advantages and disadvantages of open and closed systems for infants and neonates are reviewed in the following discussion.

Mapleson D systems do not have directional valves or a CO<sub>2</sub> absorber, thus eliminating the resistance intrinsic to the opening pressure of circuit valves and to turbulent flow through soda lime.<sup>135</sup> This may be an advantage in spontaneously breathing neonates during induction before intubation. The main disadvantage of open systems is the need for relatively high fresh gas flows and waste of expensive anesthetic agents, as well as unnecessary pollution of the environment. The work of breathing may be important for spontaneously breathing infants, so most pediatric circuits and masks are designed to eliminate both dead space and resistance. The classic example of this type of system is the Ayre T-piece; this circuit includes no valves or

**FIGURE 51-5** The T piece as described by Ayre. (From Ayre P. The T-piece technique. *Br J Anaesth* 1956;28:520-3.)

reservoir bags (Fig. 51-5).<sup>136</sup> Later modifications included changes to the T-piece and expiratory limb.<sup>137</sup> The Jackson-Rees modification involves the addition of a reservoir bag to the expiratory limb (Mapleson F).<sup>138</sup>

The Magill circuit and its various modifications, Mapleson A to E (Fig. 51-6) remain popular.<sup>139</sup> These systems consist of a source of fresh gas flow into the circuit, a reservoir bag, a pressure-relief (pop-off) valve, tubing of various lengths connecting all of these parts, and an adapter for the mask or tracheal tube. Each of these has advantages and disadvantages, which are well reviewed elsewhere.<sup>130,134,140,141</sup> The Mapleson D variety is the most commonly used because of its safety and versatility with both controlled and spontaneous ventilation.<sup>141</sup> The pop-off valve is at the end of the expiratory limb, just before the reservoir bag; thus, fresh gas washes alveolar gas out of the expiratory limb during expiration. The efficiency of this washout (to prevent rebreathing) depends on the volume of the expiratory limb, the fresh gas flow, and the size of the tidal volume.<sup>130</sup> Larger children (heavier than 15 kg) require greater fresh gas flow rates to prevent rebreathing during spontaneous ventilation.<sup>141,142</sup> Fresh gas flow rates as low as 1 times minute ventilation may be used with controlled ventilation without an increase in expired  $\text{CO}_2$  values.<sup>143</sup> Rebreathing (an increase in inspired  $\text{CO}_2$ ) can occur in children with controlled ventilation when the respiratory rate increases above 20 breaths per minute; this apparent rebreathing can be diminished by using greater fresh gas flows (E-Fig. 51-2). The reason for this phenomenon may relate to inadequate washout of expired alveolar gas before the onset of the next breath. The advantages of minimal dead space and low resistance to flow with nonrebreathing circuits are counterbalanced by the disadvantages of heat and humidity lost to the anesthetic gases and significant waste of anesthetic agents because of the high flows required.<sup>134,141</sup> A clinically important factor is that whenever a change in anesthetic gas concentration is made at the vaporizer, this change is immediately reflected at the airway. This allows a more rapid induction of anesthesia, which may be an advantage but also means a greater risk of producing an anesthetic overdose when compared with a circle system. The most common and efficacious use of the Mapleson D circuit is for the safe transport

**FIGURE 51-6** The Mapleson categories of breathing circuits. The most commonly used circuit for infants is the Mapleson D configuration. (From Mapleson WW. The elimination of rebreathing in various semi-closed anaesthetic systems. *Br J Anaesth* 1954;26:323-32.)

of a child to and from the OR and for intrahospital transport. In this situation the light weight of the system, the ability to easily adjust peak inflation pressure and provide positive end expiratory pressure, and the ability to use relatively low  $\text{O}_2$  flows make this system far superior to self-inflating (Ambu type) devices.

The circle system offers the advantage of using reduced fresh gas flows that decreases cost and decreases pollution of the atmosphere with waste anesthetic gases.<sup>144,145</sup> The use of the circle system in neonates and small infants generally requires assisted or controlled ventilation. Newer anesthesia machines use valves that require reduced pressure to open and close and the  $\text{CO}_2$  absorbers are now wider and shorter, thus reducing the resistance. The main resistance to spontaneous ventilation in infants and

**E-FIGURE 51-2** Note the marked increase in inspired carbon dioxide values during anesthesia in a 7-kg infant using a Mapleson D circuit with 3 L/min fresh gas flow when the respiratory rate is increased from 10 to 20 and 20 to 40 breaths per minute. This may result from inadequate washout of alveolar gases between breaths. Increasing fresh gas flow or decreasing respiratory rate improves washout of alveolar gases. *FG*, Fresh gas; *PIP*, peak inflation pressure. (From Rolf N, Coté CJ. Unpublished data.)

**FIGURE 51-7** The differences in compression volumes among five anesthetic circuits. The Mapleson D systems are the most efficient with the lowest compression volume, whereas the adult rubber circle system has the highest compression volume and is the least efficient circuit. (From Coté CJ, Petkau AJ, Ryan JF, Welch JP: Wasted ventilation measured in vitro with eight anesthetic circuits with and without in-line humidification. *Anesthesiology* 1983;59:442-446.)

neonates is the inner diameter and length of the tracheal tube. It is particularly important for practitioners using older systems with ventilators that do not compensate for circuit compliance or fresh gas flow to be aware of the different pressure and volume characteristics of circle systems compared with nonrebreathing systems (Fig. 51-7). Because most pediatric anesthesiologists recommend controlled ventilation in this age group, there no longer seems to be a great need for special circuits. The most important pitfall is that a tidal volume is selected based solely on weight rather than examining chest wall excursion, listening to breath sounds, observing the peak inflation pressure, and measuring end-tidal carbon dioxide (ETCO<sub>2</sub>) tension. Our in vitro studies have found that the main determinants of delivered tidal volume are peak inflation pressure, inspired to expired ratio, and respiratory rate.<sup>106-108</sup> As long as careful attention is paid to these important variables, even tiny infants can be successfully ventilated with adult circuits and adult bellows with pressure-limited ventilation (see further). No difference exists between adult circle systems and a Bain (Mapleson D) type system if pressure-limited ventilation is used and the same peak inflation pressure is generated.<sup>108</sup> The most important factor is that tidal volume per kilogram will be very large with an adult circle system compared with nonrebreathing systems, especially in infants. Many of these issues of delivering accurate small tidal volumes relative to the compliance of the circuit are simplified with the newer generation ventilators that compensate for the compliance of the system and the fresh gas flow (see later). In the final analysis,

however, the practitioner must be cognizant of the fact that the only physiologic measure of the adequacy of ventilation is the CO<sub>2</sub> tension—ETCO<sub>2</sub> or arterial CO<sub>2</sub>.

### Carbon Dioxide Absorption

When using a closed or semiclosed circle system, removal of CO<sub>2</sub> from the circuit is required. This is accomplished by inserting a CO<sub>2</sub> absorption canister into the anesthetic circuit. The canister is usually placed between the anesthesia bag or ventilator and the fresh gas inlet. In some anesthesia machines, the canister contains two levels of a CO<sub>2</sub> absorbent in series. The replacement of the absorbent can create leaks in the circuit if the seal is not reapplied tightly,<sup>146</sup> complete obstruction if the plastic packaging is not removed from the prepackaged absorbent before insertion, or intermittent obstruction if part of the packaging is left in place.<sup>147</sup> The size of the absorbent is designed to maximize CO<sub>2</sub> reabsorption while minimally increasing the resistance in the circuit. Many different commercially manufactured absorbents are available whose chemistry involves the use of materials such as calcium hydroxide, sodium hydroxide, potassium hydroxide, and barium hydroxide, so that CO<sub>2</sub> is converted into calcium carbonate, water and heat. CO<sub>2</sub> absorption, cost and chemistry are reviewed in detail elsewhere.<sup>148</sup> The most common absorbents are soda lime and Baralyme (Allied Healthcare Products, Inc., St. Louis). Soda lime contains 95% calcium hydroxide, either sodium or potassium hydroxide and the balance as water. Baralyme has been voluntarily withdrawn from the market (see later). It contains 80% calcium hydroxide, 20% barium hydroxide, and the balance as water. Newer agents exist, such as Amsorb (Armstrong Medical Limited, Coleraine, Northern Ireland), which contains 70% calcium hydroxide, 0.7% calcium chloride, 0.7% calcium sulfate, 0.7% polyvinyl pyrrolidone, and the balance as water. Potassium hydroxide and sodium hydroxide have been incriminated in the degradation of halogenated anesthetic agents in CO<sub>2</sub> absorbers; thus the absence of these compounds in Amsorb prevents the degradation of inhaled anesthetics to carbon monoxide (CO) and compound A (see later). Most absorbents contain a dye such as ethyl violet that turns color as the pH of the absorbent decreases because carbonic acid is formed as CO<sub>2</sub> reacts with water. The change in the color in the absorbent indicates it is time to replace the absorbent.

Significant concern exists regarding the interaction of anesthetic agents with CO<sub>2</sub> absorbents because this interaction is an exothermic reaction that produces potentially toxic degradation products and a large amount of heat. Sevoflurane is degraded in the presence of CO<sub>2</sub> absorbent to produce five compounds, the most common of which is an olefin compound known as compound A.<sup>149</sup> Although compound A has been shown to cause renal corticomedullary necrosis in rats, extensive studies in humans have not yielded any substantive consequences or similar renal damage.<sup>150-155</sup> Factors that increase production of compound A include use of low-flow anesthesia, use of large sevoflurane concentrations, increased minute ventilation, anesthetics of prolonged duration, increased absorbent temperature, and fresh absorbent (Baralyme > soda lime >> Amsorb).<sup>156-159</sup> The safety of low-flow (less than 2 L/min fresh gas flow) sevoflurane is still a question because of the limited number of studies in children, although no anecdotal or animal evidence exists to suggest that children may be at greater risk with compound A.<sup>160</sup> Other toxic degradation products, including CO, formaldehyde, and methanol are produced when inhaled anesthetic agents interact with desiccated carbon dioxide absorbents (see Chapter 6). Carbon

FIGURE 51-8 Sevoflurane/Baralyme interaction produced this fire in an anesthesia machine. (Courtesy Mr. A. Rich.)

monoxide poisoning has been reported in patients with carboxyhemoglobin levels reaching 30% or more.<sup>161-163</sup> These case reports were often after several days of anesthesia machine inactivity, in particular, on a Monday morning (i.e., after a weekend with a large fresh gas left flowing through the machine all weekend while it was not in clinical use and usually without a reservoir bag attached).<sup>160,161,164</sup> In some anesthetic machines in which the fresh gas enters at or near the CO<sub>2</sub> canister rather than downstream of the inspiratory valve, fresh gas can dry the CO<sub>2</sub> absorbent by flowing retrograde through the absorber and exiting where the reservoir bag would usually be connected, because of lower resistance to retrograde flow when a reservoir bag is not in the circle system. In vitro studies demonstrated that CO production from the currently used inhaled agents occurs only when the CO<sub>2</sub> absorbent has been desiccated. The order of CO production from greatest to least is desflurane > isoflurane >> halothane and sevoflurane.<sup>165,166</sup> Other factors that increase the production of CO include the degree of desiccation and type of CO<sub>2</sub> absorbent (Baralyme > soda lime), increased temperature, increased anesthetic concentration, and low fresh gas flow rates.<sup>160,167-170</sup> Newer CO<sub>2</sub> absorbents with little or no potassium or sodium hydroxide produce significantly less or no CO and compound A when they become dehydrated.<sup>158,171,172</sup> The Anesthesia Patient Safety Foundation developed a consensus statement in 2005 to address the problem of desiccation of CO<sub>2</sub> absorbents: *"The APSF recommends use of carbon dioxide absorbents whose composition is such that exposure to volatile anesthetics does not result in significant degradation of the volatile anesthetic."*<sup>173</sup> The report discusses the difficulty and impracticality of monitoring CO<sub>2</sub> absorbent for desiccation and makes specific recommendations (if absorbents are used that degrade anesthetic agents), including turning off all fresh gas flow when the machine is not in use, changing the CO<sub>2</sub> absorbent frequently (e.g., every Monday morning), and changing the absorbent when there is concern about the state of hydration of the absorbent, such as when the machine is found with high fresh gas flows for an uncertain period.<sup>173</sup> New multiwavelength pulse oximeters are now available (e.g., Masimo Rainbow SET Pulse CO-Oximetry; Masimo Corporation, Irvine, Calif.) that have the ability to measure carboxyhemoglobin and methemoglobin levels noninvasively (see later discussion of multiple wavelength pulse oximetry); however, the costs of this technology make its routine use prohibitive.

A very important interaction of the modern halogenated anesthetics and desiccated CO<sub>2</sub> absorbent is a poorly defined exothermic reaction that has resulted in fires and explosions, specifically with sevoflurane and Baralyme. There have been several reports of extremely high heat in the CO<sub>2</sub> canister and

inspiratory circuit in conjunction with fires, explosions, and various detrimental effects to patients, including burns, acute respiratory distress syndrome, and carbon monoxide poisoning (Fig. 51-8).<sup>174-176</sup> These cases often reported a very slow increase in sevoflurane concentration in the inspiratory circuit with a large gradient between the vaporizer setting and the measured inspiratory sevoflurane concentration along with a rapid color change of the CO<sub>2</sub> absorbent presumably from rapid degradation of sevoflurane and possibly a rapid change in pH or other substances causing the indicator color change. In 2003, Abbott Laboratories (North Chicago, Ill.), in conjunction with the U.S. Food and Drug Administration (FDA), released a practice alert and revised the product information about this phenomenon. This highly exothermic reaction occurs with other inhalation agents and other absorbents such as soda lime, but the highest temperatures of 392° F (200° C) and fires were associated with sevoflurane and desiccated Baralyme; Baralyme was voluntarily withdrawn from the market in 2004.<sup>177-179</sup>

## HUMIDIFIERS

The benefits of heating and humidifying inspired gases include maintenance of body temperature, improved mucociliary function, and prevention of drying secretions, particularly with non-rebreathing circuits.<sup>180,181</sup> A heated humidifier also helps maintain body temperature.<sup>31-33</sup> When using a circle system partial heat and humidification occur as part of the exothermic reaction used in the CO<sub>2</sub> absorber that adds heat and humidity to the circuit. Low fresh gas flows do increase the rebreathing of humidified and warmed gases, and when combined with passive humidification "artificial nose," provides warm, humidified gases.<sup>15</sup> However, small fresh gas flows add little heat and humidity in infants ventilated through a circle circuit.<sup>182</sup> Humidification can be further increased by active humidification systems.<sup>15</sup> Active humidification systems may create problems such as additional connections that may leak or become disconnected, "rain out" from humidified gas (resulting in water collection within the circuit or the tracheal tube and blockage of the capnograph), added resistance to gas flow, and bubbling noises that distract from the ability to auscultate heart tones and breath sounds. Inhalation of excessively heated inspiratory gases may result in "hot pot tracheitis."<sup>183</sup> Whenever a heated humidifier is added, the extra gas-containing volume of the tubing and humidifier increases the total volume of the anesthetic circuit,<sup>184</sup> in turn increasing compression volume. The degree to which anesthetic circuit efficiency is affected depends on the gas-containing volume of the humidifier and the distensibility of the tubing used.<sup>184</sup> Because of significant complexity and potential for

complications, these devices are no longer commonly used and likely soon to be of historic interest only.

## VENTILATORS

### First-Generation Anesthesia Ventilators

Nearly any adult-volume ventilator may be used with children by making appropriate adjustments to the respiratory rate, fresh gas flow, tidal volume, and inspiratory-to-expiratory time ratio. The use of first-generation adult ventilators in children, particularly neonates, requires meticulous attention to the settings before initiation of controlled respiration, to avoid barotrauma. In old anesthesia machines, most volume ventilators could be converted to pressure ventilators by adjusting the pop-off valve to the desired peak inflation pressure. When this modification is made, special attention must be paid to the peak inflation pressure because a fractional turn of the pop-off valve in either direction could result in either excessively high or inadequate peak inflation pressures.

The next generation of anesthesia machines, which have a switch at the CO<sub>2</sub> canister to change from manual to mechanical ventilation, do not allow adjustment of peak inflation pressure at the pop-off valve because in the mechanical ventilation mode the pop-off valve is out of the circuit. When such a configuration is used, *the pop-off valve of the ventilator must be used to limit the peak inflation pressure.* The excursion of the ventilator bellows may also be adjusted to limit the size of each tidal volume. Additionally, limiting the inflow of gas to the bellows will limit the bellows inflation. Any of three techniques for adjusting the excursion of the adult bellows provides equal tidal volume as long as the anesthesiologist pays careful attention to peak inflation pressure.<sup>106-108</sup> Using the adult ventilator in pressure pop-off mode allows safe use even in neonates with a very small tidal volume. The following is a suggested means for setting up an older adult ventilator for use with children in the pressure-controlled mode:

1. Set pop-off limit on ventilator to 20 cm H<sub>2</sub>O.
2. Set rate to appropriate age.
3. Set inspiratory to expiratory ratio to 1:2.
4. Set gas flow to the middle range.
5. Set tidal volume to a minimum of 10 mL/kg or minute ventilation (VE) to a minimum of 200 mL/kg/min.
6. Turn lever to ventilator mode (new systems) or attach ventilator hose to replace bag (old system).
7. Observe peak inflation pressure to be certain that it is 20 cm H<sub>2</sub>O or less. If the peak inflation pressure is less than 20 cm H<sub>2</sub>O, recheck pressure pop-off limit to make sure it is set at 20 cm H<sub>2</sub>O, and, if correctly set, slowly increase the size of the tidal volume until 20 cm H<sub>2</sub>O is achieved.
8. Auscultate both lungs and observe chest excursion and ETCO<sub>2</sub>.
9. Make certain fresh gas flow is adequate to maintain bellows at full capacity.
10. Reassess the entire process based on Step 8.
11. For noncompliant lungs or with a small-diameter tracheal tube (e.g., 2.5 mm ID), greater peak inflation pressures may be required.<sup>106-108</sup>

It is our bias that manual bag ventilation provides immediate feedback about a child's lung compliance or problems with the circuit (e.g., kinked tube, disconnections, or bronchospasm). However, the literature is unclear regarding this issue. Some experienced anesthesiologists have been able to detect an occluded endotracheal tube, whereas others have not.<sup>185,186</sup> This

may in part depend on fresh gas flow, the size of the child, and the configuration of the circuit. The use of a ventilator provides valuable assistance by freeing the anesthesiologist's hands for other use when the immediate hand-bag feedback is given up for the convenience of a mechanical ventilator. A disconnect, apnea, or peak inflation pressure alarm system is helpful to aid vigilance for these types of adverse events, although these alarms are not perfect.<sup>187</sup> A CO<sub>2</sub> detector with the alarm enabled is optimal; the American Society of Anesthesiologists' (ASA) Standards for Basic Anesthetic Monitoring require "continual monitoring for the presence of expired CO<sub>2</sub>" and the "alarm shall be audible to the anesthesiologist or the anesthesia care team personnel."<sup>188</sup>

With many first-generation ventilators, fresh gas flow may have considerable impact on tidal volume during volume-controlled ventilation<sup>189</sup>; fresh gas flow into the circuit is added to the ventilator output during the inspiratory time. This augmentation effect may result in serious errors in calculating delivered VE during volume-controlled ventilation. The following examples illustrate this situation in volume-controlled ventilation:

1. An adult has a VE of 7 L/min, I:E ratio of 1:2, and fresh gas flow of 6 L/min. If there were no compliance or compression volume losses, the patient would receive 7 L/min + ( $\frac{1}{3} \times 6$  L/min) = 9 L/min. If the fresh gas flow were reduced to 3 L/min, the patient would receive 7 L/min + ( $\frac{1}{3} \times 3$  L/min) = 8 L/min. This is a change of about 11%.
2. A child has a VE of 2 L/min, I:E ratio of 1:2, and fresh gas flow of 6 L/min. Again, assuming no compression or compliance volume losses, the child would receive 2 L/min + ( $\frac{1}{3} \times 6$  L/min) = 4 L/min. If the fresh gas flow were now reduced to 3 L/min, the child would receive 2 L/min + ( $\frac{1}{3} \times 3$  L/min) = 3 L/min. This is a 25% decrease in delivered minute ventilation (E-Fig. 51-3). Compared with the earlier example in adults, the impact on the minute ventilation in a child is magnified 2.5-fold.

Thus when using first-generation anesthesia ventilators, increases and decreases in fresh gas flow during volume-controlled ventilation result in changes in delivered VE. The potential for clinically important effects on ventilation is greatest in infants (e.g., several study patients were found to have a 40% difference in VE when fresh gas flow was changed from 1.5 L/min to 6.0 L/min without any change in the ventilator settings).<sup>190</sup> When using volume-controlled ventilation, if a change is made in fresh gas flow for any circuit used in children, the adequacy of chest expansion, breath sounds, peak inspiratory pressure, and ETCO<sub>2</sub> must be reevaluated, particularly when using older ventilators that do not automatically compensate for such changes (see later discussion of new ventilators).<sup>191</sup> This effect does not occur during pressure-controlled ventilation because excess flow is simply diverted out of the pop-off valve. However, if fresh gas flows were reduced such that the tidal volume was less than the peak pressure setting, the tidal volume delivered to the child could be reduced.

### Intensive Care Ventilators in the Operating Room

It has been suggested that ventilators used in the ICU may be of greater value compared with standard OR ventilators in children with very poor lung compliance.<sup>144</sup> One study failed to demonstrate any clinically important differences among several commonly used ICU ventilators compared with standard operating room ventilators using pressure-controlled ventilation in an infant lung model with low compliance.<sup>192</sup> However, other modes of ventilation such as volume-limited or pressure-assisted

**E-FIGURE 51-3** Changes in delivered minute ventilation using a pediatric circle system, as reflected by end-tidal carbon dioxide (CO<sub>2</sub>) measurement, in a 6-kg child during volume controlled (not pressure controlled) ventilation. The only change made was in fresh gas flow. Note the near halving of end-expired CO<sub>2</sub> when fresh gas flow was increased from 1.5 L/min to 6 L/min. Whenever a change is made in fresh gas flow during controlled ventilation, new ventilatory settings must be determined. *PIP*, Peak inflation pressure; *RR*, respiratory rate;  *$\dot{V}_E$* , minute ventilation.

ventilation have not been systematically examined. It would appear that there may not be an advantage to using ICU ventilators in pressure-limited ventilation and there may even be a disadvantage because the anesthesiologist may not be as familiar with these ICU devices, thus leading to the potential for errors in ventilator adjustments. Additionally, this requires the use of total intravenous anesthesia because these devices do not interface with the anesthesia machine.

### Current Anesthesia Ventilators

Newer anesthesia ventilators with ICU performance capabilities are now incorporated into modern anesthesia machines. The most common systems in North America are the Datex-Ohmeda systems (GE Medical, Madison, Wis.) and the Dräger systems (Dräger Medical, Telford, Pa). These ventilators have been designed to accurately volume ventilate the small lungs of neonates and infants and deliver other modes of ventilation, such as pressure-controlled ventilation, synchronized intermittent mandatory ventilation (SIMV) and pressure support ventilation, either alone or in combination with volume- or pressure-controlled ventilation. Significant advances that aid in accurate volume ventilation include fresh gas flow decoupling and compliance compensation. Unlike the older anesthesia ventilators, fresh gas flow decoupling allows the tidal volume to remain constant regardless of changes to the fresh gas flow. Compliance compensation provides measurement of breathing system compliance and accurately delivers a constant tidal volume in spite of changes in lung compliance (while compensating for the compliance of the circuit, e.g., low-volume pediatric or high-volume adult circuit). Fresh gas flow decoupling and compliance compensation can prevent unsafe changes in tidal volume that could lead to hypoventilation or hyperventilation. The Datex-Ohmeda system uses a pneumatically driven ventilation system; the Dräger uses an electronic piston-driven ventilation system.

Delivered and set tidal volume and pressure, as well as flow volume loops, can be monitored with these new machines. These machines also can detect lost volume resulting from system leaks (e.g., tracheal tube leak). Other safety features include electronic machine checkout procedures that may detect problems not detected by the anesthesiologist and more electronic control and monitoring of ventilator settings, including positive end expiratory pressure (PEEP); in older ventilators this was mechanically set or added separately.

The newer modes of ventilation may offer advantages in certain patient populations under specific conditions, but further research is required to demonstrate whether they improve patient care or patient outcomes in the OR. Examples of potential uses of the alternative modes of ventilation include SIMV for children who have not received a neuromuscular blocking drug and situations in which the anesthesiologist is attempting to establish spontaneous ventilation; the child triggers a breath by creating negative pressure or positive-flow gas flow in the circuit. Pressure support ventilation may help overcome increased resistance and improve ventilation when patients are breathing spontaneously through an endotracheal tube or LMA<sup>193</sup>; pressure support ventilation can be used in combination with SIMV to ensure adequate ventilation if a child becomes apneic.

In limited comparison study of earlier versions of the modern anesthesia ventilation systems compared with ICU ventilation systems, the anesthesia systems performed reliably under a wide range of infant conditions, including high respiratory rates, poor compliance, and small tidal volumes.<sup>192</sup>

## Equipment Cart

It is advantageous to use mobile multidrawer carts to stock the wide range and sizes of items necessary to care for the full spectrum of infants and children. The drawers should be organized for ease of use: airway equipment, drugs, intravenous supplies, monitoring equipment, circuits, and suction catheters, separated into appropriately labeled drawers. To facilitate efficient and safe delivery of anesthesia, it is prudent to design and stock each cart identically. Because pediatric anesthesia is often administered outside of the OR suite, these mobile carts simplify the safe practice of anesthesia for children and guarantee the availability of all necessary equipment in these remote locations (Table 51-2).

## Defibrillator and External Pacemakers

Every operating room facility should be equipped with a direct-current defibrillator. It is not necessary to have a unit specifically for use with children, as long as the energy range may be adjusted to the appropriate levels (2 joules/kg) and pediatric paddles are kept with the device. Ideally, the design should incorporate all controls in the paddles, facilitating use without leaving the child's side. A desirable feature is a sensing circuit, providing the capacity for synchronous defibrillation should it be needed. External defibrillators with disposable pads applied to the front and back or right chest and left lateral chest of the child have improved the rapidity of response in some circumstances. These can be placed on high-risk children (e.g., cardiac surgery, cardiomyopathy, conduction defects) before induction of anesthesia.<sup>194-197</sup> Similar devices that allow for external cardiac pacing represent a major new advance for high-risk infants and children.<sup>198-200</sup>

## Ultrasound for Regional Anesthesia and Vascular Cannulation

Ultrasound technology has advanced greatly in the last 10 years and now is routinely used in children for regional and neuraxial anesthesia and central venous cannulation (see Chapters 41, 42, and 48).<sup>201-209</sup> The advent of portable, less expensive ultrasound machines has made this more practical for most pediatric institutions. Visualization of nerves and vascular structures in children requires small probes that can provide high-frequencies (10 to 14 MHz); high-frequency is necessary for visualization of shallow tissue structures.<sup>201</sup> Most regional blocks described in children use a small high-frequency probe shaped like a hockey stick and use small needles (21 or 22 gauge) for single injection blocks or continuous infusion techniques and a Tuohy type of needle or an intravenous catheter (18 or 20 gauge) for threading an indwelling catheter.<sup>201,210-212</sup> Ultrasound-guided techniques provide real-time visualization of nerves, blood vessels, and other structures that may improve the success rate of regional nerve blocks and central venous cannulation while decreasing the complication rate<sup>210</sup> (see Chapter 41 for a more detailed description). This is particularly true in children, in whom the risk is greater than in adults because of the small size of the structures involved and the potential need to perform these procedures after induction of general anesthesia.<sup>201,202</sup> An additional potential advantage is the greater ability to perform these procedures in awake-sedated children compared with the use of nerve stimulation or blind percutaneous cannulation, which can be painful. Other potential advantages are decreased adverse effects such as

**TABLE 51-2 Suggested Pediatric Equipment Cart Inventory**

Drawer 1	Laryngoscope handles (functioning) (2)
	Laryngoscope blades (functioning)
	Miller                      Macintosh                      Wis-Hipple
	0 (2)                      1 (2)                      1½ (2)
	1 (2)                      2 (2)
Drawer 2	2 (2)                      3 (2)
	3 (2)
	Magill forceps: 1 pediatric, 1 adult; 1-inch tape (4); ½-inch waterproof tape (4); 4 each ¾-inch and ¼-inch (tourniquets of nonlatex material); scissors; flashlight; extra batteries for laryngoscope handle
	Masks: neonate (3), infant (3), toddler (3), child (3), medium adult (3), large adult (3)
	Airways: 3.5 cm (5), 5.0 cm (5), 6.0 cm (5), 7.0 cm (5), 8.0 cm (5), 9.0 cm (5)
Drawer 3	Gauze sponges (sterile and nonsterile), double-stick disks, rubber bands, adhesive bandages, alcohol swabs, antibiotic ointment, water-soluble surgical lubricant, lidocaine ointment 5%, bulldog clips, safety pins, corneal lubricant, pediatric blood tubes (blue, red, purple, and green), eye patches
Drawer 4	Adult sodium bicarbonate (2), pediatric sodium bicarbonate 8.4% (2), infant sodium bicarbonate 4.2% (2), cardiac lidocaine 100 mg (2), dextrose 50% (1), mannitol 25% (1), diphenhydramine 50 mg (2), calcium chloride 10% (4), calcium gluconate 10% (4), sterile water, lidocaine 1% (5), phenylephrine (5), neostigmine 1:2000 (10), ephedrine (5), atropine (10), isoproterenol (1), furosemide (3), epinephrine 1:1000 (10), succinylcholine (1), rocuronium (1), dexamethasone 4 mg/mL (2), dopamine (2), ondansetron (10), propofol (10)
Drawer 5	Pediatric uncuffed endotracheal tubes: 2.5 (6), 3.0 (6), 3.5 (6), 4.0 (6), 4.5 (6), 5.0 (6), 6.0 (6); pediatric cuffed endotracheal tubes: 5.0 (3), 5.5 (3); adult cuffed endotracheal tubes: 2 each of 6.0, 6.5, 7.0; styles in various appropriate sizes
Drawer 6	Pediatric and adult esophageal stethoscopes (6), adult electrocardiography pads (10), pediatric electrocardiography pads (10), 6.5F suction catheters (6), 10 of each size 8F and 14F
Drawer 7	Syringes: 60 mL (2), 20 mL (6), 12 mL (10), 6 mL (10), 3 mL 22 gauge (20), 3 mL 25 gauge (20), 1 mL 27 gauge (20)
Drawer 8	Intravenous catheters: 24 gauge, 22 gauge, 20 gauge, 18 gauge, 16 gauge, 14 gauge; pediatric intravenous boards: 2 sizes (4), T-connector, three-way stopcocks
Drawer 9	Pediatric intravenous sets (6); pediatric Buretrol (2); intravenous extension sets (2); lactated Ringer solution 250 mL 0.9 normal saline (5); air trap filters (6); head strap; blood pressure cuffs (2 each size), 1 adult size with stethoscope; oximeter sensors for infants and children

NOTE: These are only suggested equipment cart materials. Each hospital should alter the order of drawers and their contents to suit its particular needs and for convenience.

intravascular and intraneuronal injection, reduced dosage of local anesthetic, faster onset, longer duration, and improved quality of blocks.<sup>202,213,214</sup> Studies of central venous and peripheral venous cannulation in infants and children demonstrate quicker times to cannulate the vessel, fewer attempts before success, and significantly fewer failures compared with landmark-based

techniques.<sup>215-220</sup> Quality randomized, controlled trials are difficult to perform owing to the difficulty in defining the level of training and experience of the care providers and the relatively low rates of complications.<sup>221,222</sup> More studies are needed to better define the use of ultrasound techniques in infants and children; optimal outcomes require significant education, training, and hands-on experience.

## Monitoring Equipment

### THE ANESTHESIA RECORD AND BAR CODE DRUG ADMINISTRATION

In addition to its obvious role as a medicolegal document, the anesthetic record can be a very important monitor. Proper recording of a child's status on arrival in the OR encourages evaluation of the effects of any premedication, confirmation of nil per os (NPO) status, allergies, current medications, and assessment of weight and fluid balance. Careful recording of intraoperative fluid administration and losses allows assessment of a child's fluid replacement. Concurrent charting of vital signs and anesthetic drugs administered allow correlations to be made and encourages trend analysis. Many changes that are too subtle to interpret on a moment-to-moment basis become obvious when graphed out over time. In addition, a numbering system correlating events with time on the anesthesia record documents the sequence of anesthetic management and may prove very useful should a medicolegal issue arise.

Automated anesthesia records or automated anesthesia information management systems (AIMS) are increasingly used and will eventually replace hand-recorded records and likely improve the accuracy of data collection.<sup>223-226</sup> These systems can provide timely reminders for administration of antibiotics, documentation of start and stop times, compliance with regulatory requirements, reminders of blood pressure measurement gaps, and automatically provide cumulative totals in infusions of drugs, such as propofol or remifentanyl.<sup>227-230</sup> Most importantly, the automated recording of physiologic data in real time provides improved accuracy, particularly at times when the anesthesiologist is multitasking or when an emergency occurs. In fact, such data may actually be protective from medical malpractice because the veracity of the data is far improved over retrospective data recording.<sup>231,232</sup> Conversely some data recorded are spurious and may in fact be nonreflective of an actual event; neither system is perfect.<sup>233,234</sup> Currently, the widespread introduction of automated record-keeping has been very slow for several reasons, including the large capital and contract expenses for implementation, difficulty integrating all hospital-wide digitized systems in real-time terms, and costs for 24-hour support staff.<sup>225</sup>

Medication errors are quite common, particularly in high acuity areas such as the OR and the ICU.<sup>235</sup> The next area of technology improvement may be the adoption of bar code confirmation of drug administration in the operating room.<sup>236-242</sup> Such systems are currently available to provide accurate labeling of syringes (date, time, concentration) and have had great success in reducing medication errors.<sup>235,243-251</sup> Several studies have demonstrated reduced medication errors in the OR when bar coding is used.<sup>236,242,251</sup> These systems will be incorporated into the automated anesthesia record in the future as well.

### PRECARDIAL AND ESOPHAGEAL STETHOSCOPE

In infants, neonates, and small children, an experienced ear can easily detect arrhythmias but also may be able to assess changes

in cardiac output and blood pressure (soft heart tones compared with baseline).<sup>252</sup> The continuous use of a stethoscope is of particular value in situations in which more advanced noninvasive blood pressure monitoring (NIBP) is unavailable. The precordial stethoscope may be stabilized with a double adhesive disk. For specialized needs, such as bronchography, angiography, or magnetic resonance imaging, a plastic stethoscope that is not radiopaque or ferromagnetic may be used. The optimal site where both heart tones and breath sounds can be heard is usually at the apex of the heart, but occasionally the suprasternal notch provides better listening conditions. The latter position may be more advantageous during induction and emergence, because information regarding airway patency is more readily obtained. The stethoscope can provide early indications of developing airway obstruction or laryngospasm, allowing the practitioner to take corrective action (PEEP) before a full-blown episode of laryngospasm develops. However, the perception is growing among clinicians that current monitors have superseded the need for the precordial stethoscope.<sup>253</sup>

Whenever the trachea has been intubated, the precordial stethoscope may be exchanged for an esophageal stethoscope. The pediatric size esophageal stethoscope may be introduced atraumatically, even in neonates. The optimal position for the stethoscope within the esophagus can be ascertained by inserting the scope while listening for the position that provides the loudest heart and breath sounds. The less expensive adult variety is often usable in children age 6 years or older. Some disposable esophageal stethoscopes incorporate a thermistor, allowing the introduction of two monitors at once. One possible relative contraindication to using or inserting an esophageal stethoscope is during a tracheostomy. Misidentification of an esophageal stethoscope as an endotracheal tube has resulted in the surgeon opening the esophagus.<sup>254</sup> During a tracheostomy in a child, either the esophageal stethoscope should not be used or the surgeon should be informed that two stiff tubes pass through the neck structures, because this complication has occurred even in the hands of very experienced surgeons.<sup>255</sup>

The major drawback of a stethoscope as a monitor is that it provides information only when it is connected to the anesthesiologist. Custom-molded earpieces, which better exclude room noises, are much more effective and more comfortable to wear than the conventional binaural stethoscope. These earpieces have the added advantage of leaving one ear open for communication with the surgeon and ancillary personnel. Even with pulse oximetry and capnography the stethoscope can provide great reassurance that the patient has an adequate blood pressure and cardiac output. *If both the NIBP and the oximeter fail, but the child has strong heart tones, a technical problem likely exists. However, if the other monitors fail and the heart tones are very weak, then cardiac output may be compromised and attention should be immediately focused on resolving that problem rather than wasting time trying to search for a problem with the monitor.*

### BLOOD PRESSURE DEVICES

Blood pressure must be monitored in every child who requires our care. An appropriate-size blood pressure cuff should cover approximately two thirds of the length of the upper arm or thigh.<sup>256,257</sup> The cuff bladder should rest over the artery; in older children a stethoscope may be secured over the artery to listen for Korotkoff sounds. In smaller children, the flicker of the needle in an aneroid sphygmomanometer dial may be used as an indicator of systolic pressure.<sup>258</sup> If the flicker is not clearly visible, a distal pulse sensor may be used. Such a sensor can

be either a photoelectric plethysmograph on a digit that detects the return of the signal as the cuff deflates or a Doppler flow detector that is positioned over a distal artery.<sup>259</sup> Electronic oscillometer units (NIBP) are capable of repeated, frequent, and accurate measurements.<sup>260-263</sup>

If an automatic NIBP device is used, it is important that proper application, function, and adequate deflation time be ensured; venous stasis, petechiae, and nerve compression damage are possible, especially with early models.<sup>264</sup> Most automated NIBP machines have specific cuff sizes for infants, neonates, and preterm infants, as well as a requirement that the monitor settings be matched with the size of the patient (neonate, child, adult). For neonates and infants, special tubing is required to connect the cuff with the monitor. If cuffs are improperly matched with the tubing and monitor settings, the built-in algorithms will produce factitious data.<sup>265</sup> It appears that these devices offer reasonable accuracy for systolic blood pressure but may be less accurate for diastolic blood pressure.<sup>266,267</sup> NIBP monitors provide very useful information during induction of anesthesia, particularly important during that period before establishing intravenous access. The results of one study showed greater consistency and accuracy with these devices than with standard auscultatory methods.<sup>263</sup> One common practice is to place the cuff on the calf of infants as a substitute for upper extremity measurements. There is poor correlation between arm and calf blood pressures; because of this variability, one should not simply assume that one site is a substitute for the other.<sup>268-271</sup> Another study determined that the loss of the pulse oximeter waveform correlated with systolic arterial pressure in children weighing less than 15 kg.<sup>272</sup>

### ELECTROCARDIOGRAPH

Although many arrhythmias may be diagnosed by careful attention to the heart sounds conducted through the precordial or esophageal stethoscope, the electrocardiogram (ECG) remains a mandatory monitor for all instances of sedation, regional anesthesia and general anesthesia. In a healthy child, lead placement may differ from that selected for adults because the principal need is for diagnosis and resolution of arrhythmias rather than detection of ischemia. One report emphasized that children undergoing cardiac surgery or children with severe anemia may develop ST depression consistent with ischemia, although it occurs extremely rarely.<sup>273</sup> With the greater right heart predominance in the younger ages, a cross-chest lead generally provides the optimal combination of atrial and ventricular voltage signals. A QRS detector with a beeper is a useful accessory, particularly when vagal stresses occur. The ECG heart rate is used for comparison with the pulse oximeter heart rate to confirm appropriate application and function of the pulse oximeter. A built-in lead fault detector is also useful to check the cables and a patient's leads when a poor signal is obtained. Cleaning, gently abrading, and defatting the skin with alcohol can improve the contact. Tincture of benzoin may also help maintain secure adhesion in areas near the application of surgical preparation solutions. Care must be taken not to allow the leads to become wet with preparation solutions and to isolate the leads from the electrocautery dispersive electrode to avoid electrical burns.<sup>274</sup> Special ECG leads and monitors are required for use in the MRI scanner (see Chapter 45).

### OXYGEN MONITOR

Assessment of the inspired O<sub>2</sub> concentration is one aspect of the monitoring guidelines published by the ASA and Harvard

Medical School.<sup>193,275</sup> It is necessary in preterm infants and neonates to be alert to the possible relationship between high arterial O<sub>2</sub> tension (PaO<sub>2</sub>) resulting from high inspired O<sub>2</sub> concentrations and ocular toxicity, although recent evidence suggests that this relationship is not a quid pro quo.<sup>276</sup> This monitor is also helpful in guiding inspired O<sub>2</sub> concentrations in certain types of congenital heart disease in which low inspired O<sub>2</sub> is key to optimizing pulmonary artery pressures and pulmonary blood flow. An O<sub>2</sub> monitor allows easy blending of air and O<sub>2</sub> to achieve the desired inspired O<sub>2</sub> concentration. In all children, O<sub>2</sub> monitoring can help prevent hypoxemia. The standard, so-called fail-safe device built into most anesthesia machines is generally keyed only to pressure in the O<sub>2</sub> line; should the O<sub>2</sub> flow be turned off, a child may receive a potentially hypoxic mixture (air plus a large concentration of inhalational anesthetic such as sevoflurane or desflurane) without warning from the fail-safe alarm. An O<sub>2</sub> monitor on the inspiratory limb would indicate a decrease in the inspired fraction of O<sub>2</sub> and provide an accurate alarm. With the more frequent use of closed-circuit anesthesia and air–O<sub>2</sub> blends, O<sub>2</sub> monitoring assumes even greater importance. *Anesthesia machines generally provide a mechanical or electronic coupling system that delivers minimal O<sub>2</sub> flow and prevents the delivery of hypoxic mixtures of N<sub>2</sub>O and O<sub>2</sub>. However, some newer machines do not have a minimum O<sub>2</sub> flow and disable their electronic coupling system when air and O<sub>2</sub> are combined; thus it is possible to intentionally or unintentionally turn on the air without O<sub>2</sub> to deliver 21% O<sub>2</sub>. The delivery of low inspired O<sub>2</sub> is sometimes desirable in certain conditions such as hypoplastic left heart syndrome or to decrease the risk of airway fire when laser or electrocautery are being used. When high concentrations of sevoflurane or desflurane are used with air it is possible to dilute the O<sub>2</sub> and deliver a potentially hypoxic mixture. Careful monitoring of inspired O<sub>2</sub> is vital to prevent this from occurring unintentionally.* A high inspired O<sub>2</sub> alarm device is also desirable; this may detect when an air tank is empty. The O<sub>2</sub> analyzer should be calibrated and alarm limits set before anesthetic induction; a narrow band of alarm limits allows early detection of changes in gas flow ratio.

## TEMPERATURE MONITORS

Although there is medicolegal pressure to monitor temperature in every child because of the potential danger of malignant hyperthermia, in reality temperature monitoring is mandated for other reasons. Hypothermia is much more common in the OR than hyperthermia and may be associated with acidosis, myocardial irritability, coagulopathy, respiratory depression, prolonged neuromuscular blockade, greater absorption of inhalation agents, and delayed emergence from anesthesia.<sup>277-280</sup>

## NONINVASIVE OXYGEN SATURATION MONITORS

### Pulse Oximetry

Nothing has changed anesthetic practice more in the past few decades than the introduction of mandatory pulse oximetry for all cases requiring sedation and general anesthesia. This monitor determines the O<sub>2</sub> saturation of hemoglobin by spectrophotometric techniques. Measuring the amount of light transmitted through tissue between a two-wavelength light source (930 and 660 nm) and a detector allows continuous calculation of arterial O<sub>2</sub> saturation.<sup>281</sup> The use of two frequencies helps eliminate interfering absorption by other molecules, although intravenous dyes (indocyanine green, methylene blue) and colored nail polish may interfere with normal sensor function and cause the oximeter to read a factitiously low O<sub>2</sub> saturation value.<sup>275,282,283</sup> Additionally, dyshemoglobinopathies such as carboxyhemoglobinemia and methemoglobinemia may result in

significant artifact. Carboxyhemoglobinemia causes an overestimation of O<sub>2</sub> saturation because the photodetector incorrectly interprets carboxyhemoglobin as oxyhemoglobin; this artifactual change is roughly proportional to the concentration of carboxyhemoglobin.<sup>284</sup> Methemoglobinemia results in desaturation, but the saturation recorded tends to read greater than the actual saturation; at high levels of methemoglobin during episodes of desaturation, this disparity becomes greater.<sup>285</sup> Fetal hemoglobin, hyperbilirubinemia, and sickle cell disease have minimal effect on pulse oximetry.<sup>286-290</sup> This monitor is easy to use, noninvasive, and reasonably accurate, although not perfect.<sup>291,292</sup> Of greatest importance to the clinician is appreciating that the current oximeter technology underestimates the actual hemoglobin saturation as the saturation is decreasing; the more rapidly the saturation decreases, the more the saturation reading underestimates the true saturation.

The clinical efficacy of this monitor was demonstrated in a prospective single-blind study of pediatric patients; 50% of the cases were conducted with the saturation data and alarms made available to the anesthesia team, whereas in the remainder, the data were blinded and the alarms silenced. Several observations were reported<sup>293,294</sup>:

1. Twice as many “major” desaturation events (defined as saturation 85% or less for 30 seconds or longer) occurred in the blinded group.
2. The oximeter detected a greater number of desaturation events before clinical recognition by the anesthesiologist.
3. Major desaturation events were not accompanied by changes in vital signs in most cases (i.e., in only 4 of 19 such events was any change in blood pressure, heart rate, or respiratory rate noted).
4. The incidence of these events in ASA physical status 3 and 4 patients was greater than in ASA 1 and 2 patients.
5. Desaturation events occurred in children who were managed by both experienced and inexperienced anesthesia personnel.
6. Correlation between the observation of cyanosis and true desaturation was poor.
7. Desaturation events were as likely in brief as in procedures of extended duration.<sup>293</sup>

In a subsequent study, the efficacy of combined pulse oximetry and capnography was examined to determine if patient safety was improved with the addition of capnography.<sup>294</sup> In 400 children, 260 problems were observed (E-Fig. 51-4). The study confirmed that pulse oximetry was superior to the human eye in diagnosing hemoglobin desaturation. The incidence of major desaturation events when the oximeter data and alarms were blinded from the practitioners was threefold greater than when they were available. Capnography was not as helpful in diagnosing the majority of events leading to hemoglobin desaturation (E-Fig. 51-5). This is consistent with the Australia anesthesia incident study in which the authors reported that oximetry provides useful data in 85% of events.<sup>295</sup> In the pediatric study, 15 problems fulfilled the criteria of a major capnograph event. These were problems that posed a threat to life (e.g., kinked tracheal tube, circuit disconnect, esophageal intubation, accidental extubation) and would have been detected immediately by a capnograph, but 8 were diagnosed initially by pulse oximetry (E-Fig. 51-5). Capnography may have helped initially to diagnose the seven remaining events; however, pulse oximetry would have diagnosed these events as desaturation developed, 30 to 60 seconds later. This observation is also consistent with the Australia incident study.<sup>296</sup> This study also examined the incidence of

**E-FIGURE 51-4** A total of 260 problems were observed in 153 of 402 patients studied. Major desaturation events ( $SpO_2 \leq 85\%$  for  $\geq 30$  seconds) and major capnograph events (esophageal intubation, kinked endotracheal tube, circuit disconnect, accidental extubation) are within the *bold circles*. Minor desaturation ( $SpO_2 \leq 95\%$   $\geq 0$  second) and interesting events ( $SpO_2 \leq 85$  or  $\geq 30$  seconds) are also presented. Minor capnograph problems were simple hypercarbia ( $PECO_2 \geq 60$  mm Hg  $\geq 60$  second) or hypocarbia ( $PECO_2 \leq 25$  mm Hg  $\geq 60$  seconds). The total number of events that fulfilled the criteria for each category is in parentheses. Note that some events fulfilled criteria in two or more categories.  $PECO_2$ , Expired carbon dioxide;  $SpO_2$ , oxygen saturation. (From Coté CJ, Rolf N, Liu LM, et al. A single-blind study of combined pulse oximetry and capnography in children. *Anesthesiology* 1991;74:980-7.)

**E-FIGURE 51-5** Fifty-nine major desaturation events were observed. Nearly 70% were first diagnosed by oximeter, 22% by the anesthesiologist, and only 8% by the capnograph. Pulse oximetry is by far the more sensitive monitor in providing an early warning of developing desaturation. (From Coté CJ, Rolf N, Liu LM, et al: A single-blind study of combined pulse oximetry and capnography in children. *Anesthesiology* 1991;74:980-7.)

“minor” capnograph events, defined as an abnormality of ventilation that was not a threat to a child’s life (e.g., hypercarbia or hypocarbia). A significantly greater incidence of both hypercarbia and hypocarbia occurred in children whose anesthesiologist was blinded from the capnograph data and alarms.

Infants 6 months of age or younger are at greatest risk for experiencing at least one major desaturation event (E-Fig. 51-6) or a major capnograph event. The number of children with multiple problems in the group in which neither pulse oximetry nor capnography data were available to the anesthesia team was twice as great as in the group in which both were available. An interesting observation was the relatively high incidence of *clinically unrecognized endobronchial intubation that manifested as persistent, though minor, hemoglobin desaturation (93% to 95%)*.<sup>297</sup>

These studies confirm that the pulse oximeter provides an early warning of developing desaturation well before a clinician is able to detect it clinically. This is easily explained by the fact that approximately 5 g of desaturated hemoglobin is required to detect cyanosis; if a child’s hemoglobin level is 15 g/dL, the O<sub>2</sub> saturation would have to decrease to 66% (i.e., less than the normal venous hemoglobin desaturation before cyanosis would be clearly evident). Pulse oximetry detects evolving hemoglobin desaturation in advance of this value being achieved. There is some variability among manufacturers, and accuracy declines as the saturation values decrease (70% or lower).<sup>284,298</sup> The degree of inaccuracy of pulse oximeters is a function of many variables that should be carefully reviewed.<sup>286,299,300</sup> Pulse oximetry is a reliable monitor for the majority of children who are free of cyanotic congenital heart disease.

Quite apart from the hemoglobin O<sub>2</sub> saturation data, pulse oximetry provides additional information including data pertinent to the systemic blood pressure.<sup>272</sup> Pulsus paradoxus may be observed in hypovolemic children. Loss of the peripheral pulse when using pulse oximetry may accompany hypovolemia, vasoconstriction resulting from hypothermia, or inadequate cardiac output as a result of hypovolemia, allergic reaction, or anesthetic overdose.<sup>301,302</sup> Pulse oximetry is useful as a noninvasive trend monitor in individuals with anatomic or physiologic shunts, because the effects of anesthetic agents and positive-pressure ventilation are difficult to predict.<sup>303-305</sup> Pulse oximetry also can be an effective monitor for preventing hyperoxia in preterm infants by guiding the inspired O<sub>2</sub> concentration to values that correspond to hemoglobin saturations between 93% and 95%.<sup>306</sup> Preductal and postductal oximeters indicate opening and closing of a patent ductus arteriosus (PDA).

Various common OR events can affect the accuracy and reliability of pulse oximetry including electrocautery, flickering operating room lights, movement, blood pressure cuff inflation, bright light, vasoconstriction, stereotactic positioning systems,<sup>307</sup> and injected dyes (cardio green and methylene blue). Falsely high O<sub>2</sub> saturation measurements may occur despite severe hemoglobin desaturation in the presence of interference with the oximeter sensor. Darkly pigmented skin color may also affect accuracy with up to a 10% error in low saturation ranges.<sup>308</sup> Consequently, it is important to remember that this monitor is not foolproof.<sup>309</sup> One very important artifact, the penumbra effect, is caused when an adult clip-on sensor is placed on an infant’s finger or toe.<sup>310</sup> *In this situation the oximeter senses the motion of the pulse but light is transmitted around the finger or toe, thus providing a falsely high hemoglobin saturation. Only appropriate-size oximeter probes should be used in infants and children.* In critically ill children and those with thermal injuries, problems with finding a suitable site to apply

the probe can be overcome by using a modified oximeter probe applied to the tongue (see E-Fig. 34-5, *A to D*).<sup>311,312</sup> The tongue provides a rich blood supply unaffected by vasoconstriction, and electrocautery interference is less. If the tongue moves, the sensor may dislodge or record a false heart rate. Thermal injury secondary to the interface of incompatible sensor probes and cables (i.e., equipment from more than one manufacturer) has been reported, as has pressure necrosis resulting from too tight an application.<sup>313,314</sup>

Recent advances in pulse oximetry technology have attempted to make several major improvements, including (1) software that provides motion artifact compensation; (2) software that allows uninterrupted readings even in low flow states; and (3) software that provides more accurate assessment of oxygenation in cyanotic patients.<sup>315</sup> Conventional pulse oximetry time-averages a signal over 5 to 10 seconds, depending on the default settings of the oximeter. This signal represents the ratio of transmitted red and infrared light, and the instrument uses this to determine the child’s hemoglobin saturation. This averaging smoothes motion-induced artifacts but may ultimately lessen the sensitivity and response time of a conventional oximeter in situations of hypoxemia or even delay the recognition of asystole or severe bradycardia by several seconds. More recent models are designed to recognize motion artifact and discard signal aberrations secondary to motion using proprietary signal-filtering techniques. Some devices combine two different approaches to signal processing to arbitrate the correct saturation based on dual signal filtration techniques using both pattern matching and adaptive comb filtering. This technique is designed to detect motion and reject analysis of data generated during motion. Other oximeter manufacturers take a different approach, using spectrophotometer principles to generate a saturation signal. That saturation signal may contain several component saturations corresponding to different absorption artifacts of blood and other tissues, including venous blood. The signal is then processed using a discrete saturation transform (DST) algorithm that then extracts the highest and presumably the arterial component saturation and reports this value as the hemoglobin O<sub>2</sub> saturation.<sup>316-319</sup> Conventional pulse oximeters can overestimate or underestimate the degree of desaturation and therefore may have less accuracy and greater signal dropout rate (i.e., no reading or poor quality signal associated with an alarm, especially in children with hypoxemia). These deviations may be improved with the newer generation pulse oximeters, but this has yet to be definitively demonstrated.<sup>320</sup> The newer generation pulse oximeters perform better than conventional pulse oximetry in hypothermic low flow states during cardiopulmonary bypass.<sup>321</sup> Movement artifact is the main cause of false alarms in sedated or awake children who require oximetry monitoring. This artifact is significantly reduced with the current generation of pulse oximeters in both adult and pediatric patient populations.<sup>322-326</sup>

### Multiple Wavelength Pulse Oximetry

The latest advancement in pulse oximetry technology is multiple wavelength pulse oximetry, which was approved by the FDA in 2006 (Masimo Rainbow SET Pulse CO-Oximetry, Masimo Corporation, Irvine, Calif.). These systems use the principles of pulse oximetry and co-oximetry and at least seven wavelengths of light to calculate the standard measurements from new-generation pulse oximeters and continuous (1) hemoglobin, (2) carboxyhemoglobin, (3) methemoglobin, and (4) plethysmographic (Pleth) variability index. Several studies have examined the accuracy (bias and precision) of

**E-FIGURE 51-6** The pie figure on the left presents the age distribution of the 402 patients studied, and the pie on the right presents the number of patients in each category with a major desaturation event. Note that infants had a significantly higher incidence than did toddlers or children ( $P = 0.001$ ). (Modified from Côté CJ, Rolf N, Liu LM, et al. A single-blind study of combined pulse oximetry and capnography in children. *Anesthesiology* 1994;74:980-7.)

the measurements obtained via pulse co-oximetry, and data inconsistencies require further investigation. For the continuous measurement of hemoglobin it was estimated to be accurate within 1 g/dL in adult patients who had systematic hemodilution.<sup>327</sup> More studies are needed to determine whether this level of accuracy is reproducible.<sup>328,329</sup> The measurement of carboxyhemoglobin via pulse oximetry (SpCO) has been studied extensively because of its potential for screening large numbers of patients, especially in the emergency room setting. The accuracy data are not completely consistent, but in the authors' opinions are likely acceptable for patient screening. However, with the known degree of false positive and false negative results, SpCO should be used in conjunction with clinical data and blood co-oximetry to verify results when indicated.<sup>315, 330-335</sup> Initial studies of the accuracy of methemoglobin measurement by pulse co-oximetry (SpMet) demonstrated decreased accuracy with hypoxia<sup>315,336</sup> but the more recent studies using newer technology appear to be even more accurate than the measurement of SpCO and possibly as good or better than SpO<sub>2</sub> in the ranges measured in the studies—O<sub>2</sub> saturation 74% to 100% and methemoglobin 0 to 14%.<sup>337-339</sup>

All the measurements from pulse co-oximetry likely have a significant degree of decreased accuracy in the presence of abnormal hemoglobins; more studies need to be done to examine these complex interactions and the effect on the accuracy of the obtained measurements with the coexistence of different forms of hemoglobin. Pleth variability index is a measure of the degree of hypovolemia and potentially might provide guidance for decisions regarding volume administration. The measurement comes from respiratory variations in the plethysmographic waveform amplitude and uses an algorithm to determine the likelihood of improved blood pressure and cardiac index with fluid or colloid administration.<sup>340</sup> There are significant limitations in this technology and accurate assessment of volume status may require specific conditions, including general anesthesia, sinus rhythm, mechanical ventilation with a tidal volume of at least 8 mL/kg, PEEP less than 5 cm H<sub>2</sub>O, location of sensor, and an invasive arterial line depending on the algorithm or commercial product used.<sup>341,342</sup> The use of invasive arterial blood pressure and plethysmographic variations in hemodynamic parameters during the respiratory cycle has potentially significant clinical utility but requires further investigation, including evaluation in the pediatric patient population.<sup>342,343</sup>

### Reflectance Oximetry

Reflectance pulse oximetry has been available for many years, but with recent technologic improvements, several devices have received FDA approval and are currently marketed. Reflectance oximetry technology was first created to improve O<sub>2</sub> saturation data in difficult clinical conditions, such as decreased perfusion, movement, and conditions in which optimal sites for standard transmission oximetry probes may not exist (e.g., burns). The technology behind reflectance oximetry involves the emission of multiple wavelengths of red and infrared light that are sensed in two or more photodetectors located a distance away from the diodes on the same probe sensor (Fig. 51-9). These devices measure reflected rather than transmitted light. The technology used to create these oximeter probes permit usage on the forehead, in the esophagus, and on the fetal scalp. The forehead devices have had the largest use among pediatric anesthesiologists. Studies of reflectance oximeters in general demonstrated that these devices are more susceptible to erratic measurements

when the probe is placed directly over an artery<sup>344</sup> and vein.<sup>345</sup> Some potential advantages to using reflectance oximetry on the forehead include better signals during conditions of poor perfusion, lack of motion, and faster response time than conventional peripheral oximeter probes.<sup>346,347</sup> However, possible disadvantages include a potentially high signal dropout rate (no measurable signal) and poor accuracy, often measuring lower than finger transmission oximetry, particularly in cases of venous congestion (e.g., Trendelenburg position or situations that impede venous return).<sup>348</sup> Several studies, including more recent studies, report good correlation between concurrent measurements of O<sub>2</sub> saturation comparing reflectance oximetry on the forehead,<sup>349-351</sup> the esophagus,<sup>352</sup> and around the chest of premature infants,<sup>353</sup> compared with extremity pulse oximetry and arterial co-oximetry measurements; these studies also report a clear dropout rate.

### Near-Infrared Spectroscopy

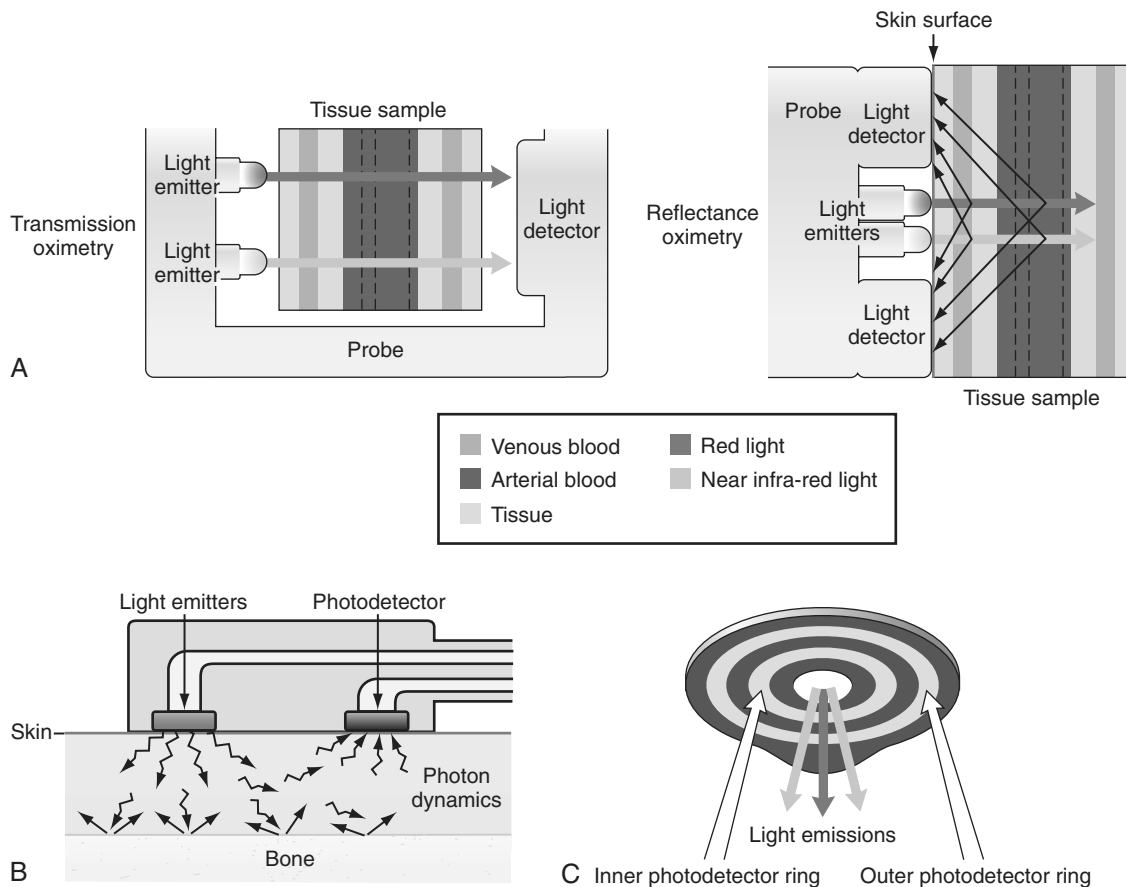

Near-infrared spectroscopy (NIRS) is a noninvasive, optical technology that bears similarities to pulse oximetry in that it uses the relative absorption of near-infrared light, 700 to 900 nm, through biologic tissues to determine tissue oxygenation (E-Fig. 51-7).<sup>354</sup> Oxyhemoglobin and deoxyhemoglobin absorb light at different frequencies, and the use of a probe that emits and detects different frequencies of near-infrared light can be used to estimate tissue oxygenation. This device has been most widely used to measure "regional" cerebral O<sub>2</sub> saturation (rSO<sub>2</sub>),<sup>355,356</sup> but measurement of oxygenation in other areas, such as kidney, bowel, spinal cord, free tissue flaps, and other areas, is possible.<sup>357-368</sup> These recent developments provide an exciting new potential to detect ischemia to various tissues before it is evident clinically.<sup>369-376</sup> Pulse oximetry requires the measurement of the pulsatile (arterial) component of the total light transmitted by the biologic tissue. Because NIRS does not require the subtraction of the pulsatile component, the signal is more than 100 times stronger and unaffected by poor perfusion compared with pulse oximetry. However, it is susceptible to motion artifact and ambient light noise but software algorithms have significantly decreased these sources of error. A probe placed on the child's forehead measures the concentration of oxyhemoglobin and deoxyhemoglobin in the tissue underlying the probe. The device functionally measures the oxygenation of blood in the underlying tissues, including blood in the arterioles, capillaries, and venules. The majority (approximately 85%) of the signal originates from the venules; skin and bone and extracranial blood absorb only limited amounts of light, which is subtracted from the signal and does not have significant impact of the measurement in infants and children.<sup>357,358</sup> NIRS thus measures the O<sub>2</sub> saturation in venous and arterial blood and thus represents an average saturation across blood vessels and tissue. In cerebral oximetry, the O<sub>2</sub> saturation of the blood in the tissue (i.e., between the sending and emitting probe) depends on factors that affect O<sub>2</sub> transport, including cerebral blood flow, hemoglobin saturation, hemoglobin–O<sub>2</sub> binding affinity, and oxygenation saturation in the arterial blood. Therapies aimed at improving O<sub>2</sub> delivery or decreasing oxygenation consumption to the brain will potentially increase cerebral oxygenation (rSO<sub>2</sub>).<sup>359-361,376</sup>

This technology is not new; however, only three devices are currently FDA approved for commercial use to measure cerebral oxygenation: the first, is the INVOS Cerebral Oximeter (Somanetics Corporation, Troy, Mich.). The absolute accuracy of the current Somanetics device is  $\pm 10\%$  to 15%, making the

**E-FIGURE 51-7** The pediatric clinical application of near-infrared spectroscopy relies on spatial resolution to extract surface tissue measurements, thereby isolating the target tissue, in this image of the neonatal cerebral cortex. The depth of measurement is resolved by the spacing of the light-emitting and light-receiving elements. Spatial resolution is illustrated in this diagram as arcs of red light traveling between light-emitters and light-receivers. Note that the short path measurements (**A**) correspond to intervening tissues, and long path measurements (**B**) correspond to the cerebral cortex. Light returned by the short path is deducted from total returned light, isolating the cerebral cortex. (Courtesy Nonin Medical, Plymouth, Mont.)

**FIGURE 51-9** **A**, Comparison of conventional transmission pulse oximetry with reflectance oximetry. Note that with conventional oximetry the light detector is located directly opposite on the other side of a digit and detects light transmitted through the digit; with reflectance oximetry the light detector is located next the light emitters and detects the light reflected back through and from the tissues. **B**, The typical configuration of a reflectance oximeter. **C**, Another configuration, in which several light detectors are located at different distances from the light emitters. In addition, reflectance oximeters may emit light in more than just 2 wavelengths, which is typical of conventional transmission pulse oximeters. (Modified from Kugelman A, Wasserman Y, Mor F, et al. Reflectance pulse oximetry from core body in neonates and infants: comparison to arterial blood oxygen saturation and to transmission pulse oximetry. *J Perinat* 2004;24:366-71; and Keogh BF, Kopotic RJ. Recent findings in the use of reflectance oximetry: a critical review. *Curr Opin Anesth* 2005;18:649-54.)

measurement of absolute oxygenation unreliable. However, it is reasonably accurate for changes in oxygenation ( $\pm 5\%$ ), making this device most useful for following trends in cerebral oxygenation.<sup>362-365</sup> This device is currently FDA approved for trend monitoring. The Somanetics Cerebral Oximeter has demonstrated that normal regional cerebral oxygen saturation ( $rSO_2$ ) is 60% to 80%.<sup>366,367</sup> In controlled hypoxic-ischemic states in animals, electroencephalogram (EEG) slowing and increased tissue lactic acid levels occur at  $rSO_2$  between 40% and 45%. The EEG becomes flat at  $rSO_2$  between 30% and 35%, and if the cerebral ischemia is protracted, it may be associated with tissue infarction.<sup>367</sup>

The second device, the Fore-Sight Absolute Tissue Oximeter (CAS Medical systems, Branford, Conn.) has been approved for actual saturation estimation and not just trending. This device uses four wavelengths of light and multiple sensors incorporated into one sensor, which is usually placed over the forehead; three sensor sizes are available, and use is based on patient weight.

The most recent device to be approved by the FDA is the EQUANOX (Nonin Medical Inc., Minneapolis, Minn.), which uses light-emitting diode (LED) technology to transmit three wavelengths (EQUANOX Classic Sensor) and most recently four

wavelengths (EQUANOX Advance Sensor, Model 8004CA).<sup>368,377</sup> The EQUANOX sensor differs from the others by having dual emitter and sensor sites. The company claims this technology decreases surface tissue variability and can obtain quicker measurements. The first sensor did not have sufficient accuracy for absolute measurements and would be best used in trend monitoring. The newest sensor claims to be very accurate (4.1%), but further study needs to confirm the accuracy of these new systems.

This technology has important limitations. The relationship between the amount of tissue damage and clinical outcome depends on the site of the tissue damage. Because these monitors only measure the saturation in tissue below the probes, they more accurately reflect on focal tissue oxygenation or damage. If the probe is placed on the forehead, it will reflect the state of the tissue in the frontal cortex and may not reflect other areas of the brain.

Although some studies suggest improved outcomes when cerebral oximetry is used including pediatric congenital heart surgery, in which neurologic complications are high (2% to 25%),<sup>362,366,378,379</sup> a fair degree of skepticism remains regarding the utility of cerebral oxygenation in clinical practice.<sup>380,381</sup> There is

hope, however, that these devices may at some time in the future provide real-time guidance of regional tissue oxygenation and the effectiveness of interventions to improve the oxygenation. Additional research, further improvements in the technology, and reduced per-patient costs are needed to clarify the role of reflectance oximetry in pediatric patient management.<sup>373</sup>

### CARBON DIOXIDE ANALYZERS

The most commonly used gas monitor is the expired CO<sub>2</sub> analyzer. This monitor is particularly useful in teaching about ventilation, CO<sub>2</sub> elimination from alveoli, and airway management, provided the response time of the instrument is rapid enough to accurately reflect end-expired CO<sub>2</sub> tension.<sup>382,383</sup> Two configurations of infrared CO<sub>2</sub> monitors are in clinical use. They differ only in the location of the CO<sub>2</sub> analysis: (1) the side-stream analyzer, which involves the aspiration of expired gas from the anesthesia circuit and remote CO<sub>2</sub> analysis, or (2) a mainstream analyzer in which an optical sensor within a cuvette is inserted into the circuit just proximal to the elbow and where analysis of the CO<sub>2</sub> occurs based on a signal detected at the cuvette. Side-stream analyzers are less cumbersome than mainstream analyzers because the former requires no additional pieces to be inserted into the anesthetic circuit. Gas for side-stream analysis only requires a narrow-gauge flexible tube to transfer the expired gas unidirectionally from the elbow of the circuit to the analyzer. The gas sampling line and water trap can become obstructed with water or secretions, requiring replacement of the parts. Mainstream gas analyzers do not obstruct with secretions, but they are heavy, and if a tracheal tube of a small caliber is used, airway obstruction may occur as a result of kinking of the tracheal tube.<sup>383</sup> Furthermore, mainstream systems require a large inventory of cuvettes, which must be sterilized between patients. Most OR monitors today use side-stream sampling. The current generation of these monitors have improved precision that reduces the gas sampling rate to just 50 mL/min and excellent accuracy even with small rapid tidal volumes.<sup>384-388</sup>

Capnography is the gold standard to ensure that the tracheal tube has been inserted within the trachea.<sup>188,389</sup> If no expired CO<sub>2</sub> is detected after a presumed tracheal intubation, one must assume that the endotracheal tube is in the esophagus. However, if the stomach has been distended by manual ventilation or crying before tracheal intubation or if carbonated soft drinks were present in the stomach, CO<sub>2</sub> could be detected immediately after intubation, even after an esophageal intubation.<sup>390</sup> In such a case, the expired CO<sub>2</sub> will be very low or decrease rapidly in a stepwise manner after placing the tracheal tube. This artifact is very short lived. In addition, the presence of CO<sub>2</sub> during cardiopulmonary resuscitation is a very important sign of pulmonary blood flow.<sup>391</sup> Alternatively, its absence during resuscitation may indicate inadequate chest compressions and pulmonary blood flow (see Chapter 39).<sup>392-395</sup>

Measurement of expired CO<sub>2</sub> tension is also helpful in detecting other clinical problems. Clinically important air embolism causes a transient but marked reduction in CO<sub>2</sub> excretion because the lungs are ventilated but not perfused; hence dead space is suddenly increased (see Chapter 24). Quantitative measurement allows detection of change in circuit flows, disconnections, endotracheal tube kinking, or accidental extubations.<sup>296,396-398</sup> Capnography also signals the earliest clinical sign of a malignant hyperthermic reaction and the effectiveness of treatment<sup>399</sup> (see also Fig. 40-3). In critically ill neonates or children in a hypermetabolic state after thermal injuries, ventilatory requirements

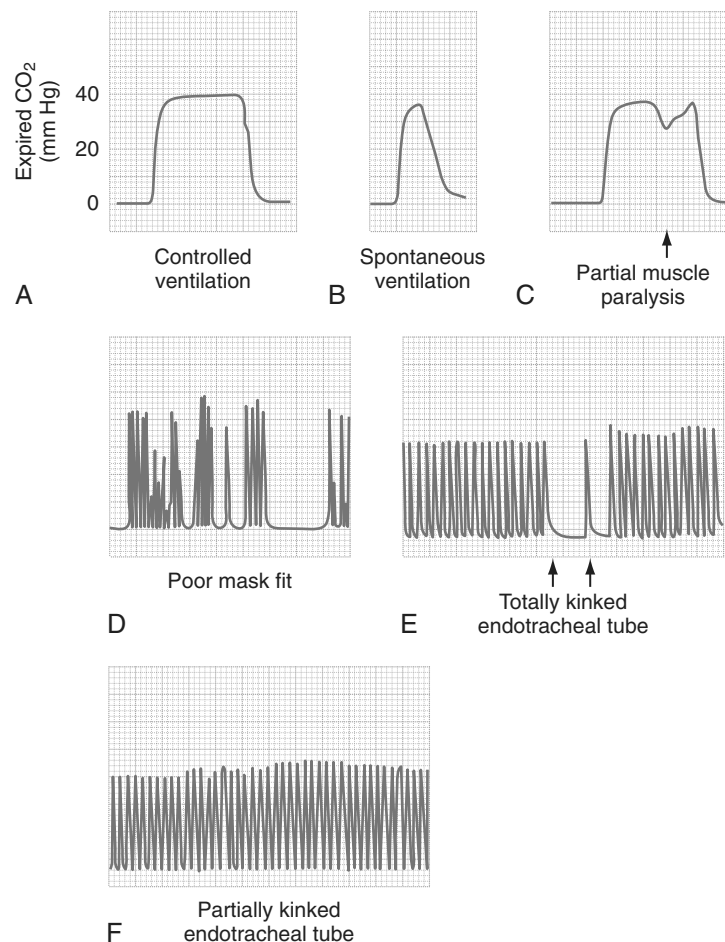

may be as much as 4 times normal and capnography may be an effective noninvasive means of assessing the adequacy of ventilation in these children as well (see Chapter 34).<sup>400</sup>

A capnograph with a recorder or a display is most valuable because the CO<sub>2</sub> waveform may help in diagnosing other types of respiratory difficulties (Fig. 51-10). Bronchospasm and its response to treatment may be identified by changes in the CO<sub>2</sub> waveform; bronchospasm causes an increasing slope of the plateau during expiration, and resolution of the bronchospasm restores the plateau to the horizontal. Data also suggest that the shape of the CO<sub>2</sub> waveform changes with growth and development. The shape of the CO<sub>2</sub> waveform achieves the normal adult configuration by adolescence.<sup>401</sup> A slow-speed recorder also allows trending, which we have found particularly useful in diagnosing small circuit leaks, partially kinked endotracheal tubes, and rebreathing. In children free from pulmonary shunts, the arterial and alveolar CO<sub>2</sub> values (PaCO<sub>2</sub> and PACO<sub>2</sub> [as reflected by a true end-expired sample]) should be within 2 to 3 mm Hg. The severity of a shunt or the diagnosis of a shunt may be made if this difference is greater than 5 mm Hg and if the CO<sub>2</sub> sensor is properly calibrated. Children with a variety of pulmonary problems may have significant differences between arterial and expired CO<sub>2</sub> values. In such cases, expired CO<sub>2</sub> monitoring may be used only for trending and as a disconnect alarm.<sup>402,403</sup> This monitor is of great value in assessing the adequacy of ventilation in children whose trachea is intubated, but of possibly less value in children whose airway is managed by facemask when it is difficult to obtain an accurate end-expired sample.<sup>294,396</sup> The accuracy of ET-CO<sub>2</sub> monitoring is slightly better with an LMA than with a facemask.<sup>404</sup>

No monitoring device is perfect, and it is possible to develop a false sense of security when monitoring the ECG, O<sub>2</sub> saturation, and expired CO<sub>2</sub> values. Anesthesiologists must not abandon stethoscopes and the powers of observation; the practitioner is still the ultimate monitor. It is our powers of observation and clinical judgment combined with our ability to synthesize and integrate the data that determine the appropriate course of action. The following case is an example:

An 8-kg infant with a 45% scald burn was anesthetized, her trachea was intubated, and she was placed in the prone position. The child was monitored with an ECG, a temperature probe, an esophageal stethoscope, an expired CO<sub>2</sub> mainstream sampler, a pulse oximeter, and an arterial line. The arterial line malfunctioned, and it took approximately 45 minutes to replace it. An arterial blood gas sample was obtained, and at that time, the O<sub>2</sub> saturation was 100% and the expired CO<sub>2</sub> was 43 mm Hg (mainstream device, no waveform, and circle system); there had been no noticeable changes in vital signs. The blood gas results were pH 6.96, PaO<sub>2</sub> 214 mm Hg, and PaCO<sub>2</sub> 103 mm Hg. This child had a partially kinked endotracheal tube and a large shunt, both of which contributed to the false data from the capnograph.

Although this is an extreme example, it emphasizes that even in the presence of highly sophisticated, properly working, noninvasive monitors, they may fail to accurately depict physiologic derangements in some clinical scenarios. Recognizing the limitations of our monitors and their potential for errors and remembering to verify physiologic indices with blood gas analyses (either arterial or venous) in the critically ill can only improve the quality of care delivered to the smallest and most critically ill infants and children under our care.

**FIGURE 51-10** Expired carbon dioxide ( $\text{CO}_2$ ) tracings (**A, B, C** = rapid recording; **D, E, F** = trend recording). **A**, Normal waveform with a long alveolar plateau indicating good alveolar gas sampling during controlled ventilation. **B**, Spontaneous ventilation with rapid respiratory rate; minimal alveolar plateau. **C**, Patient with partial muscle paralysis; note change in  $\text{CO}_2$  waveform (arrow) during inspiration, which took place during the ventilator expiration. **D**, Poor mask fit with many periods when no  $\text{CO}_2$  was detected; this also results in many false alarms. **E**, A totally kinked endotracheal tube was detected by the absence of a  $\text{CO}_2$  waveform (between arrows); a similar trace could result in a circuit disconnect, esophageal intubation, or a simple pause in respiration. **F**, A partially kinked endotracheal tube may result in a slow change in peak expired  $\text{CO}_2$ ; a similar change could be noted with an unrecognized endobronchial intubation, change in pulmonary compliance, circuit leak, or increase in metabolic rate. The reverse would occur with air embolism, hypothermia (decreased metabolic rate), improved compliance, or, increased fresh gas flow without compensatory change in ventilator settings. (From Coté CJ, Liu LM, Szyfelbein SK, et al. Intraoperative events diagnosed by expired carbon dioxide monitoring in children. *Can Anaesth Soc J* 1986;33:315-20.)

### Transcutaneous Carbon Dioxide Measurement

Transcutaneous  $\text{CO}_2$  monitoring has been available for many years, but this technology has been limited because of difficulties preparing and fixing the sensor, preparing the skin, having to rotate the sensor to prevent burns, and calibration time, as well as questions of its reliability. The most common use for transcutaneous monitoring has been in critically ill neonates.<sup>405,406</sup> Two monitors combine pulse oximetry with transcutaneous carbon dioxide ( $\text{PtcCO}_2$ ) measurement through a probe designed for application to the ear lobe (TOSCA, Linde Medical Sensors AG, Basel, Switzerland; V-Sign Sensor, SenTec Digital Monitoring System; SenTec AG, Steinhausen, Switzerland). These products use a variant of the Severinghaus-type  $\text{CO}_2$  electrodes in which the skin is warmed to  $107.6^\circ\text{F}$  ( $42^\circ\text{C}$ ) to increase blood flow to the capillary bed.<sup>407,408</sup>  $\text{CO}_2$  is measured by change in pH of the electrode where pH is proportional to the logarithm of the change in  $\text{CO}_2$ . The  $\text{CO}_2$  values are greater than the local arterial values because of the increased temperature and increased metabolic production locally. The system corrects for these

changes, is relatively easy to use because of self-calibration, and requires infrequent need for repositioning and changes of the electrolyte layer of the probe. Both systems are reliable and accurately reflect the  $\text{PaCO}_2$  in a variety of settings in both pediatric<sup>409,410</sup> and adult patients.<sup>411-413</sup> Proponents of this type of  $\text{CO}_2$  monitoring suggest that  $\text{ETCO}_2$  monitoring is often inaccurate in some clinical conditions, including neonates with a large air leak around the tracheal tube, high respiratory rates, and sampling at the end of a tracheal tube such that a true end-tidal sample is not obtained, significant cardiopulmonary disease associated with increased dead space and/or right-to-left shunt, and conditions of frequent movement. A clear disadvantage is the lack of breath-to-breath monitoring capability for apnea and disordered breathing provided by end-tidal capnography.<sup>414</sup> Transcutaneous  $\text{CO}_2$  monitoring may more closely approximate  $\text{PaCO}_2$  in children who have large ventilation-perfusion mismatch.<sup>415-417</sup> Transcutaneous  $\text{CO}_2$  monitoring may have a role in anesthetized children with severe pulmonary disease or other pathology that prevents accurate  $\text{ETCO}_2$

measurement. More studies are needed to assess its role in the pediatric patient population in various settings such as the OR and ICU and for unintubated patients undergoing sedation.

### ANESTHETIC AGENT ANALYZERS

Most current anesthetic agent analyzers use ultraviolet or infrared monochromatic (only one agent detected) or polychromatic (more than one agent detected) absorption or mass spectroscopy and provide a rapid time response.<sup>418,419</sup> Polychromatic infrared analyzers are most useful because they can detect erroneously selected anesthetic agents.<sup>420</sup> Careful assessment of the end-expired vapor tensions may provide some indication of a child's anesthetic depth, but each child must be assessed on an individual basis. Vaporizer malfunctions and miss-fills may also be diagnosed. Mass spectroscopy may be particularly valuable in providing an early warning of air embolism (after a child has been denitrogenated), because the sudden appearance of expired nitrogen is abnormal (entrainment of room air into the circuit and release of nitrogen from extremities with a tourniquet also may provide a source of nitrogen).<sup>421</sup> The purported advantages of less waste of anesthetic gases and a more rapid awakening are effects that have not been proved. However, the ability to use low flows offers the potential for significant cost savings in the form of less waste of anesthetic agent and less pollution of the atmosphere.<sup>422</sup> The report of accumulation of methane with closed circuit anesthesia and the inaccuracy of agent analysis (methane additive to the agent used) is worrisome but can be obviated with simple periodic flushing of the system.<sup>423,424</sup>

### BLOOD LOSS MONITORS

Close observation of the surgical field is the best single monitor of blood loss. A small-volume trap on the suction line before the major evacuation trap is particularly useful for small children. Routinely weighing surgical sponges on a dietary scale, assuming that 1 g of weight is equivalent to 1 mL of blood, is also helpful. Greatest accuracy is obtained by immediate weighing as the sponges come off the surgical field, thus minimizing evaporative losses. Point-of-care testing devices such as the HemoCue (HemoCue AB, Ängelholm, Sweden) and the I-STAT (Abbott Point of Care Inc., Princeton, N.J.) provide a rapid means for assessment of hemoglobin values<sup>425-431</sup> but each may underestimate the hematocrit at lower values.<sup>430,432-437</sup> Noninvasive hemoglobin measurements using multiwavelength pulse oximetry in general may be useful for trend monitoring.<sup>328,438</sup> However, overall it tends to underestimate hemoglobin values and may not be sufficiently accurate at this time to use these data for clinical transfusion decisions because discrepancy of up to 1 g of hemoglobin have been reported.<sup>327,329,436,437,439-442</sup>

### NEUROMUSCULAR TRANSMISSION MONITORS

Measuring the indirectly elicited twitch response is indicated when neuromuscular blocking agents are used. Residual or incomplete reversal of neuromuscular blockade has been shown in adults to be a common cause for delay in leaving the OR, prolonged postanesthesia care unit (PACU) recovery time, and respiratory complications in the early postoperative period.<sup>443-446</sup> It has been clearly determined that even experienced anesthesiologists cannot determine decrement in the train-of-four (TOF) accurately. Clinical signs (e.g., sustained head lift) are often difficult to perform in older patients and can be done with a significant degree of residual blockade, thus leading to undetected residual neuromuscular blockade and presumably the

potential for respiratory complications.<sup>444</sup> In general, two types of neuromuscular monitoring devices are available, those using acceleromyography and those using mechanomyography. Mechanomyography models use constant current nerve stimulation. These devices self-calibrate and then deliver a constant stimulus (30 to 70 mA) to the skin regardless of other influences. Failure to deliver a supramaximal stimulus may result in overestimation of twitch suppression. The power should generally be left off between readings to avoid possible injury secondary to prolonged, repetitious exposure to electric current. Acceleromyography uses a piezoelectric sensor to quantitate the acceleration (proportional to force) of the thumb converting this to an electrical signal. There is considerable disagreement in the published literature as to which of these techniques is most accurate.<sup>447-449</sup>

Monitors based on acceleromyography are becoming more commonly available; however, these are difficult to use in infants because of the small arc of the displaced thumb. Some consider this monitor to be more accurate than the standard mechanomyography based train-of-four monitors, but they are difficult to use in infants and are not user friendly.<sup>445,446</sup> Others think mechanomyography is more accurate because it is less influenced by external disturbances, that is, it does not go out of calibration.<sup>450</sup> Therefore at present for clinical purposes in infants and children, mechanomyography still seems to be the simplest and most helpful clinical monitor during the use of nondepolarizing competitive blockers. The TOF does not require recording capability or baseline measurement because it works strictly by comparing the fourth twitch with its own internal standard, the first twitch.<sup>451,452</sup> The unit may also be used with depolarizing relaxants, monitoring only the first twitch amplitude. A significant decrement (>50%) between the first and fourth twitch in this context suggests phase-two blockade (see E-Fig. 6-14).<sup>453</sup> Needle electrodes are hazardous because they may cause bleeding, infection, burns, or nerve injury; current density may be very high, owing to the limited contact surface and the resistance of surrounding skin. Needle electrodes should not be used. Self-adhesive electrodes designed specifically for twitch monitors are available, but they are unnecessary and expensive and tend to be too large for infants and small children. A reasonable alternative is a pair of infant-sized ECG electrodes. The choice of monitoring location depends on the nature of the surgery. Any site where a motor nerve is close to the body surface and its associated muscle group is available for observation may be chosen. The most common stimulation site is the ulnar nerve in the forearm, observing the thumb (adductor pollicis brevis); this is the standard site for most research reports. It should be noted that the majority of studies have been standardized to the ulnar nerve, thus quantitating the response of other motor nerves is less reliable. Using the facial nerve may result in false-positive responses because the muscles may be easily stimulated directly, potentially causing an overdosing of nondepolarizing neuromuscular blocking agents.

### PROCESSED ELECTROENCEPHALOGRAPH MONITORS

Monitoring the processed EEG has become a common means for monitoring patients who are anesthetized or sedated, but its role has yet to be fully defined in the pediatric patient population.<sup>454-457</sup> Analysis of the EEG waveforms and EEG data from brain response to auditory input have been used to assess the depth of sedation and anesthesia and in turn to predict or avoid awareness under anesthesia in adults. Several excellent reviews are available regarding the technology and process of validation.<sup>458,459</sup>

Awareness under anesthesia has become a major source of litigation in the United States,<sup>460</sup> and public concern prompted The Joint Commission to issue a Sentinel Event Alert.<sup>461</sup> In response to this alert, the ASA instructed a taskforce to review the available literature and the existing monitors.<sup>462</sup> Their review included studies from several processed EEG monitors (Bispectral Index [BIS], Aspect Medical Systems, Natick Mass.; Entropy, General Electric Healthcare Technologies, Waukesha, Wis.; and Narcotrend, MonitorTechnik, Bad Bramstedt, Germany) and data for auditory evoked potentials (AEP Monitor/2 (Danmeter Aps, Odense, Denmark). This task force reached several important conclusions:

*Intraoperative monitoring of depth of anesthesia, for the purpose of minimizing the occurrence of awareness, should rely on multiple modalities, including clinical techniques (e.g., checking for clinical signs such as purposeful or reflex movement) and conventional monitoring systems (e.g., electrocardiogram, blood pressure, heart rate, end-tidal anesthetic analyzer, capnography). The use of neuromuscular blocking drugs may mask purposeful or reflex movements and adds additional importance to the use of monitoring methods that assure the adequate delivery of anesthesia. . . . It is the consensus of the Task Force that brain function monitoring is not routinely indicated for patients undergoing general anesthesia, either to reduce the frequency of intraoperative awareness or to monitor depth of anesthesia.*

A few studies have suggested that the use of these monitors may decrease awareness in adults<sup>463,464</sup> but no definitive data exist in infants and children that these monitoring systems decrease the incidence of awareness under anesthesia.<sup>465</sup> The vast majority of studies have examined the Bispectral Index (BIS); therefore this section will primarily focus on this device with the understanding that other devices are available but have not been adequately evaluated in children.

Bispectral analysis generates a value (0 to 100) derived from processed electroencephalographic data that provide a measure of the depth of anesthesia.<sup>458,466,467</sup> There have been significant inconsistencies in data obtained from the BIS monitoring system in adults and even more inconsistencies in children. Some of the complexity and inconsistency of the BIS data will be reviewed to understand the possible uses and limitations of this and other EEG-based systems. Because of the nature of the data collection in the awake patient, artifacts may occur as a result of eye movement, blinking, and so forth at baseline if the device is applied before induction. Depth of anesthesia as measured by the bispectral analysis is more reliably assessed during propofol or inhalation-based anesthesia than during opioid-based anesthesia, although there is significant individual variation in the bispectral analysis reading.<sup>468-470</sup> N<sub>2</sub>O has a minimal effect on the bispectral analysis, whereas ketamine paradoxically increases the bispectral analysis.<sup>458,471-473</sup> Some well-controlled studies in adults examined the effects of a broad spectrum of medications on the bispectral analysis reading; this device monitored the effects of anesthetic drugs on awareness and patient responsiveness to painful and nonpainful stimuli.<sup>463,464,468,469,474-479</sup> Studies also have demonstrated decreased anesthetic requirement and improved recovery parameters in adults who were monitored with bispectral analysis.<sup>480,481</sup> However, although bispectral analysis technology appears to monitor the effects of hypnotics, it does not necessarily monitor the adequacy of anesthesia or analgesia.<sup>462</sup>

Bispectral analysis values in children anesthetized with sevoflurane were inversely proportional to end-tidal sevoflurane concentration in both infants and children, although the BIS values in anesthetized children had a much broader range than in adults.<sup>482,483</sup> In one study, the BIS values decreased with increasing end-tidal concentration of sevoflurane until 3%, after which the bispectral analysis value paradoxically increased with higher inspired concentrations.<sup>482,483</sup> At equi-minimal alveolar concentration (equi-MAC), bispectral analysis values are greater in children than in adults.<sup>483-485</sup> Additionally, the bispectral analysis values at equi-MAC concentrations of volatile anesthetics has been inconsistent; several studies have shown that the bispectral analysis values during halothane anesthesia are greater than those during isoflurane, sevoflurane, or desflurane in children.<sup>486-488</sup> These data indicate that BIS values may be substantially greater with halothane than with the other inhalational anesthetics.<sup>489</sup> In addition, several studies have demonstrated conflicting results in children compared with infants, suggesting greater bispectral analysis values for halothane in children but not in infants at equi-MAC.<sup>482,485,488</sup> All of these studies have suggested wide interindividual variability in the bispectral analysis values at comparable expired MAC concentrations of inhalational anesthetics. One disturbing study has found lower BIS values in intellectually impaired children compared with controls.<sup>490</sup> Other studies have found differences between the right and left side of the brain.<sup>491</sup> Limited data validate bispectral analysis readings in young children and infants. The algorithm was based on processed EEG readings from adults, and the EEG does change with age developmentally; therefore it seems reasonable that the algorithm will need to be adjusted for age if the bispectral analysis is to be used in infancy.

One study noted an incidence of awareness in children aged 5 to 12 years of approximately 0.8%.<sup>492</sup> This is fourfold to eightfold greater than the incidence of awareness reported in adults, although the clinical implications are not clear at this time. Indeed, unlike in adults, none of the children who had awareness reported distress as a result.<sup>493,494</sup> The use of N<sub>2</sub>O (when there is no contraindication) may be valuable in reducing the incidence of awareness without significantly adding to the duration of emergence.<sup>495</sup> No randomized, controlled trials in children have demonstrated a decrease in awareness using bispectral analysis or other commercially available processed EEG devices. A recently introduced device is the SEDLine (Masimo Corp., Irvine, Calif.). This device uses four EEG electrodes and therefore simultaneously measures both sides of the brain. Preliminary experience at one institution has found that N<sub>2</sub>O interferes with SEDLine monitoring (personal communication, CJC). At present, no validating studies in children have been reported; until further data are developed, we do not recommend adopting this technology.

The BIS has the longest track record, but again its value in children is still quite unsubstantiated. One study in children 3 to 18 years of age demonstrated a more rapid recovery when bispectral analysis monitoring was used. However, this did not hold true for children younger than 3 years of age.<sup>496</sup> Bispectral analysis monitoring is able to help predict voluntary patient movement during intraoperative wake-up tests during spinal fusions.<sup>497</sup> Bispectral analysis also has been used to assess the depth of sedation in children and to correlate bispectral analysis values with other measures of recovery, exclusive of ketamine-induced sedation.<sup>498-500</sup> Unfortunately, bispectral analysis values were unable to predictably separate moderate and deep sedation in

children. In yet another study, a poor correlation was reported between the bispectral analysis values and a standardized Ramsay sedation score.<sup>501</sup> Bispectral analysis values do not appear to correlate with arousal from sevoflurane anesthesia.<sup>502</sup> Limitations on the usefulness of bispectral analysis monitoring in children include fear of probe placement while they are awake (thus in most cases the bispectral analysis monitor is applied after anesthetic induction). Because many procedures in children involve the head (e.g., strabismus, tonsillectomy, neurosurgical), the use of this monitor may be impractical in nearly half of the surgeries that involve children.

At this point, bispectral analysis and other depth of anesthesia monitoring systems appear to have some potentially useful applications in older children, whose EEG pattern is likely to be similar to that of adults, such as in trauma and during certain surgeries in which anesthetic drug use may be extremely limited (i.e., motor evoked potential monitoring for scoliosis surgery). However, the variability of response in any given child, the issues relating to the effects of specific drugs, and other technical factors such as probe placement in awake children, create significant limitations to its use in infants and toddlers. It is hoped that further, controlled studies will better define the possible role of depth of anesthesia monitoring in infants and children during sedation and general anesthesia.

### INTRACRANIAL PRESSURE MONITORS

In children with increased intracranial pressure (ICP), direct monitoring of ICP may be helpful. Measurement may be accomplished by transduced pressures through either a ventricular cannula placed through a burr hole or by a subarachnoid bolt or equivalent. Measurement also can be performed noninvasively in infants with an open anterior fontanelle (see Chapter 24).

### DISCONNECT AND APNEA ALARMS

When a ventilator is used, the tactile feedback from palpating the breathing bag is lost. A disconnect alarm is useful in this circumstance, particularly in the absence of capnography. Most anesthesia ventilators incorporate a disconnect alarm, but it may also be purchased as a separate add-on for older designs. These alarms generally sense time cycling of pressure events. Most of these alarms can detect complete ventilator disconnects but may not be sensitive enough to detect extubations with small endotracheal tubes or partial circuit disconnects because of the continued presence of flow resistance. Other types of alarms, such as heat-sensing devices or capnographs, provide a more reliable means of detecting inadequate ventilation, accidental extubation, or disconnect. Besides the sensing of pressure cycles, many newer monitors include high-pressure, continuous positive-pressure, and negative-pressure alarms. Some products include an automatic switch-on when shifting from hand to machine ventilation, thereby avoiding failure to monitor.

### APNEA MONITORS

Apnea monitors, whether based on transthoracic impedance, motion, or other patient parameters, are helpful in the perioperative and recovery room phases for former preterm infants younger than 60 weeks postconceptual age.<sup>503</sup> Infants with a history of apnea spells and children with ongoing apnea spells are much more likely to develop apnea in the postoperative period. Even if a child has had a period of some months with a normal respiratory pattern at home, the anesthetic state may bring about a temporary return of apnea spells, and such a

monitor should be used according to current guidelines (see Chapters 2, 4, 35, and 36).

### VOLUME METER AND SPIROMETER

In some instances, monitoring a child's respiratory gas flow may be desirable. A Wright turbine respirometer, Dräger positive displacement spirometer, and newer designs based on the pneumotachograph operating principle, vortex detectors, or thermistor flow meters are available. Some devices allow measurement of flow-volume loops, which can be very useful in both diagnosing and correcting ventilatory issues related to bronchospasm, airway compression, or single-lung ventilation.<sup>504-509</sup> These monitors are not widely used in the clinical anesthesia care of children.

### INSPIRATORY PRESSURE GAUGE

In children who require ventilatory assistance, a pressure gauge applied at the airway allows the delivery of precise airway pressures and thus helps minimize barotrauma. When infants are treated with PEEP and continuous positive-airway pressure, airway pressures are best measured as close to the airway as possible. Such a device is useful in accurately determining leaks around an endotracheal tube when used to determine the size of the larynx (see Chapter 31).<sup>510</sup>

### URINARY CATHETER

Aseptically inserted, a catheter in the bladder connected to a closed drainage system is of little risk to most children. Urine output is a useful indicator of volume and perfusion status; the presence of hematuria or hemoglobinuria can aid in the diagnosis of surgical trauma to the urinary system, a bleeding dyscrasia, or a transfusion reaction. Indications for a urinary catheter include massive fluid shifts, prolonged radiologic procedures with large doses of contrast material, prolonged surgery, neurosurgery and cardiac surgery with osmotic diuretic therapy, and urinary reconstructive procedures. In infants, standard urinary catheters might be difficult to insert and therefore a feeding tube provides an excellent substitute. Because the urine output in infants may be scant, connecting a feeding tube to a syringe barrel may provide an adequate and accurate measurement system. Care must be taken to avoid using latex catheters, particularly in children who are latex sensitive.

### INVASIVE BLOOD PRESSURE MONITORS

When clinically indicated, arterial, central venous, or very rarely pulmonary artery pressure should be monitored. Percutaneous arterial cannulation is performed with a 22- to 24-gauge catheter-over-needle device in infants and neonates, respectively, and a 20-gauge device in older children (see Chapter 48 and Fig. 48-10, A to D).<sup>511,512</sup> Central venous and pulmonary artery cannulation are usually achieved using the Seldinger technique (see also Fig. 48-2, A to D).<sup>513,514</sup> The proper reference location for all pressure transducers is usually the level of the child's right atrium. If ICP monitoring is used or if the child is in the head-up or sitting position, a reference zero position at a reproducible cranial site (e.g., the external ear canal) is vitally important to accurately assess cerebral perfusion pressure. Placement of any of these invasive monitors provides additional benefits other than direct hemodynamic monitoring. Serial pH and arterial blood gas tension measurements from an arterial line or from determination of serial chemistries, ionized calcium, glucose concentrations, hematocrit, coagulation profiles, and osmolality allows

continual assessment of a complex case. In operations performed in the sitting position, a right atrial catheter provides an approach to therapy for air embolism (see Chapter 24).

To withdraw a valid blood sample, an adequate volume of blood must be aspirated; 2 to 3 times the dead space (the point of aspiration to the tip of the catheter) usually accomplishes this.<sup>515</sup> In infants, these systems must be flushed with small volumes at slow rates. In infant arterial lines, this amount is 0.5 mL/5 sec, to avoid dangerous fluctuations in blood pressure and retrograde flow with the risk of stroke.<sup>516</sup>

### ECHOCARDIOGRAPHY

Some reports have examined the usefulness of transesophageal echocardiography as a means of continuously monitoring cardiac output and the cardiac response to surgery and anesthetic agents. This equipment is very expensive and requires a great deal of skill and experience to take full advantage of its capacity. The practicality of this device in children appears to be primarily limited to those undergoing corrective cardiac surgery (see Chapters 14 to 16).<sup>517-524</sup> However, this device is clearly of benefit in defining the source of an adverse cardiovascular event such as an air, clot, tumor embolism, or other source of right-sided outflow tract obstruction.<sup>525-529</sup>

### CONTINUOUS INVASIVE AND NONINVASIVE CARDIAC OUTPUT MONITORS

Traditionally, cardiac output has been estimated with thermodilution, Fick O<sub>2</sub> consumption, or echocardiography. Continuous invasive techniques such as continuous analysis of central venous O<sub>2</sub> saturation is feasible and accurate even in neonates but generally not applicable in the operating room.<sup>530,531</sup> Arterial pulse contour analysis is another invasive method that requires arterial and central venous catheters; data regarding the accuracy and reliability for children are still preliminary.<sup>532-534</sup> Other noninvasive techniques such as measurement of expired CO<sub>2</sub> have been attempted but with variable success.<sup>535-542</sup> The NICO device (Philips Respironics, Amsterdam, the Netherlands) estimates cardiac output as reflected by changes in expired CO<sub>2</sub> using a Fick partial rebreathing calculation.<sup>541,542</sup> This device requires that the child is intubated, and its accuracy in children is yet unproved.<sup>536,539,541,543</sup> A new device, Cardiotronic EC (Cardiotronic, Inc., La Jolla, Calif.), has been approved by the FDA for use in children of all ages, including neonates.<sup>544-549</sup> Electrical cardiometry continuously estimates stroke volume and left ventricular outflow to calculate cardiac output, cardiac index, and a variety of other parameters through quantitation of changes in impedance associated with changes in the orientation of red blood cells (Fig. 51-11). During diastole red cells are organized chaotically, but during systole they assume a position parallel to the direction of blood flow. Thus thoracic electrical bioimpedance relates to changes in thoracic aortic blood flow, and through the use of refined algorithms, noninvasive measurement of cardiac output is achieved.

The height (cm), gender, weight (kg), and age of the patient are entered into the handheld device. Four electrodes are applied to the neck and left chest at specified locations—in infants, one lead is placed on the cheek or forehead and the fourth lead placed on a thigh (see Fig. 51-11). The device records the heart rate and averages cardiac output every 10 to 60 heartbeats depending on how the device is configured. Studies in neonates, children, and adults suggest that this is a reasonable trend monitor to estimate cardiac output in a noninvasive manner. It certainly is not a

**FIGURE 51-11** **A**, Cardiotronic cardiac output device. **B**, Electrical cardiometry continuously estimates stroke volume and left ventricular outflow to calculate cardiac output, cardiac index, and a variety of other parameters through quantitation of changes in impedance associated with changes in the orientation of red blood cells. During diastole red cells are organized chaotically, but during systole they assume a position parallel to the direction of blood flow. Thus thoracic electrical bioimpedance relates to changes in thoracic aortic blood flow and through the use of refined algorithms noninvasive measurement of cardiac output with four electrocardiography pads is achieved.

monitor that will replace the gold standard of echocardiography or thermodilution cardiac output, but the  $r^2$  value of 0.86 and Bland-Altman plot suggest reasonable efficacy for monitoring and trending purposes in adults.<sup>550</sup> Preliminary experience (CJC) with this device is favorable as an early warning device of a developing adverse cardiovascular event and as an indicator of successful intervention of such events.

### ELECTROCAUTERY

Although anesthesiologists are not directly responsible for electrocautery devices, they should have a basic knowledge of how they function and the necessary precautions to prevent burn injury or a fire. The most important means of preventing injury is to ensure that an appropriate-size grounding pad has been applied and that no blood, urine, or preparation solutions have been allowed to pool around or under the grounding pad. Additionally, the electrocautery can ignite any flammable implements, drapes, and an O<sub>2</sub>-rich environment. Severe injuries and deaths have occurred when high concentrations of O<sub>2</sub> have been allowed to build up beneath drapes (supplemental O<sub>2</sub> in awake or sedated patients) and have been ignited by the spark of the electrocautery on the other side of the surgical drape.<sup>551-556</sup>

## Operating Table

The operating table is a vital piece of anesthesia equipment. The table should provide the full range of positioning, including Trendelenburg controls in case of either regurgitation or the need to increase venous return. It must have appropriate padding to prevent patient contact with metal structures. The ability to remove the head support and to lower the foot section provides a smaller table appropriate for infants. For extremely long procedures, an alternating-pressure air mattress or silicone gel padding placed between the patient and the operating table guards against decubitus injuries.<sup>557</sup> Periodically changing the patient's head position may prevent bald spots as a result of prolonged contact pressure in one location.<sup>558</sup> The use of a silicone gel ring helps stabilize the head and reduces contact pressure at one point. The Jackson spinal table (Orthopedic Systems Inc., Union City, Calif.), along with other new tables with interchangeable modular components to maximize exposure of the surgical field and protect the patient from potentially harmful positions, have become popular for spine surgery in the past decade. This table may present unique challenges for the anesthesiologist, with access to the head of the table limited because of an immobile and obstructive block. If tracheal intubation must be performed in a smaller child who requires this table, provisions should be made to ensure that adequate access to the head can be obtained to facilitate laryngoscopy and intubation in advance of induction of anesthesia. An additional concern is to ensure that the operating table can handle the unfortunate increasing weight of the pediatric patient population; many centers are now performing bariatric surgery in teenagers.

## Transport Apparatus

Because transport environments (particularly outside the hospital in ambulances, helicopters, and fixed-wing aircraft) are exceedingly noisy, we depend on electronic monitoring for the heart rate more than we would in an operating theater (where we could use a stethoscope). The monitor must have battery-mode capability and, if possible, aircraft and ambulance power (direct current), as well as routine hospital power (alternating current). If the monitor incorporates a QRS beeper, it should be capable of high volume to compete with the noisy transport environment. The use of headphones connected directly to monitors may be useful in this circumstance. The oscilloscopic display must have bright phosphors to allow arterial, ECG, pulse oximetry, and expired CO<sub>2</sub> waveforms to be observed in minimal and bright light conditions.

## Purchasing Anesthesia Equipment

With the increasing sophistication of monitoring and life support equipment, purchasing decisions are no longer intuitive. A complete grounding in the underlying engineering concepts would probably require an advanced degree in engineering, but a reasonable working knowledge of the operating principles, advantages, and special hazards of the various types of apparatus is relatively easy to obtain. Most hospitals now have a full-time biomedical professional staff, which often have considerable engineering and practical experience to assist in the purchasing, maintenance, and safety of all of the equipment and systems used in the hospital setting. The biomedical professionals should be closely integrated into the purchasing, maintenance and ongoing

safety monitoring of all devices. Although vendors are pleased to promote a product, the manufacturer's information literature should be obtained from an unbiased source such as the equipment periodical *Health Devices*, published by ECRI (formerly Emergency Care Research Institute, Plymouth Meeting, Pa.). The biomedical or hospital safety office of each hospital usually subscribes to this periodical.

Another useful source of information is the specialty pediatric hospital. Whether through inquiry at medical meetings or by direct solicitation, practitioners at these unique resource institutions are often willing to share their special expertise.

The following are useful principles for any equipment purchase:

1. New purchases should interface with equipment that is already present. Considerable cost savings can occur if the same or compatible equipment is used in all the perioperative areas, including the OR, PACU, and ICU. Another issue to consider is how the equipment will interface with automated record-keeping systems and other hospital information systems if they are present. If an automated recording device is a possible plan for the future, the equipment should be evaluated for how well it will interface with systems that will possibly be purchased. Another compatibility issue to carefully review is the software that is required to use the equipment. Review the product information carefully to identify the need for software upgrades and compatibility, which can be important for safety and cost-effectiveness.
2. Recognize that the salesperson is inherently biased.
3. Always test proposed equipment in the environment in which it will be used, with the personnel who will be using it. What appears attractive in a display as presented by a salesperson may not function well in practice. It is also important to test the device in unusual circumstances to see how well it performs. The use of simulation is becoming an important modality to test devices under normal and unusual circumstances. Human factors must be considered, such as how easy it is to use the equipment clinically (i.e., the user interface), and equally important, the safety of the equipment or product. Evaluate systems issues that could lead to error or misuse. Software-driven products are harder to test for how they may potentially fail when connected to existing systems and products in your workstations; always test new equipment in the environment where it will be used.
4. Do not use equipment for any purpose other than that for which it has been designed.
5. Have your hospital biomedical staff be intimately involved with the safety issues of your systems, as described earlier, and periodically check for electrical leakage and other safety issues.
6. Decide explicitly how the product will be maintained; are the biomedical professionals going to perform the necessary calibration, testing, and repair of the equipment, or is a member of your department going to take on this role? Spend the necessary resources to properly maintain the product; this is typically on the order of 10% of the cost of the device per year. Consider a maintenance contract, if available. Ask that the company ensure the future availability of parts and the compatibility of subsequent modifications or design evolutions with your equipment.

7. Consider the cost and quality of disposable components of the equipment. This can also have an impact on the safety and cost of the product.
8. If two products are comparable but one has local service facilities, that one may be the better choice.
9. If areas of special needs have been recognized, be as detailed as possible with specifications. For example, if a monitor is to be used strictly in the OR, it may be reasonable to operate it from wall power. Conversely, if the monitor is to serve in the OR, and also for transport between the operating theater and the recovery room or ICU, it must have internal battery backup.

The more precisely needs can be defined, the more accurate the comparisons will be between the bids of rival vendors. Note that any given piece of equipment will occasionally be out of service, whether for regular preventive maintenance or for some unanticipated repair, although it is often difficult in this era of cost containment to convince the hospital administration, this fact dictates a need for additional spare units.

Response to Being Sued for Medical Malpractice

Summary

**MEDICOLEGAL ISSUES ARE** a continuing concern for the anesthesia care team.<sup>1-10</sup> Taken too seriously, they can alter practice so that legal concerns rather than medical principles are in control. Taken too lightly, these concerns can transform into an adverse outcome disaster. This chapter enumerates some of the medicolegal issues faced in clinical anesthesia and describes ways to balance a safe practice with avoidance of litigation.

The opinions in this chapter reflect issues of practice within the United States, but the same issues are encountered in other countries. Two problems that were taken too seriously are provided as examples. First, the U.S. Food and Drug Administration (FDA) assigned a black box warning to droperidol because of droperidol-induced QT prolongation. Although these transient findings were associated only with high-dose droperidol, most anesthesiologists have stopped using even low-dose droperidol for fear of litigation if an adverse event occurs. Many hospitals have removed it from their formulary. As a consequence, this warning has resulted in the loss of a low-cost and demonstrably effective antiemetic from use in the perioperative period. Second, guidelines of The Joint Commission (TJC, formerly called the Joint Commission on Accreditation of Healthcare Organizations [JCAHO]) required anesthesia carts to be locked. Although intended to protect against entry by nonanesthesia personnel, this guideline created the potential for delayed access to essential rescue medications and airway equipment in an emergency situation as the anesthesia caregiver struggled to open the cart in a high-pressure situation. It is difficult for practitioners to place these kinds of issues in perspective.

## Policies and Procedures

The foundation of continually upgrading medical practice is knowledge of the medical literature. The use of evidence-based or outcomes-based studies allows safe and effective adjustments in practice. Practice within a department or hospital is further guided by its policies and procedures, and the applicable standard of care is predicated on the standards developed by the

American Society of Anesthesiologists (ASA) that are incorporated in the institutional policies and procedures. Departmental policies and procedures can be used to defend a practice but can also be used against the anesthesia caregiver if his or her practice is inconsistent with the rules and guidelines. Departmental policies and procedures must be written and available to all team members.

## Practice Areas of Controversy

There are several key areas of controversy about medical practice in the United States.

### DISCLOSURE OF UNANTICIPATED EVENTS

In July 2002, TJC released The Joint Commission Patient Safety Standards, which states, "Patients and, when appropriate, their families are to be informed about the outcomes of care, including unanticipated events." There is no clear information from TJC or agreement among institutions about what is required to meet this standard. Controversy exists over the types of conditions and the severity of the outcomes that should trigger this requirement for disclosure to the patient or family. Some suggest that it should be managed as part of the sentinel event process required by TJC, encouraging the health care facility to conduct a root cause analysis. Many health care facilities have created policies that determine when disclosure is required based on *when the patient is substantially harmed*. However, what constitutes substantial harm remains an issue of debate. Harm may be viewed from a patient or family's subjective view, or it may require a more concrete approach, such as the need for additional medical care or diagnosis of a patient's injury.

This TJC standard has created much discussion and different views about what information must be shared with patients and their families. The debate is likely to continue and produce more regulations in the future. In Canada, the judiciary has declared that health care providers should disclose any and all substantive risks related to a procedure that any reasonable individual would

wish to know to provide informed consent for surgery or anesthesia. Being honest about care is always good policy, but a policy mandating disclosure of unanticipated events can be fraught with legal peril. If an adverse event occurs, the practitioner should seek risk management or legal advice to determine what information should be disclosed and the mechanism by which the information should be conveyed to the family. In many cases, avoiding a misunderstanding is crucial and may determine whether a frivolous lawsuit results.

### MANAGING ADVERSE OUTCOMES

An *adverse event* is an event that occurs during patient care that can cause an undesirable or unanticipated outcome. *Adverse outcomes* include the following:

- Patient injury
- Escalation of care
- Operational inefficiency

Patient injuries are adverse outcomes. A patient's care plan that is changed and requires an unanticipated escalation of care also is an adverse outcome. These situations may result in two types of discontent for patients and their families: disappointment in the medical outcome and disappointment with the way health care providers discuss the issues.

Preliminary research suggests that families and patients are much more distressed and disappointed when the health care providers who do not present straightforward, honest information or are perceived to be hiding the truth and facts. This has been the message of the Sorry Works movement, which advocates a proactive approach to patients and their families or legal guardians to fully disclose and discuss adverse events such as an untoward incident, therapeutic misadventure, iatrogenic injury, or undesirable outcome.

Communication must start with the medical or surgical team as they try to evaluate the unanticipated outcome, its cause, and its subsequent treatment. The entire team must fully comprehend the facts and come to a mutual understanding of the sequence and timing of the occurrence. Disclosures should be made after information has been gathered and analyzed and practitioners are comfortable with their position. Health care providers and risk management personnel should be consistently involved in the investigation and communication with the patient and family. Patients and their families desire and deserve a discussion of what transpired, an apology (e.g., Sorry Works program) that the unanticipated outcome occurred, and assurances that there will be ongoing dialogue to clarify the events and the future for the patient and family. Families also want reassurance that the event will not happen to other patients and that something good may come out of this experience through system improvements.

However, communication is often very difficult after such an event. Guilt, speculation based on incomplete information, and the need to blame something or someone can interfere with the investigative process and with communication with the patient and family.

In some centers, there is direct communication with the patient and family concerning an apology and settlement if it is determined there was an error by the hospital or the medical team. There is considerable support for apologizing for the unanticipated event, regardless of whether an error precipitated it. This process does not imply guilt, and most states have passed legislation to protect apologies from being used in litigation. However, a statement of fact that posits the cause of harm is not protected from discovery in a legal action. Rather, most

legislation is intended to protect statements of empathy, such as, "I'm sorry you have experienced this unanticipated outcome." Other types of statements, such as, "I'm sorry the nurse or doctor gave too much of the medication," are not protected from discovery in a lawsuit.

In some cases, the cause of the unanticipated event cannot be ascertained in a timely manner to a reasonable degree of certainty (i.e., the legal standard that an expert must meet). When this occurs, a candid discussion of the situation should take place with the family members, and they should be informed that further investigation is anticipated, the results of which will be communicated to them. Families often seek legal assistance because an event occurred that resulted in questions that they think were not adequately addressed by the hospital or members of the medical team (e.g., an event occurred but no one followed up with the family to explain in lay terms what had transpired).

## Problem Areas for the Anesthesia Caregiver in Dealing with Children

### WHO SHOULD ANESTHETIZE CHILDREN?

Occasionally, when a child who has a significant medical problem presents for elective surgery at a location that does not routinely provide care for a child with a complex medical problem, an adverse outcome may result. The resulting lawsuit may be difficult to defend. The nature of the anesthesia services that are appropriate to perform in a particular location and the qualifications of those who provide the services must be addressed in the policies and procedures of the facility to avoid such an event, although guidelines in this area typically are arbitrary. Children in certain age groups with certain medical conditions and in certain types of emergencies should be designated for referral to a center that is more appropriately equipped or staffed to deliver expert care.

### ISSUES OF CONSENT AND ASSENT

Consent is a process that provides patients and families with sufficient information to allow them to make an informed decision about whether to proceed. The anesthesiologist must provide sufficient information in terms that are understandable by adults with a grade 5 or equivalent education. In most instances, the patient must be an adult (18 years of age or older) to consent to a procedure. However, in some states, minors are allowed to make decisions independently, without the participation of a parent or guardian. In some circumstances, the court has the authority to override the parent's rights based on the best interests of the patient. An example is providing lifesaving blood transfusions for children of parents who are Jehovah's Witnesses. Knowledge of these special provisions for minor consent in the state's laws is important. Virginia addressed the issue of pediatric assent and adult neglect in 2007 (VA code §63.2-100 et seq.). Assent may be given when a 14-year-old with a life-threatening condition or elective surgical issue is sufficiently mature to agree to the proposed treatment (see later for a complete definition). Dissent is when the child refuses. A judge threatened to remove a 14-year-old boy from his parents because they refused chemotherapy for lymphoma and instead trusted in prayer and herbal remedies.<sup>11</sup> These discussions and decisions are influenced by the severity of the issues and whether the procedure is elective or necessary to treat a life-threatening problem.

A common difficulty that arises with consent for minors is identifying the adult who is legally responsible to provide

consent. State law governs who makes health care decisions for minors, and these laws vary from state to state. As an example, when the parents of a child are divorced, the custodial parent is most often the health care decision maker. However, this designation may vary based on the parents' custody agreement and according to state law. Reviewing the custody agreement is not feasible, and most often, the arbiter must rely on what a parent says. If questions or concerns remain regarding the appropriate decision maker, a facility administrator, risk manager, or legal advisor should be consulted. Lack of consent from the appropriate decision maker is the same as no consent, which can lead to liability.

The issue of assent deserves special consideration. *Assent* is defined as agreeing to something after thoughtful consideration. Children may not be able to assent to a procedure because they are unqualified to have thoughtful consideration. At what age and under what circumstances the minor's wishes should be followed because they mature enough to engage in thoughtful consideration is unclear. Unless there is a specific state law that grants decision-making authority to a minor in the current circumstances, the issue of a minor's assent is an ethical one, rather than a legal matter. Knowing whether the issue is ethical or legal is important in minimizing liability risks. If an older minor patient does not want a surgical procedure, a discussion should be held with the legally responsible adult, and any differences should be resolved before surgery. Even if the parents or guardians wish to proceed and the child does not, it is usually best to delay surgery and have a focused discussion to ensure that the wishes and thoughts of the minor patient have been considered and respected. Knowledge of state law and a low threshold for seeking consultation with the hospital lawyer are indicated in this situation.<sup>11</sup>

#### COMMUNICATION WITH PATIENTS AND FAMILIES

The preoperative visit is an opportunity to develop rapport with the child and the family. It is important to establish a shared relationship, because children and families who feel they have communicated well preoperatively with their health care provider usually do not sue if there is an adverse outcome. Unfortunately, the time for preoperative evaluation and discussion is greatly limited. The physician should review the record before interviewing the child to focus the discussion and be aware of any underlying issues so that they can be directly addressed during the interview session. One technique for developing rapid communication with the child and the family is to recognize that they have major concerns about the surgical procedure, such as pain management, severe anxiety, nausea and vomiting, and safety issues. The anesthesiologist should clarify how he or she will address these issues preemptively so that the child and family understand that they have an advocate who can ensure safety and comfort throughout surgery (see also Chapter 4). The next step is to determine whether the child and family have specific concerns or suggestions. If the child has had multiple operations, the anesthesiologist should inquire whether any anesthetic technique has proved superior to others and incorporate it when possible. If the lines of communication have been opened before an unanticipated outcome occurs, it will be easier to maintain rapport, which reduces the likelihood of a lawsuit being filed.

#### UNANTICIPATED EVENT RESULTING IN PATIENT INJURY OR DEATH

When a medical error in providing anesthesia results in injury or death, an anesthesia caregiver's worst nightmare has come

true. One example of an unanticipated event is a perioperative allergic reaction such as latex anaphylaxis.<sup>12</sup> This event may be avoided by a careful preoperative history, and anticipation and preparation for this possibility can aid treatment. Little has been done to develop an algorithm for management of an adverse outcome that results in injury or death. An algorithm published by the Anesthesia Patient Safety Foundation emphasizes the need for an incident manager, who is the person who takes charge of the administrative aspects of the situation while the anesthesia caregivers continue to manage the patient's problems.<sup>13</sup>

Step 1 in this algorithm is taking care of the patient. Step 2 is making plans for dealing with the family, which can be done with the help of the surgical team, the anesthesia team, and/or the risk management team. Most anesthesia caregivers have an enormous emotional jolt of depression and guilt over the bad outcome because the American system of teaching through negative reinforcement suggests that they must have done something wrong. This likely response needs to be recognized by the anesthesia caregiver, so that when the issues are discussed with the family, the caregiver can avoid his or her own emotions taking over and instead focus on known facts while offering appropriate empathy to the family. Full disclosure (previously discussed) remains a critical issue, along with complete and accurate charting and discussion of the child's care with other key providers to ensure that there is a mutual understanding of what transpired and that the documentation is consistent.<sup>14</sup> The family will understandably be very emotional and angry. A note should be entered into the child's chart providing a summary of these family discussions.

Involved physicians should notify their medical malpractice insurance carrier in the event of a medical error or when there is a significant adverse outcome without error, but the family is very angry and threatening. The insurance carrier will conduct its own investigation of the event. If the carrier thinks there is a significant likelihood of a claim being filed, it may assign an attorney to represent the physician before a lawsuit is filed. The attorney can discuss the matter with confidentiality and offer advice as the facility's quality review takes place. Regardless of whether legal action will occur, it behooves the physician to record the precise sequence of events that occurred and then to sign, date, and file the narrative with his or her risk management office and insurance carrier.

Emotional support should be available for the involved care providers. The facility may have a mechanism to provide for this, but at the very least, the anesthesia department should have a plan. Sometimes, the anesthesia caregiver may need to seek professional help from psychologists or psychiatrists to help him or her cope with the emotional impact of the event. Doing so is important for the individual's well-being and professional career. These issues are well recognized, and assistance should be readily accessible for health care providers.<sup>15</sup>

## Reducing Unanticipated Events and Adverse Outcomes

#### ANESTHESIA RECORD AND CHARTING

Poor anesthesia records and charting often lead to verdicts in favor of the plaintiff in lawsuits. A key strategy to avoid lawsuits is to ensure that documentation is complete, understandable, timely, and legible.<sup>16,17</sup> The use of automated anesthesia records (i.e., automated information management systems) is helpful in

most cases.<sup>16</sup> We think that many malpractice cases that resulted in plaintiff verdicts could have been defended if greater attention had been paid to accurate documentation in the medical records. In the middle of a difficult or complicated case, it often is impossible to ensure thorough documentation of the events. However, many modern anesthesia monitors retain recent data (until they are powered off), allowing the anesthesia caregiver to retrieve information that is missing from the medical record and to document the details in a timely manner. When completed, a note that includes the date and time and the reason that the documentation was completed after the fact should be added to the child's record. Completing a record can only help as long as the entries added are accurate and properly identified.

The second area of record keeping is the anesthesia note about the incident. After some preparation, it is written in the chart and can be compared with what the other health care professionals state in their notes. The anesthesia note should be brief, factual, and without unsubstantiated conjecture regarding what occurred. Before writing the note, the anesthesia care provider should discuss the event with the nurses and the surgeons to clarify the sequence of events and any other pertinent information to ensure that there is a consistent understanding of what transpired. Occasionally, there is a difference of opinion regarding the events that occurred. It is preferable to clarify any discrepancies immediately rather than after inconsistent documentation has been entered into the child's chart and discussed with the parents. It is important to review notes written by other caregivers at the time of the event; for example drugs administered by the anesthesia care team that are entered in the anesthesia record must also be listed on the arrest log.

The international trend toward using automated medical information systems to create an anesthesia record has been encouraged by the provision of generous financial incentives. Whatever method is used, having a full, accurate, and timely record is essential for a successful defense. Correcting errors or making additions to the record should follow the policies and procedures of the department and hospital; on paper, errors should be indicated by using a single line through the text followed by the initials of the signer and the date. Errors should never be removed with whiteout or by removing the page. Late entries should be so indicated and initialed.

## MONITORING

The ASA has set standards for basic anesthesia monitoring (Table 52-1). Specific monitors must be used with all patients who are undergoing general anesthesia, regional anesthesia, or monitored anesthesia care. The anesthesia caregiver may waive certain monitoring requirements under extenuating circumstances. However, when this is done, the reasons should be stated in the anesthesia record. The second standard for basic anesthesia monitoring states, "during all anesthesia, the patient's oxygenation, ventilation, circulation, and temperature shall be continually evaluated." The ASA standards further state, "When the pulse oximeter is used, the variable-pitch pulse tone and the low-threshold alarm shall be audible to the anesthesiologist or the anesthesia care team personnel." The section on temperature monitoring provides this standard: "Every patient receiving anesthesia shall have temperature monitored when clinically significant changes in body temperature are intended, anticipated, or suspected." This can be interpreted to mean that brief procedures and certain anesthesia locations may make temperature monitoring unnecessary or impractical or potentially dangerous because of burns. It

is essential to document when and why standard monitoring procedures are not followed. If this is not done, it increases the risk of a decision against the defendant in a malpractice claim. Physicians also must be aware of changes in these standards. For example, expired carbon dioxide monitoring becomes a requirement for the updated ASA standard in 2012 for all patients receiving moderate or deep sedation by an anesthesiologist.<sup>17a</sup>

Delay in the recognition of ventilatory or circulatory difficulties is frequently caused by the anesthesia caregiver not believing that the monitor accurately reflects the child's condition. An example of this is the pulse oximeter. Movement and mechanical problems frequently interfere with pulse oximetry readings, suggesting that an erroneous reading is not a patient-related but rather an equipment-related problem. A basic premise of monitoring is that when there are changes in the monitor, the patient must be evaluated first and the monitor evaluated second. If the accuracy of the pulse oximeter is in doubt, the other monitors should be scanned to determine whether they show consistent changes. The most useful monitor for cross-checking the pulse oximeter is the capnograph. A decrease in the child's perfusion (i.e., cardiac output) reduces oxygen saturation and end-tidal carbon dioxide (ETCO<sub>2</sub>). Another useful method is checking that the heart rates displayed on the pulse oximeter and the electrocardiogram are identical. If there is any question about the accuracy of the pulse oximeter after the child and the monitor readings have been carefully checked, the pulse oximeter sensor should be applied to the anesthesia caregiver to verify its function. Changes in ETCO<sub>2</sub> usually are caused by hyperventilation, hypoventilation, or decreased cardiac output.

Tracheal intubation may be problematic. When the breathing circuit is connected to the tracheal tube, the absence of the carbon dioxide waveform should immediately raise concerns that the tracheal tube is not in the trachea. If the functionality of the capnogram is in question, the caregiver can breathe into the sampling line for the capnogram, providing the child's oxygen saturation remains within normal limits. If the capnogram is functioning properly, laryngoscopy should be performed to confirm that the tracheal tube has passed through the vocal cords.

Another potential problem with monitoring systems is that the default alarms are set for adults, not children. This has resulted in the alarms sounding despite normal readings for children, prompting some clinicians to inappropriately disable the alarms. As irritating as these alarms may be, they should not be disabled but should be reset for the appropriate values. Alarms should only be temporarily silenced when the anesthesia caregiver knows the reason for the alarm and is taking steps to correct it. The alarms are set for the anesthesia caregiver and for the whole surgical team. If the anesthesia caregiver is having difficulty with the child's vital signs, the other members of the surgical team should be informed so that they can assist in correcting the problem. If the alarms are disabled, other members of the care team may not be aware that a problem is developing. If monitor alarms are ignored or turned off, the risk of a finding in favor of a plaintiff in a medical malpractice case increases dramatically.

## RESUSCITATION

If a child develops bradycardia and hypotension, the classic interventional sequence of airway, breathing, and circulation as taught by the American Heart Association should be followed. A common finding is that repeated doses of atropine are

**TABLE 52-1 Standards for Basic Anesthesia Monitoring**

These standards apply to all anesthesia care, although in emergency circumstances, appropriate life support measures take precedence. The standards may be exceeded at any time based on the judgment of the responsible anesthesiologist. They are intended to encourage quality patient care, but observing them cannot guarantee any specific patient outcome. They are subject to revision from time to time, as warranted by the evolution of technology and practice. They apply to all general anesthesia, regional anesthesia, and monitored anesthesia care. This set of standards addresses only the issue of basic anesthesia monitoring, which is one component of anesthesia care. In certain rare or unusual circumstances, (1) some of these methods of monitoring may be clinically impractical, and (2) appropriate use of the described monitoring methods may fail to detect untoward clinical developments. Brief interruptions of continual\* monitoring may be unavoidable. These standards are not intended for application to the care of the obstetric patient in labor or in the conduct of pain management.

**1. STANDARD I**

Qualified anesthesia personnel shall be present in the room throughout the conduct of all general anesthesia, regional anesthesia, and monitored anesthesia care.

**1.1. Objective**

Because of the rapid changes in patient status during anesthesia, qualified anesthesia personnel shall be continuously present to monitor the patient and provide anesthesia care. In the event there is a direct known hazard (e.g., radiation) to the anesthesia personnel which might require intermittent remote observation of the patient, some provision for monitoring the patient must be made. In the event that an emergency requires the temporary absence of the person primarily responsible for the anesthesia, the best judgment of the anesthesiologist will be exercised in comparing the emergency with the anesthetized patient's condition and in the selection of the person left responsible for the anesthesia during the temporary absence.

**2. STANDARD II**

During all anesthetics, the patient's oxygenation, ventilation, circulation, and temperature shall be continually evaluated.

**2.1. Oxygenation**

2.1.1. Objective: To ensure adequate oxygen concentration in the inspired gas and the blood during anesthesia

**2.2. Methods**

2.2.1. Inspired gas: During every administration of general anesthesia using an anesthesia machine, the concentration of oxygen in the patient's breathing system shall be measured by an oxygen analyzer with a low oxygen concentration limit alarm in use.<sup>†</sup>

2.2.2. Blood oxygenation: During all anesthetics, a quantitative method of assessing oxygenation such as pulse oximetry shall be employed.<sup>†</sup> When the pulse oximeter is used, the variable-pitch pulse tone and the low-threshold alarm shall be audible to the anesthesiologist or the anesthesia care team personnel.<sup>†</sup> Adequate illumination and exposure of the patient are necessary to assess color.<sup>†</sup>

**3. VENTILATION****3.1. Objective**

To ensure adequate ventilation of the patient during anesthesia

**3.2. Methods**

3.2.1. Every patient receiving general anesthesia shall have the adequacy of ventilation continually evaluated. Observation of qualitative clinical signs such as chest excursion, observation of the reservoir breathing bag, and auscultation of breath sounds are useful methods. Continual monitoring for the presence of expired carbon dioxide shall be performed unless invalidated by the nature of the patient, procedure, or equipment. Quantitative monitoring of the volume of expired gas is strongly encouraged.<sup>†</sup>

3.2.2. When an endotracheal tube or laryngeal mask is inserted, its correct positioning must be verified by clinical assessment and by identification of carbon dioxide in the expired gas. Continual end-tidal carbon dioxide analysis, in use from the time of endotracheal tube or laryngeal mask placement until extubation or removal or until initiating transfer to a postoperative care location, shall be performed using a quantitative method such as capnography, capnometry, or mass spectroscopy.<sup>†</sup> When capnography or capnometry is utilized, the end-tidal carbon dioxide alarm shall be audible to the anesthesiologist or the anesthesia care team personnel.<sup>†</sup>

3.2.3. When ventilation is controlled by a mechanical ventilator, there shall be in continuous use a device that is capable of detecting disconnection of components of the breathing system. The device must give an audible signal when its alarm threshold is exceeded.

3.2.4. During regional anesthesia (with no sedation) or local anesthesia (with no sedation), the adequacy of ventilation shall be evaluated by continual observation of qualitative clinical signs. During moderate or deep sedation, the adequacy of ventilation shall be evaluated by continual observation of qualitative clinical signs and monitoring for the presence of exhaled carbon dioxide unless precluded or invalidated by the nature of the patient, procedure, or equipment.

**4. CIRCULATION****4.1. Objective**

To ensure the adequacy of the patient's circulatory function during anesthesia

**4.2. Methods**

4.2.1. Every patient receiving anesthesia shall have the electrocardiogram continuously displayed from the beginning of anesthesia until preparing to leave the anesthetizing location.<sup>†</sup>

4.2.2. Every patient receiving anesthesia shall have arterial blood pressure and heart rate determined and evaluated at least every 5 minutes.<sup>†</sup>

4.2.3. Every patient receiving general anesthesia shall have, in addition to the above, circulatory function continually evaluated by at least one of the following: palpation of a pulse, auscultation of heart sounds, monitoring of a tracing of intraarterial pressure, ultrasound peripheral pulse monitoring, or pulse plethysmography or oximetry.

**5. BODY TEMPERATURE****5.1. Objective**

To aid in the maintenance of appropriate body temperature during anesthesia

**5.2. Methods**

Every patient receiving anesthesia shall have temperature monitored when clinically significant changes in body temperature are intended, anticipated, or suspected.

Modified from Standards for Basic Anesthesia Monitoring, Committee of Origin. Standards and practice parameters. Approved by the ASA House of Delegates on October 21, 1986, and last amended on October 20, 2010, with an effective date of July 1, 2011. Available at <http://www.asahq.org/~media/For%20Members/documents/Standards%20Guidelines%20Stmnts/Basic%20Anesthetic%20Monitoring%202011.ashx> (accessed July 2012).

\*Continual means repeated regularly and frequently in steady, rapid succession, whereas continuous means prolonged without interruption at any time.

<sup>†</sup>Under extenuating circumstances, the responsible anesthesiologist may waive the requirements marked with a dagger; it is recommended that when this is done, it should be so stated (including the reasons) in a note in the patient's medical record.

administered before epinephrine; the latter is the first drug of choice for symptomatic bradycardia (see Chapter 39). A nurse or other assistant should accurately record the timing and doses of medications administered during these events, the names of the health care providers who were present, the timing of the call for additional help, and the name of the person who directed the resuscitation. In facilities without automated anesthesia records, the anesthesia record can often be filled in after the event if the monitor stores recent vital signs that can be interrogated later, and a note should be made in the record that this is how the data were retrieved.

After this type of event, the anesthesia machine should be quarantined and the monitors left on so that the stored data can be retrieved at a later time or date to better reconstruct the sequence of the events. If there is a problem retrieving data, a technician should be called to download the information to a permanent record. This should then be handed over to risk management for preservation. Any time discrepancy between the monitors and the operating room clock used to record events should be noted.

## Anatomy of a Medical Malpractice Case

### SERVICE OF PROCESS

A defendant physician in a medical malpractice case usually is served by an official of the court (often a local sheriff) with a copy of a medical malpractice lawsuit. The heading on the lawsuit indicates the location of the court where the lawsuit has been filed and the name of the person (i.e., plaintiff) who is filing the litigation, along with the names of any other defendants.

Service of process may be accepted by anyone, but the person accepting service must sign the suit papers as accepting them on behalf of the defendant. Others at the office and those at home must immediately notify the defendant of having received a lawsuit. The defendant should then immediately notify his or her medical malpractice insurance carrier that a lawsuit has been served, and then fax a copy of the suit papers to the insurance company. If an attorney has not already been assigned, one will be soon. The insurer undertakes its own investigation and requests a copy of the medical record if it does not already have it. The hospital administration should also be informed because the hospital also may become a defendant.

### COURT PLEADINGS

Different states use different names for a civil claim filed in court (as is the case for most medical malpractice insurance claims). It may be called a complaint, motion for judgment, or another name. The attorney must file a responsive pleading within the time specified by state law, usually 21 days. If a defendant does not file a response in the required time frame, a default judgment may be entered. After a lawsuit is filed, all further interactions between plaintiffs and defendants must be through their respective attorneys. It is inappropriate for a defendant to call a plaintiff or vice versa.

### DISCOVERY

The next step in the legal process is called the discovery process. It can continue for years. Discovery provides an opportunity to investigate the plaintiff's claim and the defendant's responses. The initial step in discovery is to file interrogatories, which are written questions answered under oath. The attorney sends them to the defendant with a deadline for returning them. The

defendant's answers are reviewed by his or her attorney, who may discuss them further. The final answers must be signed by the defendant and notarized. If needed, the answers may be amended later. However, if they are not amended and the answers are different from those given in a deposition at a later date or at trial, the interrogatory responses may be used to attack the defendant's credibility. It is vitally important to answer the interrogatories as accurately as possible. The defense also is asked to identify all witnesses they will use, including experts and their expected opinions to be testified to at trial. The number and detail of questions vary from case to case and attorney to attorney. The attorney may instruct the defendant not to answer some questions based on a legal objection. The defense attorney also poses interrogatories to the plaintiff.

In addition to interrogatories, the attorneys may request the defendant to produce certain documents. The attorney works with the defendant to determine if there are objections to these documents and will make any needed objections.

Dispositions constitute the most important tool in the discovery process. All witnesses, whether experts or general witnesses, may be deposed, in addition to all parties to the lawsuit. In a deposition, questions usually come only from the attorney on the opposing side. The defendant's attorney does not want to reveal information or strategy for your defense, so his or her questions will be reserved for trial. Objections to questions are usually made but reserved for argument later if the matter goes to trial. These objections are a distraction to the defendant but are a part of the legal process. Occasionally, the issue is so important that the matter may be taken to the judge during or shortly after the deposition. However, during a deposition, the attorney makes his or her objection and then instructs the client to answer the question.

The importance of the deposition in developing a defense cannot be underestimated. The physician must know the chart, his or her entries, and the medical issues of the case. Several points should be remembered during a deposition. The defendant should give short, concise answers, not try to educate the lawyers or impress them with a superb record as a health care practitioner. Persons being deposed should be prepared to avoid traps. For example, the attorney may ask, "Do you have an independent recollection of the case?" The lawyer does not want to know if the person generally remembers the tragedy of the event but instead wants specific details of the case. Because depositions usually occur 2 to 5 years after the event, it is often difficult to remember the details of a case, and the person being deposed should rely primarily on the patient's chart. Offering a best guess is never a good idea, and if a certain detail cannot be recalled, the person should answer, "I do not recall."

An example of such a case was provided in the deposition of a nurse anesthetist defendant, who gave excellent answers. She said that she remembered the tragedy of the event but that she did not remember any details. She was asked many times about her independent recollection of the case. Her answer was always the same: "The record speaks for itself. The times may be off a little bit, but the sequence of events is [recorded] as they occurred." The total time of her deposition was 1.5 hours. The anesthesiologist defendant in the case said that he did have an independent recollection, and he tried to remember details of the events. By the end of his deposition, which took 5.5 hours, he had tied himself completely in knots. The nurse anesthetist's deposition also demonstrates the importance of having an accurate chart that is complete.

During depositions, the defendant may become angry or frustrated with the plaintiff's attorney and the legal process. When anger becomes part of the defendant's answers, the deposition often becomes protracted and confrontational. This can lead to answers that are not well thought out and consistent with records and sometimes result in angry outbursts by the defendant.

The discovery process may take place over several years. After it is complete, a case may proceed to trial. The purpose of discovery is to avoid any surprises at trial by revealing as much of the evidence as possible in advance of trial. This extensive discovery process leads to most medical malpractice cases being withdrawn or settled before trial.

### TRIAL

At trial, the plaintiff has the burden of proving his or her case by the preponderance of the evidence. The jury will decide if this burden is met, which means that the jury members must find that it is more than 50% likely that negligence occurred.

A trial begins with selection of the jury. In civil cases, there are seven jurors. The trial begins with the opening statement of the attorney for the plaintiff, followed by the opening statement of the lawyer for the defendant. These statements are not evidence but preview for the jury what evidence the attorneys expect to present.

The plaintiff's case is presented first, which often means that the defendant is called by the plaintiff as an adverse witness. If so, the defendant should give short, concise answers that respond only to the question asked to avoid being boxed into an opinion or unintended admission. All witnesses called by the plaintiff are first questioned by the plaintiff's counsel. Defense's counsel may then cross-examine a plaintiff's witness. After that, the plaintiff's attorney may have a redirect examination. On cross-examination, leading questions may be used, such as, "Isn't it true that..." At this time, the attorney can go back to the prior answers to interrogatories and deposition testimony to make the defendant appear that he is contradicting himself or changing his story, which is why it is vital to keep the answers to all questions precise and concise.

At the completion of the plaintiff's case, the defendant's lawyer may move (i.e., make a motion to strike) the court to dismiss the plaintiff's case if all the elements of the claim made have not been established. A motion to strike is rarely granted by a court. Trial usually proceeds to the defendant's evidence, which seeks to rebut the evidence introduced by the plaintiff. New evidence may also be introduced in an effort to provide an alternative theory of what occurred.

At the close of the defendant's evidence, the plaintiff has one last opportunity to put on evidence that rebuts the defendant's case. The testimony by these rebuttal witnesses must be confined to contradicting evidence of the defendant.

Before a case goes to a jury, the defendant's attorney has another opportunity to ask the court to dismiss the case on the basis of the plaintiff's failure to establish his or her case. The attorneys also submit jury instructions to the judge, who selects from those submitted as he or she deems appropriate. These instructions are read to the jury by the judge before they enter into deliberations.

The last information provided to the jury is the closing statement of attorneys. These statements are not evidence but rather summations of what the attorneys think their cases showed. Jury deliberations may last minutes, hours, or days. At this point, all

the defendant can do is wait because the verdict rests with the jurors or judges, depending on the jurisdiction.

### APPEAL

The plaintiff or defendant may appeal a case, although appeals are rare. There must be a legal basis for the appeal rather than an appeal based on the merits of the case. Rarely, an appeal may be granted because there is reasonable question that the evidence did not support the jury's decision. Because the courts give extreme deference to the jury, overturning the decision solely on this basis is unlikely. Most often, appeal is based on a mistake of law by the trial judge.

If the appeal is granted, an appellate judge usually hears oral arguments by the attorneys. No witnesses are presented. The arguments are based on evidence and events in the trial court. The appellate court may decide that there is no basis for appeal, remand the case for retrial in the lower court with instructions on the applicable law, or dismiss the case altogether. How many levels of appeal there are depends on the particular state in which the case is being heard or whether it is heard in federal court.

## Response to Being Sued for Medical Malpractice

Defendants should do the following:

- Review the record
  - Analyze the case
  - Look for other relevant documents
  - Review the literature
  - Identify experts in the field who might be willing to help with the defense
  - Make a list of fact witnesses
- Defendants should *not* do the following:
- Discuss the case with anyone (including codefendants) but legal counsel, a member of defense team (which may include a psychologist or psychiatrist), or a spouse
  - Change the records
  - Accept calls from other attorneys or the patient or their family members
  - Talk to media

The attorney and anesthesia caregiver should act as a team. The anesthesia caregiver should become educated about the issues of the case so that he or she and the defense expert can educate the defense attorney; often, this can be in the form of teaching physiology and pharmacology and providing questions to counter opinions raised by the experts for the plaintiff. Open and frank communication is essential. The anesthesia caregiver should be kept advised of all developments through correspondence and periodic meetings. Tactical and strategic considerations should be frequently discussed and decisions jointly made. The attorney and anesthesia caregiver need to work together to ensure a strong and effective defense.

Litigation stress syndrome is a well-recognized effect of being involved in a lawsuit. The emotional toll a lawsuit takes on the defendant and his or her family should not be ignored. The defendant needs appropriate support systems in place throughout the litigation process.<sup>18</sup> This involves family, colleagues, and occasionally, a psychiatrist. The most difficult emotion to deal with in the course of a trial is anger when it becomes apparent that the focus is less on the truth and more on how the lawyers can persuade the jury to their line of reasoning. Emotional stress

also is engendered by the qualifications or lack of qualifications of the plaintiff's experts, which sometimes surprise those present with distortions or exaggerations of fact.<sup>19</sup>

## Summary

The manner in which anesthesia caregivers interface with the law in their daily practice of medicine varies greatly. The need for a pediatric anesthesia caregiver to be informed of legal issues arising from his or her practice has become essential. Educational materials to keep current with pertinent legal issues are a necessary part of any practice. Other legal issues, such as billing regulations and regulations that govern the relationships between group practices and health care facilities, are beyond the scope of this chapter, but they are equally important to understand to prevent legal challenges.

### Future of Simulation

THE FIELD OF PEDIATRIC anesthesia has become increasingly subspecialized, with unique challenges that demand high-quality teaching and training. Pediatric anesthesia is a subspecialty that has become increasingly refined and technically advanced, with the advancement of complex surgical techniques and patients with a low tolerance for error.<sup>1</sup> Radiologic progress and interventions have revolutionized the field to include caring for children in remote sites outside of the operating theaters. In many countries, tertiary pediatric services are becoming increasingly centralized, whereas medical working hours have been reduced, leading to a situation where there is a decline in exposure to difficult pediatric cases and emergencies for those who are not pediatric specialists. There is an inverse correlation between the level of specialization and perioperative morbidity and mortality associated with pediatric anesthesia.<sup>2</sup> Furthermore, a significant proportion of pediatric surgical procedures will continue to be performed outside tertiary centers, at community hospitals or outpatient surgical centers where the volume-to-outcome relationship may not be favorable.<sup>3</sup> The growth and increased sophistication of pediatric anesthesia, as well as the regionalization of specialty care, has profound implications for the ability to train anesthesiologists in the safe and effective delivery of routine and emergency pediatric anesthesia. Early portions of a trainee's learning curve are inconsistent with the demands of safe and efficient patient care, thereby posing challenges for the medical education infrastructure. Advancements in simulation education techniques and technology have led to a new paradigm in training and assessment. These advances provide opportunities to improve diagnostic and decision-making skills for common as well as rare events.

Current medical training emphasizes basic science knowledge and leaves most of the clinical practice to an apprenticeship model. The focus has been on individual knowledge and skills rather than on performance or clinical team dynamics. Once a clinician has completed training, the required level of continued education declines, both in structure and formality. Within the past decade, there has been rapid progress in simulation in health care training for purposes of improving patient safety and quality of care. Interest in simulation in health care derived from the historical utility of simulation for training purposes in nonmedical

industries, such as commercial aviation, nuclear power production, and the military.<sup>4</sup> Similar to health care, these industries are known to be associated with hazards and complexities that benefit from simulation training. Many of the concepts in health care simulators, including systematic training, rehearsal, performance assessment, situational awareness, and team interactions, have been adopted from aviation flight simulators. Given that crises in pediatric anesthesia are rare, difficult to predict, and that trainees are expected to be able to successfully manage these situations, simulation technology can fill important gaps in many curricula. In this chapter, we review how simulation is applied in pediatric anesthesiology by describing its use for learning and practicing basic and advanced skills, and by defining key types of technologies and teaching approaches with illustrative videos.

## Simulation-Based Training in Anesthesia

In 1987, Gaba and colleagues identified gaps in decision making and crisis management in anesthesia training. They noted that diagnostic decisions tended to be relatively static.<sup>5-7</sup> However, in the complex, rapidly changing, time-pressured environment of the operating room (OR), anesthesiologists are challenged beyond static decision making, especially when identifying and resolving crises and leading interdisciplinary teams. As a result, the term *anesthesia crisis resource management* (ACRM), modeled after the Crew Resource Management of commercial aviation,<sup>5-7</sup> was developed. These investigators established a framework and curriculum to teach individual and team leadership skills, along with effective communication styles. ACRM provided anesthesia trainees with tools that were similar to those that made the complex dynamic world of aviation safer in the areas of decision making and crisis resource management. These skills were not systematically taught during anesthesia residency training.

ACRM was an outgrowth of the patient safety movement that began in anesthesia in the early 1980s in America. In the late 1980s, research grant funding from the Anesthesia Patient Safety Foundation (APSF) supported the early development of several forms of human patient simulators (HPS). Further publicity and advocacy from APSF propelled anesthesiology to the forefront

of specialties in the application and adoption of simulators, with strong patient safety implications through education (residents attempting new skills for the first time on a manikin), training (teamwork, critical event management, and situational awareness), and research (human performance).<sup>8</sup> Today, simulation in anesthesiology is global, with emphasis not only on medical knowledge and skills training, but also on ACRM, disaster training, debriefing, and patient safety. The American Board of Anesthesiology now requires at least one simulation-based course to satisfy its Maintenance of Certification in Anesthesia requirement.<sup>9</sup> In some institutions, such training is required as a condition of credentialing for practice and insurance coverage.

## What Is Simulation?

Simulation is a *technique* to replace or amplify real experiences with guided experiences that evoke or replicate aspects of the real world. Simulation is enabled by a diverse set of emergent *technologies*.<sup>4</sup> The application of simulation in the health care field is focused on education and training of clinicians. *Education* emphasizes knowledge, skills, and introduction to the actual work. *Training* emphasizes the actual tasks and work to be performed.<sup>4</sup> The term “simulator” is used in the health care field to refer to a device that represents a simulated patient, and interacts appropriately in response to the actions of the simulation participant. In aviation, pilots are seated in the cockpit of a flight simulator whereas in health care, clinicians are in a simulated OR, emergency ward, or patient floor in simulated clinical scenarios, caring for a simulated “patient” experiencing a critical or otherwise challenging event.

Participants in a simulation are “immersed” into a task or setting to the extent necessary to achieve the learning objectives. This may be conducted in a normal classroom or in an environment that extensively replicates the real world. In the latter case, participants are asked to “suspend disbelief” and to interact and speak as they would do in their everyday jobs.<sup>4</sup> Most importantly, it is incumbent on those who create and implement the simulation to create sufficient *realism* to enable the learner to feel the reality of the situation and respond accordingly. Thus the participant agrees to accept the “fiction contract” with their instructors.<sup>10,11</sup>

Participants in a simulation scenario experience *realism* in three distinct domains: *physical, conceptual, and emotional*.<sup>10</sup> Simulations that address all three domains are more likely to instill the intended learning objectives. A high degree of realism appropriate for the specific learning objectives is central to ensure that the learners become mentally and physically engaged. The *physical* properties of the simulator (the patient) and the clinical environment (the simulation room, center, or OR), such as weight, flexibility, tensile strength, and color, are important for developing kinesthetic awareness and muscle memory. For example, the weight of the head and force required to effectively perform laryngoscopy are important for teaching tracheal intubation, whereas the rubbery feel of the manikin skin is not. *Conceptual realism* refers to the causal relationships observed in the scenario, such as a decrease in oxygen saturation during a period of apnea or the resolution of hypotension after an appropriate intravenous fluid bolus. High conceptual reality enhances clinical reasoning and decision making. Finally, *emotional* and *experiential* fidelity is achieved when participants experience familiar and authentic feelings, such as “emotional activation,” anxiety, stress, fear, or excitement. Ultimately, realism in simulation is perceived as “an exciting simulation that captures the imagination, triggering

physiological responses and execution of ingrained clinical algorithms.”<sup>10</sup> Although realism is important, investigators emphasize that, “when learning is the focus, the flawless recreation of the real world is less important.” It is necessary to find circumstances that help participants learn, rather than circumstances that exactly mimic a clinical situation.<sup>11</sup> The degree of realism desired for a successful simulation education program is an amount sufficient to achieve the intended learning outcomes.

## Technologies Used in Simulation

### PARTIAL TASK TRAINERS

Partial task trainers are manikins or models (e.g., suturing board, IV arm, airway head, etc.) designed to allow participants to practice clinical skills and tasks (Fig. 53-1). They should be reliable, robust, and medically meaningful. Usually they represent a portion of a person rather than the whole. Although many are simple devices designed for learning or practicing a specific procedure (e.g., suturing, IV insertion, laryngoscopy, or intraosseous access), some are coupled with computers, robotic interphases, and digital graphics to provide sophisticated partial task simulators designed for learning or practicing more involved procedures (e.g., bronchoscopy and endoscopy, endovascular catheterization, or laparoscopic skills). These models are particularly useful for teaching invasive, risky, and rare procedures (e.g., emergency cricothyrotomy, transvenous pacing, or pericardiocentesis), complex psychomotor skills requiring repetitive training (e.g., ultrasound guided central venous catheterization or awake fiberoptic intubation), or those that are safe, but create increased anxiety for either the learner or the patient and their family (e.g., urethral catheterization, IV insertion, or arterial puncture), where coaching and deliberate practice can be done in a simulated environment.<sup>12</sup> Curricula that use these types of training devices focus on skills training at varying levels of skill goals, rather than a particular situation. For example, cricothyrotomy training on a partial task simulator aims to teach the procedure, regardless of the indication (e.g., angioedema, burns, obstructing mass, or hemorrhage). Specific partial task trainers for simulating aspects of children include products to learn or practice lumbar puncture, peripheral IV insertion, intraosseous needle insertion, laryngoscopy and intubation, umbilical vein and artery catheterization, and cardiopulmonary resuscitation (Video 53-1).

### HUMAN PATIENT SIMULATORS

An HPS is a representation of the human body constructed on a manikin, typically made of plastic and metal, without a bony skeletal frame. Although popularized in the 1990s, the first manikin-based simulator (SimOne) was developed at University of Southern California in the 1960s and was intended to facilitate medical education and training.<sup>13</sup> Adult HPSs became commercially available in the early 1990s; the first high-fidelity pediatric simulator was introduced in 1999. The METI PediaSIM (Medical Education Technologies, Inc., Sarasota, Fla.) represented a child between 5 and 7 years of age. Two models of integrated infant HPS became available in 2005: the METI BabySIM and the Laerdal SimBaby (Laerdal Medical, Stavanger, Norway) (Fig. 53-2). Both models exhibited standard vital signs and variable airway features (e.g., tongue swelling and laryngospasm), breathing patterns and sounds (e.g., retractions to illustrate upper airway obstruction, breath sounds [wheezing], and pneumothorax), cardiovascular features (e.g., heart sounds and peripheral pulses

**FIGURE 53-1** Examples of partial task trainers to practice (A) intubation in neonates (Laerdal SimNewB [Laerdal Medical, Stavanger, Norway]), (B) peripheral intravenous placement (Nita Newborn Model #1800 Infant Venous Access Simulator [VATA, Canby, Ore.]), and (C) central neuraxial techniques (M43C Pediatric LP Simulator [Kyoto Kagaku, Kyoto, Japan]).

**FIGURE 53-2** An infant human patient simulator (Laerdal SimBaby [Laerdal Medical, Stavanger, Norway]) exhibits standard vital signs, variable airway features (tongue swelling, laryngospasm), breath sounds (retraction, wheezing), cardiovascular features (palpable pulses, heart sounds), and others (abdominal sounds, bulging fontanelle).

[diminished or absent]), and others (e.g., abdominal sounds and distension, and fontanelle bulging). Both infant simulators produce a variety of monitor signals and allow extensive treatment interventions (e.g., intubation, laryngeal mask and nasogastric tube insertion, intravenous and intraosseous cannulation, and thoracocentesis).<sup>14</sup> Incorporated into the clinical setting or

in a simulation room outfitted with biomedical equipment and teams of health care providers, the HPS can provide a high degree of clinical authenticity and realism to facilitate participants to fully engage in the care of the simulated patient. Typically, participants in simulation scenarios reflect on their performance during the simulation, for the purpose of sustaining and improving their practice with an instructor, in the process termed *debriefing*<sup>15</sup> (see Video 53-1).

### STANDARDIZED PATIENT

In some facilities, actors who are trained to represent a patient's condition (e.g., symptoms or social situation) and who are very reliable raters of clinicians' behaviors are used as standardized patients. It is common practice to use standardized patients when a simulation session focuses on interviewing, counseling, and examining a patient. Now a required part of the medical licensing exam in the United States (USMLE Step II Clinical Skills), Objective Structured Clinical Exams (OSCEs) are common in many undergraduate and graduate medical education programs. The OSCEs have been incorporated into the national board certification exams for anesthesiology in Israel.<sup>16</sup> In pediatrics, actors are more likely to play the role of a parent (e.g., a standardized parent) and team members (e.g., a standardized nurse), although child actors have also been reported, as well as the use of youthful appearing actors who role-play adolescents.<sup>17</sup> Going beyond standardized patients, actors can be employed as standardized nurses, surgeons, even residents for the purpose of teaching supervision skills (see Video 53-1).

### HYBRID SIMULATION

*Hybrid simulation* refers to a technique of combining any of the above simulators into a single activity. For instance, in the OR, the simulation scenario may take shape using a combination of three elements: an HPS, to provide the representation of the patient and clinical feedback in the form of the physiologic parameters that can be measured and monitored; a partial task simulator deployed to integrate a surgical skill that allows cutting and suturing of tissue; and an actor trained to represent the patient's parent and enact family presence during resuscitation.

*Hybrid learning* refers to the combination of web-based instruction incorporated with physical skills practice and validation for teaching and learning. As the field of simulation education has matured, it has become clearer that learning with simulation should not be isolated. Integration of simulation into course curricula has given way to hybrid learning techniques. For example, clinicians may complete precourse work to strengthen or activate prior knowledge in the days leading up to a simulation session. Subsequently, a simulation session can take place in the simulation-training environment, allowing for integration of new skills and attitudes. This model allows participants to obtain background knowledge to assist them with understanding the planned simulated procedural skills, which can save time and resources when conducting a training course for large numbers of clinicians (e.g., central line maintenance for nursing staff) (see Video 53-1).

### SCREEN-BASED SIMULATOR: VIRTUAL PATIENTS AND IMMERSIVE ENVIRONMENTS

Virtual patients are generally two-dimensional avatars on the computer screen that serve to help learners maneuver through clinical situations or perform a task, such as the proper technique for taking a patient's medical history. They can also be incorporated into OSCE training when standardized patients are not available. For example, the American Heart Association uses a screen-based simulation to teach and assess knowledge from advanced cardiac life support and pediatric advanced life support courses.<sup>18</sup>

Immersive environments, such as Second Life (Linden Lab, San Francisco), Advanced Disaster Management Simulator (Environmental Tectonics Corp., Orlando) and multi-user virtual environments, have been used to teach disaster management using interactive virtual simulation systems.<sup>19-21</sup> Other examples include Gas Man (Med Man Simulations, Inc., Boston) for teaching, simulating, and experimenting with the uptake and distribution of inhalational anesthetics,<sup>22</sup> and a virtual reality simulator for training in regional anesthesia.<sup>23</sup> Although virtual reality has been used in advanced cardiac life support and pediatric advanced life support education,<sup>18</sup> the use of virtual reality simulators in anesthesia is novel and not yet widely incorporated into curricula (see Video 53-1).

### Sites for Simulation

The growth of simulation education centers has been exponential from the mid-1990s through the first decade of this century. There is no exact count, but there are at least 1000 centers worldwide incorporated within medical schools and residency training programs in hospital settings, as well as nursing schools and allied health professions colleges.<sup>24</sup> Different settings of simulation education centers include: hospital-based or medical school-based simulation centers, freestanding simulation facilities, and in situ simulation located within the actual clinical work environment

**FIGURE 53-3** Simulation in situ setup in an operating room at Massachusetts General Hospital. A human patient simulator (Laerdal SimBaby [Laerdal Medical, Stavanger, Norway]) is used in this setting.

(Fig. 53-3). Dedicated simulation facilities, either within an existing medical institution or a freestanding center, have been constructed throughout the industrialized world to house high-technology simulator equipment, such as manikins, laparoscopic surgical equipment, robotics, and audiovisual laboratories. For example, the Treadwell Library at Massachusetts General Hospital has a dedicated simulation learning lab that houses simulation equipment, high-fidelity manikins, partial task trainers, and simulators for students, residents, and faculty training. Although simulation education centers are expensive and require significant manpower to operate, they may serve to replace some traditional forms of clinical education for many of the reasons that simulation is generally becoming more accepted (e.g., patient safety, clinical production efficiency, and lack of standardized curricula in the apprenticeship mode). An in situ simulation location involves setting up the simulator equipment, trainers, and trainees within the actual work environment, such as the OR, emergency room, or intensive care unit. The benefits of an in situ simulation include imitation of the work environment with equipment, personnel and surroundings that are real and familiar to the trainee. Disadvantages of in situ simulation involve availability of the location, impromptu setup of equipment to operate in different locations, and increased manpower to help with set up and relocation (Table 53-1).

### Applications of Simulation in Anesthesia

Concern for patient safety has been growing since the Institute of Medicine of the U.S. National Academies of Sciences published a report, *To Err is Human*, which publicized medical errors in patient care.<sup>25</sup> Since then, numerous efforts and interventions have been implemented to mitigate medical hazards and improve patient safety.<sup>26</sup> The demand for pediatric simulation curricula is substantial, presumably driven by the perceived imbalance between the potential difficulties of incidents and emergencies, and the everyday clinical routine, particularly for anesthetizing infants and neonates. Simulator-based courses can effectively supplement bedside teaching in pediatric anesthesia for trainees, non-tertiary-center anesthetists, and pediatric anesthesiologists alike. Newer infant simulators can generate a wide range of

**TABLE 53-1** Features of Simulation-Based Education by Location

	Distance	Features	Limitations	Operations
<b>Hospital Simulation Center</b>	<i>Pro:</i> Trainees available before and after clinical duties. Other disciplines and professions available. <i>Con:</i> Interruptions may occur. Risk of simulation equipment or medication leakage back to clinical environment.	Multimodal education possible (human patient simulators, task trainer, standardized patients, hybrids). Hospital name, numbers, and infrastructure preserved.	Clinical environment may not be accurately represented (outdated equipment, medications not real).	Real estate might be at premium. Equipment and supplies must be ordered separately.
<b>Freestanding Simulation Center</b>	<i>Pro:</i> Greatest separation between working and learning environment. Psychological safety and confidentiality are easier to preserve. <i>Con:</i> Environment and equipment may be significantly different from clinical practice.	Audio and video recording without compromising patient confidentiality. Ability to recreate different clinical environments.	Generic features required to represent multiple hospital systems may lead to environments that are significantly different from the clinical environment.	Must fund and staff independent organization. May need to pay for transportation. Equipment and supply chain not readily available.
<b>In Situ Simulation</b>	<i>Pro:</i> Shortest distance to travel. Participants present for work. <i>Con:</i> Interruptions are frequent. Family and other practitioners may be disturbed or bothered. Risk of simulation equipment or medication leakage back to clinical environment.	Ability to train in the intended environment enables evaluation of system-level safety features. Findings are readily applicable.	High acuity or census may lead to cancellation of sessions. Emergency equipment may go out of service (MH cart). Equipment may be used for clinical practice during the session (bronchoscope or Glidescope). Difficult to obtain video recording and guarantee patient confidentiality.	Low facility cost (If not charged). Training at work requires no overtime. Disposable material and restocking, including medications, time, and effort to transport equipment to location.

MH, Malignant hyperthermia.

pediatric case scenarios and have the advantage of being mobile for in situ simulation in the OR, intensive care unit, or emergency department setting. Training and managing low-frequency, high-risk cases (e.g., malignant hyperthermia, difficult airway, venous air embolism, or neonatal resuscitation) can be effectively performed on these manikins.<sup>27</sup> In addition, evaluation of new procedures and technology or simulation of new hospital environments can be safely performed on these manikins before involving humans. For example, the anesthesia residents at Massachusetts General Hospital are taught basic pediatric anesthesia skills and airway management during a simulation orientation at the beginning of their dedicated pediatric month. This in situ simulation curriculum occurs monthly in the Massachusetts General Hospital ORs for residents new to the rotation, before they care for children. A combination of partial task trainers, standardized “parents,” and high-fidelity HPS infant manikins are used to orient and teach residents about the typical flow of a pediatric anesthesia case.

## Comparing Traditional Learning with Simulation-Based Learning

The medical learner at each level of higher education (i.e., undergraduate, graduate, or postgraduate) is an adult learner. An adult learner is one who learns by several methods for different reasons at various stages in his or her education.<sup>28</sup> Adult learning theory teaches that active learning (with simulation) is an effective way to prepare for the dynamic clinical environment.<sup>29</sup> Five adult learning principles to help guide medical learners have been described<sup>28-30</sup> (Table 53-2).

**TABLE 53-2** Five Adult Learning Principles That Apply to the Medical Learner

1. Adult learners need to know why they are learning
2. Adult learners are motivated by the need to solve problems
3. The previous experiences of adult learners must be respected and built upon
4. The educational approach should match the diversity and background of adult learners
5. Adult learners need to be involved actively in the process

Modified from Okuda Y, Bryson E, Demaria S. The utility of simulation in medical education: what is the evidence? Mt Sinai J Med 2009;76:330-43, and Bryan R, Kreuter M, Brownson R. Integrating adult learning principles into training for public health practice. Health Promot Pract 2009;10:557-63.

Traditional medical education emphasizes learning and mastering cognitive skills based on textbook readings, lectures, and small group discussions. Evaluation of medical knowledge relies mainly on written or oral examinations. Training models are isolated and sometimes described as being within a “silo,” in a static environment where nurses train with nurses, doctors with doctors, pharmacists with pharmacists, and so on. Retention and transfer is weak when passive learning models are employed. Simulation-based training allows for interdisciplinary, active learning, whereby participants are immersed into clinical scenarios and are able to experience how behavior and interactions and communication between disciplines affect patient care and, potentially, patient outcomes. The more realistic the case scenario, simulation environment, and actors are, the more those participating are able to become immersed in the task and

engaged in the clinical scenario. This engagement with an authentic clinical problem and the need to resolve it as a team, serves as the foundation for the debriefing, which typically follows a simulation scenario.

## Aspects of a High-Fidelity Simulation

High-fidelity simulation requires considerable manpower and preparation. A typical team consists of the following: a team leader, actors, high-fidelity manikin, simulation room, audiovisual equipment, participants and learners, a facilitator, and a debriefer.<sup>31</sup> The team leader may be compared with a director of a film production. He or she is responsible for the smooth execution of the case scenario, from assigning and delegating roles to team members and directing the evolving scenario in the console room, to handling unexpected problems and situations that may arise during the simulation. This position may be the same or different from an “operator” who is responsible for operating the manikin behind the scenes in the console room. Actors, otherwise known as “confederate actors,” are responsible for creating the realism of the case scenario by effectively performing impromptu in a case scenario. They may take roles, such as nurses, surgeons, technicians, or administrative staff, to help guide the participants in a way that is clinically familiar. The challenge for actors is to maintain their simulated character and to interact with participants to guide them, but without overt interference with the clinical decisions and management. Communication between confederate actors and control room personnel using wireless audio devices is helpful to maintain the smooth flow of the scenario.

The simulation room is ideally a flexible setting that can be converted into a range of patient care environments, such as the OR, emergency department, obstetric ward, a cafeteria or other public place—anywhere an anesthesia team might be called to respond. Elaborate scenery, anesthesia and surgical equipment used in everyday work, and moulage (e.g., fake blood and vomitus) may create very realistic scenarios. The rooms should be equipped with medical air, oxygen, and vacuum suction capabilities to run the high-fidelity manikins and to provide for their use in the scenario.<sup>31</sup> Audiovisual equipment, such as cameras and microphones, are strategically placed so as to not be obvious to the participants, whose actions are followed in the simulation for debriefing and feedback. The facilitator is responsible for observing the simulation scenario, and after the event to stimulate learning and discussion in a nonthreatening and organized way. The facilitator’s role is to identify elements of the simulation that possess educational value pertinent to the learning objectives of the course, and to facilitate discussion of these learning nuggets (e.g., point out where communication broke down or where situational awareness was lost) (Video 53-2).

## What is a Debriefing?

A debriefing is a “conversation between two or more people to review a real or simulated event in which participants analyze their actions and interactions, and reflect on the roles of thought processes, psychomotor skills, and emotional states, to improve or sustain performance in the future.”<sup>32</sup> It is generally thought that the debriefing is the most important component of simulation-based education, the time when learning is embedded. Many consider the scenario an excuse for the opportunity for debriefing. Facilitated by the debriefer, the debriefing usually

follows the simulation. “Pause and discuss” style debriefing, where the faculty interjects during pauses in a scenario has been shown to be an effective teaching method.<sup>33</sup> Video review of portions of the scenario can be helpful during a debriefing, especially when used to observe key moments, clarify recall discrepancies among participants and faculty, and to offer a global view of the room to participants who might have been focused on a task or fixated on a portion of the action. This guided reflection of the scenario allows participants to bridge the gap between experiencing an event and making sense of it.

Debriefing can be approached in three phases: *reactions*, *understanding*, and *summary*.<sup>15,32,34</sup> The *reactions phase* asks participants to share how they felt, allowing the participants to vent and deactivate from the heightened emotional state that participating in a simulation provokes. The debriefer leads the group through a description of the facts of the case, to ensure that everyone understands the clinical scenario before tackling the learning objectives. The *understanding phase* is the richest and longest phase, and is intended to help participants analyze and apply what happened and explore deeper meaning of the interactions. Discussion and teachings are involved in this phase to help simulation participants gain new perspectives and insights into group dynamics and communication. Lessons learned during the simulation can be generalized and applied to the real world, preparing participants to transfer new knowledge into their clinical practice. In the *summary phase*, participants share lessons learned, including individual and group behaviors, skills, and thinking patterns that they wish to improve, as well as those that were productive and they wish to retain for future performance.<sup>15,32,34</sup> Becoming an effective debriefer requires training and practice to acquire new skills that are not taught in traditional health care educational programs. Instructors and facilitators are encouraged to learn about the principles of effective debriefing via the literature, formal courses, and mentoring. The Debriefing Assessment for Simulation in Healthcare (DASH) is an example of a testing instrument that was developed to assess and improve debriefing skills.<sup>35</sup>

## Using Simulation for Evaluation

Although patient simulators are well accepted as a core component of crisis resource management and other clinical training, their acceptance and validity as assessment tools for clinical performance has not yet been widely established or validated. In particular, a number of senior professionals are reluctant to be assessed in a simulator environment (e.g., in the process of their recertification). However, some scoring systems for simulator-based performance assessments have been developed, such as the Anaesthetists’ Non-Technical Skills (ANTS) system.<sup>14,36</sup> Although validity is not yet rigorous (e.g., based on correlation of training with consistent transfer of skills into clinical use or improvement of patient care), there is increasing evidence that simulation-based assessment can be done with sufficient reliability to be used for testing (e.g., reproducible scenarios can be created and implemented, raters can be trained to assign reproducible scores of performance, and critical clinical skills can be simulated).<sup>37</sup> Multiscenario, simulation-based assessment has the potential to assess performance of pediatric anesthesia skills in anesthesia residents and pediatric anesthesia fellows; however, further measures of validity, including correlations with direct measures of clinical performance, are needed to establish the true utility and validity of these simulations as assessment tools.<sup>27</sup>

Simulation is widely thought to be effective in improving clinical skills in a way that is safer than the traditional apprentice model of training. Although there is not yet a large body of evidence regarding the effectiveness of simulation or the cost relative to its benefit, there is substantial literature that documents its utility. A meta-analysis has established the overall effectiveness of simulation-based training.<sup>38</sup> Furthermore, a study of simulation-based training showed improved outcomes, specifically in survival of children after cardiopulmonary resuscitation.<sup>39</sup>

## Challenges in Using Simulation

Although simulation centers are increasingly popular worldwide, there are many challenges in establishing and maintaining a simulation program. Trained educators in simulation are few and apprenticeship models require extensive time and effort. There are now several simulation programs that offer various types of courses for educators and instructors. Popular centers that consistently offer courses are the Center for Medical Simulation in Cambridge, Mass. (<http://harvardmedsim.org/>), the Multidisciplinary Simulation Center in Rochester, Minn. (<http://www.mayo.edu/simulationcenter/>), the Center for Immersive and Simulation-Based Learning in Palo Alto, Calif. (<http://cisl.stanford.edu/>), the Michael S. Gordon Center for Research in Medical Education in Miami (<http://www.gcrme.miami.edu/>), the Danish Institute for Medical Simulation in Herlev, Denmark (<http://www.regionh.dk/dims-eng/menu/>), and the Tübingen Center for Patient Safety and Simulation in Tübingen, Germany (<http://www.tupass.de/>). Fellowships in medical simulation are also becoming more widespread across the U.S., located within anesthesia, emergency medicine, and other departments, or at interdisciplinary centers, such as the Neil and Elise Wallace STRATUS Center for Medical Simulation in Boston (<http://www.stratus.partners.org>). However, availability of faculty members to develop curricula and routinely run simulation case scenarios has been a challenge due to operational costs and the high demands of clinical practice and patient care. Technical staff and support to help run a simulation center are also important factors that affect the overall cost of operating a center. Simulation equipment, computers, partial task trainers, and high-fidelity manikins are expensive, as is the maintenance of this equipment. In some institutions, funding may not be available to staff and operate a simulation center with a skills training laboratory. Other options may include implementing in situ simulations in existing hospital facilities, remodeling old facilities into a simulation room, or having mobile units that contain simulation equipment. Hence, operating and maintaining a simulation center poses monetary, time availability, and faculty availability concerns.

## Future of Simulation

Simulation-based education provides many opportunities for curriculum development in anesthesia residency training, with creative strategies to enhance clinical experiences, to practice caring for rare cases, and to improve mass-casualty training. This model will become of greater importance as residency work-hours are reduced. Although the apprenticeship model and patient care experience is unlikely to be replaced, incorporation of simulation-based training can help provide solutions to systems-based problems, improve interdisciplinary team training, ease relocation into facilities, and help adapt to new equipment and technology. Since 2004, the Society for Simulation in Healthcare has represented a growing community of educators and researchers who use simulation techniques for education, testing, and research in health care. This consistently growing international society (over 3000 members in 2012) is a broad-based, multidisciplinary, multispecialty network that ties together physicians, nurses, and allied-health professionals with educators and other social scientists, as well as with industry.<sup>40</sup> Other societies, including the Society for Simulation in Healthcare in America and the Society in Europe for Simulation Applied to Medicine, provide technical and political leadership for the simulation community.

The extent of the long-term impact of simulation on health care still remains to be determined; however, what is certain is that a large part of residency training and maintenance of skills will incorporate simulation-based education. The American Board of Anesthesiology now requires simulation-based crisis resource management training as part of its program for recertification. Other specialty medical boards are also considering using simulation as a requirement for certification and recertification. In Israel and the United Kingdom, simulation-based stations are included in the National Anesthesia Board exams and OSCEs in anesthesia, respectively.<sup>16,41</sup> Simulation-based education and research will become an integral part of health care. Future research must nonetheless focus on addressing questions of how best to use simulation to improve real-life quality of care, patient safety, and long-term care.
