## Congenital Heart Disease

### INCIDENCE

Congenital heart disease (CHD) represents the most common form of congenital pathology, with an estimated incidence of 0.3% to 1.2% of live births.<sup>1</sup> CHD is a major cause of morbidity and mortality during the neonatal period. However, with advances in medical and surgical management, including significant contributions related to anesthesia care, survival to adulthood is the expectation for most infants and children with CHD.<sup>2-4</sup>

A bicuspid aortic valve (Video 14-1) is the most common cardiac defect, occurring in up to 1% of the population.<sup>5,6</sup> Ventricular septal defects (VSD) (Video 14-2) represent the next most common congenital pathology,<sup>5,7-11</sup> followed by secundum atrial septal defects (ASD) (Video 14-3).<sup>5,12</sup> Among cyanotic lesions, tetralogy of Fallot (TOF) predominates, affecting almost 6% of children with CHD (Fig. 14-1).<sup>13</sup> In the first week of life, D-transposition of the great arteries (Fig. 14-2) is the most frequently encountered cause of cardiac cyanosis; TOF is sometimes not detected until later in life because cyanosis is absent or only mild desaturation is present.

### SEGMENTAL APPROACH TO DIAGNOSIS

Several classification schemes have been proposed to characterize and categorize various congenital cardiac defects.<sup>14-20</sup> The segmental approach to the diagnosis of CHD assumes a sequential, systematic analysis of the three major cardiac segments (i.e., atria, ventricles, and great arteries) to describe the anatomic abnormalities. The principle of this scheme is that specific cardiac chambers and vascular structures have characteristic morphologic properties that determine their identities, rather than their positions within the body.<sup>21</sup> An organized, systematic identification of all cardiac structures or segments and their relationships (i.e., connections or alignments between segments) is carried out to define a child's anatomy.<sup>22</sup>

The initial approach is to determine the cardiac position within the thorax and the arrangement or situs of the thoracic and abdominal organs. The cardiac position can be described in terms of its location within the thoracic cavity (Fig. 14-3) and the direction of the cardiac apex. Although the cardiac position within the thorax may be considered independent of the cardiac base-apex axis, for simplicity the following terms are used: *levocardia* if the heart is in the left hemithorax (as is normally the case); *dextrocardia* if the heart is located in the right hemithorax;

and *mesocardia* if the heart is displaced rightward but not completely in the right thoracic cavity. An abnormal location of the heart within the thorax (i.e., cardiac malposition) may result from displacement by adjacent structures or underlying noncardiac malformations (e.g., diaphragmatic hernia, lung hypoplasia, scoliosis).

The visceral situs, or sidedness, of the abdominal organs (i.e., liver and stomach) and atrial situs are considered independently (Fig. 14-4). Visceral situs is classified as *solitus* (i.e., normal arrangement of viscera, with the liver on the right, stomach on the left, and a single spleen on the left), *inversus* (i.e., inversion of viscera, with the liver on the left and stomach on the right), or *ambiguous* (i.e., indeterminate visceral position). Abnormal arrangements or sidedness of the abdominal viscera, heart, and lungs suggests a high likelihood of complex cardiovascular disease. The atrial situs, atrioventricular (AV) connections, ventricular looping (i.e., position of the ventricles as a result of the direction of bending of the straight heart tube in early development), ventriculoarterial connections, and the relationship between the great vessels are then delineated.

Associated malformations are described, including number and size of septal defects and valvar or great vessel abnormalities.

**FIGURE 14-1** The diagram depicts the anatomic features of tetralogy of Fallot. The abnormalities consist of right ventricular outflow tract obstruction (typically at any or a combination of valvar, subvalvar, and supravalar levels), a large ventricular septal defect (VSD), aortic override, and right ventricular hypertrophy (RVH). Purple aorta indicates desaturation. The small size of the pulmonary artery is indicative of the right outflow tract obstruction.

**FIGURE 14-2** Discordant ventriculoarterial connections are shown in the diagram of D-transposition of the great arteries. The right ventricle ejects blood into the pulmonary artery and the left ventricle ejects blood into the aorta. Mixing of blood must occur via an atrial septal defect, ventricular septal defect, or patent ductus arteriosus.

**FIGURE 14-3** Chest radiographs demonstrate various cardiac positions within the thorax. **A**, Levocardia (left-sided position). **B**, Dextrocardia (right-sided position). **C**, Mesocardia (centrally located cardiac mass).

Types of viscerotrial situs: atrial localization

**FIGURE 14-4** Three types of viscerotrial situs are shown. *Situs solitus* indicates a normal arrangement of the viscera and atria, with the right atrium (RA) on the right side and the left atrium (LA) on the left side. The stomach and spleen are on the left, and the liver is on the right. *Situs inversus* indicates inverted arrangement of viscera and atria, with the RA on the left side and the LA on the right side, as in a mirror image of situs solitus. In visceral situs inversus, the stomach and spleen are on the right, and the liver is on the left. *Situs ambiguous* denotes that the viscerotrial situs is anatomically uncertain or indeterminate because the anatomic findings are ambiguous. (From Van Praagh R. The segmental approach to diagnosis in congenital heart disease. In: Bergsma D, editor: Birth defects: original article series. Vol 8. Baltimore: Williams & Wilkins; 1972, p. 23-44. Permission granted by March of Dimes.)

Whereas many types of congenital defects fall neatly into this classification scheme, others (e.g., heterotaxy syndromes, conditions associated with malposition of the heart and abdominal organs) are often more difficult to precisely define.

### PHYSIOLOGIC CLASSIFICATION OF DEFECTS

The wide spectrum of cardiovascular malformations in the pediatric age group presents a challenge to the clinician who does not specialize in the care of these children. Even for those with a focus or interest in cardiovascular disease, the range of structural defects and the varied associated hemodynamic perturbations can be overwhelming.

A physiologic classification system can facilitate understanding of the basic hemodynamic abnormalities common to a group of congenital or acquired lesions and assist in patient management (Table 14-1).<sup>23,24</sup> Several classification schemes have been proposed, including some that categorize structural defects as simple or complex lesions, consider the presence or absence of cyanosis, or consider whether pulmonary blood flow is increased or decreased.<sup>25-27</sup> The following approach groups pediatric heart disease into six broad categories according to the underlying physiology or common features of the pathologies.

#### Volume Overload Lesions

Volume overload lesions typically are caused by left-to-right shunting at the atrial, ventricular, or great artery levels. If the location of the left-to-right shunt is proximal to the mitral valve (e.g., ASDs, partial anomalous pulmonary venous return, unobstructed total anomalous pulmonary venous return), right heart dilation will occur. Lesions distal to the mitral valve (e.g., VSD, patent ductus arteriosus [PDA], truncus arteriosus) lead to left heart dilation. Children with AV septal defects (i.e., AV canal defects) also fit into this category. The magnitude of the shunt and resultant pulmonary-to-systemic blood flow ratio ( $\dot{Q}_{\text{pulm}}/\dot{Q}_{\text{sys}}$ ) dictate the presence and severity of the symptoms and guide medical and surgical therapies. Diuretic therapy and

**TABLE 14-1** Physiologic Classification of Congenital Heart Disease (Representative Lesions)

#### Volume Overload Lesions

Atrial septal defect  
Ventricular septal defect  
Atrioventricular septal defect  
Patent ductus arteriosus  
Truncus arteriosus

#### Obstruction to Systemic Blood Flow

Aortic stenosis  
Coarctation of the aorta  
Interrupted aortic arch  
Hypoplastic left heart syndrome

#### Obstruction to Pulmonary Blood Flow

Pulmonary stenosis  
Tetralogy of Fallot  
Pulmonary atresia

#### Parallel Circulation

D-Transposition of the great arteries

#### Single Ventricle Lesions

Tricuspid atresia  
Double-inlet left ventricle  
Unbalanced atrioventricular septal defect

#### Intrinsic Myocardial Disorders

Cardiomyopathy  
Myocarditis

afterload reduction are beneficial in controlling pulmonary over-circulation and ensuring adequate systemic cardiac output. Trans-catheter approaches or surgical interventions may be required to address the primary pathology associated with ventricular volume overload (see Chapter 20).

#### Obstruction to Systemic Blood Flow

Several lesions are characterized by systemic outflow tract obstruction. Conditions characterized by ductal-dependent systemic blood flow in the neonate include critical aortic stenosis, severe aortic coarctation, aortic arch interruption, and hypoplastic left heart syndrome. Prostaglandin  $E_1$  infusion maintains ductal patency and ensures adequate systemic blood flow until surgical or transcatheter intervention is performed in the first few days of life to relieve the systemic outflow obstruction. Inotropic and/or mechanical ventilatory support are often necessary. Many of these infants also have significantly increased pulmonary blood flow with a high  $\dot{Q}_{\text{pulm}}/\dot{Q}_{\text{sys}}$  ratio, requiring diuretic therapy and manipulation of the systemic and pulmonary vascular resistances to control blood flow.

#### Obstruction to Pulmonary Blood Flow

Lesions with pulmonary outflow tract obstruction include those with ductal-dependent pulmonary blood flow. Critical pulmonary valve stenosis and pulmonary atresia with intact ventricular septum, for example, are defects that rely on patency of the ductus arteriosus for pulmonary blood flow. These infants may also require prostaglandin  $E_1$  infusions for management of their cyanosis until the pulmonary outflow obstruction is relieved or bypassed.

### Parallel Circulation

In the neonate with D-transposition of the great arteries, the pulmonary and systemic circulations operate in parallel rather than in the normal configuration in series. In this condition, the right ventricle ejects deoxygenated blood into the aorta, and the left ventricle ejects oxygenated blood into the pulmonary circulation. Mixing of blood in this setting may occur at the atrial, ventricular, or ductal levels (see Fig. 14-2). Although prostaglandin E<sub>1</sub> therapy maintains ductal patency, balloon atrial septostomy to create or enlarge an existing restrictive interatrial communication and optimize mixing may benefit some infants. Mixing at the atrial level is considered much more effective than at the ventricular or ductal levels.

### Single-Ventricle Lesions

This category is the most heterogeneous group, consisting of defects associated with AV valve atresia (i.e., tricuspid atresia), heterotaxy syndromes, and many others.<sup>28</sup> In some cases, both atria empty into a dominant ventricular chamber (i.e., double-inlet left ventricle), and although a second rudimentary ventricle may be present, the physiology is that of a single-ventricle or univentricular heart. Other cardiac malformations with two distinct ventricles (i.e., unbalanced AV septal defect) may also be considered in the functional single-ventricle category because of associated defects that may preclude a biventricular repair. A common feature of these lesions is complete mixing of the systemic and pulmonary venous blood at the atrial or ventricular level. Another common finding is aortic or pulmonary outflow tract obstruction.

Affected children are a challenge to the practitioner and require careful delineation of their anatomy. An important goal in single-ventricle management involves optimization of the balance between the pulmonary and systemic circulations early in life. This is a critical issue because low pulmonary vascular resistance and limitation of the ventricular volume load represent a prerequisite for later palliative strategies and favorable outcomes in these children. These considerations are also relevant during anesthesia management for noncardiac surgery (see Chapter 21).<sup>26,29,30</sup>

### Intrinsic Myocardial Disorders

Children with primary cardiomyopathies or other forms of acquired heart disease such as myocarditis have heart muscle disease. They frequently have impaired systolic or diastolic ventricular function, and benefit from therapies tailored to their particular disease process.

## Acquired Heart Disease

### CARDIOMYOPATHIES

The term *cardiomyopathy* usually refers to diseases of the myocardium associated with cardiac dysfunction.<sup>31,32</sup> They have been classified as primary and secondary forms. The most common types in children are hypertrophic, dilated or congestive, and restrictive cardiomyopathies. Other forms include left ventricular noncompaction<sup>33-35</sup> and arrhythmogenic right ventricular dysplasia.<sup>36</sup> Secondary forms of cardiomyopathies are those associated with neuromuscular disorders such as Duchenne muscular dystrophy, glycogen storage diseases (i.e., Pompe disease), hemochromatosis or iron overload, and mitochondrial disorders. Chemotherapeutic agents such as anthracyclines may result in

dilated cardiomyopathy.<sup>37</sup> It is important to understand the hemodynamic processes behind the myocardial disease and implications for acute and chronic management.

*Hypertrophic cardiomyopathy* (HCM) is characterized by ventricular hypertrophy without an identifiable hemodynamic cause that results in increased thickness of the myocardium. This accounts for almost 40% of cardiomyopathies in children.<sup>38-41</sup> The condition represents a heterogeneous group of disorders, and most of the identified genetic defects exhibit autosomal dominant inheritance patterns.<sup>42,43</sup> This is the most common cause of sudden cardiac death (SCD) in athletes.<sup>44,45</sup> Most children with HCM do not have systemic outflow tract obstruction (i.e., non-obstructive cardiomyopathy). It is unclear whether the few with hypertrophic obstructive cardiomyopathy, previously known as idiopathic hypertrophic subaortic stenosis, are at increased risk for SCD compared with children without obstruction.<sup>44</sup>

Most children with HCM present for evaluation of a heart murmur, syncope, palpitations, or chest pain. Occasionally, an abnormal electrocardiogram (ECG) leads to referral. An accurate family history is essential. An apical impulse is often prominent. Auscultation may reveal a systolic ejection outflow murmur that becomes louder with maneuvers that decrease preload or afterload (e.g., standing, Valsalva maneuver) or increased contractility. The murmur decreases in intensity with squatting and isometric hand grip. A mitral regurgitant murmur may also be present. The ECG meets criteria for left ventricular hypertrophy in most children (Fig. 14-5). In some, the electrocardiographic findings may be striking (Fig. 14-6). A hypertrophied, nondilated left ventricle is a diagnostic feature determined by echocardiography (Video 14-4, *A* and *B*).<sup>45</sup> In many children, the hypertrophy may be asymmetric (Video 14-5, *A* and *B*). Echocardiography is the primary imaging modality for long-term assessment of wall thickness, ventricular dimensions, presence and severity of obstruction, systolic and diastolic function, valve competence, and response to therapy. Other diagnostic approaches such as cardiac catheterization and magnetic resonance imaging (MRI) may add helpful information in some cases.

The care of children with HCM includes maintenance of adequate preload, particularly in those with dynamic obstruction. Diuretics are not indicated and often worsen the hemodynamic state by reducing left ventricular volume and increasing the outflow tract obstruction. Drugs that augment myocardial contractility (e.g., inotropic agents, calcium infusions) are not well tolerated. Patients usually undergo continuous electrocardiographic monitoring (i.e., Holter recording) and exercise testing for risk stratification.<sup>46</sup>  $\beta$ -Blockers and calcium channel blockers are the primary agents for outpatient drug therapy.<sup>47</sup> Therapies range widely and include longitudinal observation with medical management of heart failure and arrhythmias, implantation of cardioverter-defibrillators, surgical myotomy or myectomy, transcatheter alcohol septal ablation, and cardiac transplantation.

*Dilated cardiomyopathy* (DCM), also known as congestive cardiomyopathy, is characterized by thinning of the left ventricular myocardium, dilation of the ventricular cavity, and impaired systolic function.<sup>48-50</sup> The broad number of etiologies range from genetic or familial forms to those caused by infections,<sup>51</sup> metabolic derangements, toxic exposures, and degenerative disorders.<sup>52,53</sup> Chronic tachyarrhythmias can also lead to DCM that may or may not improve after the rhythm disturbance is controlled.<sup>54-56</sup>

Most children with DCM present with signs and symptoms of congestive heart failure (e.g., tachypnea, tachycardia, gallop

**FIGURE 14-5** The electrocardiogram from an adolescent with hypertrophic cardiomyopathy demonstrates left ventricular hypertrophy (i.e., deep S wave in  $V_1$  and tall R waves over the left precordial leads). The ST-segment depression and T-wave inversion over the left precordial leads is related to repolarization changes associated with left ventricular hypertrophy, also known as a *strain pattern*. Reciprocal ST-segment elevation can be seen over the right precordial leads. This recording is consistent with sinus bradycardia (heart rate average of 50 beats per minute).

**FIGURE 14-6** Pompe disease is an inherited disorder characterized by the accumulation of glycogen in cells. The electrocardiographic tracing for an infant with this glycogen storage disease and a severe form of hypertrophic cardiomyopathy displays dramatic right and left ventricular voltages, in addition to ST-segment and T-wave abnormalities. The recording is displayed at full standard (10 mm/mV), meaning that the electrocardiogram was not reduced in size to fit on the paper.

**FIGURE 14-7** Chest radiographs of a young child with dilated cardiomyopathy in the posteroanterior (A) and lateral (B) projections demonstrate moderate to severe cardiomegaly and pulmonary vascular congestion. The lateral radiograph shows the heart bulging anteriorly against the sternum.

rhythm, diminished pulses, hepatomegaly). The chest radiograph typically demonstrates cardiomegaly, pulmonary vascular congestion, and in some cases, atelectasis (Fig. 14-7). The ECG may identify the likely cause of the cardiac dysfunction in those with cardiomyopathy due to rhythm disorders or anomalous origin of the left coronary artery from the pulmonary root (ALCAPA). The echocardiogram can confirm the diagnosis by demonstrating a dilated left ventricle with decreased systolic function (Video 14-6, A and B).<sup>57</sup> Therapy in the acute setting is supportive and aimed at stabilization. Management may include afterload reduction, inotropic support, and mechanical ventilation. Unlike children with HCM, those with DCM have a volume-loaded, poorly contractile ventricle. Gentle diuresis is beneficial. The infusion of large fluid boluses may be poorly tolerated and result in

hemodynamic decompensation and cardiovascular collapse. The outcomes of children with dilated cardiomyopathy vary. For most, recovery of left ventricular systolic function occurs, but others eventually require cardiac transplantation.<sup>58</sup> In a subset of children with severe disease, mechanical circulatory support may be necessary as a bridge to recovery or cardiac transplantation (Fig. 14-8) (see Chapter 19).<sup>59-61</sup>

*Restrictive cardiomyopathy* (RCM) is the least common of the major types of cardiomyopathies (5%) and portends a poor prognosis when it manifests during childhood.<sup>62-67</sup> The disorder is characterized by diastolic dysfunction related to a marked increase in myocardial stiffness resulting in impaired ventricular filling. Most cases are thought to be idiopathic. Presenting symptoms are nonspecific and primarily respiratory. Occasionally, the diagnosis is made after a syncopal or sudden near-death event. The physical examination may demonstrate hepatomegaly, peripheral edema, and ascites.

The echocardiographic hallmark of RCM is that of severe atrial dilation and normal- to small-sized ventricles (Video 14-7). The marked diastolic dysfunction leads to increased end-diastolic pressures, left atrial hypertension, and secondary pulmonary hypertension. Children with RCM are prone to thromboembolic complications, and anticoagulation therapy is frequently recommended. This is an important consideration during perioperative care because adjustments in the anticoagulation regimen may be necessary. Atrial and ventricular tachyarrhythmias may also occur. Optimal medical treatment is controversial because no specific agents or strategies have been shown to significantly alter outcomes.<sup>67</sup> Similar to children with HCM, diuretics often cause a decrease in the needed preload with detrimental effects on hemodynamics. Inotropic agents are not indicated because systolic function is preserved and the arrhythmogenic properties of inotropic drugs can induce a terminal event. In many centers, cardiac transplantation has been effectively used.<sup>68,69</sup>

## MYOCARDITIS

*Myocarditis* is defined as inflammation of the myocardium, often associated with necrosis and myocyte degeneration. In the United States, it is most often caused by a viral infection. Over the past 20 years, the spectrum of viral pathogens causing myocarditis has changed, such that adenovirus, enteroviruses (e.g., coxsackievirus B), and parvovirus have become the most frequent causes of fulminant disease.<sup>70-72</sup>

The overall incidence of myocarditis is unknown because it is frequently underdiagnosed and unrecognized as a nonspecific viral syndrome. A large, 10-year, population-based study on cardiomyopathy found an annual incidence of 1.24 cases per 100,000 children younger than 10 years of age; only a fraction of cases represented those with myocarditis.<sup>73</sup> The diagnosis is made using clinical history, physical examination, and imaging modalities. Myocarditis is highly suspected when a child presents with new-onset congestive heart failure or ventricular arrhythmias without evidence of structural heart disease. The ECG typically demonstrates low-voltage QRS complexes with tachycardia, which sometimes is ventricular in origin. Chest radiography often shows cardiomegaly with pulmonary vascular congestion (Fig. 14-9). Echocardiography displays ventricular dilation with decreased systolic function, similar to DCM, and it is useful in the exclusion of alternative diagnoses, such as pericardial effusion or anomalous origin of a coronary artery. Myocarditis is a clinical diagnosis because definitive confirmation requires the analysis of tissue obtained through myocardial biopsy in the catheterization laboratory or the operating room (rarely performed).<sup>74</sup>

**FIGURE 14-8** Some children with severe dilated cardiomyopathy (DCM) require mechanical circulatory assist devices. **A**, Chest radiograph of a child with end-stage DCM after placement of a Micromed DeBakey ventricular assist device for circulatory support as a bridge to cardiac transplantation. This miniaturized device includes a titanium pump, inlet cannula placed in the left ventricle, percutaneous cable, flow probe, and outflow graft placed in the aorta (not radiopaque). **B**, The Berlin Heart ventricular assist device allows paracorporeal placement and circulatory support in infants and small children.

**FIGURE 14-9** The chest radiograph of a child with acute myocarditis shows severe cardiomegaly and increased pulmonary vascularity.

Many children with myocarditis have subclinical or mild clinical disease, whereas others progress to overt heart failure or arrhythmias, or both. Among children with heart failure, approximately one third will regain full ventricular function, one third will recover but continue to demonstrate impaired

systolic function, and one third will require cardiac transplantation.<sup>75,76</sup> A subset of children, not all of whom initially manifest severe symptoms in the acute period, will progress to have DCM.

Although no specific therapies have been identified to directly treat the myocardial injury, a variety of strategies have been employed.<sup>77-80</sup> The current paradigm includes diuresis and after-load reduction to improve myocardial performance without placing a large burden on an already failing heart.<sup>81</sup> Rhythm disturbances are treated appropriately. Therapy with immune modulation or suppression with intravenous immunoglobulin is the standard of care at many centers.<sup>81-83</sup> Mechanical circulatory support may be required in fulminant disease.<sup>84-89</sup>

#### RHEUMATIC FEVER AND RHEUMATIC HEART DISEASE

Acute rheumatic fever and rheumatic heart disease are leading causes of acquired cardiac disease in developing countries and still occur, albeit infrequently, in developed countries.<sup>90</sup> In the United States, the availability of antibiotic therapy for streptococcal pharyngitis has markedly reduced the incidence of this disease, but sporadic cases still occur.<sup>91</sup> In children, the peak incidence occurs between 5 and 14 years of age.

Rheumatic fever results from infection by particular strains of group A  $\beta$ -hemolytic *Streptococcus* or *Streptococcus pyogenes* leading to a multisystemic inflammatory disorder. The incubation period for most strains of group A  $\beta$ -hemolytic *Streptococcus* is typically 3 to 5 days, although some children present with a more remote history of pharyngitis.

The clinical diagnosis of rheumatic fever is based on the modified Jones criteria.<sup>92</sup> Major criteria include carditis,

## Selected Vascular Anomalies and Their Implications for Anesthesia

### ABERRANT SUBCLAVIAN ARTERIES

An aberrant or anomalous subclavian artery usually arises from the descending aorta as a separate vessel distal to the usual last subclavian artery in a posterior location. In a left aortic arch, this arrangement is usually

This anomaly has several implications:

- The presence of an aberrant subclavian artery may influence the location of placement of a systemic-to-pulmonary artery shunt.
- This anomaly should be considered in the selection of a site for arterial line placement if transesophageal echocardiography is planned during surgery. The aberrant vessel may be compressed along its retroesophageal course by the imaging probe, resulting in inaccurate recordings.<sup>224</sup> Regardless of the site of arterial line placement, it may be wise to monitor the arm supplied by the anomalous vessel by pulse oximetry or other methods during esophageal instrumentation.
- An aberrant subclavian artery sometimes is part of a vascular ring.
- Rarely, older children with a left aortic arch and aberrant right subclavian artery and without the findings of a complete vascular ring may complain of mild dysphagia (i.e., dysphagia lusorium).

#### PERSISTENT LEFT SUPERIOR VENA CAVA TO THE CORONARY SINUS

A persistent left superior vena cava (LSVC) is a form of anomalous systemic venous drainage identified in 4.4% of children with CHD, most frequently those with septal defects.<sup>225</sup> It represents a venous remnant that typically involutes during development. If it persists, it remains patent and drains into the right atrium through an enlarged coronary sinus. Bilateral superior vena cavae may be present (Fig. 14-14), or the right superior vena cava may be absent. Bilateral superior vena cavae may communicate through an innominate or bridging vein. This anomaly has several implications:

- In the absence of an innominate vein, a catheter placed in the left arm or left internal jugular vein and advanced into the central circulation may rest within the coronary sinus, a potentially undesirable location in a small infant. On chest

radiography, an unusual course is identified as the catheter courses along the left aspect of the mediastinum and can be mistaken for intracarotid, intrapleural, or mediastinal locations.

- An LSVC may be of relevance during venous cannulation for cardiopulmonary bypass to ensure adequate venous drainage and optimal operating conditions.
- The presence of an LSVC is important in patients with single-ventricle physiology undergoing palliation involving a cavo-pulmonary (Glenn) connection.
- The anomaly may be associated with a dilated coronary sinus. On transesophageal echocardiography, it may be confused with other defects, including an ostium primum ASD (i.e., one that lies in the inferior aspect of the atrial septum) or anomalous pulmonary venous return to the coronary sinus.
- On occasion, an LSVC may drain to an unroofed coronary sinus or directly into the left atrium, in which case a right-to-left shunt is present. It may be identified by injection of agitated saline into a left arm or left neck vein while performing an echocardiogram, and it may be associated with systemic arterial desaturation. This constitutes a risk for paradoxical systemic embolization.
- During cardiac surgery, an enlarged coronary sinus may interfere with the administration of retrograde cardioplegia.
- It may confound placement of a pulmonary artery catheter and cardiac output determinations in the adolescent or adult.

### Evaluation of the Child with a Cardiac Murmur

The finding of an incidental murmur during the perioperative period may result in significant distress to the child or family; may trigger additional diagnostic studies, including a cardiology consultation; and has the potential to delay the scheduled

**FIGURE 14-14** Bilateral superior vena cavae may exist separately or may communicate through an innominate or bridging vein. **A**, The angiogram depicts the superior vena cava, normally a right-sided structure, as it drains into the right atrium. **B**, In the same patient, an angiogram shows drainage of a large left superior vena cava into the coronary sinus. The catheter courses from the inferior vena cava into the right atrium, coronary sinus, and left superior vena cava. Contrast into the left superior vena cava demonstrates no innominate vein between the two cavae. The coronary sinus is dilated.

procedure when identified preoperatively. Although cardiac auscultation is a challenging skill that takes many years of practice to master,<sup>226</sup> it is important for the anesthesiologist who routinely cares for children to recognize the main physical findings that may distinguish an innocent cardiac murmur from a pathologic one. Knowledge of several core concepts and red flags can help avoid overlooking potentially important diagnoses.

About 90% of normal children have a murmur at some point in their lives. It is most commonly identified during the neonatal period and early school years. Most murmurs are functional, considered innocent in nature, and require no special treatment. This diagnosis is based on physical findings consistent with the benign nature of the specific murmur.

Although a complete discussion of cardiac murmur evaluation is beyond the scope of this chapter, it is pertinent to review a few key concepts related to the distinction between innocent and pathologic murmurs.<sup>227,228</sup> The basic systematic approach when assessing a heart murmur is the same as when evaluating any child's cardiovascular system. Auscultation with the diaphragm and bell of the stethoscope in the positions of the four primary cardiac valves should occur with the child and environment as quiet as possible. Innocent murmurs of infancy and childhood include pulmonary flow murmur, a Still murmur, physiologic pulmonary branch stenosis, venous hum, and carotid bruit. Innocent murmurs are usually of low intensity (grades I and II of VI) and are associated with a normal cardiovascular examination (e.g., normal precordial activity, first and second heart sounds, peripheral pulses, capillary refill). Innocent murmurs, such as those associated with peripheral pulmonary branch stenosis, right ventricular outflow murmurs, and Still murmurs, tend to be soft, systolic ejection type, and not holosystolic in duration. Physiologic murmurs often resolve by changing the child's hemodynamic state with maneuvers such as lying down or sitting up or with temporal changes such as resolution of fever and improvement in anemia. Diastolic or continuous

murmurs are typically abnormal, with the exception of a venous hum. This murmur is thought to be related to turbulent flow of systemic venous return in the jugular veins and superior vena cava and is best heard at the base of the neck. *Murmurs accompanied by a palpable thrill are always pathologic.*

When there is doubt regarding the benign or pathologic nature of a murmur, consultation with a pediatric cardiologist is indicated. A chest radiograph and ECG, although thought by some to add minimal value in the initial diagnostic assessment of a cardiac murmur<sup>229,230</sup> and to not be cost-effective,<sup>231</sup> can be helpful when considering if further consultation is indicated.

## Basic Interpretation of the Electrocardiogram in Children

Despite the increasing applications of imaging modalities in the structural and functional assessment of pediatric heart disease, electrocardiography continues to play a significant role in the diagnosis and management of these children. An ECG is considered an integral part of the evaluation of most children with congenital or acquired cardiovascular pathology.

Although the characteristic features of a normal ECG in infants and children were described many decades ago, it is surprising that it continues to be one of the most often misinterpreted screening tests in pediatric medicine.<sup>232</sup> This is largely because of the developmental changes that occur in the normal individual as he or she progresses from the neonatal period through childhood, adolescence, and adulthood.<sup>233</sup> Normal values for children of various ages have been established.<sup>234</sup> Knowledge of normal configurations and values for various ages of children is essential for accurate interpretation.<sup>233-236</sup> Immediately after birth, there is a predominance of right ventricular forces represented by tall R waves in the right precordial leads (V<sub>1</sub> and V<sub>2</sub>) (Fig. 14-15). Over the first several years, the typical

**FIGURE 14-15** Normal electrocardiogram for a 2-day-old infant shows a predominance of right ventricular forces during the neonatal period (i.e., tall R waves over the right precordial leads V<sub>1</sub> and V<sub>2</sub>). The inverted T waves in V<sub>1-3</sub> are normal for this age.

**FIGURE 14-16** The normal electrocardiographic tracing was recorded for a 10-year-old child. The typical left heart–dominant configuration of children this age is characterized by gradual RS progression with tall R waves in the left precordial leads ( $V_5$  and  $V_6$ ). This contrasts with the right ventricular–dominant pattern seen during infancy and early childhood. The tracing demonstrates normal sinus rhythm as documented by positive P waves in leads I and aVF.

electrocardiographic changes to a more familiar left heart–dominant configuration with larger S waves in the right precordial leads and a gradual RS progression with tall R waves in the left precordial leads ( $V_5$  and  $V_6$ ) (Fig. 14-16). The predominance of right heart forces and the need to evaluate for dextrocardia are the primary reasons that pediatric ECGs should include the  $V_3R$  and  $V_4R$  leads, which are not routinely obtained in adult studies. These electrodes are placed in the corresponding  $V_3$  and  $V_4$  locations over the right precordium.

Clinical information of relevance in the interpretation of an ECG includes the child's age, gender, suspected or documented diagnosis, and indications for the examination. Several requirements are essential for accurate interpretation, including appropriate skin preparation, electrode placement, and an artifact-free recording. The approach to the pediatric ECG should be systematic and organized. Determination of the rate and rhythm, with evaluation of the P-wave vector and the relationship between each P wave and QRS complex, is the first step. It is important to consider the influences of age, autonomic nervous system, level of physical activity, medications, pain, and temperature on the child's heart rate. The P wave should be upright or positive in leads I and aVF, indicating that the sinus node is the pacemaker of the heart (i.e., sinus rhythm) (see Fig. 14-16). Normally, the P wave should precede the QRS complex. Next, the QRS electrical axis should be determined. The QRS frontal plane axis is determined by identifying the most isoelectric lead, which is perpendicular to the direction of ventricular depolarization. Alternatively, the direction of depolarization in leads I and aVF can be examined to roughly estimate the axis. As with all other components of the evaluation, the physiologic changes that occur with growth are responsible for the change in normal values for the QRS axis based on age. Regardless of age, QRS axes that lie in the northwest quadrant (between 180 and 270 degrees with an S-wave–dominant pattern in leads I and aVF) are always abnormal and merit further investigation. This is a

frequent finding in children with AV septal defects. Evaluating the T wave, or repolarization axis, is also important, because a difference of greater than 90 degrees between the QRS and T-wave axes can represent strain on the ventricle, a potential finding in ventricular hypertrophy (see Fig. 14-5).

After the evaluation of rhythm and axes is complete, each component of the cardiac cycle as reflected by the ECG should be examined. The P wave represents atrial systole; and its morphology, with particular interest in leads II and  $V_1$ , can demonstrate right atrial (P-wave amplitude greater than 2.5 mm or 3.0 mm based on age) or left atrial (P-wave duration greater than 100 to 120 msec based on age) enlargement (Fig. 14-17). The PR interval represents the time required for passage of an impulse from the sinoatrial node until ventricular depolarization and is largely composed of the AV nodal delay. A prolonged PR interval, which is age specific, indicates first-degree AV block. A short PR interval should prompt evaluation of the QRS duration for signs of preexcitation (i.e., Wolff-Parkinson-White syndrome) (Fig. 14-18), although a short PR interval may also reflect a low right atrial pacemaker.

The QRS complex represents ventricular depolarization. The QRS duration should be examined in a lead with a Q wave present (often lead  $V_5$  or  $V_6$ ) for signs of conduction delay. Age-dependent normal values are important, because the upper limit of normal QRS duration is only 80 msec in neonates. The presence of a wide QRS complex with an RSR' pattern in  $V_1$  indicates a right bundle branch block, whereas a QS pattern in  $V_1$  and a tall notched R wave in  $V_6$  is consistent with a left bundle branch block. Other conditions associated with prolongation of the QRS duration include ventricular preexcitation and ventricular pacing.

In addition to the QRS duration, the components of the QRS complex should be examined. Q waves are often present in the lateral and inferior leads and in lead aVR, but they should be narrow (less than 40 msec) and shallow (age dependent but usually less than 5 mm deep). Deep or wide Q waves suggest

**FIGURE 14-17** The tracing was obtained in the emergency room for a patient subsequently found to have restrictive cardiomyopathy. Biatrial enlargement is established by the tall and wide P waves in leads II and V<sub>1</sub>, respectively.

**FIGURE 14-18** The tracing demonstrates the typical electrocardiographic features of the Wolff-Parkinson-White syndrome: short PR interval, delta wave (arrows), and prolongation of the QRS interval.

myocardial ischemia and require further evaluation. An uncommon but crucial finding occurs in infants with ALCAPA. Classically, the ECG in this lesion demonstrates deep, wide Q waves in leads I and aVL with ST-segment and T-wave changes in the anterior distribution (V<sub>2</sub> to V<sub>4</sub>) consistent with compromised myocardial blood flow (Fig. 14-19). The QRS amplitudes are also important in assessing left and right ventricular hypertrophy. Conditions associated with increased QRS voltages that likely require echocardiographic assessment include HCM, left ventricular noncompaction, and Pompe disease (see Fig. 14-6).

ST segments should be flat and should not be depressed more than 0.5 mm or elevated more than 1 mm in any lead. The major exception to this rule is when there is gradual upsloping of the ST segment in the mid-precordial leads, as seen in early repolarization. T waves represent ventricular repolarization and should all be upright in the precordial leads at birth. Within 1 to 3 days they become inverted, initially in V<sub>1</sub> and eventually in V<sub>2</sub>, V<sub>3</sub>, and sometimes in V<sub>4</sub>. Starting at several years of age, the T waves return to the upright position in the reverse order. In normal adolescents and adults, the T wave in lead V<sub>1</sub> may be upright or

**FIGURE 14-19** Electrocardiographic tracing for an infant with poor ventricular function who was found to have anomalous origin of the left main coronary artery from the pulmonary root. The presence of Q waves in aVL and the diffuse ST-T wave changes suggest ischemia and are classic for this anomaly.

inverted. The only limb lead that typically displays an inverted T wave is aVR.

An aspect of the cardiac cycle that must be examined on any ECG is the QT interval, the time from the onset of ventricular depolarization (marked by the onset of the QRS complex), until the completion of repolarization (marked by the end of the T wave). It represents the duration of electrical activation and recovery of the ventricular myocardium, and it is measured as follows:

$$\text{Corrected QT (QTc)} = \frac{\text{Measured QT interval}}{\text{Square root of preceding R-R interval}}$$

A QTc that exceeds 460 msec is considered abnormal, regardless of age. All QTc values that exceed normal values for age merit further investigation. Medications that prolong the QT interval should be avoided until the child has been evaluated by a cardiologist.

Although a detailed organized approach to interpretation of a pediatric ECG is necessary, there are occasions when particular conditions or circumstances cause global electrocardiographic changes that must be quickly recognized. One such case that may occur in the operating room is related to the electrocardiographic changes associated with hyperkalemia. As the potassium level increases, the T-wave amplitude increases. This is followed by widening of the QRS duration (Fig. 14-20) due to an intraventricular conduction delay and by AV block and arrhythmias, including ventricular tachycardia and fibrillation. Other electrolyte disturbances may result in characteristic changes on the ECG:

- Hypokalemia: decreased T-wave amplitude, ST-segment depression, and the presence of U waves
- Hypercalcemia: shortening of the QT interval, sinus rate slowing, and sinoatrial block
- Hypocalcemia: lengthening of the QT interval
- Hypomagnesemia: enhanced effects of hypocalcemia

## Essentials of Cardiac Rhythm Interpretation and Acute Arrhythmia Management in Children

Rhythm abnormalities may be identified during the preoperative assessment, in the operating room, or in the postoperative period. Considerations usually include identification of the rhythm disorder, establishing the need for acute therapy, deciding whether to consult a pediatric cardiologist, and conveying pertinent information to the consultant to assist in the characterization of the rhythm disturbance and to establish a management plan. The following principles should be considered in addressing these issues:

1. Operating room, bedside, or transport monitors and strip recordings facilitate the recognition of rhythm disorders, but in most cases, they are inadequate for definitive diagnosis. A 15-lead surface ECG and rhythm strip should be obtained for all children when feasible.
2. Clinicians caring for children should have a basic knowledge of cardiac rhythm interpretation. Although a comprehensive discussion of arrhythmia interpretation is beyond the scope of this chapter, a brief overview of the characteristic features of normal and abnormal cardiac rhythms in the pediatric age group is presented in the following section.
3. The need for acute therapy for a rhythm disturbance should be based primarily on the nature of the disorder, urgency of the situation, and the likelihood that this abnormality would or would not be tolerated beyond the immediate short-term period. The guidelines established by the American Heart Association for Pediatric Advanced Life Support should be followed in all patients.<sup>237</sup> In otherwise healthy children and in contrast to ventricular arrhythmias, supraventricular tachyarrhythmias are rarely life-threatening.
4. The degree of comfort in the characterization and management of pediatric cardiac arrhythmias is likely to be quite

A 25 mm/sec 10 mm/mV 100 Hz

B

**FIGURE 14-20** These electrocardiographic changes may result from hyperkalemia. **A**, Marked widening of the QRS complexes is associated with peaked T waves. If untreated, this condition may progress to ventricular fibrillation and asystole. **B**, A tracing obtained several hours after treatment of electrolyte disturbance in the same patient demonstrates resolution of the electrocardiographic changes.

variable among anesthesia care providers. For arrhythmias caused by respiratory compromise, electrolyte imbalance, or metabolic derangements, consultation with a pediatric cardiologist is probably not required. This is also the case for variants or benign rhythm disturbances such as sinus arrhythmia, low atrial rhythms, or occasional premature atrial beats. Consultation is appropriate for most children with known structural or acquired cardiovascular pathology, in those with a history of a cardiac rhythm disorder under the care of a cardiologist, and in most of those with acute arrhythmias, particularly when initiation of antiarrhythmic drug therapy is contemplated.

- Information that may be helpful to a consultant includes pertinent details regarding the child's history, clinical diagnosis, nature of the procedure/intervention, relevant laboratory values, description or characterization of the rhythm abnormality, associated hemodynamic parameters, circumstances surrounding the event (including the presence or absence of an intracardiac catheter), review of the pharmacologic agents administered (including anesthetic agents), and other therapies if applicable. The specialist should assist in the characterization of the rhythm disorder, advise about whether further evaluation is indicated, make recommendations for treatment, and facilitate diagnostic/therapeutic interventions as necessary.

**FIGURE 14-21** The rhythm tracing displays the normal heart rate variability with respiration. There is a normal increase in heart rate during inspiration. This sinus arrhythmia is a natural response and is more commonly seen in children than adults.

## BASIC RHYTHMS

### Sinus Rhythm

Sinus rhythm is characterized by a P wave that precedes every QRS, a QRS that follows every P wave, and an upright P wave in leads I and aVF (see Fig. 14-16).

### Sinus Arrhythmia

Sinus arrhythmia represents cyclic changes in the heart rate during breathing. This is a normal finding in healthy children (Fig. 14-21).

### Sinus Bradycardia

Sinus bradycardia is characterized by sinus rhythm with heart rates below normal for age (see Fig. 14-5). Slow heart rates can be observed during sleep or at times of high vagal tone. When there is significant sinus bradycardia, a slow junctional escape rhythm or a slow atrial rhythm originating from an ectopic focus may be present. Certain forms of CHD may be prone to slow heart rhythms (i.e., heterotaxy syndromes).

In the intraoperative setting, particularly on induction of anesthesia, with laryngoscopy, endotracheal intubation, or tracheal suctioning, sinus bradycardia may occur. Sinus bradycardia may also result from drug administration (i.e., opioids) or increased parasympathetic tone. This type of sinus bradycardia rarely poses significant hemodynamic compromise and, if necessary, can be easily treated with removal of the stimulus, administration of a vagolytic agent (e.g., pancuronium), or with chronotropic drugs such as atropine or epinephrine. Sinus bradycardia may also result from hypoxemia, hypothermia, acidosis, electrolyte imbalance, or increased intracranial pressure. Bradycardia related to hypoxemia should be treated promptly with the administration of supplemental oxygen and appropriate airway management (see Chapter 39). The approach to other secondary forms of sinus bradycardia should focus on addressing the underlying cause. For worrisome slow heart rates, particularly in small infants, or for clinical evidence of compromised hemodynamics,

pharmacologic therapy (i.e., epinephrine, atropine, or isoproterenol infusion) or temporary pacing should be considered.

### Sinus Tachycardia

During sinus tachycardia, sinus rhythm occurs at a heart rate above normal for age (Fig. 14-22). In the perioperative setting this is often the result of surgical stimulation, stress, pain, hypovolemia, anemia, fever, medications (i.e., inotropic agents), malignant hyperthermia, or a high catecholamine state. Treatment is directed at the underlying cause. Prolonged periods of sinus tachycardia may impair diastolic filling time, limit ventricular preload, and compromise cardiac output. Children at risk for hemodynamic decompensation include those with significant degrees of ventricular hypertrophy or diastolic dysfunction, aortic stenosis, Williams syndrome, and HCM.

### Junctional Rhythm

A junctional rhythm is characterized by QRS complexes of morphology identical to that of sinus rhythm without preceding P waves. This rhythm is slower than the expected sinus rate. When this rhythm completely takes over the pacemaker activity of the heart, retrograde P waves and AV dissociation may be seen. Junctional rhythm during cardiac surgery is frequently the result of manipulation or dissection near the right atrium. The central venous pressure contour typically demonstrates prominent v waves (i.e., right atrial pressure wave at the end of systole) due to the loss of AV synchrony (Fig. 14-23). The lack of atrial contribution to ventricular filling may result in decreases in the systemic arterial blood pressure.

## CONDUCTION DISORDERS

### Bundle Branch Block

Incomplete right bundle branch block pattern (rSR' in right precordial leads with near normal QRS duration) occurs in children with right ventricular volume overload (e.g., those with ASDs). Complete right bundle branch block (QRS complex

**FIGURE 14-22** Electrocardiogram for a febrile infant with sinus tachycardia, characterized by a heart rate above normal for age and QRS complexes of normal appearance preceded by P waves, which are upright in leads I and aVF.

**FIGURE 14-23** The intraoperative tracing obtained during cardiac surgery at the time of right atrial dissection demonstrates the features of a junctional rhythm. Retrograde P waves are identified after the QRS complexes. The central venous pressure (CVP) tracing demonstrates prominent v waves (arrows) related to the loss of atrioventricular synchrony (scale of 0 to 30 mm Hg for CVP).

greater than 100 msec for infants, 120 msec for older children) is frequently seen in children after surgical procedures that involve the right ventricular outflow tract. This is characterized by an rSR' wave pattern in  $V_1$ , an inverted T wave, and a wide and deep S (slurred) wave in  $V_6$ . Left bundle branch block is an uncommon finding in the pediatric age group that may result from cardiac interventions along the left ventricular outflow tract. Criteria for this conduction disorder include a prominent QS or rS complex in lead  $V_1$  and tall, wide, and often notched R wave in leads I, aVL, and  $V_6$ .

### Atrioventricular Block

#### First-Degree Atrioventricular Block

In first-degree AV block, there is prolongation of the PR interval beyond the normal range for age. Each P wave is followed by a conducted QRS. This may be found in healthy individuals but can also be seen in various disease states. First-degree AV block is a benign condition requiring no specific treatment.

#### Second-Degree Atrioventricular Block

There are two forms of second-degree AV block: Mobitz type I (Wenckebach) and Mobitz type II. They are characterized by a periodic failure to conduct atrial impulses to the ventricle (i.e., P wave without following QRS complex). In a type I, second-degree AV block, there is a gradual lengthening of the PR interval with eventual failure of conduction of the next atrial impulse to the ventricle. The RR intervals concomitantly shorten. The degree of AV block is expressed as the ratio of P waves per QRS complexes (i.e., 2:1, 3:2). This can occur during periods of high vagal tone or in the postoperative setting. It is usually a benign phenomenon that requires no therapy. In the less frequent type II second-degree AV block, there is a relatively constant PR interval before an atrial impulse that fails to conduct. This is considered a more serious conduction disturbance and merits further investigation.

#### Third-Degree Atrioventricular Block

Third-degree (complete) AV block is characterized by total failure of conduction of atrial impulses to the ventricle. It can be congenital or acquired. There is complete AV dissociation, with more atrial than ventricular contractions, and the ventricular rate is usually slow and regular (Fig. 14-24). Temporary pacing may be indicated in the acute setting.

### CARDIAC ARRHYTHMIAS

#### Supraventricular Arrhythmias

##### Premature Atrial Contractions or Beats

Isolated premature atrial contractions (PACs) are relatively common in infants and small children. On the ECG, the early P waves exhibit a morphology and axis that are different from those in normal sinus rhythm. Premature atrial contractions may be conducted to the ventricles normally, blocked at the AV node, or conduct aberrantly (i.e., abnormal QRS morphology). They

are usually benign and require no therapy. If a central venous catheter is present, the tip position should be evaluated.

#### Supraventricular Tachycardia

Supraventricular tachycardia (SVT) is the most common significant arrhythmia in infants and children.<sup>238,239</sup> It is characterized by a regular tachyarrhythmia (tachycardia heart rate is age dependent but typically more than 230 beats/min in children) with a narrow or usual complex QRS morphology. Supraventricular tachycardia can occur in structurally normal hearts and in various forms of CHD. *Usual complex* implies that the QRS morphology in tachycardia is similar to that in normal sinus rhythm (Fig. 14-25). Occasionally, widening of the QRS in SVT may result from bundle branch block or related to the tachycardia mechanism (i.e., SVT with aberrancy). A wide QRS complex may make the distinction between supraventricular and ventricular tachycardia difficult.

The two types of SVT are automatic and reentrant. They can be differentiated by evaluating characteristics of the tachycardia, usually assisted by the input from a specialist. The evaluation of a tachyarrhythmia should include a surface 15-lead ECG and continuous rhythm strip to document onset and termination. If a medication such as adenosine has been administered, a recording of the response to the drug or pacing maneuvers should be obtained. The management of SVT depends on the clinical status of the child, type of tachycardia, and precise electrophysiologic mechanism. General management principles include the following:

- Hemodynamic stability should be determined. Synchronized direct current cardioversion (0.5 to 1.0 J/kg) should be performed for hemodynamic instability.<sup>237</sup>
- Antiarrhythmic therapy is based primarily on the clinical condition and suspected tachycardia mechanism. Vagal maneuvers may be considered but should not delay treatment. Adenosine is the drug of choice in the acute setting for diagnosis and termination of most supraventricular tachycardias.<sup>240</sup>  $\beta$ -Blockers are most often used for chronic therapy.
- Others measures include treatment of fever if present, sedation, correction of electrolyte disturbance, decreasing or withdrawing medications associated with sympathetic stimulation (i.e., inotropic agents) or with vagolytic properties (i.e., pancuronium).
- In addition to pharmacologic therapy, atrial pacing or cardioversion may be required.

#### Ventricular Arrhythmias

##### Premature Ventricular Contractions or Beats

Premature ventricular contractions (PVCs) are characterized by prematurity of the QRS complex, a QRS morphology that is different from that in sinus rhythm, usually a prolongation of the QRS duration for age, abnormalities of the ST segment and T wave, and premature ventricular activity not preceded by a

**FIGURE 14-24** Rhythm strip demonstrates independent atrial and ventricular activity (i.e., atrioventricular dissociation) and failure of any atrial impulses to conduct to the ventricles. These features characterize a complete atrioventricular block.

**FIGURE 14-25** The initial portion of the intraoperative recording demonstrates normal sinus rhythm. A premature atrial beat initiates a narrow complex tachycardia (i.e., QRS morphology the same as in sinus rhythm). The supraventricular tachycardia is associated with hemodynamic changes such as a decrease in the systemic arterial pressure (ART 1, scale of 0 to 100 mm Hg) (arrow) and increase in the central venous pressure (CVP, scale of 0 to 30 mm Hg) (broken arrow). *Spo<sub>2</sub>*, Oxygen saturation.

premature atrial beat. PVCs of a single QRS morphology (i.e., uniform), without associated symptoms, and in children with structurally normal hearts are considered benign. An ECG during sinus rhythm should allow careful measurement of the QT interval. Further investigation and consultation are warranted in the presence of PVCs of multiple morphologies (i.e., multiform), if they occur with moderate frequency or in succession (i.e., couplets or runs) and are associated with symptoms or a structurally abnormal heart.

Ventricular ectopy in the perioperative period may be the result of profound hypoxemia, electrolyte disturbances, or metabolic derangements. Other causes include the use of recreational drugs, myocardial injury, poor hemodynamics, and prior cardiac surgical intervention.

#### **Ventricular Tachycardia**

Ventricular tachycardia (VT) is relatively uncommon in children. It is defined as three or more consecutive ventricular beats occurring at a rate greater than 120 beats/min (Fig. 14-26). The QRS morphology in VT is different from that in sinus rhythm, and the QRS duration is typically prolonged for age. ECG features that support this diagnosis include AV dissociation, intermittent fusion (i.e., QRS complex of intermediate morphology between two other distinct QRS morphologies), QRS morphology of VT similar to that of single PVCs, and tachycardia rate in children usually below 250 beats/min.

Acute onset of VT in pediatric patients may be caused by hypoxia, acidosis, electrolyte imbalance, or metabolic problems. Ventricular tachycardia may also occur in the context of depressed ventricular function, halothane anesthesia with or without hypercarbia, poor hemodynamics, prior surgical interventions, cardiomyopathies, myocardial tumors, acute injury (e.g., inflammation, trauma), and prolonged QT syndromes.<sup>241,242</sup>

#### **Long QT Syndrome**

Long QT syndrome (LQTS) (Fig. 14-27) is an electrical cardiac disturbance that can predispose children to arrhythmias that include torsades de pointes ventricular tachycardia (Fig. 14-28), ventricular fibrillation, and bradyarrhythmias, and any of these can result in syncope, cardiac arrest, or sudden death.<sup>243</sup> It occurs with an incidence of 1 case per 2500 births; congenital and acquired forms have been described. The congenital varieties are likely the result of genetic defects in the cardiac ion channels responsible for maintaining electrical homeostasis.<sup>244</sup> Thirteen genotypes have been described on five chromosomes. The cLQT1-3 (Romano-Ward) cases account for 90% of the children. The Romano-Ward syndrome has an incidence of 1 case per 10,000 births and an autosomal dominant pattern of inheritance. The Jervill Lange-Nielsen syndrome has an incidence of 1 case per 1,000,000 births, an autosomal recessive pattern of inheritance, and an association with deafness. Diagnostic criteria proposed for the long QT syndrome include electrocardiographic findings, clinical history (e.g., deafness, syncope), and family history.<sup>245</sup> A frequent feature is prolongation of the QTc on the resting ECG.

An important consideration in the care of children with cLQTS is ensuring adequate  $\beta$ -adrenergic blockade preoperatively and minimizing adrenergic stimulation.<sup>243</sup> Since the introduction of  $\beta$ -adrenergic blockade in patients with cLQTS in 1975, the mortality rate has decreased more than 10-fold. The risk for developing torsades de pointes from the many drugs known to trigger it is almost unpredictable; these drugs have been divided into several groups that are listed and updated online ([www.qtdrugs.org](http://www.qtdrugs.org)).

In a retrospective study of children with cLQTS, three adverse events were reported during emergence from anesthesia immediately after administration of ondansetron and anticholinesterase medications; one was described as torsades de pointes.<sup>244</sup> These

**FIGURE 14-26** The tracing demonstrates frequent, uniform premature ventricular beats and episodes of nonsustained, monomorphic ventricular tachycardia.

**FIGURE 14-27** For a patient with long QT syndrome, the electrocardiogram demonstrates prolongation of the QT interval.

**FIGURE 14-28** The rhythm strip displays positive and negative oscillation of QRS complexes, which is characteristic of torsades de pointes ventricular tachycardia.

arrhythmias resolved quickly with intravenous  $\beta$ -blockers, lidocaine, or the administration of both agents. This report suggests that children with cLQTS are at risk for arrhythmias during periods of enhanced sympathetic activity (i.e., during emergence), particularly in the presence of drugs that prolong the QT interval. Conditions (e.g., hypothermia) and drugs (www.qtdrugs.org) that are known to prolong the QT interval should not be combined if possible. Despite the fact that most intravenous and inhalational medications routinely administered during anesthesia prolong the QT interval, adverse events are rare. This may be attributed in part to the need for a second abnormality beyond a prolonged QT interval to be present to trigger arrhythmias (i.e., increased dispersion of repolarization). Fortunately, most anesthetics do not increase the dispersion of repolarization.

Torsades de pointes is a rare but potentially life-threatening arrhythmia, even in the presence of prolonged QT interval. To trigger torsades de pointes, a second phenomenon must occur (i.e., increased dispersion of repolarization). Dispersion of repolarization refers to the variance in the rate of repolarization; in this case, it is a circumscribed region in the heart muscle (i.e., transmurally from the epicardium to the endocardium). There is much debate over how to quantify an increased dispersion of repolarization from surface ECGs. Some suggest the dispersion is the QTc-max to QTc-min, whereas others recommend measuring the duration of the T wave from its peak to the end; in both instances the upper limit of normal is 65 msec and abnormal values exceed 100 msec.

Prolongation of the QT interval and genesis of torsades de pointes occur more commonly in the presence of several conditions and drugs: electrolyte derangements (e.g., hypokalemia, hypocalcemia, hypomagnesemia), combination drug therapies (e.g., antibiotics, antiarrhythmic agents, class III antiarrhythmics such as amiodarone and procainamide), antipsychotic drugs, cisapride, neurologic or endocrine abnormalities (e.g., hypothyroidism), 5-HT<sub>3</sub> receptor-blocking drugs (except palonosetron), neostigmine, stress (including induction of and emergence from anesthesia and laryngoscopy), female sex, bradycardia, and coronary artery disease. Although many anesthetics prolong the QT interval, few affect the dispersion of repolarization (as in the case of sevoflurane),<sup>246</sup> and the risk of torsades de pointes during general anesthesia in children is rare.

Management of torsades de pointes includes the following considerations:

1. Although some atypical forms of supraventricular tachyarrhythmias may mimic VT, a wide QRS tachycardia should always be considered to be of ventricular origin.
2. The initial approach in the setting of an acute ventricular rhythm disturbance consists of prompt evaluation of clinical status and hemodynamic stability. Sustained ventricular arrhythmias are poorly tolerated and require immediate attention. In the unstable child, cardiopulmonary resuscitation should be instituted while preparing for cardioversion. Expert consultation is advisable when advanced drug therapy is contemplated. Potential pharmacologic interventions include lidocaine, amiodarone, and procainamide.<sup>247</sup> The latter two should not routinely be administered during torsades de pointes due to QT prolongation.
3. Magnesium sulfate is considered the first-line treatment of torsades de pointes. Procainamide and amiodarone are contraindicated due to prolongation of the QT interval. Isoproterenol and overdrive pacing may be effective for bradycardia. Electrical cardioversion (1 to 2 J/kg) should be

performed only if the arrhythmia is refractory to pharmacologic treatment.

4. cLQTS should be treated with  $\beta$ -blockade (not overdrive pacing); some forms of the cLQTS may require the implantation of a cardioverter-defibrillator.

### Ventricular Fibrillation

Ventricular fibrillation (VF) is an uncommon arrhythmia in children. It is characterized by chaotic, asynchronous ventricular activity that fails to generate an adequate cardiac output. The ECG during VF demonstrates low-amplitude, irregular deflections without identifiable QRS complexes. A loose ECG electrode may mimic these surface electrocardiographic features, and immediate clinical assessment should be performed and adequate pad contact ensured when VF is suspected.

Management of VF includes the following considerations:

1. This is a lethal arrhythmia if untreated.
2. Immediate defibrillation (initial dose of 2 J/kg) is the definitive therapy. Cardiopulmonary resuscitation, beginning with chest compressions, should be immediately resumed and continued for 2 minutes. If defibrillation is unsuccessful, the energy dose should be doubled (4 J/kg) and repeated. Pediatric paddles (2.2 cm in diameter) are recommended for children weighing less than 10 kg. Adult paddles (8 to 9 mm in diameter) are suggested for children weighing more than 10 kg to reduce impedance and maximize current flow.
3. Adequate airway control and chest compressions should be rapidly instituted while preparing for defibrillation or between shocks if several defibrillation attempts are needed. Resuscitative drugs and amiodarone should be considered without delaying defibrillation.

## Pacemaker Therapy in the Pediatric Age Group

### PACEMAKER NOMENCLATURE

Pacemaker nomenclature follows the guidelines of the North American Society of Pacing and Electrophysiology and the British Pacing and Electrophysiology Group<sup>248</sup> (Table 14-5):

- First letter: chambers paced (A = atrium, V = ventricle, D = dual or both, O = none)
- Second letter: chambers sensed (A = atrium, V = ventricle, D = dual or both, O = none)
- Third letter: pacemaker's response to sensing (I = inhibited, T = triggered, D = dual response, O = none)
- Fourth letter: rate modulation (R = rate modulation, O = none)
- Fifth letter: multisite pacing (A = atrium, V = ventricle, D = dual or both, O = none)

### PERMANENT CARDIAC PACING

#### Indications

The most recent guidelines for permanent pacing in children, adolescents, and patients with CHD were published in 2008.<sup>249</sup> Indications include symptomatic sinus bradycardia, bradycardia-tachycardia syndromes, congenital third-degree AV block, and advanced second- or third-degree AV block.<sup>249,250</sup>

#### Perioperative Considerations

Preoperative evaluation of children with implanted pacemakers should include device interrogation.<sup>251</sup> Familiarity with unit type,

**TABLE 14-5 NASPE/BPEG Generic Pacemaker Codes\***

Position Number and Category				
I: Chambers paced	II: Chambers sensed	III: Response to sensed event	IV: Rate modulation	V: Multisite pacing
A = Atrium	A = Atrium	I = Inhibited	R = Rate modulation	A = Atrium
V = Ventricle	V = Ventricle	T = Triggered		V = Ventricle
D = Dual (A + V)	D = Dual (A + V)	D = Dual (I + T) response restricted to dual-chamber devices		D = Dual (A + V)
O = None	O = None	O = None	O = None	O = None
<b>Most Common Pacing Modes</b>				
<i>Single-chamber pacing</i>				
AAI: atrial demand pacing (atrial pacing and sensing, inhibited on sensed beat)				
AAIR: atrial demand pacing (atrial pacing and sensing, inhibited on sensed beat), rate responsiveness				
VVI: ventricular demand pacing (ventricular pacing and sensing, inhibited on sensed beat)				
VVIR: ventricular demand pacing (ventricular pacing and sensing, inhibited on sensed beat), rate responsiveness				
<i>Asynchronous pacing (no sensing)</i>				
AOO: fixed rate atrial pacing				
VOO: fixed rate ventricular pacing				
DOO: fixed rate AV pacing				
<i>Dual-chamber pacing</i>				
DDD: paces and senses both chambers				
DDDR: paces and senses both chambers, sensor-driven rate responsiveness				

Modified from Bernstein AD, Daubert JC, Fletcher RD, et al. The revised NASPE/BPEG generic code for anti-bradycardia, adaptive-rate, and multisite pacing. *Pacing Clin Electro-physiol* 2002;25:260-4.

NASPE/BPEG, North American Society of Pacing and Electrophysiology/British Pacing and Electrophysiology Group.

\*The pacemaker mode, specified by a code, describes the mode in which the pacemaker is operating. The most common modes are listed.

settings, date of and indications for implantation, device location, and underlying rhythm is highly recommended. If records are not available and there is no identification card providing details about the unit implanted, a radiopaque marker on a chest radiograph may assist in the identification of the device. Major pacemaker manufacturers can also be contacted at any time because they maintain computerized records of all implanted devices. Results of a recent 12-lead ECG should be reviewed if available.

Reprogramming may be required before the planned procedure to avoid potential problems with pacemaker malfunction related to electrocautery. This represents one of the most common potential sources of electromagnetic interference in children with implanted cardiac devices. Recommendations for the perioperative management of these children include the use of bipolar cautery versus a unipolar configuration if possible, avoidance of cauterization near the generator, and positioning of the indifferent plate for electrocautery away from the pacemaker so that the device is not between the electrocautery electrodes.<sup>252</sup> Devices such as the harmonic scalpel and battery-operated, hot wire, hand-held cautery units do not interfere with implanted cardiac devices. Rate-responsive features should be deactivated in most cases.

Chronotropic drugs and alternate pacing modalities should be readily available in the event of pacemaker malfunction and compromising underlying rate. Although insertion of a transvenous pacing system has been advised in children with complete AV block undergoing pacemaker implantation, a 10-year review indicated no benefit to routine preoperative temporary pacing.<sup>253</sup> Capture thresholds can be affected by pharmacologic agents, and this should be considered if pacing is required in the child receiving antiarrhythmic drug therapy.

Perioperative conditions may also influence pacing thresholds. A magnet should be accessible to allow asynchronous pacing if required.<sup>254,255</sup> Most generators respond to magnet application by pacing at a fixed rate asynchronously (i.e., AOO, VOO, or DOO). A potential problem is that the specific magnet rate, as determined by the manufacturer for the particular device, may be different from the desirable or optimal pacing rate. The use of a magnet should not be considered a substitute for preoperative pacemaker interrogation/programming. In addition to perioperative electrocardiographic monitoring, additional modalities that confirm pulse generation during pacing (e.g., esophageal stethoscope for assessment of heart sounds, pulse oximetry, invasive arterial blood pressure monitoring) are strongly encouraged. The device should be tested and reprogrammed after the procedure is completed.

### Transcutaneous Pacing

Several devices that combine defibrillation and cardioversion capabilities with external pacing features are available. Emergency transthoracic pacing may be considered as a temporizing measure for children with symptomatic bradycardia,<sup>256</sup> but this has not been effective in the treatment of asystole in children.<sup>257</sup> Pacing electrode size should be selected according to patient size (e.g., smaller adhesive pads for weight less than 15 kg). Device settings typically include pacing rate and power output. Sedation may be necessary to tolerate soft tissue discomfort. Prolonged periods of transcutaneous pacing may result in local cutaneous injury. In addition to monitoring for pacemaker capture by ECG, ongoing clinical assessment of the adequacy of cardiac output should be undertaken.

### Implantable Cardioverter-Defibrillators

The primary goal of an implantable cardioverter-defibrillator (ICD) is the prevention of sudden death. Children with long QT syndrome, HCM, history of near-death events, arrhythmogenic right ventricular dysplasia, and operated CHD with a history of malignant arrhythmias may be considered suitable candidates for device implantation.<sup>250,258,259</sup> The capabilities of these units include pacing and defibrillation. It may be feasible to terminate tachyarrhythmias by pacing.

Over the past several years, more children have been considered for device implantation.<sup>249,259-263</sup> This implies an increasing number of children with these devices who may require anesthetic care. The primary issues associated with intraoperative management of these devices relate to patient monitoring, managing issues with potential for electromagnetic interference, and performing emergent defibrillation, cardioversion, or heart rate support.<sup>252</sup> Perioperative consultation with a cardiologist or electrophysiologist is essential. These devices should be interrogated and likely require programming before and at the conclusion of the planned procedure.

## Diagnostic Modalities in Pediatric Cardiology

### CHEST RADIOGRAPHY

The standard posteroanterior and lateral chest radiographs provide clues to a child's underlying cardiovascular anatomy; however, plain radiographs are an insensitive screening tool for cardiac disease.<sup>264</sup> Children with numerous types of significant CHD may have initially normal-appearing radiographs; alternatively, an infant with a poor inspiratory effort and the presence of a large thymus may give the appearance of cardiomegaly and have normal intracardiac anatomy (Fig. 14-29).

Interpretation of a chest radiograph begins with identification of the patient's name and ensuring that the right-left orientation of the radiograph is correct. All catheters and tubes should be followed to verify their location, course, and likely site of

**FIGURE 14-29** For a neonate with apneic episodes undergoing evaluation for potential cardiac disease, the radiograph demonstrates a poor inspiratory effort resulting in a large cardiothymic silhouette, making interpretation of cardiac size difficult. No evidence of cardiac disease was identified in this child.

termination. The bones and soft tissues should be inspected for evidence of sternal wires, fractures, vertebral anomalies, or wide intercostal spaces, suggesting a prior thoracotomy. Sidedness, including the location of the gastric bubble, liver, and position and orientation of the cardiac mass, should be observed. The lung parenchyma should be examined for evidence of focal consolidation, such as pneumonia or atelectasis, and for pulmonary vascular markings.

The cardiac silhouette and great vessels should be assessed. In young children, the thymus may obscure the superior portions of the cardiac shadow. Careful inspection of the cardiac silhouette includes an assessment of overall size and evidence of individual chamber or vessel dilation. The size of the main pulmonary artery segment may provide further evidence of the degree of pulmonary overcirculation in children with left-to-right shunt lesions. The tracheal indentation can usually be seen and is useful in determining aortic arch sidedness, although in a young child with a prominent thymus, this can be difficult to assess.

More useful than an individual radiograph as a diagnostic tool are serial chest films obtained to monitor a child's cardiovascular status over time. In a young child with a volume overload lesion, the physical examination and growth parameters coupled with the degree of cardiomegaly and pulmonary overcirculation are more helpful than more advanced imaging techniques. A plain chest radiograph may also guide initiation and titration of pharmacologic therapy and the timing of a surgical intervention.

### BARIUM ESOPHAGRAM

The current applications and uses of barium esophagram (swallow) studies in the diagnosis of CHD are limited. This modality has been largely replaced by MRI and chest tomography.<sup>265-267</sup> In some cases, a barium esophagram is used as an initial screening tool when there is concern about the presence of a vascular ring.<sup>268,269</sup> A double aortic arch represents one of the most common types of vascular rings in young children, but other vascular anomalies such as a right aortic arch with an aberrant left subclavian artery and left-sided ligamentum arteriosus may also cause symptoms. The indentation pattern in the barium column is consistent with the specific vascular anomaly (Fig. 14-30).

### ECHOCARDIOGRAPHY

Echocardiography is the primary diagnostic modality for the initial evaluation and serial assessment in most types of pediatric heart disease.<sup>270,271</sup> Using a variety of transducers, ultrasound is used to acquire real-time images of cardiovascular structures. Various echocardiographic modalities are available, including transthoracic,<sup>272</sup> transesophageal,<sup>273-276</sup> fetal,<sup>277,278</sup> epicardial,<sup>279</sup> intracardiac imaging,<sup>280</sup> and intravascular ultrasound.<sup>281</sup> Each plays an important role in the diagnostic evaluation and management of children with suspected or confirmed cardiovascular disease.

Advantages of echocardiography include its noninvasive nature, provision of excellent temporal and spatial resolution, generation of portable real-time images, cost-effectiveness, and ease of use. As with any type of ultrasound, these waves are transmitted well through homogeneous tissues and fluid but poorly through air and bone. Another limitation of echocardiography is related to limited acoustic windows in certain patient groups, such as those who have undergone multiple cardiopulmonary procedures, older individuals, or children with a significant amount of soft tissue or body fat. For this reason,

cardiovascular MRI is being increasingly used for noninvasive imaging. Additional challenges of echocardiography include the need to obtain serial two-dimensional tomographic images by sweeping the transducer scan in multiple planes to synthesize these images into three-dimensional structures in one's mind and to achieve expert interpretation. Despite these limitations, echocardiography remains the main diagnostic imaging modality for most children. Many medical and surgical management

**FIGURE 14-30** Barium swallow in a child with respiratory symptoms demonstrates a filling defect posteriorly in the mid-esophagus, which is consistent with an aberrant subclavian artery.

strategies are primarily based on the findings allowed by this approach.

A standard transthoracic study consists of a two-dimensional examination, M-mode imaging, and Doppler evaluation (i.e., color flow, pulsed-wave, or continuous-wave modalities). Two-dimensional imaging provides structural assessment of the heart and adjacent vasculature. Cross-sectional images are obtained from several windows that allow excellent anatomic detail in multiple planes (Video 14-11). In most cases, this is adequate for a detailed segmental evaluation of the cardiac anatomy as described earlier. M-mode echocardiography allows one-dimensional imaging of the heart with excellent temporal resolution (Fig. 14-31). It is known as an *ice pick view* of the heart in real time and is primarily used in the assessment of ventricular dimensions and function.

Color flow Doppler techniques allow evaluation of directionality and velocity of blood flow. In addition to detecting flow across cardiac valves and great vessels, color flow imaging allows detection of subtle lesions such as small septal defects that can be difficult to identify by standard two-dimensional imaging alone. Traditionally, flow toward the transducer is displayed in red, and flow away is represented as blue. Turbulent blood flow is associated with increased Doppler velocities and can be readily identified as a mosaic of colors; it typically has a greenish tint (Video 14-12).

Pulsed- and continuous-wave Doppler represent spectral modalities that complement the color flow data and provide quantitative information. Pulsed-wave interrogation localizes specific sites of stenosis or turbulence but is limited in the magnitude of velocities it can detect. Continuous-wave Doppler allows quantification of much higher velocities (see Video 14-12). Velocities obtained with pulsed- and continuous-wave Doppler provide estimates of pressures within various cardiac chambers by applying the simplified Bernoulli equation. It states that the difference

**FIGURE 14-31** An M-mode echocardiogram enables determination of left ventricular dimensions and calculation of shortening fraction. IVS, Interventricular septum; LV, left ventricle; LVEDD, left ventricular end-diastolic dimension; LVESD, left ventricular end-systolic dimension; LVPW, left ventricular posterior wall; RV, right ventricle.

in pressure between two locations is approximately four times the square of the velocity of the jet of flow between them:

$$\text{Pressure gradient (in mm Hg)} = 4 \cdot v^2$$

The applications of three-dimensional echocardiography in CHD continue to be investigated.<sup>282-284</sup> This approach can provide clear and useful volumetric assessments when the images are adequate. A significant advantage of this modality is that it is able to display cardiovascular structures and their interrelationships in detail, in many cases facilitating the understanding of pathologic conditions over two-dimensional imaging. Three-dimensional echocardiography may also be useful when interventions are planned.

### Interpretation of an Echocardiographic Report

#### *Measurements of Cardiac Chambers and Vessel Dimensions*

Several measurements are routinely performed during an echocardiographic examination. They include ventricular dimensions such as left ventricular end-diastolic (LVED) and left ventricular end-systolic (LVES) dimensions, thickness of the interventricular septum and left ventricular posterior wall, and measurements of valve sizes and great artery dimensions. To determine whether these are appropriate for the child being examined, the measurements are referenced to values obtained in normal children matched for body surface area. This is accomplished by reporting the measured value in addition to a Z score, representing standard deviations of measured values from the mean in a comparative population.

#### *Assessment of Ventricular Function*

Several echocardiographic techniques are able to provide information regarding ventricular performance. Two of the most commonly reported indices of ventricular systolic function are shortening fraction and ejection fraction. Shortening fraction (SF) represents the percent of change in left ventricular diameter during the cardiac cycle. This is calculated using the following equation:

$$\text{SF (\%)} = (\text{LVED dimension} - \text{LVES dimension} / \text{LVED dimension}) \cdot 100$$

Values range from 28% to 44%, with a normal mean value of 36%. This index, however, depends on ventricular preload and afterload.

Ejection fraction (EF) is the fraction of blood ejected by the ventricle (stroke volume) relative to its end-diastolic volume. This represents the percentage of blood ejected from the left ventricle with each heart beat. Ejection fraction is derived by volumetric analysis of the left ventricle by means of the following equation:

$$\text{EF (\%)} = (\text{LVEDV} - \text{LVESV} / \text{LVEDV}) \cdot 100$$

In the equation, LVEDV is the left ventricular end-diastolic volume, and LVESV is the left ventricular end-systolic volume. Normal values range between 56% and 78%. A low ejection fraction is associated with systolic functional impairment, but cardiac dysfunction may occur in the presence of a normal ejection fraction. Such may be the case of a child with diastolic heart failure.

Although these functional indices are routinely and easily obtained, they have significant limitations. Estimation of ejection fraction is based on geometric assumptions for the elliptical left ventricle, and this may not be applicable to a systemic right ventricle or other types of ventricular geometries.<sup>285</sup> This accounts

for an escalating interest in alternative approaches that may provide more sensitive and comprehensive information regarding ventricular performance, even in the absence of clinical disease. These techniques include the myocardial performance index (MPI), also known as the Tei index, which combines systolic and diastolic intervals to assess global ventricular function<sup>286-288</sup>; Doppler tissue imaging (DTI), which is used to evaluate intramural myocardial velocities<sup>289</sup>; and strain and strain rate imaging to quantitate the rate of segmental myocardial deformation.<sup>290</sup> Although values in normal children have been established for these imaging modalities and alterations in the presence of pathologic conditions have been described,<sup>291,292</sup> additional studies documenting their clinical applications in specific types of cardiovascular pathology are needed.

#### *Estimation of Pressures*

The peak velocity of a tricuspid regurgitant jet can be used to estimate right ventricular systolic pressure and pulmonary artery systolic pressure in the absence of pulmonary stenosis or outflow obstruction (Video 14-13). For example, if a peak regurgitant velocity of 3 m/sec is recorded across the tricuspid valve using the simplified Bernoulli equation, the pressure gradient or difference between the right atrial and right ventricular systolic pressures can be estimated to be  $4 \times 3^2 = 36$  mm Hg. If a normal right atrial pressure is assumed (4 to 6 mm Hg), it would predict a right ventricular systolic pressure of approximately 40 mm Hg. Similarly, if the peak or maximal flow velocity across a ventricular septal defect is measured at 4.5 msec, it predicts a pressure gradient of  $4 \times 4.5^2 = 81$  mm Hg between the ventricles, implying that the defect is pressure restrictive and the right ventricular and pulmonary artery systolic pressures are relatively low.

#### *Evaluation of Gradients*

Estimation of a peak instantaneous gradient is the most clinically useful method for quantifying the severity of obstructions across semilunar valves and outflow tracts. It is derived by application of the simplified Bernoulli equation. When obtained across the pulmonary valve, these estimates tend to have a better correlation with catheterization peak-to-peak gradients than those measured across the aortic valve, for which mean gradients (obtained by automated integration of the velocities under a spectral Doppler tracing) have been shown to have a greater correlation.<sup>293</sup> The mean gradient rather than a peak gradient determined by Doppler echocardiography is considered a better indicator of the severity of the obstruction across AV valves and other low-flow venous pathways.

#### *Evaluation of Regurgitant Lesions*

Evaluation of the severity of regurgitant lesions in most pediatric cardiac centers remains largely a qualitative assessment. It is usually characterized as mild, moderate, severe, or a combination thereof when there is overlap among these categories. Serial echocardiographic assessments and comparative data are clinically more meaningful than an isolated report.

### MAGNETIC RESONANCE IMAGING

Cardiovascular MRI-angiography has emerged as a complementary technology to other imaging modalities (Videos 14-14 and 14-15). Benefits have been reported in the assessment of complex pathology,<sup>294-300</sup> delineation of systemic and pulmonary vascular anomalies,<sup>299,300</sup> evaluation of global and regional ventricular function,<sup>301</sup> assessment of myocardial viability,<sup>302</sup> and

**FIGURE 14-32** Computed tomography images show the aortic arch anatomy in an infant with severe aortic arch obstruction (arrows).

characterization of pulmonary blood supply in children with structural alterations of the pulmonary vascular tree.<sup>303</sup> Additional applications that may further expand the utility of cardiovascular MRI include the quantification of left-to-right shunts<sup>304-306</sup> and measurement of blood oxygen saturation.<sup>307</sup> MRI is beneficial for guiding interventions in pediatric heart disease.<sup>308-310</sup>

Although the temporal resolution of MRI is inferior to echocardiography, new sequences and techniques allow real-time acquisition similar to that of fluoroscopy. An important aspect in the acquisition of MRI data with high spatial resolution is the use of cardiac and respiratory gating to allow sampling during only specific portions of the cardiac and respiratory cycles. Slow heart rates and low respiratory rates facilitate this process. MRI, in contrast to computed tomography (CT), does not involve radiation exposure, making it preferable for serial examinations that many young children with cardiovascular pathology require. However, this may be associated with the need for multiple episodes of anesthesia and their inherent risks.

Because of the nature of the magnetic fields generated in MRI, the presence of several types of metal, including pacemakers, ICDs, cerebrovascular clips/coils, or recently implanted intracardiac or intravascular coils and devices, are considered contraindications. Titanium hardware may minimize the artifact produced by the foreign material; stainless steel generates significant artifacts within the study.

An additional limitation of MRI is the need for patient immobility during long examinations for optimal image quality. For small children, this requirement usually necessitates the use of deep sedation or general anesthesia.<sup>311-313</sup> For infants with complex and often cyanotic CHD, specialists are often asked to provide care during the procedures. The severity of the cardiovascular disease and the need for breath holding may add to the challenges presented to the anesthesia care provider in a remote location.<sup>314,315</sup> The lengthy nature of the studies and the significant time requirements to perform postprocessing of the images cause MRI to be much more time intensive for the interpreting physician than other noninvasive imaging modalities.

A significant advantage of this technique is avoidance of harmful radiation inherent to traditional catheterization techniques. As MRI technology improves, with faster scans, increasing availability, and decreasing cost, it will continue to play an increasing role in the diagnosis and longitudinal follow-up of congenital and acquired pediatric heart disease.

### COMPUTED TOMOGRAPHY

Cardiac CT, with or without electrocardiographic gating, has become an option among the various cardiovascular imaging modalities (Fig. 14-32).<sup>294,298,316,317</sup> The major advantage of CT over MRI is the very rapid scan times, and for most children, sedation is minimal or unnecessary. A significant drawback of CT is the large radiation burden, although typically estimated to be similar to or slightly greater than a diagnostic cardiac catheterization, and the likely need for iodinated contrast agents with their concomitant risks.

Cardiac CT is not as accurate as MRI for delineation of intracardiac anatomy, but it provides excellent spatial resolution and information on extracardiac structures. CT has been beneficial in the evaluation of aortic arch anomalies and vascular rings and for defining systemic and pulmonary venous returns. In adult patients, multislice CT provides excellent information on coronary arteries and the presence of atherosclerotic disease; in infants and children with smaller vessels and more rapid heart rates, these images are more difficult to obtain.

### CARDIAC CATHETERIZATION AND ANGIOGRAPHY

Cardiac catheterization involves the invasive measurement of intracardiac and vascular pressures and blood oxygen saturation coupled with angiography to assess cardiac anatomy and hemodynamics (Figs. 14-33 and 14-34). Before the era of two-dimensional echocardiography, cardiac catheterization was frequently used for diagnostic purposes. With the advances in noninvasive imaging, diagnostic procedures represent a relatively small proportion of these studies. Current indications for cardiac catheterization at most centers include the assessment of physiologic parameters such as pressure and resistance data, anatomic definition when other diagnostic modalities are inadequate, need for electrophysiologic testing or treatment, and when interventions are anticipated.

Most catheterizations are performed for interventions, including endomyocardial biopsies; angioplasties and stenting of stenotic vessels, dilation of valves, and conduits; and occlusion techniques for native defects, fistulous connections, and surgically created defects no longer considered necessary (Fig. 14-35, Video 14-16) (see Chapter 20). In some cases, such as critically ill neonates with complex heart disease, catheter-based interventions such as balloon atrial septostomy and other procedures can be lifesaving.

Weight 3.3 kg

#### Diagnosis

1. Heterotaxy
2. Dextrocardia
3. Complete atrioventricular canal
4. Double-outlet right ventricle
5. Pulmonary stenosis, severe
6. L-Transposition of the great arteries
7. Interrupted inferior vena cava with azygous continuation
8. After innominate to main pulmonary artery shunt
9. Right pulmonary artery isolation

**FIGURE 14-33** A cardiac catheterization diagram is valuable when caring for patients with structural anomalies, such as this child with complex congenital heart disease. Data routinely obtained at cardiac catheterization are shown, including oxygen saturation determinations (in %), pressure measurements (in mm Hg), and hemodynamic calculations. Catheter courses are indicated by arrows. The atrial pressures are given for the a wave (a), which represents the atrial systole; v wave (v), which represents the end of systole (rise in atrial pressure before atrioventricular valve opening); and mean (m), all in mm Hg. See section on "Interpretation of a Cardiac Catheterization Report," this page.

In most children, access to the central circulation is accomplished percutaneously through a femoral approach. Most examinations involve hemodynamic evaluation with recording of pressure data through catheters positioned at various sites of interest. Oxygen saturation data are obtained by reflectance oximetry or blood gas measurement from various cardiac chambers and vessels. In contrast to the oxygen saturation calculations derived from a blood gas analysis, reflectance oximetry provides measured values. This allows determination of oxygen content (i.e., total amount of hemoglobin in the blood) and, when combined with values of oxygen consumption, assessment of blood flows and other calculations (e.g., shunts).<sup>318</sup> Additional data that may be obtained include pressure gradients, cardiac output, and parameters for deriving vascular resistances and valve areas.

Fluoroscopy and cineangiography are essential components of most cardiac catheterization studies. Of the two, cineangiography accounts for most of the radiation exposure as images are recorded during the injection of contrast material, typically at 15 or 30 frames/sec.<sup>319</sup> Most angiograms are obtained during biplane imaging by positioning the equipment to obtain optimal views allowing for delineation of the pathology in question (i.e., axial angiography) (Video 14-17, *A* and *B*).<sup>320,321</sup>

Although cardiac catheterization has evolved over the years, providing an improved margin of safety, it remains an invasive procedure involving several risks. They include excessive blood loss, vascular complications,<sup>322,323</sup> infection, arrhythmias, vascular or cardiac perforation,<sup>324</sup> systemic air embolization, myocardial ischemia, and those associated with the administration of contrast agents. These complications are more likely in infants and small children.<sup>325</sup> Interventional catheterizations, by the nature of the procedures, are associated with a greater rate of complications and greater potential for morbidity and mortality. However, as transcatheter interventions become safer and more effective, an increasing number of children may obviate the need for surgery, often undergoing procedures on an outpatient basis.<sup>326</sup> Evolving approaches in this field include percutaneous implantation of valves,<sup>327</sup> strategies that combine cardiac catheterization and surgical intervention (hybrid procedures),<sup>328-330</sup> and catheter-based interventions during fetal life.<sup>331</sup>

#### Interpretation of a Cardiac Catheterization Report

##### Pressure Data

Atrial pressure tracings are characterized by several waves (a, c, and v waves) and descents (x and y). Reported values correspond to the a and v waves and the mean pressures. The right atrial pressure is typically a wave dominant. The mean right atrial pressure is normally less than 5 mm Hg. In the presence of significant tricuspid valve regurgitation or a junctional rhythm, the v wave becomes the dominant wave. The left atrial pressure tracing, in contrast to the right atrium, displays v wave dominance, which is accentuated during mitral regurgitation. The mean left atrial pressure rarely exceeds 8 mm Hg.

Ventricular pressures are recorded and reported during systole, at end systole, and at end diastole. For the right ventricle the systolic pressure is normally in the 25 to 30 mm Hg range, with end-diastolic pressure of 5 to 7 mm Hg. The systolic pressure in the left ventricle normally increases with age and should equal the systolic arterial pressure; the end-diastolic pressure is typically less than 10 mm Hg.

The pulmonary artery pressure is reported in terms of systolic, diastolic, and mean pressures. The systolic pulmonary artery pressure in a normal child should be equal to the right ventricular systolic pressure, and the mean pulmonary artery pressure should not exceed 20 mm Hg. The pulmonary artery wedge pressure is obtained by advancing a catheter into a distal vessel until it is occluded, reflecting the left atrial pressure.

The aortic pressure and contour of the tracing depends on the site of interrogation. Typically, there is an increase in the systolic pressure as the catheter navigates toward the peripheral circulation. This phenomenon is known as *pulse wave amplification*.

Pressure gradients, or the pressure differences between two distinct sites, can be measured in several ways (i.e., mean gradient and peak gradient). It is important to consider that several factors may affect their determination. This is significantly influenced by the severity of the obstruction and the ventricular function. Smaller gradients may be seen under sedation or anesthesia.

**FIGURE 14-34** In the hemodynamic tracing obtained during cardiac catheterization, notice that the pulmonary artery systolic pressure (100 mm Hg) is at systemic levels in this child with multiple, left-sided obstructions. ART, Systemic arterial pressure; PA, pulmonary artery pressure.

**FIGURE 14-35** Several types of interventions are performed in a pediatric cardiac catheterization laboratory. **A**, Balloon atrial septostomy. **B**, Blade atrial septostomy. **C**, Double-balloon mitral valvuloplasty. **D**, Placement of a ductal coil occluder device. **E**, Transcatheter closure of a secundum atrial septal defect. **F**, Pulmonary artery dilation with stent placement.

### Shunt Calculations

Shunts are characterized in terms of their direction (e.g., left-to-right, right-to-left, bidirectional) and magnitude. Left-to-right shunts can be quantified based on the pulmonary ( $\dot{Q}_{\text{pulm}}$ ) to systemic ( $\dot{Q}_{\text{sys}}$ ) blood flow ratio. In the equation,  $S_{\text{sys}}\text{aO}_2$  is the systemic arterial  $\text{O}_2$  saturation,  $\text{S}\bar{\text{v}}\text{O}_2$  is the mixed venous  $\text{O}_2$  saturation,  $S_{\text{pulm}}\text{vO}_2$  is the pulmonary venous  $\text{O}_2$  saturation, and  $S_{\text{pulm}}\text{aO}_2$  is the pulmonary arterial  $\text{O}_2$  saturation.

$$\frac{\dot{Q}_{\text{pulm}}}{\dot{Q}_{\text{sys}}} = \frac{(S_{\text{sys}}\text{aO}_2 - \text{S}\bar{\text{v}}\text{O}_2)}{(S_{\text{pulm}}\text{vO}_2 - S_{\text{pulm}}\text{aO}_2)}$$

A  $\dot{Q}_{\text{pulm}}/\dot{Q}_{\text{sys}}$  ratio that exceeds 3 to 1 is considered a significant shunt, although smaller ratios may be associated with considerable symptoms.

### Cardiac Output Determinations

The volume of blood ejected by the heart into the systemic circulation, or cardiac output, can be derived in several ways. Thermodilution measurements use saline as an indicator to measure pulmonary blood flow. In the absence of intracardiac shunts, this is equivalent to cardiac output (expressed as liters per minute). In the Fick method, oxygen is used as an indicator, and cardiac output is obtained by the application of the following formula:

$$\dot{Q}_{\text{sys}} (\text{L/min}) = \frac{\dot{V}\text{O}_2 (\text{L/min})}{C_{\text{sys}}\text{O}_2 - C\bar{\text{v}}\text{O}_2}$$

In the equation,  $\dot{V}\text{O}_2$  is the oxygen consumption (assumed or measured),  $C_{\text{sys}}\text{O}_2$  is the systemic arterial  $\text{O}_2$  content, and  $C\bar{\text{v}}\text{O}_2$  is the mixed venous  $\text{O}_2$  content. The  $\text{O}_2$  content =  $\text{O}_2$  saturation  $\times (1.36 \times 10 \times \text{hemoglobin concentration})$ .

### Vascular Resistances

Resistance represents the change in pressure in the systemic or pulmonary circulation with respect to flow. It is expressed in Wood units (mm Hg/L/min) and is usually normalized for body surface area. The systemic vascular resistance (SVR) and pulmonary vascular resistance (PVR) are derived as follows:

$$\begin{aligned} \text{SVR} &= (\text{aortic mean pressure} - \text{right atrial mean pressure}) / \dot{Q}_{\text{sys}} \\ \text{PVR} &= (\text{pulmonary artery mean pressure} \\ &\quad - \text{pulmonary capillary wedge pressure} \\ &\quad \text{or left atrial pressure}) / \dot{Q}_{\text{sys}} \end{aligned}$$

## Perioperative Considerations for Children with Cardiovascular Disease

### GENERAL ISSUES

Anesthesia for children with heart disease<sup>332</sup> is challenged by the following factors:

- The remarkable spectrum of disease
- The wide range of congenital lesions and their underlying physiologic consequences
- The numerous interventional and surgical options in CHD (Table 14-6), in addition to their hemodynamic implications
- The fact that many parents are unaware of the full extent or details of the child's lesion or abnormalities

To optimally care for these children, the following objectives should be met:

- Familiarity with the cardiovascular defects

- Understanding of the physiologic abnormalities and available therapies
- Recognition of compensatory mechanisms, signs of limited reserve, and potential perioperative risks<sup>333</sup>
- Ability to identify the potential impact of the proposed intervention/surgical procedure on the child's underlying condition and anticipate how it will be tolerated

This combination of daunting challenges and difficult objectives can be intimidating even for the most experienced clinician. When caring for children with cardiovascular disease, an interdisciplinary approach is recommended, allowing for the formulation and execution of optimal individualized management plans. If available, consultation with the child's cardiologist or primary care physician should include inquiries about the details of the child's disease, overall clinical status, past and current medical treatment, prior catheterization or surgical interventions, and presence of residual pathology. The interaction between members of the perioperative team should allow an exchange of information, discussion of concerns, and recommendations that may facilitate patient care and the development of comprehensive care plans.<sup>334</sup> This is particularly important in the management of children with complex disease.

A complete medical history and focused examination is essential during the preoperative assessment. In addition to evaluating the child's disease processes, overall clinical status, and functional reserve, this allows appraisal of issues that may affect anesthesia management (e.g., limited vascular access, difficult airway, gastroesophageal reflux, manipulations to manage pulmonary and systemic blood flow and pressures). Available diagnostic studies (e.g., ECG, chest radiograph, echocardiogram, Holter monitor, cardiac catheterization) should be reviewed. Depending on the nature of the procedure, complexity of the disease, and potential impact on perioperative outcome, additional evaluation and diagnostic studies may be warranted. In many cases, the anesthesiologist plays a major role in determining whether the available information is adequate.

A fundamental goal in the preoperative evaluation is the identification of children who are at increased risk because of cardiac and pulmonary limitations imposed by their cardiovascular disease. After the preoperative visit, the anesthesiologist caring for a child with CHD should have an understanding of the pathophysiology of the cardiac defect and implications of any previous interventions. Abnormal indices that should raise potential concerns include hypoxemia ( $\text{SpO}_2$  less than 75%),  $\dot{Q}_{\text{pulm}}/\dot{Q}_{\text{sys}}$  exceeding 3 to 1, outflow tract gradients greater than 50 mm Hg, pulmonary hypertension (i.e., mean pulmonary artery pressure above 30 mm Hg), increased pulmonary vascular resistance index (more than 2 Woods units/ $\text{m}^2$ ), or polycythemia (i.e., hematocrit greater than 60%). Several clinical states may place children at significant risk for severe cardiopulmonary decompensation during anesthesia and surgery: recent congestive heart failure, uncontrolled arrhythmias, severe ventricular dysfunction, unexplained syncope, substantial exercise intolerance, or any condition associated with significant functional cardiac or pulmonary impairment. For some children, a planned admission to the intensive care unit (with or without a tracheal tube) should be discussed with the parents, child, and whole care team.

### CLINICAL CONDITION AND STATUS OF PRIOR REPAIR

Children with CHD may present for anesthesia care before or after palliation or for definitive procedures. Corrective

**TABLE 14-6** Surgical Procedures for Congenital Heart Disease

Procedure	Description	Goal or Result
Arterial switch (Jatene) operation	Arterial trunks transected above the level of the semilunar valves, relocated to their appropriate respective ventricles, coronary arteries reimplanted into the neo-aortic root	Establishes the normal ventricular-arterial connection (right ventricle to pulmonary artery and left ventricle to aorta) in transposition of the great arteries
Atrioventriculoseptal defect (atrioventricular canal) repair	Patch closure of atrial and ventricular communications, reconstruction of atrioventricular valves, closure of cleft in left-sided atrioventricular valve	Eliminates the intracardiac shunt
Blalock-Taussig shunt	Subclavian artery to pulmonary artery communication; modified implies placement of a graft	Allows or increases pulmonary blood flow
Central shunt, Waterston shunt, Pott shunt	Creation of communication between systemic and pulmonary circulations	Allows or increases pulmonary blood flow
Closure of septal defects	Patch or primary closure of communications at the atrial or ventricular levels	Eliminates the intracardiac shunt
Coarctation repair	Relief of aortic arch obstruction (various approaches)	Establishes patency across the aortic arch
Damou-Kaye-Stansel procedure	End-to-side anastomosis of main pulmonary artery onto the aorta; necessitates reestablishing pulmonary blood flow through an alternative route (graft from a systemic artery into the pulmonary artery or a right ventricular to pulmonary artery conduit)	Allows unobstructed systemic outflow in the context of single ventricle associated with obstruction to aortic flow or other settings
Division or ligation of a patent ductus arteriosus	Obliteration of the ductus arteriosus	Eliminates shunting at the level of the great arteries
Fontan procedure	Connection that directs inferior vena cava blood into the pulmonary circulation	Separates the pulmonary and systemic circulations in patients with single ventricle physiology; usually the final step in the single-ventricle palliation pathway
Glenn anastomosis (cavopulmonary connection)	Superior vena cava to pulmonary artery direct anastomosis (bidirectional implies flow from superior vena cava into both pulmonary arteries)	Provides pulmonary blood flow while unloading the single ventricle; may be the first or intermediate step in the single-ventricle palliation pathway
Konno-Rastan procedure (aortopulmonary anastomosis)	Enlargement of the left ventricular outflow tract and aortic annulus; defect created in the ventricular septum to enlarge the outflow tract repaired with a large patch	Alleviates subvalvar and valvar aortic obstruction; when the aortic root is replaced by an autologous pulmonary root, it is referred to as a Ross-Konno procedure. Alternatively, cryopreserved homograft tissue may be used in the form of an extended aortic root replacement.
Norwood procedure (stage I palliation)	Involves aortic reconstruction, an atrial septectomy, and placement of a systemic-to-pulmonary artery shunt	Addresses systemic outflow tract obstruction by allowing the right ventricle to eject into a reconstructed aorta. Atrial septectomy provides unobstructed drainage of the pulmonary venous return into the right atrium. The systemic-to-pulmonary artery shunt supplies the pulmonary blood flow.
Pulmonary artery banding	Constrictive band placed around the main pulmonary artery	Limits excessive pulmonary blood flow
Rastelli operation	Creation of an intracardiac tunnel that allows left ventricular output into the aorta while closing a ventricular septal defect and placement of a right ventricular conduit to pulmonary artery	Allows the left ventricle to eject solely into the aorta, abolishes intracardiac shunting at the ventricular level, and provides unobstructed pulmonary blood flow. The procedure results in separation of the pulmonary and systemic circulations.
Sano modification of the Norwood procedure	Placement of graft between the right ventricle and main pulmonary artery as an alternative to a modified Blalock-Taussig shunt in the Norwood operation	Provides pulmonary blood flow
Senning or Mustard procedure (atrial switch)	Intraatrial baffle procedure	Allows pulmonary venous blood to be rerouted through the tricuspid valve into the right ventricle (as the systemic chamber that ejects into the aorta). Systemic venous return is channeled across the mitral valve into the left ventricle, which pumps into the main pulmonary artery.
Tetralogy of Fallot repair	Closure of ventricular septal defect and relief of right ventricular outflow tract obstruction	Eliminates intracardiac shunting at the ventricular level (cyanosis) and addresses right ventricular outflow tract obstruction (often at several levels)
Truncus arteriosus repair	Closure of the ventricular septal defect and establishment of right ventricular to pulmonary artery continuity (usually with a homograft)	Abolishes intracardiac shunting and restores the normal connection between the ventricles and great arteries
Valvectomy	Valve excision	Relieves valvar obstruction
Valvotomy	Opening of stenotic valve	Relieves valvar obstruction
Valve replacement	Placement of bioprosthetic or mechanical valve	Addresses valvar pathology (obstruction and regurgitation)
Valvuloplasty	Valve repair	Relieves valvar regurgitation and stenosis

procedures are those that result in a normal life expectancy and full cardiovascular reserve.<sup>335</sup> Children undergoing these interventions usually require no further medical or surgical treatment. In the strict sense, only a few procedures fulfill these criteria: ligation, division, or occlusion of a PDA and closure of an isolated secundum ASD. Other interventions or surgical procedures may result in repair or correction but not necessarily in normal hemodynamics or life expectancy. The clinician should assume some limitation in cardiovascular reserve, a need for close follow-up, further medical management, and potential or additional surgical therapies. In other cases, as in children with palliated CHD, the circulation may still be abnormal. These individuals have been reported to be at greater risk for adverse perioperative events.<sup>336-338</sup> Published data from the Pediatric Perioperative Cardiac Arrest (POCA) Registry examined anesthesia-related cardiac arrests in children with congenital and acquired heart disease.<sup>339</sup> Compared with other children, cardiac arrests were found to occur more frequently in children with heart disease. Causes were primarily cardiovascular in nature. These events occurred more frequently in the general operating room, usually during the surgical maintenance phase. The most common anatomic substrate in this setting was that of a single ventricle, particularly those early in the palliation pathway. The overall mortality rate for children with heart disease was greater than those without heart disease, with the greatest mortality rate occurring in children with aortic stenosis and cardiomyopathy.

The effects of previous procedures on the heart and other systems require careful consideration. Problems may remain or develop after surgical intervention include residual shunts, valvar stenoses or outflow tract obstruction, valvar regurgitation, pulmonary hypertension, arrhythmias, and ventricular dysfunction. Children who require a detailed appraisal of perioperative risks include those with residual significant pathology, suspected or known pulmonary hypertension, or single-ventricle physiology and those after conduit placement or cardiac transplantation (see Chapters 15, 16, and 21).

## Summary

Caring for children with heart disease is a major aspect of pediatric anesthesia practice. The spectrum of cardiovascular disease includes a wide range of structural defects and varied acquired diseases. The ability to provide optimal perioperative care heavily relies on a clear understanding of the basic pathophysiology of the lesions (e.g., how a red cell gets from here to there); familiarity with the commonly used diagnostic modalities and their clinical applications; and medical and surgical treatment options available to affected individuals. In this chapter, we have presented basic concepts in cardiology that can enhance the overall knowledge of the practicing anesthesiologist in pediatric cardiovascular disease.

## ACKNOWLEDGMENT

We wish to thank Timothy C. Slesnick, MD, for his prior contributions to this chapter.

- Bai W, Voepel-Lewis T, Malviya S. Hemodynamic changes in children with Down syndrome during and following inhalation induction of anesthesia with sevoflurane. *J Clin Anesth* 2010;22:592-7.
- The retrospective study evaluated whether children with Down syndrome (n = 96) are at increased risk for bradycardia and hypotension during and after sevoflurane induction. The investigation reported a significantly higher prevalence and degree of bradycardia in children with Down syndrome during and after sevoflurane induction. Despite these findings, there were no differences between Down syndrome and control groups in the prevalence of hypotension or pharmacologic interventions.*

- This article focuses on the benefits of three-dimensional echocardiography; the realistic, unique, and comprehensive views of cardiac valves and congenital abnormalities; and the utility of this method in the intraoperative and postoperative settings.*
- Murphy T, Smith J, Ranger M, et al. General anesthesia for children with severe heart failure. *Pediatr Cardiol* 2011;32:139-44.
- This retrospective study examined the frequency of complications during anesthesia for short noncardiac surgical interventions or diagnostic procedures in children with severe heart failure. Two children (10%) of the 21 who underwent 28 procedures requiring general anesthesia experienced a cardiac arrest, requiring unplanned intensive care admission. In 27 (96%) of the 28 anesthesia procedures, perioperative inotropic support was required. The study authors concluded that general anesthesia for children with severe heart failure was associated with a significant complication rate.*

## Preoperative Evaluation

In the United States, 40,000 children are born each year with congenital heart disease (CHD),<sup>1</sup> representing an incidence of 6 to 8 cases per 1000 live births.<sup>2</sup> Children with chromosomal abnormalities such as trisomy 21 (i.e., Down syndrome) have a greater incidence of CHD. Having a sibling with CHD increases the risk of CHD, as does the presence of other congenital abnormalities.<sup>3</sup> With improving diagnostic techniques, many children with CHD are diagnosed in the antenatal or early postnatal period. Associated with this improvement in diagnostic ability is a trend in most centers to undertake definitive repair earlier, with many patients undergoing corrective surgery in the neonatal period. Overall, about one half of all children with CHD undergo cardiac surgery in the first year of life, and about 25% undergo surgery in the first month of life.<sup>4,5</sup>

The perioperative management of children with complex cardiac defects requires a dedicated team of surgeons, cardiologists, anesthesiologists, intensivists, perfusionists, and nurses. Anesthesiologists caring for these children are challenged by some of the greatest physiologic aberrations encountered in clinical medicine. The anesthesiologists responsible for the care of these children require a comprehensive understanding of cardiac physiology and pathophysiology. The anesthesiologist must be able to adapt to each nuance of rapidly changing pathophysiology as it is encountered.

In addition to treating children with CHD, the pediatric cardiac anesthesiologist may also be responsible for the care of

adults with CHD. This patient population with “grown-up CHD” is expanding as more children with CHD survive to adulthood. Along with CHD, they have some of the comorbidities of older age. The ideal approach for this group of patients is to be cared for in specialist units, but few are available. In the meantime, the care of these patients may fall to the most qualified physicians and the pediatric cardiac anesthesiologist. Some children have acquired rheumatic heart disease, some have cardiomyopathy, and others have undergone heart transplantation and require care from specialists.

For managing children with complex cardiac defects, there is increasing reliance on echocardiography and magnetic resonance imaging (MRI) to acquire diagnostic data. Although fewer children are being subjected to diagnostic angiography, more interventional cardiac catheterization procedures are being performed. Many conditions that would previously have been treated surgically are now treated in the angiography suite by interventional cardiologists, such as atrial septal defects (ASDs), patent ductus arteriosus (PDA), and ventricular septal defects (VSDs). Other interventions include dilating arteries with balloon catheters with and without stents and coiling of aberrant or excessive collateral vessels. The pulmonary artery is commonly balloon dilated and stented, and coarctation of the aorta is treated similarly by balloon dilation. Stenotic valves are also commonly dilated. These procedures have led to the risk being transferred from the angiography suite to the operating room.<sup>6</sup> For the individual child, there has been a dramatic decrease in morbidity as

increasing numbers of conditions are treated in the angiography suite, but the risks of complications that occur in the angiography suite have increased as more complex procedures are performed (see Chapter 20).

### THE PREOPERATIVE VISIT AND EVALUATION

The preoperative visit is an important part of the overall management of anesthesia for children with CHD.<sup>7</sup> The preoperative visit has several aims:

- Medical assessment
- Prescribing premedication
- Providing information
- Creating a relationship with the child and family
- Formulating an anesthetic plan

#### Medical Assessment

The anesthesiologist must have a clear and detailed understanding of the cardiac pathophysiology, the surgery to be undertaken, and associated congenital abnormalities or medical conditions. The medical assessment includes collation of information from the history, physical examination, and review of imaging and laboratory data. Most diagnostic information is obtained from the medical record. Particular attention should be paid to the echocardiographic, MRI, angiographic, and other imaging data; the chest radiograph; and the electrocardiogram. Many centers have joint cardiac conferences where decisions about treatment are discussed in a multidisciplinary forum. Reports from these meetings are valuable in the preoperative assessment.

In addition to gathering this specific diagnostic information, a directed history and physical examination should be performed to assess the overall condition of the child. Attention should be directed toward assessing the degree of cardiac failure, cyanosis, or risks of pulmonary hypertension and the prior surgical procedures and how this information may alter access to the central circulation and placement of invasive monitors. The general nutritional state of the child should be assessed; poor growth and development may be a sign of severe CHD. Other information should be sought that may have a bearing on the anesthetic plan. For example, is this repeat surgery, and does it require a repeat sternotomy? This has a bearing on line placement because a femoral bypass may be required, and it should be avoided for line placement. The previous use of aprotinin is important because the risk of anaphylaxis is increased in a second exposure and particularly if it has been given in the previous 6 months.<sup>8</sup>

The type of surgery to be performed is important. For example, if a Blalock-Taussig shunt is placed on the left, the arterial line should not be placed in the left arm because the trace will be lost or distorted during subclavian cross-clamping. If a Glenn shunt is planned, a short internal jugular line can be useful to monitor pulmonary artery pressure, but it should be removed early in the postoperative period so as not to risk the formation of thrombosis in the superior vena cava (SVC).

Good veins should be sought and marked for the application of local anesthetic cream. This is useful in sick children even if an inhalational induction is planned because it allows placement of a venous cannula during a very light plane of anesthesia and avoids myocardial depression from high concentrations of inhalation anesthetics.

#### Prescribing Premedication

The use of sedative premedication can be useful in cardiac anesthesia, but this practice varies widely. Numerous medications

may be used, and numerous recommendations exist. Premedication for infants younger than 6 months of age is usually unnecessary. Premedication for older, healthy children who show little anxiety and with whom good preoperative rapport can be established is often unnecessary. However, older children, particularly those who have undergone previous surgery, have fears about anesthesia and surgery. It is important to address the fears of these children. Sedative premedication may play a pivotal role in achieving adequate anxiolysis for separation from the parents and induction of anesthesia. I prefer to avoid premedication in children with severe congestive heart failure. Cyanotic children such as those with tetralogy of Fallot (TOF) often benefit from sedative premedication because crying and struggling during induction of anesthesia may worsen their cyanosis. However, it is important that these cyanotic children are well supervised after premedication because they have a blunted response to hypoxia.<sup>9</sup> In the United States, supplemental premedication is sometimes administered under the direct supervision of the anesthesiologist in the preoperative facility, providing for a calm child and gentle separation from the parents. In the United Kingdom, where induction of anesthesia takes place in a dedicated anesthesia room, parents are present until after the induction, often making additional premedication unnecessary.

The most common premedication is oral midazolam (0.5 to 1.0 mg/kg).<sup>10</sup> However, the effect of midazolam may be unpredictable and may cause dysphoria. Numerous other medications have been recommended for this purpose, including ketamine, clonidine, temazepam, and chloral hydrate. The use of these drugs is often dictated by local preferences and is not always evidence based.

#### Giving Information

Providing information to the parents and to the child if they are capable of understanding is a key element of the preoperative visit. This information includes the use of sedative premedication, the type of induction, fasting times, the type and likely position of invasive lines, the need for a stay in an intensive care unit (ICU) postoperatively, and the expected length of that stay. The use of other monitors such as transesophageal echocardiography (TEE) should be outlined and any contraindications sought, along with the probability of needing a blood transfusion. Questions about the risk of anesthesia and surgery should be addressed to the satisfaction of the parents (see Chapter 4).

#### Creating Rapport with the Child and Family

By creating a good relationship with the family, the anesthesiologist can reduce the anxiety of the child and the parents. The family develops a sense of trust, which can improve their hospital experience.

#### Formulating an Anesthetic Plan

After assessing the patient, it is possible to formulate a detailed anesthetic plan.

### UPPER RESPIRATORY TRACT INFECTION AND CARDIAC SURGERY

Otherwise healthy children undergoing elective noncardiac surgery in the presence of an upper respiratory infection (URI) are more likely to suffer respiratory complications (Table 15-1). These complications typically are minor, are easily managed, and usually result in minimal morbidity.<sup>11-13</sup> The decision about

**TABLE 15-1** Diagnosis of Upper Respiratory Tract Infection

At least two of the following signs plus confirmation by a parent:
Rhinorrhea
Sore or scratchy throat
Sneezing
Nasal congestion
Malaise
Cough
Fever >100.4° F (38° C)

Data from Schreiner MS, O'Hara I, Markakis DA, Politis GD. Do children who experience laryngospasm have an increased risk of upper respiratory tract infection? *Anesthesiology* 1996;85:475-80.

whether to proceed with noncardiac surgery in a child with a URI is made on an individual basis.<sup>14</sup>

The decision to proceed with cardiac surgery in children is difficult. Although children with cardiac failure are prone to multiple URIs, they may also have signs that can mimic URIs. Surgery may be relatively urgent, and postponing surgery exposes the child to an increased risk. Cardiac surgery in children with URIs results in a prolonged stay in the ICU and prolonged ventilation times, although overall hospital stay is not prolonged. There is an increased incidence of pulmonary atelectasis and an increase in postoperative bacterial infections. There appears not to be any statistically significant increase in mortality rates (4.2% with URIs versus 1.6% without URIs) or long-term sequelae in children with URIs who undergo cardiac surgery. The URI group was significantly younger and smaller, which may account in part for the greater but statistically insignificant increased mortality rate.<sup>15</sup> Although this increase in mortality was not statistically significant, it does raise concerns about the risks posed by URIs before cardiac surgery. Children who are scheduled for a Glenn shunt or completion of the Fontan circulation may be at particular risk because an increase in pulmonary vascular resistance (PVR) can adversely affect outcome. It is prudent to postpone surgery in a child with a URI who is scheduled for elective cardiac surgery. If the surgery is urgent, discussion with the surgical team is required to correctly assess the risks and benefits to the child.

## Perioperative Challenges in Pediatric Cardiac Anesthesia

### CYANOSIS

Children with cyanotic cardiac defects compensate for chronic hypoxia with increased erythropoiesis, increased circulating blood volume, vasodilation, and metabolic adjustments of factors, such as circulating 2,3-diphosphoglycerate (2,3-DPG). These changes allow greater tissue delivery of oxygen. The increase in blood viscosity with polycythemia leads to increased vascular resistance and sludging, which may result in renal, pulmonary, and cerebral thromboses, especially in dehydrated children.<sup>16</sup> Long periods without oral intake preoperatively and postoperatively should be avoided in children with polycythemia, unless adequate intravenous hydration is provided.

PVR increases more than systemic vascular resistance (SVR) with an increasing hematocrit, further decreasing pulmonary blood flow in children who already have a compromised pulmonary circulation. Coagulopathies are common in children with

cyanotic CHD and may adversely influence surgical hemostasis.<sup>17,18</sup> When the hematocrit exceeds 65%, excessive viscosity impairs microvascular perfusion and outweighs the advantages of increased oxygen-carrying capacity. Reduction of red blood cell volume can correct the coagulopathy and improve hemodynamics when increases in hematocrit are extreme.<sup>19</sup>

### INTRACARDIAC SHUNTING

In CHD, much of the pathophysiology involves communications between chambers or vessels that are normally separate, resulting in shunting of blood between ventricles, atria, the great arteries, or a combination of these, depending on the nature of the lesion. Management of shunting is a major consideration during anesthesia and requires an understanding of the factors that control shunting.

#### Restrictive and Unrestrictive Shunts

When communications are small, the size of the defect limits shunting and considerations of relative PVR and SVR become correspondingly less important in determining the amount of shunting. When there is a large pressure differential at the same level of the circulation on either side of a communication, the communication is restrictive. Flow is limited across the defect, and other factors determining shunt flow become less important. This is usually the situation in children with mild heart disease that is asymptomatic or minimally symptomatic, such as small ASDs and VSDs or a small PDA.

#### Dependent Shunting during Anesthesia

In children with dependent shunts, the direction and degree of intracardiac shunting are determined by the circulatory dynamics. Control of circulatory dynamics to minimize the shunt is a major goal of anesthesia management. Because shunting depends on the relationship between SVR and PVR, anesthesia management often revolves around control of relative vascular resistances.

In children with dependent right-to-left shunts, the shunt increases when SVR decreases or PVR increases. In children with dependent left-to-right shunts, the shunt increases when SVR increases and PVR decreases. In children with bidirectional or balanced shunting, changes in vascular resistance increase the net shunt away from the side with increased vascular resistance.

For practical purposes, acute increases in left-to-right shunts during anesthesia are of clinical importance in several situations. A substantial steal of systemic blood flow by the pulmonary circulation can occur in conditions such as atrioventricular (AV) canal, truncus arteriosus, and hypoplastic left heart syndrome. Left-to-right shunting is well tolerated, except when pulmonary steal leads to systemic hypotension, increasing acidosis or insufficient coronary perfusion. Shunting from right-to-left, because it is accompanied by at least some degree of arterial oxygen desaturation, is more frequently a problem during anesthesia.

### IMPAIRED HEMOSTASIS

Hemostasis is impaired after bypass in infants and children. This results from a combination of immature coagulation factor synthesis, hemodilution after bypass, and a complex interaction involving consumption of clotting factors and platelets. At birth, the levels of vitamin K-dependent coagulation factors in healthy, full-term neonates are only 40% to 66% of adult values. During the first month of life, these levels increase to 53% to 90% of adult values.<sup>20</sup> However, in children with CHD, especially those

with cyanosis or systemic hypoperfusion, coagulation factors often continue to be depressed due to impaired hepatic protein synthesis. Although antithrombin III levels are also low, true heparin resistance is rare in infants because of parallel decreases in coagulation factors.

At the onset of cardiopulmonary bypass (CPB), the introduction of the prime volume, which is two to three times greater than the child's blood volume, dilutes the factor concentrations, particularly fibrinogen, to 50% of values before bypass and the platelet count to 30% of values before bypass. This degree of dilution occurs even when the pump circuit is primed with whole blood. Greater dilution may occur when packed red cells are used in the priming volume. At the conclusion of neonatal bypass, the activity of clotting factors is often extremely low, the fibrinogen concentration is frequently less than 100 mg/dL, and the platelet count has been reduced to 50,000 to 80,000/mm<sup>3</sup>.<sup>21,22</sup> In addition to these quantitative changes, functional changes in the platelets occur during bypass. Extracorporeal circulation causes a loss of platelet adhesion receptors, activation of platelets, and formation of leukocyte-platelet conjugates. Platelet adhesion receptors are more depressed in children with cyanotic compared with acyanotic cardiac defects. Heparin also impairs platelet function independent of CPB.<sup>23</sup>

Cardiac surgery is associated with significant activation of the fibrinolytic system.<sup>24</sup> Inadequate heparin levels during CPB may also contribute to postoperative bleeding because inadequate anticoagulation may allow activation of the hemostatic pathways. Activation causes the consumption of platelets and clotting factors. The standard measurement of anticoagulation, the activated clotting time (ACT), shows a poor correlation with heparin levels in children undergoing CPB.<sup>25</sup> In one study, the use of heparin monitoring and heparin titration was associated with larger doses of heparin but smaller doses of protamine for antagonism.<sup>26</sup> Activation of clotting cascades is also reduced, decreasing bleeding in the postoperative period.<sup>26</sup> As a result of this multifactorial coagulopathy, blood loss is a greater problem in children than in adults and is a particular problem in neonates and small infants (see Chapter 17).<sup>27</sup>

### Strategies to Reduce Bleeding after Bypass

In an effort to normalize factors and platelets to effective concentrations, some medical centers use fresh whole blood in the cardiopulmonary circuit prime. In adult patients and an *in vitro* aggregation study, transfusion of fresh whole blood provided equal or greater hemostatic and functional benefit when compared with transfusion of platelet concentrates. In children, transfusion of fresh whole blood less than 48 hours from harvest is associated with less blood loss compared with transfusion of reconstituted whole blood (e.g., packed erythrocytes, fresh frozen plasma [FFP], and platelets).<sup>28</sup> However, fresh whole blood is often difficult to obtain. The units must be refrigerated for 24 to 48 hours while donor screening is performed, and storage causes significant platelet injury. Insistence on fresh whole blood places tremendous pressures on the transfusion service and donor center to coordinate the matching of donor types with recipient needs.

In practice, individual component therapy is used. In neonates and small infants with dilutional coagulopathy, platelets should be given in combination with cryoprecipitate to correct the defect in clotting. An initial dose of 10 mL of platelets/kg of body weight may need to be repeated. Platelets may be administered if bleeding persists and the platelet count is less than

100,000/mm<sup>3</sup>.<sup>29</sup> Cryoprecipitate contains high concentrations of fibrinogen, factor VIII, von Willebrand factor, and factor XIII. Fibrinogen and von Willebrand factor are required for platelet adhesion and aggregation to occur. Platelet adhesion and aggregation are the fundamental first steps in primary hemostasis (see Chapter 10). The subsequent step of platelet degranulation switches on the entire coagulation cascade and cannot take place without adhesion and aggregation.<sup>30</sup> Administration of FFP, for which there is no evidence of effectiveness in treating this type of coagulopathy, to the infant may excessively dilute the red cell mass and platelets.<sup>31</sup>

Transfusion guidelines have been described for adults and have been shown to reduce postoperative bleeding and transfusion requirements.<sup>32,33</sup> However, similar guidelines have not been forthcoming for children in whom the practice appears to be more empirical. This is a less than ideal situation, and more work is urgently needed to produce well-validated guidelines. The thromboelastogram and the platelet count may be used to identify which children are likely to bleed after cardiac surgery.

### Antifibrinolytics

The antifibrinolytics used in pediatric cardiac surgery include  $\epsilon$ -aminocaproic acid (EACA) and tranexamic acid (TA). In many countries, aprotinin is no longer available, and in other countries, it has only very limited availability after its marketing license was withdrawn due to safety concerns. EACA and TA are lysine analogues that reduce bleeding after cardiac surgery in adults and children.<sup>34,35</sup> They do not exert any antiinflammatory activity. Doses for pediatric cardiac surgery have not been clearly established.

Aprotinin is a serine protease inhibitor that has been studied thoroughly in adults. Early evidence demonstrated that it reduces bleeding, reduces the time taken to extubation, shortens ICU stay, and reduces overall mortality rates.<sup>36</sup> However, subsequent studies have contradicted these earlier findings.<sup>37</sup> The same volume of evidence has not been published for children, although several studies suggest that it is effective in reducing bleeding and that it reduces the time spent on the ventilator and in the ICU.<sup>38-41</sup> An increased risk of renal failure or stroke in adults undergoing revascularization surgery has been reported.<sup>42</sup> The same investigators reported an increase in the 5-year mortality rate for adults after the use of aprotinin in revascularization surgery.<sup>43</sup> Aprotinin has increased the 30-day mortality rate by as much as one third compared with TA or EACA.<sup>37</sup> Comparable data for children have not been forthcoming (see Chapter 18). Aprotinin is available for use in New Zealand, Australia, and Canada. It appears that the early data regarding increased death rates have not been supported by subsequent studies and that the benefits may outweigh risks in specific populations.<sup>44</sup>

### Topical Agents

The use of topical agents to promote clot formation and reduce bleeding in children after cardiac surgery is common. The most commonly used topical agents are fibrin sealants. Fibrin sealants mimic the stages of the blood coagulation process. Unlike the synthetic adhesives, they are biocompatible.<sup>45</sup> Fibrin sealants are usually sourced from plasma components, and most contain virally inactivated human fibrinogen and thrombin with different quantities of factor XIII, antifibrinolytic agents, and calcium.<sup>45</sup> When the fibrinogen and thrombin are mixed during the application process, the fibrinogen is converted to fibrin monomers. This results in the formation of a semirigid fibrin clot.

By mimicking the later stages of the coagulation process, these sealants stop bleeding and assist in wound healing.<sup>45</sup> They have significantly reduced bleeding in children.<sup>46</sup>

### Ultrafiltration

Ultrafiltration is a process that removes ultrafiltrate from a child during and after CPB. It provides many benefits, including increasing the hematocrit, concentrating the clotting factors and platelets, increasing blood pressure, reducing PVR, and removing inflammatory mediators in the ultrafiltrate. It has significantly reduced bleeding after cardiac surgery in children.<sup>47,48</sup>

### Desmopressin

Desmopressin acts by increasing plasma concentrations of factor VIII and von Willebrand factor. It has been effective in reducing bleeding after CPB in adult cardiac surgery.<sup>49</sup> Unfortunately, studies in children failed to demonstrate a similar effectiveness in reducing bleeding or transfusion requirements.<sup>50</sup>

## Anesthesia Management for Surgery Requiring Cardiopulmonary Bypass

### MONITORING

Noninvasive monitoring during pediatric cardiac surgery includes pulse oximetry, five-lead electrocardiography, an automated blood pressure cuff, a precordial or esophageal stethoscope, continuous airway manometry, inspired and expired capnography, anesthetic gas and oxygen analysis, multiple-site temperature measurement, and volumetric urine collection. The pulse oximeter is especially important when managing children with congenital cardiac disease. At least two probes should be placed on different limbs in the event that one fails during the procedure. In children with cyanotic heart disease, conventional pulse oximetry overestimates arterial oxygen saturation as saturation decreases<sup>51</sup>; this error tends to be exacerbated in the presence of severe hypoxemia.<sup>52</sup> When monitoring children with a shunt across the ductus arteriosus, a probe should be placed on a right hand digit to measure preductal oxygenation, and a second probe should be placed on a toe to measure postductal oxygenation (children with a right-sided aortic arch may require the probe to be placed on a left-hand digit). Children undergoing repair of coarctation of the aorta should be monitored with a pulse oximeter on the right upper limb, because it may be the only reliable monitor during the repair, and blood pressure cuffs should be placed before and after the coarctation. These two cuffs may be cycled and the differential documented before and after surgical correction.

Monitoring end-tidal carbon dioxide tension (PETCO<sub>2</sub>) is of value in most children. However, in children with cyanotic-shunting cardiac lesions, the PETCO<sub>2</sub> measurement may be less reflective of PaCO<sub>2</sub> because of ventilation-perfusion mismatching.<sup>53</sup> Arterial blood gases are the most accurate measure of the adequacy of ventilation and oxygenation. To provide rapid decision making, it is helpful to have the blood gas analysis machine located in or near the cardiac operating room.<sup>54</sup>

Monitoring ionized calcium concentrations is essential during surgical procedures in which significant quantities of citrated blood are infused rapidly or when entire blood volumes are replaced. Neonates are particularly prone to disturbances in their ionized calcium concentration when citrated whole blood, FFP, or platelets are infused. Those with limited cardiac reserve

tolerate ionized hypocalcemia poorly because of their greater sensitivity to the myocardial effects of citrate infusion (see Chapter 10).<sup>55</sup> In isolation, the total serum calcium concentration is misleading.

Temperature monitoring during CPB is a critical guide to adequate brain cooling and to appropriate rewarming before separation from bypass. Because it is not practical to measure brain temperature directly, surrogate measuring sites are used. The tympanic membrane, nasopharyngeal, and rectum have been used; the nasopharyngeal site most closely matches true brain temperature and is the site at which temperature is most often monitored. The tympanic and rectal sites tend to overestimate the brain temperature.<sup>56,57</sup> Measurement of skin temperature gives an indication about peripheral perfusion and provides information about adequate peripheral rewarming.

After induction of anesthesia, an arterial catheter should be placed in children who will undergo CPB. The radial artery may be percutaneously cannulated with relative ease, even in infants. In small infants, the femoral arteries are frequently used for arterial access, and the axillary arteries are commonly used. The brachial artery is avoided because it is an end artery. Catheters placed in the dorsalis pedis or posterior tibial artery often provide inaccurate hemodynamic data, especially after separation from bypass, and it may become difficult to sample blood for laboratory testing. In the rare circumstance that peripheral arterial cannulation cannot be accomplished, the surgeon may place a catheter in the internal mammary artery after sternotomy, and a sterile monitoring line may be passed over the drapes. Ultrasound guidance often is used for insertion of arterial catheters.

Central venous lines can be very useful. For cardiac surgical procedures, there are two commonly used methods of obtaining central access. The decision of which to use may be determined in part by institutional bias. In the first method, the cardiac surgeons expose the heart quickly and have it available for inspection and estimation of filling pressures. Central lines can be readily established from the field and handed off to the anesthesia team. These transthoracic central lines are useful but carry a small amount of risk.<sup>28</sup> In the second method, percutaneous insertion of central venous lines is particularly indicated for long, complex procedures, especially when access to the infant is limited or the heart is not exposed. Percutaneous cannulation of the central circulation through the internal jugular approach or the subclavian approach has been demonstrated to be safe.<sup>29</sup> However, it is important to appreciate that insertion of central venous lines through the internal jugular or subclavian route may fail or may be associated with pneumothorax, hemorrhage, and hematoma formation after puncture of major arteries.<sup>29-31</sup> Cannulation of the external jugular vein may avoid some of these serious complications when the catheter can be successfully threaded into the central circulation.<sup>32</sup> Increasingly, ultrasound-guided techniques are being employed to establish central venous access (see Chapter 48). In the United Kingdom, the use of ultrasound for the placement of these lines is recommended by the National Institute of Clinical Excellence (NICE), and ultrasound is used routinely for the placement of central lines.

In children with unrestrictive VSDs or ASDs, including hearts with a single ventricle or single atrium, central venous pressure is equivalent to left ventricular filling pressure. Cannulation of vessels that drain into the SVC should be approached with caution in children with univentricular anatomy who may undergo the Fontan procedure, because thrombosis of the SVC can be a devastating complication. In such circumstances, the

femoral veins may be the preferred sites for venous pressure monitoring.

Pulmonary arterial catheters in children with intracardiac defects usually provide little more information than a simple central line, are difficult to insert without fluoroscopy, and may not provide meaningful measurements of cardiac output. As a result, they are rarely used in pediatric cardiac patients.

### Transesophageal Echocardiography

Use of perioperative echocardiography has become the standard of care in the United States.<sup>58,59</sup> In adult practice, anesthesiologists usually perform the TEE, but in children, the TEE is more commonly performed by a pediatric cardiologist. This may reflect the increased complexity of congenital lesions and the difficulty in accurately assessing these lesions and their repairs. TEE has been cost-effective when used routinely during pediatric cardiac surgery.<sup>60</sup> The use of TEE can have a significant impact on surgical and medical management. In one large study, a second bypass run was undertaken in 7.3% of cases based on the findings of the TEE. There was a surgical alteration in the management of 12.7% and medical alteration in 18.5% of cases. Pediatric cardiac anesthesiologists usually can perform TEE before and after bypass if they have received adequate training.<sup>61</sup>

The introduction of small probes with multiplane capability has greatly increased the use of TEE, even in infants and neonates.<sup>62,63</sup> In 1999, a survey of centers in the United States indicated that 93% used intraoperative echocardiography and that all but one used TEE.<sup>64</sup> The American Society of Echocardiography and the Society of Cardiovascular anesthesiologists have published guidelines for performing a comprehensive intraoperative TEE in adults<sup>65</sup> and children.<sup>66</sup>

Although the use of TEE in children usually is safe, complications do occur and may be more common in small infants.<sup>67</sup> Complications include damage to the mouth, oropharynx, esophagus, and stomach. Other complications include hemodynamic disturbance as a result of compression of the left atrium or other structures. Interference with the airway also occurs in a small number of cases. This includes inadvertent extubation, right main-stem intubation, and compression of the tracheal tube. However, the overall incidence is small, approximately 2%.<sup>68</sup> Information gathered from the TEE examination takes place before and after bypass and may be divided broadly into two categories: hemodynamic assessment with monitoring and structural diagnostic information. Hemodynamic information includes information about ventricular function and filling.<sup>69</sup> Diagnostic information relates to confirmation or otherwise of preoperative findings and assessment of the adequacy of the surgical repair.

### Near-Infrared Spectroscopy

Cerebral near-infrared spectroscopy (NIRS) is becoming widely used during cardiopulmonary bypass in children. This noninvasive monitor is used to determine the degree of brain tissue oxygenation.<sup>70,71</sup> It is likely to lead to improved neurological outcomes after cardiac surgery although there is no clear evidence in humans (see Chapter 51).

## INDUCTION OF ANESTHESIA

In the United Kingdom, induction of anesthesia takes place in an anesthesia room, which is immediately adjacent to the operating room, and the parents are almost always present for

induction. Anesthesia is commonly induced while the child is sitting with or being held by a parent. It is possible to involve some parents to the extent that they can hold the mask for the child as he or she is anesthetized. After the child is asleep, he or she is transferred to the anesthetic trolley, where venous and arterial access is secured and the trachea is intubated. This practice differs from most centers in North America, where induction of anesthesia occurs in the operating room.

Induction can be achieved using an intravenous or inhalational technique. Ketamine may be given intramuscularly or orally when intravenous access is difficult and mask induction is refused. The type of induction should be tailored to the child and the cardiac defect. If intravenous access has already been established, an intravenous induction is preferred. If intravenous access has not been achieved, a decision is made about the optimal induction technique. In severely ill children, it is advisable to obtain intravenous access before induction of anesthesia. The use of local anesthetic cream such as EMLA or Ametop Gel helps to reduce the pain of injection. Use of local anesthetic cream is also helpful if an inhalational induction is to be used because it allows insertion of an intravenous cannula during a much lighter plane of anesthesia. This requires that the appropriate veins are selected during the preoperative visit and that clear instructions are given to nursing staff about where the cream should be applied.

The most common inhalational induction agent is sevoflurane. Sevoflurane is very rapid acting and should be used with care in the child with CHD because high concentrations can produce bradycardia, hypotension, and apnea if not titrated carefully. Concentrations should be rapidly reduced after an adequate level of anesthesia is achieved. In children who are cyanotic with a right-to-left shunt and reduced pulmonary blood flow, inhalational inductions are slow. The addition of nitrous oxide can aid an inhalational induction in two ways. First, because it is odorless, it can be started before the introduction of the sevoflurane, allowing the child to be somewhat sedated before the stronger smelling agent is started. Second, it allows a smoother and more rapid induction compared with sevoflurane alone. Concentrations of up to 70% nitrous oxide can be used to smooth induction of anesthesia even in cyanotic children, but the nitrous oxide should be replaced with air and oxygen or 100% oxygen as soon as intravenous access is obtained and a muscle relaxant is given. It is not always necessary to use a mask for an inhalational induction because cupped hands are often more acceptable to the child, particularly one who is frightened of the mask. It is important to tell the child about each event before it happens and to demonstrate the action on yourself, a parent, or toy animal. You should also offer the child the opportunity to hold the mask, or if the child is accompanied by a parent, offer the child the choice of the parent holding the mask. Good premedication often aids this process (see Chapter 4).

For sick children in whom it may be preferable to use an intravenous induction, various options are available. For example, in neonates with coarctation of the aorta or with hypoplastic left heart syndrome who are not ventilated before coming to the operating room, one approach is to administer fentanyl in a dose of 2 to 3  $\mu\text{g}/\text{kg}$ , followed by pancuronium and then by a very low dose (i.e., sedative dose) of sevoflurane or isoflurane. Fentanyl obtunds the hypertensive response to intubation, and the pancuronium maintains cardiac output by maintaining the heart rate. The very-low-dose volatile agent provides the sedation or anesthesia. In older children, etomidate is a very good induction

agent, providing stable hemodynamics, although it does cause pain on injection. Ketamine is also widely used for intravenous induction in neonates and older children. Ketamine maintains or increases blood pressure, heart rate, and cardiac output. The exact mechanism of these effects of ketamine is unknown; ketamine may stimulate the release of endogenous stores of catecholamines, although it is a negative inotrope in the denervated heart.<sup>72</sup> This negative inotropic effect may make ketamine a poor choice in children in whom catecholamine stimulation may already be maximal, such as in severe cardiomyopathy. It may also be a poor choice if tachycardia is undesirable, such as in the case of aortic stenosis.

Monitoring should ideally be applied before induction begins, but applying monitoring can upset the child, which can be detrimental (e.g., the child with TOF who begins to cry and precipitates a "tet spell"). A pulse oximeter probe may be the only monitor that is applied before induction of anesthesia. Sevoflurane or isoflurane may provide another advantage by offering a degree of ischemic preconditioning to the heart and to other organs, particularly the brain and kidney. In a double-blind study of adult patients undergoing coronary bypass grafting, exposure to 4% sevoflurane for 10 minutes before cross-clamping reduced the degree of myocardial dysfunction and renal damage postoperatively.<sup>73</sup> It is thought that the same effect is observed in children.<sup>74</sup>

### MAINTENANCE OF ANESTHESIA

Maintenance of anesthesia in children with CHD depends on the preoperative status and the response to induction of anesthesia. Whether inhalational agents, additional opioids, or other intravenous agents are used for maintenance depends on the tolerance of the child and postoperative plans for ventilation. If a primary opioid-based anesthetic is chosen, additional opioid should be administered on initiation of CPB to offset dilution from the pump prime and to maintain adequate opioid plasma concentrations. Awareness during adult cardiac surgery has been reported when amnestic agents are not used. Although small children may be unable to describe such events, the potential for awareness during pediatric cardiac surgery should not be underestimated. To prevent awareness, isoflurane may be administered through the membrane oxygenator with an anesthetic vaporizer or intravenous midazolam (0.2 mg/kg) may be administered. Alternatively propofol may be given by infusion during the bypass period to reduce the possibility of awareness.

### INSTITUTION AND SEPARATION FROM BYPASS

Before initiation of CPB, the surgeon requests heparin to be given. After administration of heparin (preferably flushed through a central venous catheter) but *before the initiation of bypass*, the ACT should be determined. The ACT measurement should be at least three times greater than the baseline value. When bypass is started, any additional anesthetic drugs should be administered, and ventilation should cease. Both hypertension and hypotension may complicate bypass. Blood pressure may be controlled within the normal range using  $\alpha$ -adrenergic blockers or agonists such as phenylephrine and phentolamine. The child is usually cooled at this stage, using the nasopharyngeal temperature as a guide. If the heart is to be stopped, cardioplegia is given by the perfusionist after the aorta is cross-clamped to provide myocardial protection during the period of ischemia. Cardioplegia is usually repeated every 20 to 30 minutes, although it is not required if the surgery is performed while the heart is beating.

Myocardial damage is related to the duration of the aortic cross-clamping and the effectiveness of the myocardial protection.

At an appropriate time during the surgery, the cross-clamp is removed, and perfusion to the heart is restored. The heart usually starts to beat in normal sinus rhythm, although this is not always the case. In the early phase of reperfusion, it is possible for various degrees of heart block to occur. However, these effects are usually short-lived, and as the effects of cardioplegia wear off, normal sinus rhythm is usually restored. In addition, heart block may result from damage to the conducting system during surgery.

After release of the cross-clamp, any inotropes or vasodilators that are required are usually started. Rewarming may have begun before release of the cross-clamp, but more commonly, the child is rewarmed after release of the clamp.

When the child has adequately rewarmed, as reflected by a normal core and minimal core-peripheral temperature difference, good heart function has returned, the child's lungs are adequately ventilated, and any inotropes required have been started, the child is ready to be separated from bypass. If a TEE probe is in place, the heart should be scanned for the presence of air. If air is present, further de-airing should occur before attempting to come off bypass. In the initial stages after separating from bypass, additional volume can be administered by the perfusionist through the aortic cannula, usually under the direction of the surgeon or anesthesiologist. Many centers institute modified ultrafiltration at this point. This involves taking arterial blood from the aortic cannula and passing it through the ultra-fine filter. This blood, which is oxygenated and warm, is then reinfused into the right atrium. When this process is complete, a thorough TEE examination can be undertaken.

When the team is satisfied with the TEE result, the surgeon asks for protamine to be administered. Before this is done, the perfusionist and the surgical team should be informed that protamine is about to be administered. The surgeons should remove any pump suckers from the field, and the perfusionist should stop all pump suction. This is done to ensure that no protamine enters the bypass circuit in case it is necessary to go back on bypass for any reason. The ACT can be checked along with the blood gas analysis. The ACT should return to levels before bypass. Any blood products required are usually given after the administration of protamine, usually while the surgeons are achieving hemostasis. As soon as the chest is closed, the child can then be transferred to the ICU.

## Control of Systemic and Pulmonary Vascular Resistance during Anesthesia

In some children with hypoplastic left heart syndrome (HLHS) who present for a Norwood procedure, excessive blood flow to the lungs resulting from a relatively low PVR and a relatively high SVR steals blood from the systemic circulation, leading to hypotension, myocardial ischemia, and progressive acidosis. However, when the reverse occurs and the PVR is greater than the SVR, the child develops progressive desaturation. Similar pathophysiology exists with other duct-dependent circulations and to some extent with other shunting lesions. It may prove difficult to manipulate the SVR and PVR predictably because control of PVR is poorly understood, vasoactive drugs usually are distributed on both sides of the circulation, and pharmacologic attempts to modify shunting have produced unpredictable results.<sup>75</sup> Despite these problems, several techniques have proved useful in

manipulating the relative PVR and SVR. Potent inhalational anesthetics appear to reduce SVR more than PVR. PVR is decreased in children by increasing inspired oxygen to 100% and by hyperventilation to a pH of 7.6 or greater. Positive end-expiratory pressure, acidosis, hypothermia, and the use of 30% or less inspired oxygen can increase PVR. Because vasoconstrictors such as phenylephrine increase SVR more than PVR, they are effective acutely in reducing right-to-left shunting and increasing left-to-right shunting in the operating room.

During cardiac surgical procedures, a direct method of selectively increasing PVR or SVR is to have the surgeon place partially obstructing tourniquets around pulmonary arteries or the aorta to increase resistance so that flow to the opposite side of the circulation increases. Although these are only temporary measures, they may reestablish a better relative balance of resistances and a more normal physiology in a deteriorating clinical situation.

## Anesthetic Drugs Used in Pediatric Cardiac Anesthesia

### INHALATIONAL AGENTS

#### Sevoflurane

Sevoflurane is the induction agent of choice in pediatric anesthesia.<sup>76,77</sup> It is associated with little myocardial depression or dysrhythmias.<sup>78-80</sup> It has specific advantages over halothane when used in children with CHD, particularly in children younger than 1 year of age and in cyanotic children.<sup>81</sup> In contrast to halothane, sevoflurane causes no reduction in heart rate at 1.0 and 1.5 minimal alveolar concentrations (MACs) in healthy children compared with awake values.<sup>82</sup> However, at greater concentrations, it can slow the heart rate and cause respiratory depression. Both features are important in children with CHD because a slow heart rate reduces cardiac output and hypoventilation leads to hypercarbia and hypoxia, which can increase PVR. In the absence of nitrous oxide, sevoflurane causes less depression of myocardial contractility than halothane during induction of anesthesia. Sevoflurane does cause a mild decrease in SVR, but in common with halothane and isoflurane, it does not perturb the shunt between the right and left sides of the heart through an ASD or VSD when it is given in anesthetic concentrations of about 1 MAC in 100% oxygen.<sup>83</sup> Sevoflurane has caused conduction abnormalities in susceptible patients.<sup>84</sup> It should also be used with great caution in children with severe ventricular outflow tract obstruction (see Chapter 6).<sup>85</sup>

#### Isoflurane

At equipotent concentrations, isoflurane causes similar hemodynamic depression in neonates and infants compared with halothane. Isoflurane typically is not used for induction of anesthesia because of the high frequency of laryngospasm (greater than 20%).<sup>86</sup> Inadequate ventilation because of laryngospasm or other causes quickly leads to large increases in PVR due to hypoxemia and hypercarbia. This increase in PVR and the resulting pulmonary hypertension is poorly tolerated in small children with heart disease, especially in the presence of right-to-left shunting (see Chapter 6).

#### Halothane

In the United States and the United Kingdom, the use of halothane has all but ceased, but it is still widely used in other parts

of the world. It is included here for completeness. Uptake of halothane in infants younger than 3 months of age is more rapid than it is in adults. This also is the case for the uptake of halothane by the myocardium.<sup>87</sup> Although the effects of halothane on the human neonatal myocardium are unknown, young rodents have a reduced cardiovascular tolerance for halothane but require greater amounts for anesthesia.<sup>88</sup> Studies have shown a significant incidence of hypotension with bradycardia in infants with normal cardiovascular systems during induction with halothane.<sup>89</sup> During induction of anesthesia in normal infants, halothane decreases the cardiac index to 73% of awake values at 1.0 MAC and to 59% at 1.5 MAC.<sup>90</sup> The MAC for halothane in infants 1 to 6 months of age is the greatest of any age group.<sup>91</sup> This increased anesthetic requirement in infants, combined with the immaturity of their cardiovascular system, explains in part the relative cardiovascular intolerance of halothane by infants. Atropine has been used intramuscularly before induction to partially compensate for the myocardial depression of halothane by reducing bradycardia and hypotension. Although halothane may produce some degree of hypotension, an increase in arterial saturation in children with cyanotic CHD may occur.<sup>92</sup>

A careful induction with sevoflurane is usually well tolerated in children with mild to moderate heart disease. However, large concentrations of potent inhalational agents may be an unwise choice for induction in young infants with severe cardiac disease. In children of any age with marginal cardiovascular reserve and in those with severe desaturation of systemic arterial blood due to right-to-left shunting, inhalational anesthetic-induced myocardial depression and systemic hypotension are poorly tolerated. A more appropriate use of these anesthetic agents in children with severe heart disease is the addition of low concentrations of the inhalational agent to control hypertensive responses after an intravenous induction (see Chapter 6).

#### Nitrous Oxide

Nitrous oxide should be avoided for maintenance of anesthesia in children with CHD because of the risk of enlarging intravascular air emboli and the potential to increase the PVR. Nitrous oxide may expand microbubbles and macrobubbles, increasing obstruction to blood flow in arteries and capillaries. In all children with right-to-left shunts, there is a potential for these bubbles to be shunted directly into the systemic circulation and coronaries. Care must be taken to ensure that no air bubbles are accidentally injected into the veins. Adverse outcomes after coronary air embolism are exacerbated by nitrous oxide.<sup>93</sup> The hemodynamic effects of venous air embolism are increased by nitrous oxide, even without paradoxical embolization.<sup>94</sup> In children with preexisting right-to-left shunts, paradoxical air embolism is clearly a potential problem; but even those with large left-to-right shunts can transiently reverse their shunts. This is particularly true during coughing or a Valsalva maneuver, when the normal transatrial pressure gradient is reversed. Several studies have demonstrated right-to-left shunting of microbubbles of air after injection of saline into the right atrium during these maneuvers.<sup>95-97</sup> Because coughing and Valsalva maneuvers may occur during anesthesia induction, even the most rigorous attention to avoiding air bubbles in intravenous lines may not prevent small amounts of air from reaching the systemic circulation. Microbubbles have also been observed after CPB.<sup>98</sup>

Nitrous oxide can increase PVR in adults.<sup>99,100</sup> However, in a 50% inspired concentration, it does not appear to affect PVR or pulmonary artery pressure in infants.<sup>101</sup> Nitrous oxide mildly

decreases cardiac output at this concentration.<sup>102</sup> Avoidance of the use of nitrous oxide has been suggested in children with limited pulmonary blood flow, pulmonary hypertension, or depressed myocardial function. In the well-compensated child who does not require 100% inspired oxygen, nitrous oxide (usually at concentrations of 50%) may be used during induction of anesthesia but discontinued before tracheal intubation. If a reduced inspired oxygen concentration is indicated to maintain an appropriate balance between PVR and SVR after tracheal intubation, air may be added to the inspired gas mixture (see Chapter 6).

## INTRAVENOUS INDUCTION AGENTS

### Ketamine

Ketamine is a dissociative anesthetic agent that is a good analgesic. It increases blood pressure, heart rate, and cardiac output. Although the mechanism of the stimulation of blood pressure and heart rate has not been established, it is thought to stimulate the release of endogenous stores of catecholamines. Ketamine exerts a negative inotropic effect on the denervated heart.<sup>103</sup> I think that this combination of effects makes it a poor choice for children in whom sympathetic stimulation may already be maximal, such as in those with severe cardiomyopathy. It is also a poor choice if tachycardia is undesirable, such as in a child with aortic stenosis. Ketamine is thought to have minimal effect on PVR in children with CHD as long as the airway and ventilation are well preserved,<sup>104,105</sup> although it has occasionally increased PVR in children undergoing cardiac catheterization. Ketamine is quite a versatile anesthetic that may be administered intramuscularly and orally when intravenous access is difficult or an inhalational induction is contraindicated. The usual intravenous dose of 2 mg/kg produces a very predictable response, and an intramuscular dose of 8 to 10 mg/kg (combined with 0.1 mg/kg of intramuscular midazolam) is less predictable. The oral dose of ketamine is 5 to 6 mg/kg. The use of ketamine varies greatly from one institution to another, with some units using it extensively and others using it rarely (see Chapter 6).

### Etomidate

Etomidate is a very safe drug, with an LD<sub>50</sub> to ED<sub>50</sub> ratio of 26 in animals models.<sup>106</sup> This ratio indicates that the lethal dose (LD) is 26 times greater than the effective dose (ED). It is a short-acting anesthetic with little effect on systemic blood pressure, heart rate, and cardiac output after a single dose in healthy children.<sup>107</sup> Etomidate has a favorable hemodynamic profile even when used in shocked children and appears to have a low risk of clinically important myoclonus or status epilepticus, pain on intravenous injection, and nausea and vomiting.<sup>108,109</sup> The major concern about etomidate is the increased mortality rates reported when it is administered as a continuous infusion. This grave side effect has been attributed to adrenal suppression.<sup>110-112</sup> The inhibition of steroid synthesis occurs after a prolonged infusion and after a single dose of etomidate, and it has created a controversy about its use as an anesthetic agent, particularly in the ICUs in some jurisdictions.<sup>113</sup> However, newer analogues of etomidate have addressed these deficiencies and may lead to a surge in its use in the future (see Chapter 6).

### Propofol

Propofol is a rapidly acting intravenous hypnotic agent that may be administered as a single dose or by continuous infusion. It has no analgesic properties. Propofol has mild antiemetic

properties.<sup>114</sup> Its short duration of action is the result of rapid redistribution and metabolism, which also allows the drug to be given by continuous infusion without accumulation. Induction doses decrease SVR, blood pressure, and cardiac output; the effect on heart rate varies. The ED<sub>50</sub> for propofol in infants and small children is greater than it is in adults.<sup>110-117</sup> If propofol is given very slowly, smaller doses are required to achieve the anesthetic state, although the induction time increases. A slower infusion also results in more stable hemodynamics.<sup>118</sup> Pain on injection and involuntary movement after intravenous propofol have been concerns that have been overcome (see Chapter 6). Although propofol can be used safely in children with CHD, it is typically avoided as an induction agent in those with severe CHD because of its effects on SVR and blood pressure. It should be avoided in those with a fixed cardiac output such as severe aortic or mitral stenosis because it may cause severe hypotension. It can be used by infusion during CPB to reduce awareness and may be particularly useful if an early extubation is planned (see Chapter 6).

## OPIOIDS

### Fentanyl

As in adults with severe cardiac disease, intravenous fentanyl combined with pancuronium and 100% oxygen or air and oxygen provides an excellent induction technique in very sick children with CHD, although it is not an amnestic. Inclusion of intravenous midazolam or another amnestic agent is strongly urged to avoid awareness. In neonates and infants, the use of high-dose opioid anesthesia provides excellent hemodynamic stability, with suppression of the hormonal and metabolic stress response.<sup>119,120</sup> When fentanyl or other opioids are combined with nitrous oxide, the negative inotropic effects of nitrous oxide may be evident, particularly in sicker children.<sup>121</sup> The high-dose fentanyl technique is effective in preterm neonates undergoing ligation of a PDA.<sup>122</sup> In high-risk, full-term neonates and in older infants with severe CHD, the high-dose fentanyl technique in doses of up to 75 µg/kg, combined with pancuronium maintains stable hemodynamics during induction, tracheal intubation, and surgical incision.<sup>123</sup> Oxygen saturation is well maintained and often improves during induction, even in cyanotic children.<sup>124</sup> The cardiac index, SVR, and PVR in infants given 25 µg/kg of fentanyl do not change significantly.<sup>125</sup> Combining pancuronium with fentanyl is desirable because the vagolytic effects of pancuronium offset the potential vagotonic effects of fentanyl. The hemodynamic stability reported in infants with the combination of high-dose fentanyl and pancuronium may not be replicated when other muscle relaxants are used (see Chapter 6).<sup>126</sup>

### Sufentanil

Sufentanil (5 to 20 µg/kg), an alternative to fentanyl, is 5 to 10 times more potent than fentanyl but has a large margin of safety.<sup>127</sup> It is highly lipophilic and is rapidly distributed to all tissues. It is infrequently used in infants and children with CHD.

### Remifentanyl

Remifentanyl is an ultra-short-acting opioid that is rapidly metabolized in the plasma and tissue by nonspecific esterases to an inactive metabolite. It has a very brief elimination half-life, with a context-sensitive half-life of only 3 minutes, independent of the duration of infusion. In pediatric cardiac surgery, it is an attractive alternative to fentanyl that provides intense analgesia during the most stimulating parts of surgery but facilitates rapid

awakening and weaning from mechanical ventilation without residual opioid effect. Its pharmacodynamics are unaffected by CPB.<sup>128</sup> It provides stable hemodynamic conditions in children, although there is a tendency toward bradycardia and systemic hypotension.<sup>129-131</sup> It has no negative inotropic effect, even in the failing heart.<sup>132</sup>

A significant concern is the development of acute tolerance with increasing analgesic requirements after discontinuing remifentanyl.<sup>133-135</sup> Some studies have suggested that this is not clinically important.<sup>136</sup> Strategies to prevent tolerance to remifentanyl have included intravenous magnesium infusions as well as nitrous oxide.<sup>137,138</sup> Remifentanyl is also used for prolonged sedation of children in the ICU. Many units have moved toward early extubation and discharge from the ICU after cardiac surgery (i.e., fast tracking), and remifentanyl is a useful drug in this setting (see Chapter 6). Consideration must be given to transitioning to a longer-acting opioid before discontinuation of remifentanyl.

### NEUROMUSCULAR BLOCKING DRUGS

Pancuronium has been studied in depth in children with CHD. When administered over a 60- to 90-second interval, pancuronium maintains heart rate and blood pressure.<sup>140</sup> An intubating bolus dose of pancuronium may produce tachycardia and increase cardiac output. This bolus dose effect is sometimes desirable to support cardiac output in infants in congestive heart failure because their stroke volume is fixed. Pancuronium may be the muscle relaxant of choice when high-dose opioid techniques are used to offset the vagotonic effects of opioids such as fentanyl. Other muscle relaxants are also widely used, particularly if they are to be extubated in the operating room or early in the ICU.

### LONG-TERM NEUROCOGNITIVE-DEVELOPMENTAL OUTCOMES ASSOCIATED WITH ANESTHESIA

Concerns have been raised about the possibility that many of the anesthetic agents such as inhalational anesthetics, propofol, ketamine, and midazolam may cause long-term neurocognitive-developmental problems in neonates and young infants.<sup>139</sup> This effect is thought to result from the neuronal apoptosis caused by these agents. The opioids have not been implicated in these changes, but this may change in time. There is no evidence to directly link anesthetic exposure in infancy to long-term neurocognitive defects. There is much ongoing research in this area (see Chapter 23).

## Regional Anesthesia

The use of regional anesthesia to provide pain relief during and after cardiac surgery in adults also reduces the stress response to surgery and may reduce morbidity and mortality. In adults undergoing cardiac surgery, the benefits of regional anesthesia include earlier extubation, fewer respiratory complications, a reduction in renal failure, fewer strokes, and less myocardial damage after CPB.<sup>141-143</sup> In animals, thoracic epidural anesthesia reduces myocardial damage after coronary occlusion.<sup>144</sup> The same benefits may be achieved by using intrathecal (spinal) analgesia. High spinal anesthesia using bupivacaine reduces the stress response to CPB and  $\beta$ -adrenergic dysfunction and improves cardiac performance after cardiac surgery in adults.<sup>145</sup>

Good research into regional anesthesia and analgesia in pediatric cardiac surgery is limited. Caudal morphine has been used to provide postoperative analgesia and has produced

good analgesia for about 6 hours while reducing analgesic requirements for up to 24 hours.<sup>146</sup> Two retrospective studies in children<sup>147,148</sup> included a variety of regional anesthetic techniques. Most children were extubated in the operating room, although ~4% of them required reintubation within 24 hours. Adverse effects included emesis (39%), pruritus (10%), urinary retention (7%), postoperative transient paresthesia (3%), and respiratory depression (1.8%). The rate of adverse effects was less with a thoracic catheter epidural approach compared with various caudal, lumbar epidural, and spinal approaches. Hospital duration of stay was unaffected by the presence of regional anesthesia complications. Although this study appears to indicate that regional analgesia is safe, the numbers in the study are too small to conclude that regional analgesia is safe for pediatric cardiac surgery.

The use of regional anesthesia in cardiac surgery for children remains controversial.<sup>149,150</sup> The main concern is the risk of bleeding and the potential for disastrous neurologic complications. The risks may be greater in children than in adults because of the presence of collateral vessels, increased venous pressure, coagulopathy related to cyanosis, and the use of aspirin. There remain many unanswered questions regarding neuraxial block in children, such as the true incidence of epidural hematoma, the time delay required between placement of the epidural catheter and full anticoagulation, and the correct management of a bloody tap. The estimated risk of epidural hematoma during cardiac surgery in adults is 1 case per 1000 patients and 1 case per 2400 patients for spinal and epidural block, respectively.<sup>151</sup> Whether the risks are similar or greater in children cannot be determined because the numbers of children involved in studies are too small. A large, randomized, prospective study to evaluate a true risk-benefit ratio without bias is needed; until such data are available, various commentators have advised great caution with the use of regional analgesia for cardiac surgery, and some have suggested that it may not be possible to perform the study required because of ethical considerations.<sup>152</sup>

## Fast Tracking

Fast tracking refers to abbreviating the perioperative period of children undergoing cardiac surgery. It should include every phase of the child's journey from referral and preoperative evaluation to less invasive surgery, early weaning from respiratory support, extubation, and discharge from the ICU and hospital.

Early extubation of pediatric patients after cardiac surgery offers advantages in terms of cost and reduced morbidity associated with longer ICU stays.<sup>153-157</sup> The success of this approach depends on the close teamwork of a multidisciplinary team, with every member of the team working toward the same goal. Successful fast tracking usually requires the development of care pathways to ensure that the quality of patient care is not compromised.<sup>158</sup> Early extubation and discharge from the ICU requires preplanning and the adoption of a technique that facilitates this goal. The use of very large doses of fentanyl is not appropriate; alternative techniques have been used, including smaller doses of fentanyl in combination with inhalational agents<sup>159,160</sup> or the use of remifentanyl in combination with inhalational agents or with propofol. Others have advocated regional anesthesia as a means of speeding extubation, but this approach remains controversial. It is important to choose a neuromuscular blocking drug with a shorter duration of action than pancuronium

to ensure that it is easy to reverse the neuromuscular block at the end of surgery. Other important considerations to ensure that early extubation is a success include adequate pain relief in the form of intravenous paracetamol (where available), patient-controlled or nurse-controlled analgesia, and antiemetics because nausea appears to be more of a problem in children who are extubated early.

Some clinicians advocate extubating the trachea in the operating room, whereas others advocate waiting until the child is in the ICU. Delaying the extubation until the child is in the ICU may save operating room time and may reduce the risks of cardiovascular instability, bleeding, and hypothermia.<sup>161</sup> Despite these concerns, the tracheas of many children are extubated in the operating room with good outcomes.

## Cardiopulmonary Bypass

Cardiopulmonary bypass is discussed in Chapter 17.

## Stress Response to Cardiac Surgery

Cardiac surgery and CPB are altered physiologic conditions associated with exaggerated stress responses characterized by the release of numerous metabolic and hormonal substances, including catecholamines, cortisol, growth hormone, prostaglandins, complement, glucose, insulin, and  $\beta$ -endorphins.<sup>162,163</sup> The cause of the elaboration of these substances is multifactorial: contact of blood with foreign surfaces, low perfusion pressure, anemia, hypothermia, myocardial ischemia, low levels of anesthesia, and nonpulsatile flow. Other factors that contribute to the increase in stress hormones are delayed renal and hepatic clearance and exclusion of the pulmonary circulation during extracorporeal circulation.<sup>164</sup>

Neonates of all viable gestational ages, older infants, and children have nociceptive systems that are sufficiently developed and integrated with brainstem cardiovascular control centers to trigger humoral and circulatory responses to pain and stress.<sup>165</sup> Substantial humoral, metabolic, and cardiovascular responses to painful and stressful stimulation during surgery have been documented in neonates of all gestational ages and in older infants.<sup>166,167</sup> Hormonal stress responses in neonates subjected to cardiac and noncardiac operations are threefold to fivefold greater than those in adults after similar surgeries. Circulatory responses to stressful stimuli in children include systemic and pulmonary hypertension.

Humoral stress responses are particularly extreme during and after cardiac surgery. These responses are characterized by increases in circulating catecholamines, glucagon, cortisol,  $\beta$ -endorphins, growth hormone, and insulin; circulating concentrations of catecholamines may increase by as much as 400% over baseline preoperative concentrations. This is evidence of a massive activation of sympathetic outflow in response to surgical stimulation. Some of these responses may continue for several days postoperatively.<sup>168</sup>

It has been suggested that such extreme stress responses and neuroendocrine activation may be associated with greater morbidity and mortality. In adults, intraoperative adrenergic activation of 50% above baseline is associated with significant postoperative alterations in  $\beta$ -adrenergic receptor function, including increased  $\beta$ -receptor density and decreased receptor affinity. Mortality among adults with severe congestive failure

is associated with increased levels of hormones regulating cardiovascular function, including aldosterone, epinephrine, and norepinephrine.<sup>169</sup> In neonates undergoing cardiac surgery, increased concentrations of stress hormones may be associated with increased mortality rates.<sup>168</sup>

The metabolic response to stress in children includes increased oxygen consumption, glycogenolysis, gluconeogenesis, and lipolysis. These metabolic responses cause substantial intraoperative and postoperative catabolism. The metabolic responses are usually related to changes in plasma cortisol, catecholamines, and other counterregulatory hormones such as glucagon and growth hormone. The most prominent clinical effects that result from activation of these processes are perioperative hypoglycemia and hyperglycemia, lactic acidemia, and negative nitrogen balance extending well into the postoperative period. Neonates and infants tolerate such metabolic derangements poorly. Their impaired tolerance is the result of a relative lack of endogenous reserves of carbohydrates, proteins, and fats; the large metabolic cost of rapid growth; a high obligate requirement for glucose by the relatively large brain; the immature hormonal control of intermediary metabolism; and the limited functional capabilities of immature enzyme systems in the metabolic organs. Severe stress responses superimposed on the normal neonatal and infant physiology may be poorly tolerated. However, it remains unclear whether these metabolic alterations may provide some beneficial effects for mobilizing the bodily resources to provide a metabolic milieu for healing tissues or they are purely maladaptive, resulting in detrimental effects on postoperative outcome.

Another factor is the potential effect of stress-induced hyperglycemia on the neurologic outcome. Neonates and young infants are capable of substantial rates of glucose production, mainly from glycogenolysis and gluconeogenesis during surgical stress that can result in hyperglycemia. Such hyperglycemic responses may be associated with poorer neurologic outcomes, particularly after a period of cerebral ischemia.<sup>170</sup> The use of high doses of fentanyl (more than 50  $\mu$ g/kg) has reduced the hormonal stress response and resultant hyperglycemia and may lessen the risk of neurologic injury.<sup>171</sup>

In sufficient doses, opioids can blunt the stress responses in neonates, infants, and adults.<sup>172-174</sup> This blunting results in a more normal, homeostatic humoral and metabolic milieu in the circulation by reducing neuroendocrine activation and levels of regulating hormones. In infants, the use of high-dose opioids for major surgical procedures and postoperative sedation substantially attenuates the neuroendocrine response to surgically induced pain and stress. Catecholamine release that results from intraoperative stress responses may predispose the vulnerable myocardium to dysrhythmias. In neonates with HLHS, sudden ventricular fibrillation occurred in 50% during surgical manipulation under halothane anesthesia. This incidence was dramatically reduced when high doses of fentanyl were introduced as the primary analgesic/sedative.<sup>175</sup> With the use of high-dose opioids, intraoperative ventricular fibrillation has virtually disappeared as a problem in this group of neonates.<sup>176</sup> In several studies, opioids have been shown to increase the ventricular fibrillation threshold in isolated cardiac Purkinje fibers and to alter action potential duration similar to that with class III antiarrhythmic agents.<sup>177,178</sup> Even electrophysiologic events in the neonatal heart, in addition to humoral and hemodynamic responses, may be altered by using high-dose fentanyl anesthesia to attenuate the effects of pain and stress.

## REDUCING THE STRESS RESPONSE TO SURGERY AND BYPASS

### Corticosteroids

Corticosteroids are used in many centers in an attempt to reduce the inflammatory response to surgery and bypass.<sup>179</sup> However, there is a huge variability in the formulation of the corticosteroids used, the doses, the timing of administration, and the indications for their use. The literature lacks adequate evidence for the use of corticosteroids, although several small studies in humans and animals suggest they confer a benefit.<sup>180,181</sup> Many investigators have called for a large multicenter study to determine the benefit of corticosteroids before bypass and the optimal dose and timing.<sup>182</sup>

### Aprotinin

Aprotinin, which was originally used to reduce bleeding after CPB, is now also appreciated to confer significant antiinflammatory effects.<sup>183-187</sup> In adults, it reduces mortality and length of ICU stay.<sup>188</sup> In children, it improves pulmonary function in the post-operative period and reduces the time to extubation and ICU stay. However, aprotinin is no longer available for routine use in the United States or continental Europe. In the United Kingdom, it is available for use on a named patient basis, but its use has been dramatically reduced as a result.

### Allopurinol

Allopurinol is thought to provide protection against oxygen free radicals during reperfusion by inhibiting xanthine oxidase. It reduces oxygen free radical production and may reduce neurologic and cardiac damage after deep hypothermic cardiac arrest.<sup>189</sup> This strategy does not appear to have developed widespread use.

### Ischemic Preconditioning

The heart is capable of short-term rapid adaptation to brief ischemia such that during a subsequent, more severe ischemic insult, myocardial necrosis is delayed. The infarct-delaying properties of ischemic preconditioning have been observed in all species studied. Five minutes of ischemia is sufficient to initiate preconditioning, and the protective period lasts for 1 to 2 hours. Laboratory experiments have demonstrated that the stimulation of adenosine receptors initiates preconditioning and the intracellular signal transduction mechanisms involve protein kinase C and adenosine triphosphate (ATP)-dependent potassium channels, although there may be some differences between species. An analysis of studies of myocardial infarction in humans has demonstrated that some adults who report having had angina in the days before infarction have a better outcome after their infarction in part due to the ischemic preconditioning. More direct evidence has come from an investigation of adults undergoing percutaneous transluminal angioplasty in whom the ST-segment changes induced by balloon inflation were more marked during the first inflation than the second. In adults undergoing coronary artery bypass grafting, the decline in ATP content during the first 10 minutes of ischemia was reduced in those subjected to a brief preconditioning protocol.<sup>190-194</sup>

It may be possible to protect organs other than the heart by ischemic preconditioning. It may even be possible to protect organs remotely by producing a period of ischemia in one area such as a limb, which then confers protection to remote organs.<sup>195</sup>

Cheung and coworkers have demonstrated that the use of a blood pressure cuff to produce short periods of limb ischemia can produce beneficial effects on the heart, lungs, and generalized inflammatory response.<sup>196</sup>

### Glucose-Insulin and Potassium

The use of glucose-insulin and potassium has been advocated for more than 40 years in adult cardiac surgery. It is thought to protect the myocardium from the effects of ischemia caused by aortic cross-clamping.<sup>197-200</sup> Its effects have not been studied in children undergoing cardiac surgery.

## Anesthesia Considerations for Specific Cardiac Defects

Discussion of anesthesia considerations for repair of every form of CHD is beyond the scope of this chapter. However, a brief discussion of the problems that may be encountered during repair of the more common congenital heart lesions is presented. It is useful to group lesions together because the management principles can be applied more generally within groups (Table 15-2).

### SIMPLE LEFT-TO-RIGHT SHUNTS

Simple left-to-right shunts increase pulmonary blood flow. If the shunt is large, blood flow to the lungs can be as much as threefold to fourfold greater than normal, resulting in volume loading of the right heart. This can lead to right atrial enlargement and right

**TABLE 15-2** Classification of Congenital Heart Disease

#### Simple Left-to-Right Shunt: Increased Pulmonary Blood Flow

Atrial septal defect (ASD)  
Ventricular septal defect (VSD)  
Patent ductus arteriosus (PDA)  
Endocardial cushion defect (e.g., atrioventricular septal defect [AVSD])  
Aortopulmonary window (AP window)

#### Simple Right-to-Left Shunt: Decreased Pulmonary Blood Flow with Cyanosis

Tetralogy of Fallot (TOF)  
Pulmonary atresia  
Tricuspid atresia  
Ebstein anomaly

#### Complex Shunts: Mixing of Pulmonary and Systemic Blood Flow with Cyanosis

Transposition of the great arteries (TGA)  
Truncus arteriosus  
Total anomalous pulmonary venous connection (TAPVC)  
Double-outlet right ventricle (DORV)  
Hypoplastic left heart syndrome (HLHS)

#### Obstructive Lesions

Aortic stenosis  
Mitral stenosis  
Pulmonary stenosis  
Coarctation of aorta  
Interrupted aortic arch

**TABLE 15-3 Clinical Features of Cardiac Failure in Children**

Failure to thrive	Cardiac murmur

Breathlessness	Cardiomegaly
Recurrent chest infection	Pulmonary plethora
Tachycardia	Wheezing

ventricular enlargement that is perhaps associated with tricuspid and pulmonary regurgitation. This combination results in cardiac failure (Table 15-3).

Medical management of these children is primarily achieved with diuretics. If pulmonary blood flow is large and left untreated, pulmonary vascular disease begins to develop, resulting in pulmonary hypertension. In the early stages, the changes are reversible, but in time, the changes may become irreversible.<sup>201-206</sup> Eisenmenger syndrome refers to severe pulmonary hypertension that leads to suprasystemic pulmonary artery pressures that cause the shunt to reverse, leading to cyanosis. The previous left-to-right shunt reverses to become a right-to-left shunt. At this point, the child's condition becomes inoperable.

Increasingly, definitive surgery is being performed at a younger age to reduce the risk of developing pulmonary vascular disease. If early definitive surgery is not possible, a pulmonary artery band is applied to reduce pulmonary blood flow. This is performed through a sternotomy incision but without the need for CPB. This provides the infant the opportunity to grow, postponing the need for definitive surgery without increasing the risk of developing pulmonary hypertension. In the presence of significantly increased pulmonary blood flow, pulmonary vascular disease is often severe and irreversible by 1 year of age. Definitive surgery should be performed between 3 and 6 months of age to avoid this complication.

### Atrial Septal Defect

ASD is a common heart defect in children, occurring in 1 of 1500 live births and accounting for approximately 10% of all CHD.<sup>207</sup> Several types of ASDs exist.

- Patent foramen ovale (PFO) is a normal fetal communication between the two atria that usually closes soon after birth. The PFO remains patent in up to 30% of people. PFO is usually left untreated in children.
- Primum ASD (Fig. 15-1, *A*) is located in the inferior part of the atrial septum close to the AV valve and may be associated with a cleft mitral valve. This is a variant of AV septal defect (AVSD).
- Secundum ASD (see Fig. 15-1, *B*) is found in the region of the fossa ovalis and results from a deficiency in the septum secundum.
- Sinus venosus ASD (see Fig. 15-1, *C*) occurs high in the atrial septum, often close to the opening of the SVC. It may be associated with partial anomalous pulmonary venous drainage.
- Coronary sinus ASD (i.e., unroofed coronary sinus) is a defect in the atrial wall allows blood to flow from the left atrium to right atrium through the coronary sinus.
- Common atrium has a complete absence of the atrial septum. The AV valves may be abnormal or unaffected.

Many ASDs can be closed using a percutaneous, transcatheter device. PFO and secundum ASDs are most commonly closed using this technique.

### Anesthesia Considerations

- These children can frequently be extubated on the operating table or early in the ICU, and smaller doses of opioids can be used. Alternatively, short-acting drugs (e.g., remifentanyl) administered by infusion and possibly in combination with propofol are useful if early extubation is planned.
- The problems of postoperative pulmonary hypertension are seldom encountered.

### Ventricular Septal Defect

VSD is the most common congenital defect in children, occurring in 1.5 to 3.5 of 1000 live births and accounting for 20% of CHD (Fig. 15-2, *A*).<sup>208</sup> Four types are described: subarterial (5%), perimembranous (80%), inlet (5%), and muscular (10%). If the flow through the VSD is small, it is referred to as *restrictive*, but if the flow is large, it is called *unrestrictive*. It is possible to close a small percent of VSDs using a percutaneous, transcatheter device.

### Anesthesia Considerations

- Inotropic support may be required postoperatively.
- Postoperative pulmonary hypertension may be a problem if the left-to-right shunt has been significant preoperatively or if the surgery is undertaken late.

### Atrioventricular Septal Defect

AVSDs are also known as AV canal defects or endocardial cushion defects, and they result from a defect in the AV septum. The incidence is about 0.2 cases per 1000 live births, and they account for about 3% of CHD. They are commonly associated with trisomy 21, TOF, and DiGeorge syndrome (Table 15-4). Two common types of AVSD exist:

- Partial AVSD usually consists of a primum ASD with a cleft in the anterior mitral valve leaflet (see Fig. 15-1, *A*).
- Complete AVSD consists of a large septal defect with atrial and ventricular components and a common AV valve (see Fig. 15-2, *B*).

Other descriptions of AVSD refer to balanced or unbalanced conditions, depending on whether the AV valve is stenotic or atretic or some of the valve chordae are straddling (i.e., crossing to the other side of the ventricular septum). The hemodynamic effects associated with AVSD include shunting at the atrial or ventricular level and AV valve regurgitation.

### Anesthesia Considerations

- If the child has trisomy 21, the anesthesia implications need to be managed.
- Inotropes are frequently required.
- Postoperative pulmonary hypertension may occur.
- TEE is particularly helpful in assessing the repair of the left AV valve.
- Heart block may occur postoperatively.

### Aortopulmonary Window

Aortopulmonary window is a rare CHD defect in which there is a communication between the main pulmonary artery and the ascending aorta, and it accounts for 0.1% of CHD (Fig. 15-3). Four types are classified according to the size and exact position

**FIGURE 15-1** A, Diagram of a primum atrial septal defect (ASD) with the great vessels removed to show the left-to-right shunt through the defect and a cleft of the mitral valve (MV), also called a partial atrioventricular septal defect (AVSD). B, Diagram of a secundum ASD with the great vessels removed to show the left-to-right shunt through the defect. C, Diagram of a sinus venosus ASD shows the left-to-right shunt through the defect close to the superior vena cava (SVC) and an anomalous pulmonary vein (PV) draining to the right atrium (RA). IVC, Inferior vena cava; LA, left atrium; LV, left ventricle; RV, right ventricle. (Modified from May LE. Pediatric heart surgery: a ready reference for professionals. Milwaukee: Maxishare; 2005.)

of the defect.<sup>209</sup> A left-to-right shunt is usually present. These children present with heart failure and are at risk for pulmonary vascular disease if not treated early. It is frequently associated with other cardiac and noncardiac anomalies:

- VACTERL: *v*ertebral anomalies, *a*nal atresia, *c*ardiac defect, *t*racheo*e*sophageal atresia, *r*enal anomalies, and *l*imb abnormalities
- CHARGE: *c*oloboma of the eye and central nervous system anomalies, *h*ear defects, *a*tresia of the choanae, *r*etardation of growth and development, *g*enital or urinary defects, and *e*ar anomalies
- CATCH-22 association (i.e., mnemonic for DiGeorge syndrome): *c*ardiac defect, *a*bnormal facies, *t*hymic hypoplasia,

*d*eft palate, *h*ypocalcemia (velocardiofacial syndrome), with 22q11 chromosome microdeletion (see Table 15-4)

#### Anesthesia Considerations

- Postoperative pulmonary hypertension may be problematic.
- Inotropes may be required.

#### Patent Ductus Arteriosus

The ductus arteriosus, a remnant from the fetal circulation, extends from the descending aorta to the main pulmonary artery and usually closes soon after birth. However, it remains patent in approximately 1 of 2500 live births and accounts for about 10% of all CHD (Fig. 15-4). In the fetus, blood from the right

**FIGURE 15-2** **A**, Diagram of a ventricular septal defect (VSD) shows a left-to-right shunt. **B**, Diagram of a complete atrioventricular septal defect (AVSD) with the great vessels removed to show the left-to-right shunt through both atrial and ventricular components of the defect and a single common atrioventricular (A-V) valve. ventricle is directed into the pulmonary artery, but because of the high PVR, it flows into the descending aorta. After birth, the PVR decreases, and blood flows from the aorta to the lungs. PDA is common in preterm infants, and its presence may explain an ongoing requirement for mechanical ventilation. In these infants, a left thoracotomy is required to ligate or divide the PDA. It may also occur in older children; but at this age, percutaneous closure by an interventional cardiologist is the preferred approach. The anesthesia implications are similar to those of other lesions described with left-to-right shunts preoperatively.

In many centers, PDA closure in preterm infants who weigh less than 1000 g and who are already mechanically ventilated is undertaken in the neonatal intensive care unit (NICU). This avoids the need to transfer these very small infants to the operating room and the associated problems, particularly hypothermia.

Preoperative requirements include the following:

- Crossmatched blood
- Antibiotics (risk of endocarditis)

**FIGURE 15-3** Diagram of an aortopulmonary window shows a left-to-right shunt through the defect. Ao, Aorta; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle; SVC, superior vena cava. (Modified from May LE. Pediatric heart surgery: a ready reference for professionals. Milwaukee: Maxishare; 2005.)

**FIGURE 15-4** The diagram of a patent ductus arteriosus shows a left-to-right shunt. Ao, Aorta; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle; SVC, superior vena cava. (Modified from May LE. Pediatric heart surgery: a ready reference for professionals. Milwaukee: Maxishare; 2005.)

- Vitamin K
- Particular perioperative risks include the following:
  - Difficulty ventilating or hemoglobin desaturation because of lung retraction
  - Tearing the PDA with massive hemorrhage
  - Inadvertent ligation of the aorta or pulmonary artery
  - Endocarditis
  - Paradoxical air embolism

#### Monitoring

Monitoring includes the use of all standard monitors, including end-tidal carbon dioxide assessment, and two additional pulse oximeters should be placed, one on the right hand and one on a lower limb. If the pulse is lost from the lower limb during a test clamping of the duct, it may indicate that the aorta has been clamped inadvertently. At my institution, all the requirements are stipulated in a protocol and monitoring and other requirements are in place before the arrival of the operating room team.

Invasive blood pressure monitoring is helpful if already established but is not usually placed if not already in place. Monitors used in non-operating room sites may not be compatible with the electrocautery equipment, resulting in loss of monitoring whenever the cautery is used.

#### Anesthesia Considerations

- A dedicated intravenous line for fluids and drugs with a long (100 to 150 cm), low-caliber extension to allow access from a distance (space around the cots in NICU is limited)
- High-dose opioids
- Muscle relaxation

**FIGURE 15-5** The diagram shows the features of the tetralogy of Fallot: ventricular septal defect, overriding aorta, right ventricular hypertrophy, and pulmonary stenosis. Pulmonary and subpulmonary obstructions are shown. The result is right-to-left shunting leading to cyanosis. Ao, Aorta; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle; SVC, superior vena cava. (Modified from May LE. Pediatric heart surgery: a ready reference for professionals. Milwaukee: Maxishare; 2005.)

- The tracheal tube should have only a small air leak. A large leak may prevent adequate ventilation during lung retraction (recheck security and correct position of the tip of the tube after repositioning in the decubitus position, before starting surgery).
- Intercostal nerve block by surgeon at the completion of surgery
- Glucose-containing fluids maintained at basal rates

#### SIMPLE RIGHT-TO-LEFT SHUNTS

##### Tetralogy of Fallot

TOF is the most common cyanotic CHD defect and accounts for 6% to 11% of CHD. It has four features (Fig. 15-5):

- VSD
- Overriding aorta
- Right ventricular outflow tract obstruction (RVOTO)
- Right ventricular hypertrophy

The RVOTO ranges from mild to severe, and the level of the obstruction also varies. Commonly, a dynamic subpulmonary infundibular obstruction is present. Dynamic narrowing of the infundibulum is frequently the cause of hypercyanotic episodes, also known as *tet spells*, in which there is an increase in the shunting of blood from right to left. However, the RVOTO may also be at the level of the pulmonary valve or main or branch pulmonary arteries. Pulmonary atresia may exist as a variant of TOF. Children with pulmonary atresia who have well-developed pulmonary arteries derive their pulmonary blood supply from a PDA, but those with hypoplastic pulmonary arteries derive their

pulmonary blood supply from major aortopulmonary collateral arteries.

The right-to-left shunt and cyanosis observed in children with TOF results from a combination of the RVOTO and VSD. The degree of hypoxemia depends on the relationship between the RVOTO and the SVR that determines the degree of right-to-left shunting. TOF may be associated with a large number of other cardiac and extracardiac anomalies. Extracardiac anomalies include DiGeorge syndrome (see Table 15-4) and trisomy 21.

### *Hypercyanotic Episodes*

Hypercyanotic spells are episodes of cyanosis that occur in 20% to 70% of untreated children. They may be initiated by crying or feeding, and they may occur during anesthesia. The cause of these spells is unclear, but metabolic acidosis, increased PaCO<sub>2</sub>, circulating catecholamines, and surgical stimulation have all been implicated.

Management of a tet spell requires urgent intervention. Early and aggressive use of a vasoconstrictor is essential. Phenylephrine should be premixed and in a syringe for immediate use in a concentration of 100 µg/mL. The initial dose is 0.5 to 1 µg/kg, which is repeated and doubled in 1-minute intervals until a satisfactory response is observed. Preterm infants may require as much as 30 µg/kg. Management may require any of the following:

- 100% oxygen
- Hyperventilation
- Intravenous fluid bolus
- Sedation or analgesia (e.g., fentanyl, morphine)
- Sodium bicarbonate
- Vasoconstriction
  - Norepinephrine is given as a 0.5-µg/kg bolus and then at a rate of 0.01 to 0.2 µg/kg/min.
  - Phenylephrine is given as a 0.5-µg/kg bolus and doubled at 1-minute intervals until a satisfactory response is achieved; this is followed by an infusion at 1 to 5 µg/kg/min (larger bolus doses may be required in small preterm infants).
- β-Blockers are administered to relax infundibular spasm and reduce the heart rate.
  - Propranolol is given as a 0.1- to 0.3-mg/kg bolus.

### *Surgical Management*

The optimal surgical management of children with TOF remains controversial. The choice is between initial palliation with a systemic-to-pulmonary shunt followed by a complete repair when the infant is older and complete repair during the neonatal or early infant period. The current trend is toward early complete repair.<sup>210,211</sup> Complete repair involves closure of the VSD and relief of the RVOTO. Relief of the RVOTO most commonly requires a transannular patch that involves a right ventriculotomy. Right ventricular dysfunction is a particular problem after repair, and a degree of pulmonary regurgitation is usually present if a transannular patch has been done. Junctional ectopic tachycardia (JET) is a particular risk after complete correction.

### *Anesthesia Considerations*

**SYSTEMIC-TO-PULMONARY SHUNT.** The systemic-to-pulmonary shunt typically is a modified Blalock-Taussig shunt. This is a shunt from the subclavian artery to a branch pulmonary artery.

- The patient is usually a neonate or small infant.
- Sedative premedication is useful to prevent crying during induction, which may provoke a hypercyanotic spell.
- There is a risk of a hypercyanotic spell during induction and surgery.
- Inhalational or intravenous induction is appropriate.
- Surgery is usually performed through a thoracotomy (left or right) but may be through a sternotomy.
- CPB is not usually required.
- Arterial and central venous access is required.
- Tracheal tube should be snug, with no or minimal air leak because lung retraction during surgery makes ventilation very difficult.
- The arterial line should not be in the arm on the side that the shunt will be placed because the subclavian artery will be clamped, and the arterial pressure will be lost.
- Hemodynamic and respiratory disturbance can be problematic during surgery.
- The surgeon may request a small dose of heparin.
- Bleeding may occur after clamps are released; be prepared for a blood transfusion.
- Postoperatively, the pulmonary blood supply predominantly depends on the size of the shunt. If the shunt is too small, the infant may have a low saturation level; if the shunt is too large, the infant may develop heart failure or pulmonary edema and hypotension.
- Pulmonary blood flow also depends on systemic blood pressure; the greater the blood pressure, the more blood flows to the lungs and the higher the saturation.
- Milrinone is often combined with norepinephrine because the norepinephrine increases the low diastolic pressure created by the shunt but does not produce the unwanted tachycardia seen with epinephrine.
- A period of postoperative ventilation may be required.

**COMPLETE REPAIR.** If the child is scheduled for early complete correction with no systemic pulmonary shunt, the child is likely to be a neonate or small infant. These children remain at risk for hypercyanotic spells. However, if the child has had a shunt placed previously, he or she is likely to be older and much less likely to have a hypercyanotic episode. Some children with less severe disease may not require a shunt and may be operated on when they are a bit older because they remain asymptomatic. Good sedative premedication is important in those at risk for hypercyanotic episodes.

- Both intravenous and inhalational induction agents are appropriate.
- CPB is required.
- Right ventricular dysfunction and pulmonary regurgitation may be postoperative problems.
- Too much of an inotrope may worsen RVOTO postoperatively by dynamic narrowing of the RVOT.
- Milrinone may be particularly useful because it promotes diastolic relaxation of the stiff right ventricle.
- Pyrexia and excessive β-adrenergic stimulation may help precipitate junctional ectopic tachycardia postoperatively.
- Surgeons frequently measure right ventricular pressure to assess the quality of the repair.
- Perioperative echocardiography is useful in assessing repair and right ventricular function.

**COMPLEX SHUNTS.** In complex shunts (i.e., mixing shunts), there is mixing of pulmonary and systemic blood flow, with resulting cyanosis.

### Transposition of the Great Arteries

Transposition of the great arteries (TGA) is common and accounts for about 6% of all CHD. It frequently occurs as an isolated lesion and is rarely associated with extracardiac anomalies. The operation most commonly performed in these infants is the arterial switch operation (ASO), the short- and long-term results of which have improved to such an extent that children with a good repair can expect a normal life.

TGA refers to the situation in which the aorta arises from the morphologic right ventricle and the pulmonary artery arises from the morphologic left ventricle (Fig. 15-6). In this ventriculoarterial (VA) discordance, the atria are related to the ventricles in the normal way (i.e., AV concordance). This results in two circulations that run in parallel rather than in series, which is the normal anatomic arrangement. Without some mixing of the two circulations, the systemic circulation would remain completely deoxygenated. However, some mixing does occur through the PDA or through a VSD that is present in approximately 25% of cases. If there is no VSD and mixing is inadequate, ductal patency is maintained after birth with an intravenous prostaglandin E<sub>1</sub> infusion, and a balloon atrial septostomy is performed urgently in the neonatal period.

In TGA with an intact ventricular septum, the ASO should be performed early in the neonatal period, preferably in the first 2 to 3 weeks of life, because the left ventricle is exposed only to the pressure of the pulmonary circulation. The longer this situation is allowed to continue, the less the left ventricle is able to

**FIGURE 15-6** Diagram of transposition of the great arteries (TGA) shows an intact ventricular septum. The aorta (Ao) arises from the right ventricle (RV), and the pulmonary artery (PA) arises from the left ventricle (LV). The coronary arteries arise from the aorta. These children are cyanotic. ASD, Atrial septal defect; IVC, inferior vena cava; LA, left atrium; PDA, patent ductus arteriosus; RA, right atrium; SVC, superior vena cava. (Modified from May LE. Pediatric heart surgery: a ready reference for professionals. Milwaukee: Maxishare; 2005.)

adapt to the work required to pump blood at systemic pressure after the ASO. However, if there is an unrestrictive VSD, the left and right ventricles are exposed to systemic blood pressure, and the left ventricle is better conditioned to perform the work of the systemic ventricle after the ASO.

If untreated, most infants with TGA die in the first year of life of hypoxia and heart failure. Pulmonary vascular disease develops early and contributes to this high mortality rate.<sup>212,213</sup> The mechanism for the early development of pulmonary vascular disease is complex and not simply related to high pulmonary blood flow. However, the presence of a VSD further accelerates this process. These infants are at risk for pulmonary hypertensive crises in the postoperative period.<sup>214</sup>

### Surgical Options

**ARTERIAL SWITCH OPERATION.** An ASO is the operation of choice if the intracardiac anatomy is appropriate. The ASO involves transecting the two main arterial trunks distal to their respective valves and switching them to produce VA concordance (Fig. 15-7). It also involves disconnecting the coronary arteries from the “old” aorta and reconnecting them to the neo-aorta. This restores anatomic and physiologic normality. The coronary anatomy varies widely in TGA but must be well assessed preoperatively because moving the coronary arteries to the neo-aorta is difficult but crucial to a successful outcome. In some cases, the coronary arteries run in the wall of the aorta (intramural), and this poses particular difficulties for the surgeon. Ventricular function after surgery depends largely on unrestricted flow in the coronary arteries.

**MUSTARD AND SENNING PROCEDURES.** The Mustard and Senning procedures are ASOs. They involve the use of intraatrial baffles to redirect deoxygenated blood from the venae cavae to the left atrium, left ventricle, and pulmonary artery and oxygenated pulmonary venous blood to the right atrium, right ventricle, and aorta. They create AV discordance, restore physiologic but not anatomic normality, and leave the physiologic right ventricle as the systemic ventricle. These procedures were performed as definitive procedures before the arterial switch became successful but are rarely used today as definitive repairs. They are still used as palliation in children with TGA, VSD, and pulmonary vascular disease.<sup>215</sup> In these cases, the VSD is left open.

**RASTELLI PROCEDURE.** The Rastelli procedure is used in children with TGA, VSD, and left ventricular outflow tract obstruction (LVOTO). The procedure closes the VSD in a way that directs blood from the left ventricle to the aorta. The pulmonary artery is ligated just distal to the pulmonary valve, and a valved conduit is inserted from the right ventricle to the pulmonary artery. The result is continuity between the left ventricle and aorta and between the right ventricle and the pulmonary artery, and the LVOTO (i.e., subpulmonary area) is bypassed. In the past, the Rastelli procedure was performed at 2 to 3 years of age with a Blalock-Taussig shunt performed for palliation in the neonatal period. However, there is a trend toward neonatal Rastelli repair without the need for a shunt.

### Anesthesia Considerations for the Arterial Switch Procedure

- The patient is a neonate in the first few weeks of life.
- Inhalational or intravenous induction is possible.
- Invasive arterial and central venous lines are required. If VSD closure is required, bicaval cannulation may be required for CPB, and because an internal jugular central venous pressure line may interfere with this, a femoral central venous pressure

**FIGURE 15-7** Diagram of an arterial switch operation. **A**, The original anatomy. The aorta (Ao), pulmonary arteries (PA), and coronary arteries are disconnected from their origins. **B**, The PA is moved anterior to the Ao. **C**, The Ao is connected to the left ventricle (LV), and the PA is connected to the right ventricle (RV). **D**, The coronary arteries are connected to the neo-aortic root. **E**, Final configuration. **E-TABLE 16-1** Combined Cardiac Output and Distribution in Human Fetuses during the Second Half of Pregnancy

	PERCENTAGE OF COMBINED CO AT GESTATIONAL AGE		
	20 weeks	30 weeks	38 weeks
Combined CO	210 mL/min	960 mL/min	1900 mL/min
Left ventricle	47%	43%	40%
Right ventricle	53%	57%	60%
Foramen ovale	34%	18%	19%
Lungs	13%	25%	21%
Ductus arteriosus	40%	32%	39%

Data from Rasanen J, Wood DC, Weiner S, Ludomirski A, Huhta JC. Role of the pulmonary circulation in the distribution of human fetal cardiac output during the second half of pregnancy. *Circulation* 1996;94:1068-73.  
CO, Cardiac output.

heart. Along with elimination of the placenta and the low-resistance umbilical circulation, the LV is suddenly subjected to increased volume and afterload (Table 16-1). Typically, LV end-diastolic pressure, and thus LA pressure, increases enough to exert hydrostatic pressure on the septum primum, resulting in functional closure of the foramen ovale. In contrast to the increased stress for the LV, the RV is relatively unloaded by the transition to extrauterine life.

The three fetal connections (ductus arteriosus, ductus venosus, and foramen ovale) close over a variable period. The ductus arteriosus has functionally (but not anatomically) closed in 58% of normal full-term infants by 2 days of life and in 98% by day 4.<sup>15</sup> Although many substances such as eicosanoids have been implicated, initial constriction probably occurs primarily in response to the increased arterial oxygen tension<sup>16,17</sup> and the reduction in circulating prostaglandins that follow separation of the placenta.<sup>18</sup> The response to oxygen is age dependent: Term neonates usually demonstrate effective constriction of the smooth muscles in the ductal tissue when exposed to oxygen, whereas preterm infants poorly respond and often require medical (prostaglandin inhibitor) or even surgical therapy. Additional catecholamine-induced changes in PVR and systemic vascular resistance (SVR) and other substances such as acetylcholine contribute to ductal closure. Within 2 to 3 weeks, functional constriction is followed by a process of ductal fibrosis, leaving a band-like structure, the ligamentum arteriosum.<sup>19,20</sup> With ligation

of the umbilical vein, the portal pressure falls, triggering functional closure of the ductus venosus. This process rarely requires more than 1 to 2 weeks; by 3 months only fibrous tissue, the ligamentum venosum, is left.

The foramen ovale is functionally closed when the LA pressure exceeds the pressure in the RA, but it remains anatomically patent in most infants, in 50% of children younger than 5 years of age, and in 25% to 30% of adults.<sup>21</sup> Echocardiographic studies have confirmed right-to-left shunting via the foramen ovale in healthy infants emerging from general anesthesia, and this can be a significant cause of persistent arterial desaturation at that time despite ventilation with 100% oxygen.<sup>22</sup>

## NEONATAL CARDIOVASCULAR SYSTEM

Compared with the adult, the neonatal myocardium is immature and incompletely developed (Table 16-2). Differences in cytoarchitecture and metabolism account for many of the functional limitations. The neonatal heart contains fewer muscle cells and more connective tissue than the adult myocardium. Contractile elements add up to only 30% of the total cardiac mass, in contrast to 60% in the adult.<sup>23</sup> The ratio of surface area to mass and that of water to collagen content are larger. There are fewer myofibrils within the muscle cells, and they tend to be less organized (i.e., not parallel to the long axis of the cell). The sarcoplasmic reticulum and the T-tubule network, both important components of rapid and effective calcium regulation, are incompletely developed, and the immature myocardium relies substantially on the calcium flux through the sarcolemma to initiate and terminate contraction.<sup>24-26</sup> One likely practical consequence is a greater degree of contractile dysfunction in the infant exposed to substances that decrease extracellular ionized calcium, such as citrate (blood products) and albumin; there is also increased sensitivity to volatile anesthetics and calcium channels blockers.

Reduced numbers of underdeveloped mitochondria and maturational differences in various signaling pathways and related messenger systems are also characteristic of the neonatal myocardium. Immature mitochondrial enzyme activity for fatty acid transport may explain the primary use of carbohydrates and lactates as energy sources and might be a reason for the greater anaerobic tolerance and faster recovery after periods of

**TABLE 16-1 Hemodynamic Changes at Birth**

Right Ventricle	Left Ventricle
Decreased afterload: Decreased pulmonary vascular resistance Ductal closure	Increased afterload: Placenta eliminated Ductal closure
Decreased volume load: Eliminated umbilical vein return Output diminished 25%	Increased volume load: Increased pulmonary venous return Output increased almost 50% Transient left-to-right shunt at ductus

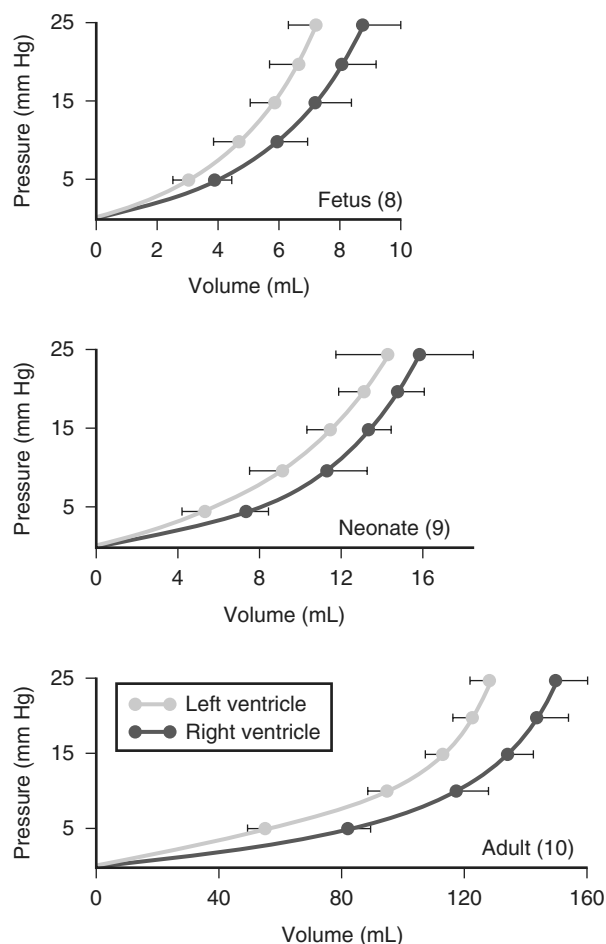

**TABLE 16-2 Characteristic Differences between the Immature and the Adult Myocardium**

	Immature Myocardium	Adult Myocardium
Cytoarchitecture	Fewer mitochondria and SR Poorly formed T tubules Limited contractile elements and increased water content Dependence on extracellular calcium for contractility	Organized mitochondrial rows, abundant SR Well-formed T tubules Increased number of myofibrils with better orientation Rapid release and reuptake of calcium via SR
Metabolism	Carbohydrates and lactate as primary energy sources Increased glycogen stores and anaerobic glycolysis for ATP Decreased nucleotidase activity, retained ATP precursors Better tolerance to ischemia with rapid recovery of function	Free fatty acids as primary source for ATP Limited glycogen stores and glycolytic function Increased 5'-nucleotidase activity, rapid ATP depletion Less tolerance to ischemia
Function	Decreased compliance Limited CO augmentation with increased preload Decreased tolerance to afterload Immature autonomic innervation: parasympathetic dominance, incomplete sympathetic innervation	Normally developed tension Able to improve CO with increased preload and to maintain CO with increasing afterload

Philadelphia: Lippincott, Williams & Wilkins; 2005. p. 266-90; and DiNardo J, Zwara DA. Congenital heart disease. In: DiNardo J, Zwara DA, editors. *Anesthesia for cardiac surgery*. 3rd ed. Malden, Mass.: Blackwell Publishing; 2008. p. 167-251.

ATP, Adenosine triphosphate; CO, cardiac output; SR, sarcoplasmic reticulum.

**FIGURE 16-3** Comparison of ventricular pressure–volume curves for fetal, neonatal, and adult sheep. Differences between ventricles are significant only in adult sheep. Notice that the right and left ventricles have similar compliance curves in the neonates, making the physiologic relationship between ventricles more intimate (i.e., infants tend to develop biventricular failure). (From Romero T, Covell J, Friedman WF. A comparison of pressure-volume relations of the fetal, newborn and adult heart. *Am J Physiol* 1972;222:1285-90.)

ischemia. A variety of developmental changes in contractile proteins occur from fetal through early postnatal life, including changes in pH, calcium sensitivity, and adenosine triphosphate (ATP) hydrolyzing activity. The key features of the immature cardiac function are summarized in Table 16-2.

The increased amount of non-contractile tissue in the neonate results in poor ventricular compliance and limited response to increased preload. Compliance of both ventricles progressively increases during fetal life and the postnatal period so that maximal stroke volume occurs at a significantly reduced atrial pressure in the neonate compared with the fetus (Figs. 16-3 and 16-4).<sup>27-29</sup> The extraordinarily high metabolic rate of the neonate (oxygen consumption, 6 to 8 mL/kg/min, compared with 2 to 3 mL/kg/min in the adult) requires a proportional increase in cardiac output. The neonatal heart functions at close to maximal rate and stroke volume just to meet the basic demands for oxygen delivery.<sup>30,31</sup> The cardiac output is commonly described as being primarily heart rate (HR) dependent due to a fixed stroke volume, but echocardiographic studies in human fetuses and neonates clearly demonstrate the capacity to increase stroke volume

(Fig. 16-5).<sup>32</sup> In fact, the neonate employs both tachycardia and stroke volume adjustments simply to meet metabolic demand. On the other hand, neonates exhibit exquisite sensitivity to pharmacologic agents that produce negative inotropic or chronotropic effects. At birth both ventricles are equal in mass and connected via a common septum. Increased pressures in one ventricle lead to a septal shift and decreased compliance of the opposite ventricle, causing a reduction in cardiac output. Neonates and infants often present with biventricular failure as a result of this interventricular dependence.

Immature autonomic regulation of cardiac function persists throughout the neonatal period. Both sympathetic and parasympathetic innervation of the heart can be demonstrated at birth. However, evidence suggests that development of the sympathetic nervous system is incomplete at both the postganglionic nerve-receptor level and the receptor-effector level.<sup>33</sup> The sympathetic system reaches maturity by early infancy, whereas the parasympathetic system reaches maturity within a few days after birth.<sup>34</sup> The relative imbalance of these two components of the autonomic nervous system at birth may account for the clinical observation that neonates are predisposed to exhibit marked vagal responses to a variety of stimuli.

### PULMONARY VASCULAR PHYSIOLOGY

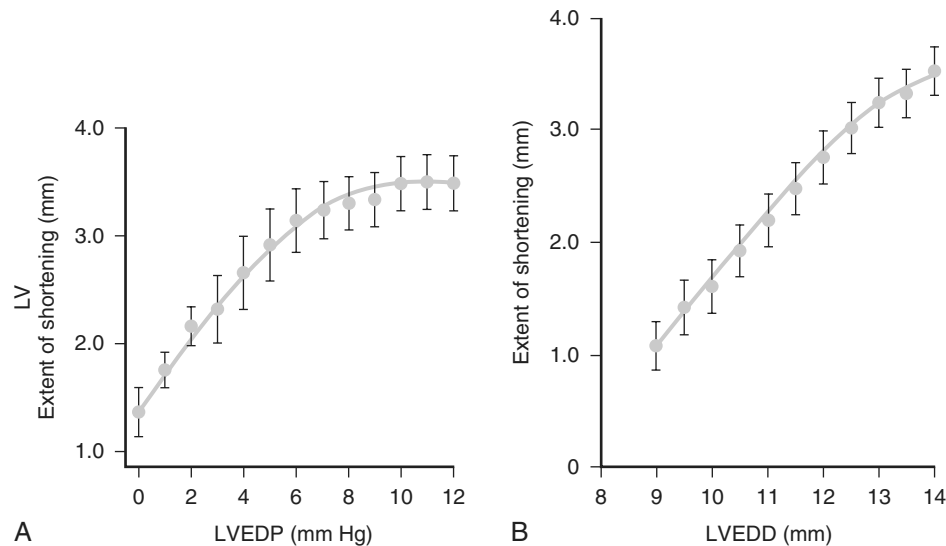

At birth, pulmonary vascular development is incomplete. Lung sections demonstrate diminished numbers of arterioles, and the arterioles exhibit thick medial muscularization (Fig. 16-6).<sup>35-37</sup> The pulmonary vasculature matures during the first few years of life. During this period, arterioles proliferate faster than alveoli, and the medial smooth muscle thins and extends more distally in the vascular tree. PVR continues to decrease as long as pulmonary mechanics and alveolar gas composition remain favorable, with a significant decrease occurring immediately after birth due to lung expansion and oxygenation. Progressive remodeling of the pulmonary vasculature facilitates further decreases in PVR (assuming normal physiology) during the first 2 to 3 months of life; by 6 months of age, the PVR has almost reached the level seen in healthy adults.<sup>37</sup>

The fetal pulmonary vasculature is extremely reactive to a number of stimuli. Hypoxia, acidosis, increased levels of leukotrienes, and mechanical stimulation can cause significant and prolonged increases in PVR (e.g., reactive pulmonary hypertension). On the other hand, acetylcholine, histamine, bradykinin, prostaglandins,  $\beta$ -adrenergic catecholamines, and nitric oxide are strong vasodilators.<sup>35</sup> In the first days of life, many pathophysiologic conditions can trigger severe and sustained increases in PVR<sup>38,39</sup> and prevent the normal adjustment to extrauterine life (E-Table 16-2). The acute load imposed on the RV can induce diastolic dysfunction and promote right-to-left shunting via the foramen ovale. Once PVR exceeds the SVR, a right-to-left shunt develops via the ductus arteriosus and patent foramen ovale. This situation is called *persistent fetal circulation*,<sup>40</sup> and it can result in a life-threatening hypoxemia that may require inhaled nitric oxide,<sup>41-45</sup> sildenafil,<sup>46</sup> or extracorporeal support (i.e., extracorporeal membrane oxygenation)<sup>47,48</sup> (see Chapter 19) to provide oxygenation and sustain life.

*Pulmonary vascular occlusive disease* (PVOD) is a term used to describe structural changes in the pulmonary vasculature after longstanding exposure to abnormal pressures and flow patterns in utero and after birth. Lung biopsies demonstrate thickened muscle layers in the small pulmonary arteries, intimal hyperplasia, scarring, and thrombosis as well as a decreased number of

**E-TABLE 16-2** Conditions Prolonging Transitional Circulation

Prematurity	Sepsis
Pulmonary disease	Acidosis
Hypoxemia	Hypothermia

Congenital heart disease	Prolonged stress

**FIGURE 16-4** Frank-Starling relationship in fetal lamb model (gestational age,  $135 \pm 5$  days). **A**, The relationship between left ventricular end-diastolic pressure (LVEDP) and shortening in a chronically instrumented fetal lamb model. Although myocardial performance improves with increasing LVEDP, the effect achieves a plateau at 10 mm Hg. **B**, In the same model, the relationship between left ventricular end-diastolic diameter (LVEDD) and left ventricular shortening. Taken together, these experiments support the capacity, albeit blunted, of the fetal heart to change stroke volume on the basis of volume loading conditions. Each point and vertical bars represent mean  $\pm$  standard error (SE). (From Kirkpatrick SE, Pitlick PT, Naliboff J, et al. Frank-Starling relationship as an important determinant of fetal cardiac output. *Am J Physiol* 1976;231:495-500.)

**FIGURE 16-5** Doppler echocardiographic comparison of the effect of spontaneous changes in heart rate on stroke volume in a normal human fetus in utero, illustrating decreased stroke volume with increased heart rate. These observations confirm the ability of the fetal heart to change stroke volume under normal physiologic conditions. (From Kenny J, Plappert T, Doubilet P, et al. Effects of heart rate on ventricular size, stroke volume, and output in the normal human fetus: a prospective Doppler echocardiographic study. *Circulation* 1987;76:52-8.)

distal (intraacinar) arteries.<sup>36</sup> Over time, these changes lead to progressive and finally irreversible obstruction of pulmonary blood flow with increases in PVR and PA pressures. The highly muscularized pulmonary arteries are also extremely reactive to pulmonary vasoconstrictors, which can easily trigger a pulmonary hypertensive crisis.

Many cardiac defects are associated with abnormal pulmonary flow patterns and can be categorized into three basic groups:

- *Exposure of the pulmonary vasculature to systemic arterial pressures and high flow:* The classic example is a large, nonrestrictive ventricular septal defect (VSD) with rapid progression of PVOD.
- *Exposure of the pulmonary vasculature to high flow without increased pressure:* Large atrial septal defects (ASDs) and small, restrictive patent ductus arteriosus (PDA) defects fall into this category. PVOD develops much more slowly in this setting.
- *Obstruction of pulmonary venous drainage resulting in increased PA pressures:* Pulmonary vein stenosis (e.g., total anomalous pulmonary venous return [TAPVR], cor triatrium) or increased LA pressures (e.g., mitral atresia, congenital aortic stenosis, severe coarctation) can cause back pressure in the pulmonary vasculature and induce PVOD.

The muscle tone in the pulmonary arteries is regulated by numerous factors, and various therapeutic interventions can be used to manipulate the PVR (Table 16-3)<sup>14</sup>:

- *Arterial oxygen tension ( $PaO_2$ ):* Alveolar as well as arterial hypoxia increases PVR. A  $PaO_2$  value lower than 50 mm Hg, especially when associated with an acidic pH ( $<7.4$ ), leads to significant pulmonary vasoconstriction. On the other hand, increased inspired oxygen can lead to pulmonary vasodilation.
- *Arterial carbon dioxide tension ( $PaCO_2$ ):* Hypercapnia increases PVR, independent of the blood pH. In contrast, hypocapnia induces alkalosis and thereby decreases PVR. Reliable pulmonary vasodilation can be achieved with  $PaCO_2$  of 20 to 33 mm Hg and a pH of 7.5 to 7.6.

**FIGURE 16-6** Peripheral pulmonary artery development. The normal pattern of pulmonary vascular development and that of a 2-year-old child with pulmonary vascular changes accompanying a large ventricular septal defect (VSD). Rabinovitch characterized the pulmonary vasculature morphometrically in three respects: vessel thickness, muscular extension, and the ratio of alveoli to arteries seen on lung biopsy specimens. The normal neonate exhibits thick vascular smooth muscle, but this extends only as far as the arterioles accompanying the respiratory bronchiole. In neonates, the alveoli/artery ratio is 20:1. In the first few months of life, the vessels thin substantially and proliferate relative to the alveoli, so that by the age of 2 years, the normal child has an alveoli/artery ratio of 12:1 and thin muscles extending to the arteries associated with alveolar ducts. In the normal adult, the alveoli/artery ratio is 6:1 and muscle extends all the way to the arteries in the alveolar wall. In contrast, in the 2-year-old child with a large VSD, the vessel numbers are markedly diminished (alveoli/artery ratio, 25:1), and persistent neonatal muscle thickness extends all the way to the alveolar wall. AD, Artery at alveolar duct; AW, artery at alveolar wall; RB, respiratory bronchiole; TB, artery at terminal bronchiole. (From Steven JM, Nicolson SC. Congenital heart disease. In: Miller RD, series editor. Atlas of anesthesia. vol 7: Pediatric anesthesia [Greeley WJ, volume editor]. Orlando, Fla.: Harcourt Publishers; 1998, p. 6.6; modified from Rabinovitch M, Haworth SG, Castaneda AR, et al: Lung biopsy in congenital heart disease: a morphometric approach to pulmonary vascular disease. *Circulation* 1978;58:1107-22.)

- **pH:** Respiratory and metabolic acidosis increase PVR; alkalosis reduces PVR.
- **Lung volumes:** PVR is optimized at a lung volume close to the FRC; larger volumes lead to compression of small intra-alveolar vessels, and smaller volumes can cause atelectasis and vascular collapse.

**TABLE 16-3** Manipulations of Pulmonary Vascular Resistance (PVR)

Increasing PVR	Decreasing PVR
PEEP	No PEEP
High airway pressures	Low airway pressures
Atelectasis	Lung expansion to FRC
Low $FiO_2$	High $FiO_2$
Respiratory and metabolic acidosis	Respiratory and metabolic alkalosis
Increased hematocrit	Low hematocrit
Sympathetic stimulation	Blunted stress response (deep anesthesia)
Direct surgical manipulation	Nitric oxide
Vasoconstrictors: phenylephrine	Vasodilators: milrinone, prostacyclin, others

$FiO_2$ , Fraction of inspired oxygen; FRC, functional residual capacity; PEEP, positive end-expiratory pressure.

- **Stimulation of the sympathetic nervous system:** Catecholamine surges from stress, pain, or light anesthesia can trigger significant increases in PVR.
- **Vasodilators:** Most intravenous (IV) agents used for pulmonary vasodilation also affect the systemic circulation and induce hypotension. Alternatively, inhaled substances such as nitric oxide (NO) or prostacyclin can provide a more selective pulmonary vasodilation (see “Cardiovascular Pharmacology”).

In summary, the pulmonary vasculature undergoes a complex maturation process that can be influenced by a multitude of external factors and congenital heart defects. Persistent fetal circulation and PVOD are examples of inadequate adaptation and development. In cases of increased PVR, ventilator strategies using greater inspired oxygen concentrations, lung volumes close to the FRC, and interventions aiming for a  $PaO_2$  greater than 60 mm Hg, a  $PaCO_2$  of 30 to 35 mm Hg, and a pH of 7.5 to 7.6 can improve pulmonary blood flow.

## Incidence and Prevalence of Congenital Heart Disease

CHD can be defined as “a gross structural abnormality of the heart or intrathoracic great vessels that is actually or potentially of functional significance.”<sup>49</sup> This definition covers a wide array of defects, which are among the most common congenital malformations. However, the precise incidence of CHD, both collectively and by individual anatomic subset, varies depending on definition, method of case identification, and epoch (E-Table 16-3). Including all categories of CHD, large epidemiologic surveys place the prevalence anywhere between 4 and 50 cases per 1000 live births.<sup>50-53</sup> When stratified according to trivial, moderate, and severe forms, the incidence for moderate and severe forms of CHD is relatively consistent at about 6 per 1000 live births.

Anatomic diagnoses within the population of infants with CHD vary according to the method used to identify cases. In 2002, Hoffman and colleagues compiled 62 epidemiologic studies published after 1955 and investigated the potential causes for the wide variability in the reported incidence of CHD.<sup>54</sup> More recent studies based mainly on prenatal and postnatal

AV, Atrioventricular; CHD, congenital heart disease; D-TGA, D-type transposition of the great arteries; DORV, double-outlet right ventricle; NERICP, New England Regional Infant Cardiac Program; SD, standard deviation; TAPVR, total anomalous pulmonary venous return.

\*Excluding bicuspid valves, isolated partial anomalous venous connection, and silent ductus arteriosus.

echocardiographic screening data often include a large number of trivial lesions (e.g., tiny VSDs, nonstenotic bicuspid aortic valve, “silent” PDA) for which no interventions may be required; other data collections, such as the New England Regional Infant Cardiac Program (NERICP), a registry of children with CHD who died or required catheterization or surgery during the first year of life, are clearly biased toward more severe forms of CHD.<sup>1</sup>

The increasing availability of prenatal diagnostic methods may exert an impact on the relative prevalence of reported lesions as well as their outcome. When fetal echocardiography is used, the apparent shift toward more complex lesions may reflect technical limitations in identifying simple defects.<sup>55</sup> In addition, evaluation in utero skews the results because it includes fatally malformed fetuses that will not survive to term. The prevalence of CHD among spontaneous abortions reaches 20% and remains as large as 10% among stillborn infants.<sup>56</sup> In one study, 50% of women whose children were given a prenatal diagnosis of CHD elected to terminate the pregnancy, particularly when presented with complex heart lesions.<sup>55</sup>

On the other hand, female infants with severe CHD have a 5% lower mortality rate than similarly affected male infants,<sup>1</sup> and with increased survival rates, more females will reach childbearing age. The recurrence risk of CHD for their offspring is about 3% to 4%.<sup>57,58</sup>

A study from Canada examined the changing epidemiology of CHD with respect to prevalence and age distribution in the general population between 1985 and 2000.<sup>59</sup> The prevalence of all categories of CHD in 2000 was 11.89 per 1000 in children (<18 years of age), 4.09 per 1000 in adults, and 5.78 per 1000 in the general population. For the subcategory of severe CHD, the prevalence was 1.45 per 1000 in children and 0.38 per 1000 in adults. In 2000, 49% of all patients with severe CHD were adults, compared with 35% in 1985, and females accounted for 57% of the adult CHD population. The prevalence of CHD increased for both children and adults between 1985 and 2000, although the increase for severe CHD was 85% in adults compared with 22% in children. The median age of all patients with severe CHD was 11 years in 1985 and 17 years in 2000, reflecting the fact that more children with CHD were surviving to adulthood (E-Fig. 16-1). Improved survival may be attributed to improved prenatal care, early diagnostic imaging, and major advances in pediatric cardiac care, particularly for those with severe CHD; these improved outcomes will continue to influence the future demographic profile. The growing number of adolescents and adults with CHD will require long-term follow-up with experienced cardiologists and access to specialized care facilities; this will require a thorough understanding of their underlying pathophysiology by all members of the adult care team, including anesthesiologists.

## Pathophysiologic Classification of Congenital Heart Disease

CHD consists of an almost endless array of anatomic and functional variants. Many different classification systems have been introduced, some using a segmental approach to anatomic features, others by examining the amount of pulmonary blood flow (cyanotic versus acyanotic) or the common physiologic characteristics (e.g., volume versus pressure overload).<sup>60-70</sup> Several of these classifications are discussed in Chapter 14. However, certain defects are better described using the concepts of shunting

(physiologic, anatomic, simple or complex), intercirculatory mixing, and single ventricle physiology, which are presented in the following sections.

### SHUNTING

Shunting occurs when blood return from one circulatory system (systemic or pulmonary) is recirculated to the same system, completely bypassing the other circulation. For example, if deoxygenated blood from the systemic veins flows directly to the aorta, the result is a right-to-left shunt with recirculation of deoxygenated blood in the systemic circulation. In contrast, redirection of oxygenated blood from the pulmonary veins to the PA causes a left-to-right shunt with recirculation of oxygenated blood within the pulmonary circulation. The terms *physiologic* and *anatomic* are often used to describe shunting. Basically, any kind of recirculation of blood within one circulatory system is called *physiologic shunting*. In most cases, physiologic shunting is caused by an anatomic shunt (i.e., a communication between the cardiac chambers or the great vessels), but physiologic shunting can also exist by itself, as in the classic transposition physiology.

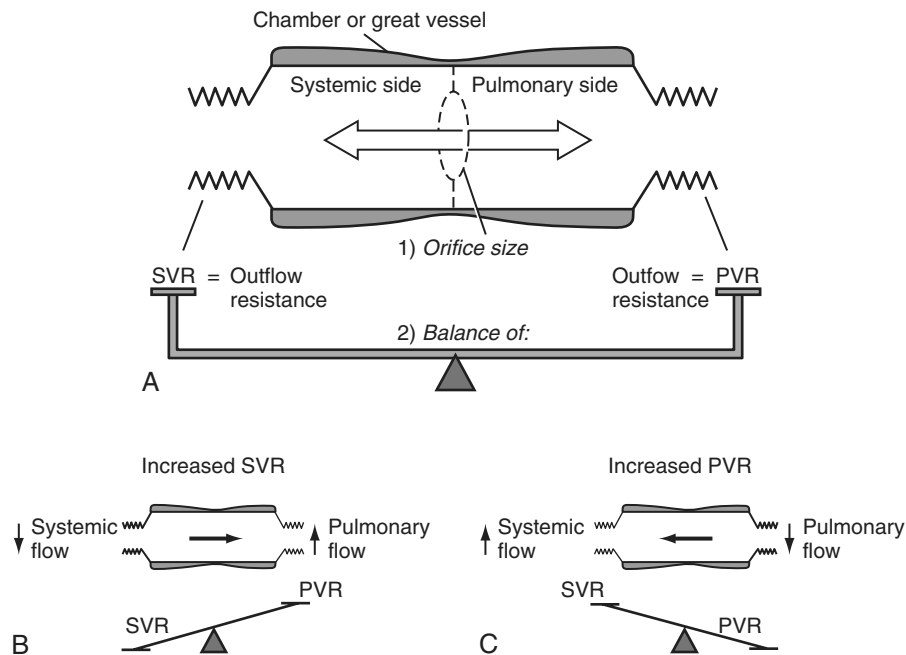

To really understand the pathophysiology of shunting and its implications, it is important to introduce the concepts of effective and total systemic/pulmonary blood flows. *Effective blood flow* is the quantity of venous blood from one circulatory system that reaches the arterial system of the other circulatory system. *Effective pulmonary blood flow* is the volume of systemic venous blood reaching the pulmonary circulation, whereas *effective systemic blood flow* is the volume of pulmonary venous blood reaching the systemic circulation. *Effective pulmonary blood flow* and *effective systemic blood flow* are always equal, no matter how complex the lesions. *Total blood flow*, on the other hand, is the sum of recirculated and effective blood flow and a measure of the workload of the circulatory system. Total systemic and pulmonary blood flows are not equal. Even in healthy patients there is a small amount of normal physiologic shunting (e.g., thebesian cardiac veins, bronchial vessels), but with CHD the difference can be quite significant. Physiologic shunting or recirculation should be viewed as a noneffective, superfluous load added to the essential nutritive blood flow (effective blood flow).

*Anatomic shunts* are communications between the two circulatory systems, either within the heart or at the level of the great vessels. They can be divided into simple and complex shunts, depending on the presence of additional outflow obstructions. In *simple shunts* without any additional outflow obstruction, the size of the communication (the so-called *shunt orifice*) determines the flow characteristics. For small orifices (restrictive shunts) with large pressure gradients across the communication, the size of the opening essentially regulates the amount of shunting. Changes in SVR or PVR have little influence. In contrast, for large orifices or nonrestrictive shunts (also classified as *dependent shunts*), the quantity and direction of blood flow are controlled by the respective outflow resistances (i.e., the ratio of SVR to PVR) (Table 16-4 and Fig. 16-7).

*Complex shunts* are defined by an additional outflow obstruction, which can be at various levels within the ventricle, valves, or great vessels and is often described as subvalvular, valvular, or supra-valvular. These obstructions can be fixed (e.g., valvular stenosis) or variable (e.g., dynamic infundibular obstruction by muscle bundles). Shunt flow and direction are determined by the combined resistance across the outflow obstruction and the pulmonary/systemic vascular beds. For severe obstructions

**E-FIGURE 16-1** Change in prevalence of congenital heart disease (CHD) from 1985 to 2000 among patients of different age groups. (From Marelli AJ, Mackie AS, Ionescu-Ittu R, Rahme E, Pilote L. Congenital heart disease in the general population: changing prevalence and age distribution. *Circulation* 2007;115:163-72.)

**FIGURE 16-7** Influence of orifice size and the ratio of pulmonary vascular resistance (PVR) to systemic vascular resistance (SVR) on the magnitude and direction of a simple shunt. **A**, PVR and SVR are balanced, resulting in equal pulmonary and systemic blood flows. **B**, PVR is reduced relative to SVR, resulting in an increase in pulmonary blood flow and a decrease in systemic blood flow. **C**, PVR is elevated relative to SVR, resulting in a decrease in pulmonary blood flow and an increase in systemic blood flow. (Modified from DiNardo J, Zwara DA. Congenital heart disease. In: DiNardo J, Zwara DA, editors. Anesthesia for cardiac surgery. 3rd ed. Malden, Mass.: Blackwell Publishing; 2008. p. 167-251.)

**TABLE 16-4** Characteristics of Simple Shunts (without Additional Outflow Obstruction)

	Restrictive (Small Shunt Orifice)	Nonrestrictive (Large Shunt Orifice)
Examples	Small ASD, VSD, or PDA; modified Blalock-Taussig shunt	Large VSD, PDA, CAVC
Pressure gradient across shunt	Large	Small or none
Direction and magnitude of shunt	Independent of PVR/SVR	PVR/SVR dependent
Influence of pharmacologic and ventilatory interventions	Minimal	Large

Modified from DiNardo J, Zwara DA. Congenital heart disease. In: DiNardo J, Zwara DA, editors. Anesthesia for cardiac surgery. 3rd ed. Malden, Mass.: Blackwell Publishing; 2008. p. 167-251.

ASD, Atrial septal defect; CAVC, common atrioventricular canal; PDA, patent ductus arteriosus; PVR, pulmonary vascular resistance; SVR, systemic vascular resistance; VSD, ventricular septal defect.

downstream, SVR or PVR will have little influence on the shunt. Tetralogy of Fallot is a good example of a complex shunt lesion. The amount of right-to-left shunt and therefore the amount of cyanosis are influenced by the degree and type of right ventricular outflow tract obstruction (RVOTO). This is especially evident in the setting of a dynamic infundibular obstruction, where changes in preload, contractility, and HR can lead to significant decreases in pulmonary blood flow and increased shunting (Table 16-5).

### INTERCIRCULATORY MIXING

The concept of intercirculatory mixing is often used to explain the unique physiology in children with transposition of the great

**TABLE 16-5** Characteristics of Complex Shunts (with Additional Outflow Obstruction)

	Partial Outflow Obstruction	Complete Outflow Obstruction
Examples	TOF, VSD/PS, VSD/coarctation	Tricuspid or mitral atresia Pulmonary or aortic atresia
Shunt magnitude and direction	Relatively fixed	Totally fixed
Dependence on PVR/SVR ratio	Inversely related to obstruction	Independent
Pressure gradient across shunt	Dependent on shunt orifice and degree of obstruction	Dependent only on shunt orifice

Modified from DiNardo J, Zwara DA. Congenital heart disease. In: DiNardo J, Zwara DA, editors. Anesthesia for cardiac surgery. 3rd ed. Malden, Mass.: Blackwell Publishing; 2008. p. 167-251.

PS, Pulmonary stenosis; PVR, pulmonary vascular resistance; SVR, systemic vascular resistance; TOF, tetralogy of Fallot; VSD, ventricular septal defect.

arteries (TGA). In this cardiac defect, the aorta arises from the RV, transporting deoxygenated blood back to the right heart, and the PA originates from the LV, returning oxygenated blood to the pulmonary circulation (see Fig. 15-6). Unless there is some mixing of blood via an ASD, VSD, or PDA, this defect will result in a complete separation of the two systems, a parallel circulation with 100% physiologic shunting or recirculation of oxygenated and deoxygenated blood that is incompatible with life once the fetal ductus arteriosus has closed. Effective pulmonary blood flow (i.e., deoxygenated blood reaching the pulmonary vascular bed for oxygenation) has to be provided by some form of right-to-left shunt; effective systemic blood flow (i.e., oxygenated blood returning to the systemic circulation) must be achieved by

**FIGURE 16-8** Depiction of saturations, pressures, and blood flows in transposition of the great arteries with a nonrestrictive atrial septal defect<sup>134</sup> and a small left ventricular (LV) outflow tract gradient. Intercirculatory mixing occurs at the atrial level. Effective pulmonary and effective systemic blood flows are equal (1.1 L/min/m<sup>2</sup>) and are the result of a bidirectional anatomic shunt at the atrial level. The physiologic left-to-right shunt is 9.0 L/min/m<sup>2</sup>; this represents blood recirculated from the pulmonary veins to the pulmonary artery (PA). The physiologic right-to-left shunt is 1.2 L/min/m<sup>2</sup>; this represents blood recirculated from the systemic veins to the aorta (Ao). Total pulmonary blood flow ( $\dot{Q}_p$  = 10.1 L/min/m<sup>2</sup>) is almost five times higher than the total systemic blood flow ( $\dot{Q}_s$  = 2.3 L/min/m<sup>2</sup>). The bulk of pulmonary blood flow is recirculated pulmonary venous blood. In this depiction, pulmonary vascular resistance (PVR) is low (approximately 1/35 of systemic vascular resistance [SVR]) and there is a small (17 mm Hg peak to peak) gradient from the LV to the PA. These findings are compatible with the high pulmonary blood flow depicted. LA, Left atrium; RA, right atrium; RV, right ventricle. (From DiNardo J, Zwara DA. Congenital heart disease. In: DiNardo J, Zwara DA, editors. Anesthesia for cardiac surgery. 3rd ed. Malden, Mass.: Blackwell Publishing; 2008. p. 167-251.)

a left-to-right shunt. Intercirculatory mixing is the combined systemic and pulmonary effective blood flow and is only a small portion of the total blood flow. The bulk of the respective systemic and pulmonary total blood flow consists of recirculated blood (Fig. 16-8). Usually the total blood flow and the volume in the pulmonary system are two to three times greater than in the systemic circulation.

The arterial saturation ( $\text{SaO}_2$ ) is influenced by the volumes and saturations of recirculating and effective systemic blood flows and can be calculated with the use of the following equation:

$$\text{Aortic saturation} = \frac{[(\text{Systemic venous saturation} \times \text{Recirculated blood flow}) + (\text{Pulmonary venous saturation} \times \text{Effective blood flow})]}{[\text{Total systemic venous blood flow}]}$$

Increasing the intercirculatory mixing will improve the arterial saturations, and in severely cyanotic neonates with TGA, intact ventricular septum, and inadequate atrial communication, a balloon atrial septostomy (balloon dilation of an existing patent foramen ovale or small ASD, either echo-guided at the bedside or under fluoroscopy in the catheterization laboratory) can be lifesaving. Additional measures to improve systemic and pulmonary venous saturations (e.g., blood transfusion, inotropic support, ventilatory strategies) can help to stabilize the arterial saturation.

### SINGLE VENTRICLE PHYSIOLOGY

*Single ventricle physiology* defines the circulation present in a wide variety of complex cardiac defects. It is characterized by complete mixing of systemic and pulmonary venous blood return at either

the atrial or the ventricular level; the mixed blood is then distributed to both systemic and pulmonary circulations in parallel. The defects can consist of one anatomic single ventricle with severe hypoplasia and inflow or outflow obstruction of the other one (hypoplastic left heart syndrome [HLHS] or pulmonary atresia with intact ventricular septum) or even two well-developed ventricles with atresia of the outflow tract or severe obstruction (tetralogy of Fallot with pulmonary atresia, interrupted aortic arch). In some lesions, a PDA is the only source of systemic or pulmonary blood flow; these are called duct-dependent circulations. In others, intracardiac communications provide adequate blood flow to both circulations (Table 16-6).

Irrespective of the anatomic features, in single ventricle physiology the ventricular output (delivered by one or two ventricles) is the sum of the pulmonary and systemic blood flows. The distribution of the respective flows is directly dependent on the relative outflow resistances into the two parallel circulations. Oxygen saturations in the aorta and PA are equal. The severity and location of anatomic obstructions and the ratio of PVR to SVR determine the balance of flows to the two circulations.

The following equation illustrates the various factors that influence the arterial saturation ( $\text{SaO}_2$ ) in a single ventricle physiology:

$$\text{Aortic saturation} = \frac{[(\text{Systemic venous saturation} \times \text{Total systemic venous blood flow}) + (\text{Pulmonary venous saturation} \times \text{Total pulmonary venous blood flow})]}{[(\text{Total systemic venous blood flow} + \text{Total pulmonary venous blood flow})]}$$

Accordingly, three major variables determine arterial saturation and the initial management options for patients with single ventricle physiology:

**TABLE 16-6** Examples of Single Ventricle Physiology

<b>Congenital Heart Defect</b>	<b>Aortic Blood Flow from</b>	<b>Pulmonary Blood Flow from</b>
Hypoplastic left heart syndrome	PDA	RV
Neonatal critical aortic stenosis	PDA	RV
Interrupted aortic arch	Proximal LV, distal PDA	RV
Tetralogy of Fallot with pulmonary atresia	LV	PDA, MAPCAs
Pulmonary atresia with intact septum	LV	PDA
Tricuspid atresia 1B (VSD and PS)	LV	LV through VSD to RV
Truncus arteriosus	LV and RV	Aorta
Double inlet left ventricle, no TGA	LV	LV through VSD to bulboventricular foramen

Modified from DiNardo J, Zwara DA. Congenital heart disease. In: DiNardo J, Zwara DA, editors. Anesthesia for cardiac surgery. 3rd ed. Malden, Mass.: Blackwell Publishing; 2008, p. 167-251.

LV, Left ventricle; MAPCAs, major aortopulmonary collateral arteries; PDA, patent ductus arteriosus; PS, pulmonary stenosis; RV, right ventricle; TGA, transposition of the great arteries; VSD, ventricular septal defect.

- *The ratio of pulmonary to systemic blood flow ( $\dot{Q}_{\text{pulm}}/\dot{Q}_{\text{sys}}$ ).* With high  $\dot{Q}_{\text{pulm}}/\dot{Q}_{\text{sys}}$ , a greater percentage of the blood in the ventricle (or ventricles) is oxygenated because more fully saturated pulmonary venous blood is entering the heart to mix with desaturated systemic venous return. Saturations greater than 85% can be achieved only by significant pulmonary overcirculation.  $\dot{Q}_{\text{pulm}}/\dot{Q}_{\text{sys}}$  can be influenced by careful manipulations of the PVR/SVR ratio.
- *Systemic venous saturation ( $S_{\text{sys}}vO_2$ ):* For a given  $\dot{Q}_{\text{pulm}}/\dot{Q}_{\text{sys}}$  and pulmonary venous saturation ( $S_{\text{pulm}}vO_2$ ), any decrease in  $S_{\text{sys}}vO_2$  causes a decrease in arterial saturation. Oxygen delivery and consumption are the basic determinants for  $SvO_2$ . Adequate oxygen delivery depends on cardiac output and arterial oxygen content and thus on hemoglobin levels and arterial saturation. All measures that increase oxygen delivery (e.g., transfusion to raise hematocrit levels to between 45% and 50%) or decrease consumption (e.g., adequate analgesia and sedation during painful procedures) improve arterial saturations.
- *Pulmonary venous saturation ( $S_{\text{pulm}}vO_2$ ):* Normally the blood in the pulmonary veins should be fully saturated ( $S_{\text{pulm}}vO_2 = 100\%$ ) on room air, but lung disease,  $\dot{V}/\dot{Q}$  mismatch, or large intrapulmonary shunts can cause significant desaturations.  $\dot{V}/\dot{Q}$  mismatch usually responds to therapy with increased inspired oxygen, whereas intrapulmonary shunts are refractory to oxygen therapy. Pulmonary venous desaturation will decrease arterial saturations.

## Special Situations

### EXERCISE PHYSIOLOGY IN THE CHILD WITH REPAIRED CONGENITAL HEART DISEASE

As summarized in E-Table 16-4, children with CHD, including those with lesions considered repaired, exhibit an array of abnormalities elicited during exercise testing consistent with reduced

exercise capacity. It is worthwhile to review the various exercise testing abnormalities in order to gain insight into the limitations imposed by the presence of congenital heart lesions.

*Oxygen consumption ( $\dot{V}O_2$ )* is equal to cardiac output times  $O_2$  extraction.  $O_2$  extraction is equal to the arterial–venous oxygen content difference. Peak  $\dot{V}O_2$  is the greatest measure of  $\dot{V}O_2$  obtained during a progressively more difficult exercise test.  $\dot{V}O_2$  at rest is defined as 1 metabolic equivalent energy expenditure unit or 1 MET (approximately 3.5 mL  $O_2$ /kg/min).<sup>71</sup> A typical elite endurance athlete can reach 20 to 22 METs, or 70 to 77 mL  $O_2$ /kg/min, at peak exercise. Activities of daily living require at least 4 METs or 14 mL  $O_2$ /kg/min. Peak  $\dot{V}O_2$  is the best overall assessment of the capabilities of the cardiovascular system, but determination of normal values is difficult due to the effects of age, gender, effort, and lean body mass versus adipose tissue on peak  $\dot{V}O_2$ . Nonetheless, peak  $\dot{V}O_2$  has been demonstrated to be a reliable predictor of hospitalization and mortality in patients with a wide variety of congenital heart lesions.<sup>72</sup>

During exercise, the HR normally increases linearly with increases in  $\dot{V}O_2$ . Normal peak HR is generally defined (in beats/min) as 220 minus age in years. In children with chronotropic incompetence, which is defined as the inability to increase HR to greater than 80% of the predicted value at peak exercise, the relationship between HR and  $\dot{V}O_2$  is depressed. Chronotropic incompetence is an indicator of poor prognosis and is most commonly the result of sinus node dysfunction. By comparison, well-trained endurance athletes have a normal peak HR and a depressed HR/ $\dot{V}O_2$  relationship, because they can generate a larger-than-normal stroke volume increase as exercise progresses. The inability to increase stroke volume (discussed later) during exercise results in an increased HR/ $\dot{V}O_2$  relationship as a compensatory mechanism.

The *oxygen pulse* is the quantity of oxygen delivered per heart-beat. The peak  $O_2$  pulse is calculated by dividing the peak  $\dot{V}O_2$  by the peak HR. Because peak  $\dot{V}O_2 = \text{cardiac output} \times O_2 \text{ extraction}$  and because  $O_2$  extraction remains remarkably constant over a wide range of exercise,  $O_2$  pulse is proportional to stroke volume. Determination of normal peak  $O_2$  pulse is hampered by the same factors that confound determination of normal peak  $\dot{V}O_2$ . In addition,  $O_2$  pulse overestimates stroke volume in the presence of erythrocytosis and underestimates it in the presence of anemia or reduced arterial  $O_2$  saturation.  $O_2$  pulse is reduced in patients with impaired ventricular function, severe valvular regurgitation, or pulmonary vascular disease.<sup>72</sup> It is also uniformly reduced in those with Fontan physiology as a consequence of the inability of this circulation to augment systemic ventricular preload during exercise.<sup>73</sup>

The *respiratory exchange ratio (RER)* is defined as the ratio  $\dot{V}CO_2/\dot{V}O_2$  (ratio of the volume of  $CO_2$  produced per minute to the volume of oxygen consumed per minute). A normal resting RER is between 0.67 and 1.0, depending on the precise composition of protein, carbohydrates, and fat in the diet. As exercise intensifies, anaerobic metabolism commences and the lactate threshold is reached; buffering of lactic acid with bicarbonate causes the carbon dioxide production ( $\dot{V}CO_2$ ) to increase out of proportion to oxygen consumption ( $\dot{V}O_2$ ), resulting in an increased RER. An RER of 1.09 or greater is thought to indicate the onset of anaerobic metabolism and to be consistent with a good effort.<sup>71,72</sup> Because RER increases only if anaerobic metabolism occurs, exercise limitation and low  $\dot{V}O_2$  due to musculoskeletal problems or poor effort are associated with an RER below this threshold.

Modified from Rhodes J, Tikkanen AU, Jenkins KJ. Exercise testing and training in children with congenital heart disease. *Circulation* 2010;122:1957-67.

*Peak HR*, Heart rate at peak exercise; *peak  $O_2$  pulse*, oxygen pulse at peak exercise; *peak  $\dot{V}O_2$* , oxygen consumption at peak exercise; *PR*, pulmonary regurgitation after valvuloplasty; *PVOD*, pulmonary vascular obstructive disease; *TOF*, tetralogy of Fallot;  $\dot{V}_E / \dot{V}CO_2$ , slope of the linear portion of the minute ventilation vs carbon dioxide production curve; *VAT*, ventilatory anaerobic threshold; +, rarely present; ++, sometimes present; +++, often present; +++, usually present.

\*This table assumes that the patient is not receiving  $\beta$ -blocker or other antiarrhythmic therapy that might impair the chronotropic response to exercise.

The *ventilatory anaerobic threshold* (VAT) is used to identify the onset of anaerobic metabolism that occurs before peak  $\dot{V}O_2$  and is relatively effort and motivation independent. As aerobic exercise progresses, minute ventilation ( $\dot{V}_E$ ) increases in direct proportion to  $\dot{V}CO_2$  and  $\dot{V}O_2$ . When anaerobic metabolism commences and  $CO_2$  production increases as lactic acid is buffered,  $\dot{V}_E$  increases accordingly. VAT is the point at which  $\dot{V}_E/\dot{V}CO_2$  and  $\dot{V}_E/\dot{V}O_2$  diverge, with  $\dot{V}_E$  rising in proportion to  $\dot{V}CO_2$  but out of proportion to  $\dot{V}O_2$ . An important characteristic of successful endurance athletes is the ability to reach and sustain effort at an anaerobic threshold that is a large percentage (80% to 85%) of peak  $\dot{V}O_2$ .

Ventilation efficiency can be assessed with the use of the  $\dot{V}_E/\dot{V}CO_2$  slope. This relationship is defined as  $863 \cdot \dot{V}CO_2 / [PaCO_2 \cdot (1 - V_D/V_T)]$ , where  $V_D/V_T$  is the ratio of physiologic dead space to tidal volume.<sup>75</sup> The  $\dot{V}_E/\dot{V}CO_2$  slope can be thought of as the number of liters of ventilation required to eliminate 1 L of  $CO_2$ . Normal children have a  $\dot{V}_E/\dot{V}CO_2$  slope of less than 28.<sup>72</sup> In order to maintain a normal  $PaCO_2$  during exercise, children with increased  $V_D/V_T$  and reduced ventilatory efficiency have a greater than normal increase in  $\dot{V}_E$  and therefore a steeper  $\dot{V}_E/\dot{V}CO_2$  slope. Increased  $V_D/V_T$  is the consequence of either reduced  $V_T$  in the setting of a normal  $V_D$  or pulmonary flow maldistribution and subsequent  $\dot{V}/\dot{Q}$  mismatch that increases  $V_D$ . The latter is the major source of inefficient ventilation and steepening of the  $\dot{V}_E/\dot{V}CO_2$  slope in children with cardiac disease.

In children with PA stenoses such (e.g., repaired tetralogy of Fallot), pulmonary hypertension, or increased LA pressure from any cause (e.g., LV systolic or diastolic dysfunction, mitral valve disease), an increase in the  $\dot{V}_E/\dot{V}CO_2$  slope is associated with increased mortality. When pulmonary stenosis is corrected in children with tetralogy of Fallot, the  $\dot{V}_E/\dot{V}CO_2$  slope and peak  $\dot{V}O_2$  improve.

Children with Fontan physiology also exhibit an increase in  $\dot{V}_E/\dot{V}CO_2$  slope. These children have inherent nonhomogeneous pulmonary perfusion at rest due to the lack of pulsatile pulmonary blood flow. In addition, there is poor recruitment of distal pulmonary vasculature during exercise. The presence of a Fontan fenestration further contributes to this increase in the  $\dot{V}_E/\dot{V}CO_2$  slope by allowing mixed venous blood high in  $CO_2$  to be shunted into the systemic circulation. This produces, via central chemoreceptor stimulation, an increase in  $\dot{V}_E$  out of proportion to  $\dot{V}CO_2$ .<sup>76</sup> Fontan fenestration closure eliminates this right-to-left shunt and reduces the  $\dot{V}_E/\dot{V}CO_2$  slope but does not improve peak  $\dot{V}O_2$ .<sup>76</sup> The reason is that the primary limitation to increases in  $\dot{V}O_2$  during exercise in Fontan patients is the inherent inability of the pulmonary vascular bed to substantially increase surface area, flow, and preload delivery to the systemic ventricle.

## FONTAN PHYSIOLOGY

Francis Fontan, a French cardiac surgeon, described a new treatment for complex cardiac malformations with only one ventricle in 1971.<sup>77</sup> To decrease the chronic volume overload for the single ventricle and normalize oxygenation, he separated the systemic and pulmonary circulations by directly connecting the systemic venous return (SVC and IVC) to the PA, without a pumping chamber. This created a circulation wherein pulmonary blood was driven solely by a nonpulsatile pressure gradient across the pulmonary vascular bed, with the single ventricle being the sole source of kinetic energy. All other shunt connections were interrupted. The original indication was tricuspid atresia, but over the years the classic Fontan technique has been modified in many

ways and is now used for various complex cardiac lesions with single ventricle physiology, such as HLHS, double-inlet RV, and pulmonary atresia with intact septum (see also Chapters 15 and 21).<sup>78-82</sup>

It is impossible to create a Fontan circulation at birth; high PVR and small vessel sizes prevent adequate pulmonary blood flow. In the neonatal period, palliative procedures such as stage I Norwood operation with aortic arch reconstruction, atrial septostomy, and aortopulmonary shunts (modified Blalock-Taussig shunt) or the Sano modification of the Norwood procedure (RV-to-PA conduit) aim for balanced systemic and pulmonary blood flows, allowing the baby to grow for several months despite cyanosis and volume load on the ventricle. At the age of 3 to 6 months, an intermediate procedure called the bidirectional Glenn operation or superior cavopulmonary anastomosis, is performed. The SVC is connected directly to the PA, providing nonpulsatile pulmonary blood flow, whereas the IVC remains connected to the heart. As a result, the volume load on the ventricle is significantly reduced, but oxygenated and deoxygenated blood still mix and the saturations remain in the low 80% region. By the age of 1 to 5 years, most of these children are ready for the Fontan circulation. With adequate growth and maturation of the pulmonary vascular bed, the resistance should be low enough to allow the complete separation of the systemic and pulmonary flows. The IVC is now also connected to the PA, most often via a lateral tunnel in the atrium or an extracardiac conduit, with or without a small fenestration (small opening in the baffle or conduit connecting the systemic venous return with the common atrium of the single ventricle). The fenestration can provide a residual right-to-left shunt in case of sudden increases in PVR, maintaining ventricular preload and function. This seems to facilitate the adaptation to the new loading conditions, shorten the recovery time, and decrease the incidence of early complications. The fenestration often occludes spontaneously, or it is closed during a cardiac catheterization and hemodynamic evaluation with a special device (Fig. 16-9; see also Figs. 15-11 through 15-13).<sup>83-86</sup>

The Fontan operation has dramatically improved the mortality rates for children with single ventricles, but the success comes at a price: Chronic systemic venous hypertension and congestion has been implicated in a multitude of potential early and long-term complications, including arrhythmias, residual right-to-left shunts, coagulopathies with increased risk for thrombosis and stroke, lymphatic dysfunction with pleural effusions, and protein-losing enteropathy.<sup>87-92</sup> Late cardiac failure and poor functional outcome remain risks for patients with Fontan circulations. The

**FIGURE 16-9** Fontan modifications: extracardiac conduit (*left*) and lateral tunnel with fenestration (*right*). (From the Children's Hospital Boston web site. Available at [http://www.childrenshospital.org/cfapps/mml/index.cfm?CAT=media&MEDIA\\_ID=1837](http://www.childrenshospital.org/cfapps/mml/index.cfm?CAT=media&MEDIA_ID=1837))

anatomy of the single ventricle and the type of Fontan connection influence the duration of freedom from complications. Children with systemic RVs and the classic atriopulmonary Fontan (RA directly anastomosed to the PA) tend to have a shorter duration of freedom from complications than those with systemic LVs and newer Fontan modifications (E-Figs. 16-2 and 16-3).<sup>93</sup>

Inherent limitations of the Fontan circulation, such as altered control of cardiac output with decreased hemodynamic response to stress and reduced exercise tolerance, have been documented (Fig. 16-10).<sup>94-102</sup> Even at rest, cardiac output is usually only 70% (range, 50% to 80%) of normal for body surface area. Cardiac output is classically determined by four factors: preload, contractility, HR, and afterload. Over a physiologic range, cardiac output improves with increased preload, contractility, and HR and with decreased afterload. For the Fontan circulation, the determinants of CO are more complex (Fig. 16-11).<sup>97,103</sup> The classic determinants of cardiac output are less effective, while other factors, such as transpulmonary gradient and PVR, must be considered. The following mechanisms regulate cardiac output in children with Fontan physiology.

- **Preload:** The RV usually provides the kinetic energy to distend the pulmonary vasculature and create a preload reservoir for the LV, thereby enabling an increase in cardiac output up to fivefold or greater with exercise.<sup>103,104</sup> The lack of a pre-pulmonary pump leads to a significant decrease in available pulmonary blood volume and, consequently, reduced or absent LV preload reserve.<sup>97,105,106</sup>
- **Contractility:** During the staged palliation, the single ventricle typically develops from a volume-overloaded and dilated ventricle to a hypertrophied, underfilled ventricle.<sup>107,108</sup> Although the contractile response to  $\beta$ -adrenergic stimulation seems to be preserved, the resulting increase in cardiac output is diminished, most likely due to limited preload reserve.<sup>100,106</sup>
- **Heart rate and rhythm:** Within the physiologic range, atrial pacing at different HRs does not alter cardiac output because there is a simultaneous decrease in stroke volume.<sup>109</sup> Normalization of HR increases the reduced cardiac output associated with severe bradycardia or tachycardia.<sup>110</sup> During exercise testing, Fontan patients demonstrate chronotropic incompetence, a blunted HR response to exercise. This is likely the result of autonomic dysfunction or abnormal reflex control. In contrast to the HR, cardiac rhythm is of utmost importance. Ectopy or loss of atrioventricular (AV) synchronization compromises ventricular filling and decreases the transpulmonary gradient.<sup>111</sup>
- **Afterload:** The Fontan circulation is characterized by increased afterload, which is a physiologic response to decreased cardiac output and occurs because a single ventricle is ejecting into two large resistance beds (systemic and pulmonary vascular) arranged in series.<sup>97,106,112,113</sup> Autonomic regulation and activation of various endocrine systems increase the systemic venous resistance and help to maintain adequate perfusion pressures and venous tone. Because of the limited preload reserve, attempts at afterload reduction often result in significant hypotension. On the other hand, excessive afterload, such as that which occurs with residual aortic arch obstruction, is poorly tolerated.
- **Transpulmonary flow:** Transpulmonary flow is directly proportional to the gradient between the systemic venous pressure (usually between 10 and 15 mm Hg, rarely greater than 20 mm Hg) and the pre-ventricular atrial pressure, which is determined by the functional status of the AV valve, the

ventricle, the rhythm, and the potential presence of outflow obstruction. Transpulmonary flow is inversely proportional to the resistance over the Fontan circuit. This resistance is largely determined by PVR, but mechanical obstruction such as stenosis or thrombosis may also play a role. The geometry of the cavopulmonary connections are also important in that turbulent flow produces energy loss and a reduction in effective driving pressure. It has been suggested that PVR is the key determinant of transpulmonary flow, delivery of pulmonary venous flow to the systemic ventricle, and, consequently, cardiac output (Fig. 16-12).<sup>97,114-124</sup>

In conclusion, the Fontan circulation can be described as a serial circulation with a single kinetic energy pump. Increased systemic venous pressures are necessary to create the transpulmonary pressure gradient that drives flow across the pulmonary vascular bed. Cardiac output depends on adequate preload and low PVR. Decreased cardiac output at rest and limited exercise tolerance are characteristics of the Fontan circulation.

### PHYSIOLOGY OF THE TRANSPLANTED HEART

According to the International Society of Heart and Lung Transplantation (ISHLT), children younger than 18 years of age account for about 12.5% of all heart transplantations. Every year, approximately 450 new pediatric cardiac transplantation cases are reported to this voluntary registry, mainly from centers in Europe and North America.<sup>125</sup> Major indications are cardiomyopathies, CHD, and a growing number of re-transplantations, especially in older children. The average survival time is currently 18 years for infants, 15 years for children (aged 1 to 10 years), and 11 years for teenagers. Ninety-two percent of transplant recipients describe a normal functional status with no limitations during physical activity.<sup>126,127</sup>

As survival continues to improve, more and more children with transplanted hearts will present to operating rooms and sedation suites for diagnostic studies and general procedures. A basic understanding of the physiologic changes in the transplanted heart and the implications of current immunosuppressive therapy are important for safe management.

### Physiology of the Denervated Heart

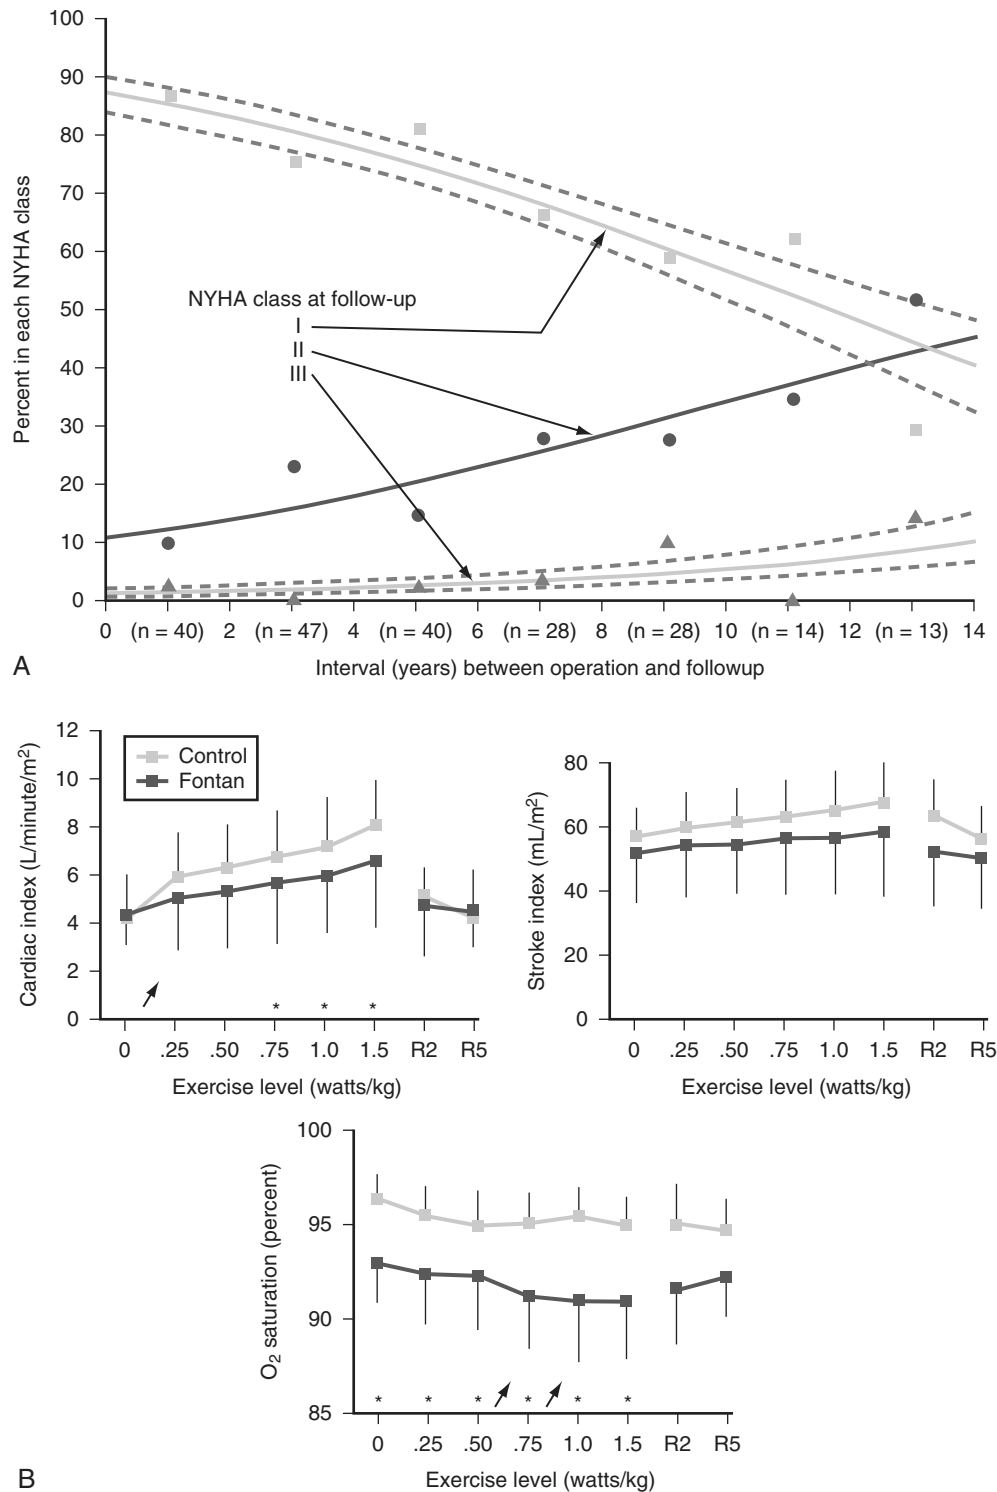

After transplantation, the function of the surgically denervated heart is primarily dependent on an intact Frank-Starling mechanism and stimulation from circulating catecholamines. The classic Frank-Starling mechanism describes the ability of the cardiac muscle to increase contractility in response to stretch or tension (e.g., increasing cardiac output with increases in venous return). Afferent and efferent denervation has multiple effects on circulatory control mechanisms and leads to significant physiologic changes, including an increase in the resting HR and a blunted response to stress and exercise. Despite excellent physical activity, exercise testing easily demonstrates that heart transplant recipients can usually achieve only 60% to 70% of normal capacity. In the transplanted heart, exercise-induced increase in cardiac output is initially caused by increase in stroke volume, a highly preload dependent process. Tachycardia occurs only later, in response to circulating catecholamines.<sup>128</sup> Further details of the altered physiology are summarized in Table 16-7.<sup>128</sup> The incidence, timing, and extent of sympathetic reinnervation are still being investigated, but the positive effects on cardiac performance have been clearly demonstrated.<sup>129</sup> During standardized exercise testing, transplant recipients with evidence of reinnervation show

**E-FIGURE 16-2** Change in peak oxygen uptake  $\dot{V}O_2$  over time in individual Fontan patients according to the presence of a morphologically right ventricle (orange circles) or left ventricle (blue circles). Solid and dashed lines indicate the average of the individual slopes of decrease of peak  $\dot{V}O_2$  in patients with morphologically right versus left ventricle, respectively. (From Giardini A, Hager A, Pace Napoleone C, Picchio FM. Natural history of exercise capacity after the Fontan operation: a longitudinal study. *Ann Thorac Surg* 2008;85:818-21.)

**E-FIGURE 16-3** Change in peak oxygen uptake  $\dot{V}O_2$  over time in individual Fontan patients according to the type of Fontan surgery. Orange circles indicate atriopulmonary or atrioventricular connections; blue circles refer to intracardiac or extracardiac total cavopulmonary connection (TCPC). The dashed and solid lines, respectively, indicate the average of the individual slopes of decrease of peak  $\dot{V}O_2$  in patients with and without a TCPC. (From Giardini A, Hager A, Pace Napoleone C, Picchio FM. Natural history of exercise capacity after the Fontan operation: a longitudinal study. *Ann Thorac Surg* 2008;85:818-21.)

**FIGURE 16-10 A**, Symptomatic outcomes of 334 survivors of Fontan operations who were monitored for 1 month to 20 years. The graph illustrates the changes since surgery in patients assessed as New York Heart Association (NYHA) classification I (blue squares), II (purple circles) or III (brown triangles). Although most children exhibited good functional status (NYHA class I) immediately after surgery, mild functional limitations evolved over time. Broken lines indicate 70% confidence intervals. **B**, Results of exercise studies (cardiac index, stroke index, and oxygen saturation versus exercise level) of 42 children after Fontan operation (purple squares) compared with normal control subjects (blue squares). Although the protocol was designed to achieve modest targets, significant differences emerged in the capacity of Fontan children to increase cardiac output with exercise, and systemic arterial oxygen saturation remained below normal throughout. The primary reason for the inability to increase cardiac output appears to be an inability to increase pulmonary blood flow and, consequently, systemic ventricular filling. Potential reasons for decreased arterial saturation include intrapulmonary shunting due to arteriovenous malformations and ventilation/perfusion imbalance. Arrows indicate a significant difference ( $P < 0.05$ ) in values between consecutive exercise levels. (**A** from Fontan F, Kirklin JW, Fernandez G, et al. Outcome after a "perfect" Fontan operation. *Circulation* 1990;81:1520-36; **B** from Gewillig MH, Lundstrom UR, Bull C, et al. Exercise responses in children with congenital heart disease after Fontan repair: patterns and determinants of performance. *J Am Coll Cardiol* 1990;15:1424-32. Reprinted with permission from the American College of Cardiology.)

**FIGURE 16-11** In the normal cardiovascular circulation (*left*), the pulmonary circulation (*P*) is connected in series with the systemic circulation (*S*). The right ventricle (*RV*) maintains a right atrial (*RA*) pressure that is lower than the left atrial (*LA*) pressure and provides enough energy for the blood to pass through the pulmonary resistance. In the Fontan circuit (*right*), the systemic veins are connected to the pulmonary artery (*PA*) without a subpulmonary ventricle or systemic atrium. In the absence of a fenestration, there is no admixture of systemic and pulmonary venous blood, but the systemic venous pressures are markedly elevated. Ao, Aorta; CV, caval veins; LV, left ventricle; V, single ventricle. (From Gewillig M, Brown SC, Eyskens B, et al: The Fontan circulation: who controls cardiac output? *Interact Cardiovasc Thorac Surg* 2010;10:428-33.)

**FIGURE 16-12** Several factors determine the transpulmonary gradient in the Fontan circulation. These include unobstructed venous return, adequate preload, and low intrathoracic pressure on the venous side; low pulmonary vascular resistance (*PVR*) and unobstructed pulmonary vessels; and, on the atrial side, adequate ventricular function, competent atrioventricular valves, normal sinus rhythm, and no evidence of outflow obstruction. LAP, Left atrial pressure; MPAP, mean pulmonary arterial pressure. (Courtesy A. Schure.)

improved endurance with greater peak HRs and better contractile function.

Chronic denervation also causes an altered response to many medications. Atropine, glycopyrrolate, digoxin, and pancuronium have no chronotropic effect on the denervated heart. Sympathomimetics that act indirectly, such as ephedrine and dopamine, have a blunted response, whereas direct-acting adrenergic agents such as epinephrine, isoproterenol, and dobutamine can cause exaggerated effects and should be carefully titrated.<sup>130</sup> Several case reports have described profound bradycardia and even cardiac arrest after neostigmine used for reversal of neuromuscular

Data from Schure AY, Kussman BD. Pediatric heart transplantation: demographics, outcomes, and anesthetic implications. *Paediatr Anaesth* 2011;21:594-603; and Cotts WG, Oren RM. Function of the transplanted heart: unique physiology and therapeutic implications. *Am J Med Sci* 1997;314:164-72.

AV, Atrioventricular; LVEDP, left ventricular end-diastolic pressure.

blockade.<sup>131-134</sup> Neostigmine has been shown to produce an atropine-sensitive, dose-dependent bradycardia in both recent (<6 months) and remote (>6 months) cardiac transplants. Direct stimulation of postganglionic nicotinic cholinergic receptors with denervation hypersensitivity, a direct effect of the old sinoatrial node on the pacemaker cell of the new sinoatrial node, and parasympathetic reinnervation have been postulated as potential mechanisms.<sup>135-137</sup> Avoidance of neuromuscular blockade, use of short-acting neuromuscular blocking agents without reversal, and use of edrophonium for reversal have all been suggested.<sup>133,134</sup> Edrophonium seems to have less effect on the HR in this population than neostigmine.<sup>138</sup>

The denervated heart is also extremely sensitive to adenosine. The magnitude and duration of the effect on the AV node is three to five times greater, and the dose should be reduced by 50%.<sup>139</sup> Calcium channel blockers and  $\beta$ -blockers are associated with exaggerated bradycardia and hypotension. The lack of reflex tachycardia can also lead to profound hypotension with the use of direct vasodilators such as nitroglycerine, nitroprusside, or hydralazine.

### Transplant Morbidity

Children who have undergone cardiac transplantation continue to experience significant morbidity associated with immunosuppressive therapy. Rehospitalization for treatment of infections

and episodes of rejection are common, especially during the first year (50%). Acute rejection episodes are a major threat. The incidence decreases from 30% during the first year to 12% after 5 years. Rejection is thought to be associated with the development of cardiac allograft vasculopathy (CAV) or coronary artery disease, which is a major cause of morbidity and graft failure. Indeed, 10 years after transplantation, 34% of children have CAV.<sup>127</sup> Most centers include annual coronary angiography or intravascular echocardiography as a part of regular rejection surveillance. Children with CAV present the same anesthetic challenges as adults with severe coronary artery disease and ischemic heart disease. Aggressive immunosuppressive therapy with induction and maintenance regimens carries its own risks. A detailed discussion is beyond the scope of this chapter, but in general, monoclonal or polyclonal T-cell antibodies (OKT, ATG) and specific interleukin 2 receptor antagonists (basiliximab, daclizumab) are used for the induction phase and various combinations of corticosteroids, calcineurin inhibitors (cyclosporine, tacrolimus, FK506), antiproliferative agents (azathioprine, mycophenolate mofetil), and target of rapamycin inhibitors (sirolimus) for maintenance. Side effects are common and include neurotoxicity with seizures, hypertension, liver and renal dysfunction, hyperlipidemia, diabetes, gingival hypertrophy, hypertrichosis, bone marrow suppression, and posttransplantation lymphoproliferative disease (PTLD).<sup>140</sup>

Several excellent review articles describe the anesthetic management of children with heart transplants (see also Chapter 21).<sup>141-143</sup> A thorough preoperative evaluation with attention to episodes of rejection, presence of coronary artery disease, and organ dysfunction; a detailed medication history with investigation of major side effects; consideration of the denervated physiology; and appropriate choice of anesthetic drugs and other medications are essential components of a sensible anesthetic plan for those with a transplanted heart.

## Cardiovascular Pharmacology

### RATIONAL USE OF VASOACTIVE DRUGS

Many factors influence the selection of appropriate inotropic and vasopressor therapies, including the clinical situation, underlying cardiac abnormalities, and perfusion requirements of other organs. The major goal is to improve tissue oxygenation. Oxygen delivery is principally dependent on cardiac output and oxygen content. In addition to an increased cardiac output (i.e., optimal HR, preload, contractility, and afterload), adequate hemoglobin concentration and oxygen saturation values are often important components. On the other hand, a careful balance of pulmonary and systemic blood flows can be crucial for certain congenital heart defects.

Catecholamines and catecholamine-like agents remain the most commonly used inotropic and vasoconstrictor drugs. It is likely that improvements in cardiac output in neonates in response to drugs such as dopamine or dobutamine are the result of increases in both HR and contractility. Some evidence exists in infants and young children after cardiac surgery that the increases in cardiac output produced by dopamine and dobutamine may be more related to a positive chronotropic effect than to an increase in the intrinsic contractile state.<sup>144-146</sup> With few exceptions, drugs that primarily increase afterload, such as  $\alpha$ -adrenergic agonists, have limited use in children. Large increases in afterload without corresponding improvements in contractile state are often poorly tolerated by infants and children,

particularly in the context of significant underlying contractile dysfunction.

### PRACTICAL CONSIDERATIONS FOR THE USE OF VASOACTIVE AGENTS

Commonly used drugs, their doses, and a summary of their effects on selected cardiac functions are presented in Table 16-8. Most of this information has been empirically derived from studies in adults. Limited direct information regarding the effects of commonly used vasoactive drugs in children at different ages and in various pathophysiologic states is available. Neonates, infants, and small children demonstrate unique responses to inotropic and vasoactive drugs due mainly to age-specific pharmacokinetics; differences in receptor types, number, and function; and a high variability in drug delivery. Substantial variations in volume of distribution and measured plasma concentrations have been observed in children receiving inotropic agents. As much as a 10-fold range in plasma concentration has been reported for a given infusion rate.<sup>147-149</sup>

Substantial pharmacodynamic variability (i.e., variability in the serum concentration required to produce the desired effect) can also be observed. Some of these differences are related to receptor maturation and function. For example, it appears that  $\beta$ -adrenergic receptors have a high density in the term neonate and young infant but their coupling to adenylyl cyclase may be incomplete.<sup>33,150</sup> In addition to developmental changes, which are to some extent controlled by thyroid hormone,  $\beta$ -receptor and adenylyl cyclase activities are diminished in response to sustained administration of exogenous  $\beta$ -agonists and also as a result of increased endogenous catecholamine concentrations, which are often seen as a complication of moderate to severe heart failure and other forms of severe stress (e.g., sepsis).<sup>151-153</sup>

In the neonatal myocardium, chronic catecholamine exposure may upregulate adrenergic receptor number or function, or both, perhaps mimicking the normal developmental program of increasing sympathetic nervous system activity as term approaches.<sup>154</sup> With further maturation in early postnatal life,  $\beta$ -adrenergic receptor density declines. The impacts of various pathophysiologic states on these processes have been incompletely identified. For example, congestive heart failure, cardiopulmonary bypass, and ischemic reperfusion all lead to decreased  $\beta$ -receptor and adenylyl cyclase expression and activity.<sup>155-158</sup> On the other hand, the myocardium of infants with tetralogy of Fallot exhibits increased  $\beta$ -receptor density and greater receptor-stimulated adenylyl cyclase activity with increased gene and protein expression.<sup>159,160</sup>

One must pay particular attention to technical issues when administering vasoactive infusions to infants. Infusions are often specifically prepared as very concentrated, nonstandardized solutions to minimize the amount of volume infused; hence, the potential for dose or concentration error is substantial. One study at a tertiary care children's hospital demonstrated that the actual concentration of prepared solutions varied significantly.<sup>161</sup> Because of the high concentration of these drugs relative to the child's size, small errors (either in calculation or in infusion pump flow rate) can have a large impact on the actual amount of drug delivered. The extremely small infusion rates can also lead to a delay in drug effect (see Chapter 51). Confirming that the pump drive mechanism is actually delivering drug at the distal end of the infusion tubing, connecting the infusion tubing as close to the child as possible, and using a carrier infusion to "push" the medication at a constant rate are important steps to ensure the

**TABLE 16-8** Inotropics and Vasopressors

Agent	Intravenous Dose	Comments
Dopamine	2-20 µg/kg/min infusion	Primary effects at $\beta_1$ , $\beta_2$ , and dopamine receptors, somewhat related to dose; lower doses (2-5 µg/kg/min) can increase contractility and can also have a direct dopaminergic receptor effect to increase splanchnic and renal perfusion; increasing doses increase contractility via $\beta$ -effects and also increase likelihood of $\alpha$ -mediated vasoconstriction; effects depend on endogenous catecholamine stores.
Dobutamine	2-20 µg/kg/min infusion	Relatively selective $\beta_1$ stimulation; also potential $\beta_2$ stimulation, tachycardia, and vasodilation, especially at higher doses (>10 µg/kg/min); may be less potent than dopamine, especially in immature myocardium; no significant $\alpha$ -adrenergic effects; tachydysrhythmias perhaps more likely than with dopamine; effects are independent of endogenous catecholamine stores.
Epinephrine	0.02-2.0 µg/kg/min infusion	Primary $\beta$ -effects to increase contractility and vasodilation at lower doses (0.02-0.10 µg/kg/min); increasing doses (>0.1 µg/kg/min) are accompanied by increased contractility and also increased $\alpha$ -mediated vasoconstriction; may be best choice to augment contractility and perfusion, especially in situations of severely compromised ventricular function, shock, or anaphylaxis.
Isoproterenol	0.05-2.0 µg/kg/min infusion	Pure, nonselective $\beta$ -agonist; significant inotropic, chronotropic ( $\beta_1$ and $\beta_2$ ) and vasodilatory ( $\beta_2$ ) effects; may be an effective pulmonary vasodilator in some children; tachycardia and increased myocardial oxygen consumption may be dose limiting; tachydysrhythmias may also occur; bronchodilator.
Phenylephrine	1-10 µg/kg bolus, 0.1-0.5 µg/kg/min infusion Preterm and term infants may require as much as 30 µg/kg (see Chapter 15).	Pure $\alpha$ -mediated vasoconstriction; no increase in contractility.
Amrinone	0.75-1 mg/kg repeated twice, maximum 3 mg/kg. Neonates and infants may require loading doses of 2-4 mg/kg and infusions of 10 µg/kg/min.	Increases cyclic adenosine monophosphate by phosphodiesterase inhibition; positive inotropy, positive lusitropy, and smooth muscle vasorelaxation; hypotension; reversible thrombocytopenia.
Milrinone	50-75 µg/kg loading dose, 0.5-1.0 µg/kg/min infusion	Similar to amrinone (antiplatelet effects may be less).
Calcium chloride Calcium gluconate	10-20 mg/kg/dose (slowly) 30-60 mg/kg/dose (slowly)	Positive inotropic and direct vasoconstricting effects; inotropy is significant only if ionized calcium is low and/or ventricular function is depressed by other agents; can slow sinus node; increases electrophysiologic abnormalities from hypokalemia and digoxin.
Digoxin	Total digitalizing dose (TDD): Premature: 20 µg/kg Neonate (1 month): 30 µg/kg Infant (<2 years): 40 µg/kg Child (2-5 years): 30 µg/kg Child (>5 years): 20 µg/kg Maintenance: 2.5-5 µg/kg q12hr	TDD given in divided doses: $\frac{1}{2}$ TDD followed by $\frac{1}{4}$ TDD q8-12hr $\times$ 2 increases cardiac contractility; slows sinus node and decreases atrioventricular (AV) node conduction; long half-life (24-48 hours) that is prolonged by renal dysfunction; numerous drug interactions; toxicity includes supraventricular tachycardia, AV block, ventricular dysrhythmias; symptoms include drowsiness, nausea, vomiting; toxicity exacerbated by hypokalemia.

safety and efficacy of drug infusions. The rate of the carrier infusion is also crucial. Most standard infusion setups require rates in excess of 5 mL/hr to effect rapid (less than about 10 minutes) changes in the concentration of drug delivered to the infant and therefore preclude all attempts of fluid limitation.

## VASOACTIVE DRUGS

### Dopamine

Dopamine continues to be the most frequently used inotropic agent in neonates, infants, and children. It has activity at  $\alpha$ -,  $\beta$ -, and dopaminergic receptors. Dopamine augments cardiac contractility through two mechanisms. First, it directly stimulates cardiac  $\beta_1$ -receptors and provokes norepinephrine release from cardiac sympathetic nerve terminals. Second, circulating concentrations of endogenous epinephrine and norepinephrine increase significantly during dopamine infusion, leading to the suggestion that at least some of the effects of a dopamine infusion are indirectly mediated via induced release of endogenous

catecholamines.<sup>162</sup> Because of its indirect effects, particularly the release of myocardial norepinephrine stores, the response to dopamine may be diminished in children with congestive heart failure or other relatively long-standing forms of hemodynamic stress.

Activity at dopaminergic receptors in the kidney and gastrointestinal tract can lead to improved perfusion of these organ systems. The evidence that dopamine specifically and selectively improves renal perfusion via stimulation of renal dopaminergic receptors (i.e., as opposed to a nonspecific and generalized improvement in cardiac output that might occur with any positive inotrope) is conflicting.<sup>163-167</sup> Regardless of the mechanism, most evidence indicates that renal blood flow and perfusion are increased by dopamine, even at very large doses.

Similar to the situation with other inotropes, pharmacokinetic studies of dopamine have shown wide variability in serum concentration in neonates and children.<sup>168,169</sup> Because of this variability in plasma concentration for a given infusion rate, as well as the wide range of serum concentrations necessary to produce

a given effect, doubling or halving a given dopamine infusion rate may be a logical way to approach alterations in therapy. The frequent practice of increasing or decreasing the infusion rate by small proportions (i.e., 5% to 10%) may not be consistent with what is currently known about the pharmacokinetics and pharmacodynamics of most inotropes.

Neonates have classically been considered to have a greater dependence on HR, a reduced myocardial compliance, and a relative resistance to inotropic effects of exogenous catecholamines. Nonetheless, there is substantial echocardiographic evidence of increased myocardial contractility occurring at small dopamine infusion rates ( $\leq 5 \mu\text{g/kg/min}$ ) and before significant increases in HR.<sup>170,171</sup> Evidence about the effects of dopamine in sick preterm infants is also somewhat controversial.<sup>164,172-176</sup> There may be a relative dissociation between its effects on the renal and mesenteric beds in these infants, such that a portion of the increase in arterial blood pressure seen with a dopamine infusion is the result of mesenteric vasoconstriction and an actual decrease in mesenteric blood flow.

Although it is generally believed that vasoconstriction is significant when large infusion rates ( $>10$  to  $15 \mu\text{g/kg/min}$ ) of dopamine are employed, studies have shown evidence of improved cardiac output and renal blood flow even at very large doses ( $\geq 20 \mu\text{g/kg/min}$ ) in neonates and infants.<sup>171a</sup>

The effects of dopamine on PVR are variable. Both minimal effect and increased PVR have been found.<sup>146,177-183</sup> The effects of dopamine on PVR most likely depend on the dose as well as the underlying state of the vascular endothelium and smooth muscle. Vasoconstriction may be more likely after ischemia-reperfusion and in the presence of hypoxia. Conversely, the presence of vasodilators, such as nitroprusside, or  $\alpha$ -adrenergic blockers, such as phenoxybenzamine, can prevent increased PVR in response to dopamine.<sup>184,185</sup> Overall, dopamine remains the drug of choice in most infants and children, owing to its beneficial effects on mesenteric and renal blood flow, lesser chronotropic effects than some other agents, and a somewhat reduced arrhythmogenic potential.

### Dobutamine

Dobutamine is a structural analogue of isoproterenol. It was developed to provide relatively selective  $\beta$ -adrenergic receptor stimulation. The inotropic effects are somewhat less potent than those of dopamine, and it has considerably less overall  $\alpha$ -adrenergic potential compared with dopamine. Dobutamine does possess significant  $\beta_2$ -adrenergic receptor agonist properties, and for this reason it can cause peripheral vasodilation. Substantial vasodilation and tachycardia occur at larger infusion rates ( $\geq 10 \mu\text{g/kg/min}$ ).<sup>145,186-189</sup> The tendency toward significant tachycardia and tachyarrhythmia may be greater in neonates than in older children or adults. There is some evidence that the efficacy of dobutamine is reduced in immature animals, perhaps because of greater circulating catecholamine concentrations and alterations in  $\beta$ -receptor expression and function in these immature animal models.<sup>144,145</sup>

Because the actions of dobutamine do not depend on endogenous catecholamine stores, the drug may be more effective in increasing cardiac output in patients with severe congestive heart failure or cardiogenic shock.<sup>190,191</sup> In children with normal LV function, dobutamine has been shown to significantly increase LV relaxation. A decrease in end-systolic wall stress likely contributes to the improved diastolic relaxation caused by dobutamine.<sup>192</sup> As with dopamine, questions of a relative resistance in neonates have arisen, although evidence indicates that

dobutamine improves LV contractility in neonates with LV dysfunction.<sup>193</sup> Dobutamine does not selectively improve renal or mesenteric blood flow independently of its effect of increasing cardiac output. The improvement in cardiac output seen with dobutamine is related to both increased contractility and decreased SVR via vasodilation. Pulmonary vasodilation in the presence of increased PVR may also occur.<sup>194</sup>

As was discussed with dopamine, exponential increases in serum concentrations are required to produce linear improvements in cardiac index. There is also substantial pharmacokinetic variability in dobutamine plasma concentrations.<sup>148,195,196</sup> Tolerance may occasionally develop.<sup>197</sup> In one animal study, high-dose dobutamine infusion was associated with significant dysfunction of platelet aggregation after hypoxia and reoxygenation.<sup>198</sup>

### Isoproterenol

Isoproterenol is a pure, nonselective  $\beta$ -adrenergic agonist.<sup>199</sup> It increases HR and contractility and causes vasodilation in mesenteric, renal, and skeletal muscle tissue beds. Isoproterenol is also a fairly effective vasodilator of the pulmonary circulation.<sup>200</sup> Significant tachycardia almost always accompanies its use. The tachycardia and greater contractility cause a significant increase in myocardial oxygen consumption, which is usually well tolerated. However, these changes may be limiting in compromised hearts. The pulmonary vasodilation produced by isoproterenol may be useful in settings in which tachycardia is either unimportant or somewhat beneficial.<sup>201</sup> Systemic vasodilation induced by isoproterenol can be sufficiently profound as to cause systemic hypotension.<sup>182,202</sup> The positive chronotropic effects of isoproterenol may be useful in children with bradycardia.<sup>203</sup> The drug is increasingly used in electrophysiology suites to facilitate the detection of abnormal conduction pathways in infants and children under general anesthesia.<sup>204</sup> Isoproterenol is also a potent bronchodilator. Prolonged use or high doses of isoproterenol and other catecholamines may be associated with the development of myocardial fibrosis.<sup>205</sup>

### Epinephrine

Epinephrine has  $\alpha$ -,  $\beta_1$ -, and  $\beta_2$ -adrenergic agonist effects. Data derived mainly from studies in adults indicate that lower doses of  $0.02$  to  $0.1 \mu\text{g/kg/min}$  are associated with predominantly  $\beta$ -adrenergic effects. In this range, increases in HR and systolic blood pressure and reduced diastolic blood pressure due to skeletal muscle vasodilation predominate. Doses between  $0.1$  and  $0.2 \mu\text{g/kg/min}$  have mixed  $\alpha$ - and  $\beta$ -effects. At larger doses,  $\alpha$ -adrenergic-induced vasoconstriction is significant, and hence there is reduced skin, muscle, renal, and mesenteric blood flow. Compared with pure  $\alpha$ -agonists, epinephrine provides significant inotropic effect. The effects of epinephrine do not depend on endogenous tissue catecholamine stores. Based on experience, epinephrine seems to be effective in children who do not respond to dopamine or dobutamine, particularly those with significant dysfunction of the systemic ventricle in the immediate postoperative period. The addition of moderate vasoconstriction to increased contractility may be advantageous to maintain myocardial perfusion and may also increase both systemic and pulmonary blood flow in children with shunt-dependent circulations. Important adverse effects include dysrhythmias (usually ventricular) and, at larger doses, regional ischemia and hypoperfusion due to vasoconstriction. Pharmacokinetic studies have shown a linear relationship between serum concentration and infusion rate, but again there is significant variability in the individual response to a specific concentration.<sup>206</sup>

### Phenylephrine

Phenylephrine is a pure  $\alpha$ -adrenergic agonist. As such, its major function is to cause peripheral vasoconstriction. It has no  $\beta$ -adrenergic or inotropic effect and therefore does not increase contractility. It may be temporarily used to improve afterload, systemic blood pressure, and, therefore, critical organ blood flow. But without concurrent inotropic support, an isolated acute increase in afterload is often poorly tolerated, particularly by a compromised ventricle. There are a few situations in which phenylephrine can be extremely useful. For example, it can be given to increase systemic afterload and thereby decrease right-to-left shunting in children with tetralogy of Fallot and dynamic RVOTO ("Tet-spell"). Any additional increase in contractility would worsen the outflow obstruction in this situation. Phenylephrine is also beneficial in cyanotic children who depend on a systemic-to-PA shunt for pulmonary blood flow and adequate oxygenation. The increased afterload may increase flow across the shunt and improve pulmonary blood flow. Treatment of acute hypotension in children with hypertrophic obstructive cardiomyopathy or critical aortic stenosis is another potential indication.<sup>207-210</sup>

### Vasopressin

Arginine vasopressin is a peptide secreted by the pituitary gland. Secretion is promoted by angiotensin II and increased stimulation from hypothalamic osmoreceptors; increased activity from cardiopulmonary baroreceptors and increased levels of natriuretic peptide inhibit the secretion of vasopressin. Vasopressin acts at the tissue level by binding to specific receptors. It causes vasoconstriction via vasopressin<sub>1</sub> ( $V_{1a}$ ) receptors and renal reabsorption of water, renal secretion of renin, and synthesis of renal prostaglandins via vasopressin<sub>2</sub> ( $V_2$ ) receptors. In addition, vasopressin may mediate vasodilatation via  $V_2$  receptors by increasing the release and synthesis of nitric oxide and vasodilating prostaglandins. Vasopressin also sensitizes baroreceptors and therefore may cause vasodilatation by decreasing sympathetic activity. Normally, vasopressin acts primarily via  $V_2$  receptors in the kidney to promote water retention. However, during extreme hypotension, vasopressin may act via  $V_{1a}$  receptors in the vascular endothelium to induce intense vasoconstriction.

In adults, vasopressin has been shown to be beneficial in the treatment of vasodilatory shock and during cardiopulmonary resuscitation.<sup>211</sup> A few pediatric case reports and small observational studies have demonstrated improved blood pressure and accelerated weaning of inotropic support with low-dose vasopressin.<sup>212-215</sup> However, a multicenter randomized, controlled trial in children with vasodilatory shock could not confirm these findings. Low-dose vasopressin (0.0005-0.002 U/kg/min) had no beneficial effects compared with placebo; there was even a suggestion of increased mortality.<sup>216</sup> Further studies are necessary to establish the effectiveness and safety of vasopressin in children. Currently its role as a "rescue" medication for the treatment of catecholamine-resistant vasodilation during or after congenital cardiac surgery<sup>217,218</sup> and for refractory hypotension in infants with extremely low birth weight<sup>219</sup> is being investigated. A relative deficiency of arginine vasopressin has been reported in some children with CHD who underwent open heart surgery. In a subgroup of children, baseline concentrations of arginine vasopressin were reduced and remained reduced for up to 48 hours after cardiopulmonary bypass. Interestingly, only children with

reduced concentrations of vasopressin responded to vasopressin therapy.<sup>220</sup> Extrapolated from adult data, pediatric dosing algorithms currently range from 0.0003 to 0.002 U/kg/min. Careful attention to the infusion rate is important, especially when programming syringe pumps. The literature and common reference tools often cite the doses in U/min, U/kg/hr, U/kg/min or even mU/kg/min, which can be quite confusing and can lead to potential errors.

### Phosphodiesterase Inhibitors

Phosphodiesterase inhibitors, which include amrinone, milrinone, and enoximone, are the most commonly used non-catecholamine-mediated inotropic agents. Their mechanism of action is also relatively straightforward. Phosphodiesterases degrade cyclic adenosine monophosphate (cAMP) to 5'-AMP. Phosphodiesterase inhibitors prevent this degradation and therefore increase levels of cyclic nucleotides, primarily cAMP. The increased concentration of this secondary messenger leads to an increase in calcium availability and thus increased contractility. Because the response is related to an increase in cAMP and not purely to inhibition of phosphodiesterase, the greatest effect occurs if initial levels of cAMP exceed normal values. In this way, synergy exists with  $\beta$ -agonists.<sup>221</sup> The absence of adrenergic stimulation minimizes effects on HR, rhythm, and dependency on endogenous tissue catecholamine stores. In addition to positive inotropic effects, these drugs also have significant lusitropic properties (i.e., diastolic relaxation) and promote peripheral vasodilation.<sup>222-224</sup> Phosphodiesterase drugs may also have substantial antiinflammatory properties that are not well understood at present.<sup>225-227</sup>

### Amrinone

As with all phosphodiesterase inhibitors, there has been an ongoing debate about the relative contribution of systemic vasodilation and afterload reduction versus increased cardiac contractility as the underlying mechanism for improving cardiac output. The bulk of evidence currently indicates that amrinone produces significant increases in myocardial contractility and reduces ventricular afterload.<sup>223,228,229</sup> Evidence of amrinone-induced improvements in cardiac performance in neonates and infants after cardiac surgery has been demonstrated in a number of situations, including postoperatively in children who have undergone the arterial switch procedure and in older children who have undergone the Fontan operation.<sup>224,228,230</sup> Pharmacokinetic data in children suggest that the loading and infusion doses for amrinone need to be approximately twice those reported for adults.<sup>231</sup> In addition to differences in volume of distribution and clearance (both greater in infants), binding of amrinone to the oxygenator membrane may be another factor that needs to be considered if the loading dose is administered during cardiopulmonary bypass.<sup>232</sup> Overall, these data suggest that loading doses of 2 to 4 mg/kg and infusion rates starting in the range of 10  $\mu$ g/kg/min may be indicated in the neonate and infant.<sup>232</sup> Large bolus doses of amrinone can cause significant systemic hypotension, particularly in the period immediately after cardiac surgery. From a practical standpoint, it may be best to administer the loading dose of amrinone slowly over the period of 1 hour. Caution is also indicated because the elimination half-life of amrinone is large (3 to 15 hours). Other side effects include thrombocytopenia that is reversible, occasional drug-related fever, and increased hepatic enzymes.

### Milrinone

Several studies have demonstrated improved cardiac output and overall efficacy of milrinone after cardiac surgery in neonates and infants and with other states associated with ventricular dysfunction.<sup>233-238</sup> Milrinone has a larger volume of distribution and greater rate of clearance in infants and children compared with adults; adjustments to bolus dosing and infusion rates have therefore been recommended.<sup>233,238</sup> Unlike amrinone, milrinone does not appear to bind to the cardiopulmonary bypass circuit and has less deleterious effect on platelet function. Loading doses of 50 to 100  $\mu\text{g/kg}$  (typically 75  $\mu\text{g/kg}$ ) and initial infusion rates of 0.50 to 1.0  $\mu\text{g/kg/min}$  have been recommended.<sup>233,236</sup> Neonates with HLHS who underwent stage I palliation exhibited reduced renal clearance in the immediate postoperative period, and dose adjustments should be considered (i.e., infusion rates of 0.2  $\mu\text{g/kg/min}$ ).<sup>239</sup> Milrinone increases cardiac output, reduces cardiac filling pressures, and reduces afterload; its effects are typically not associated with tachyphylaxis and are independent of  $\beta$ -adrenergic receptor density or activity. A recent multicenter, double-blind, placebo-controlled trial demonstrated that prophylactic use of high-dose milrinone significantly reduced the development of low cardiac output syndrome relative to placebo after cardiac surgery in high-risk pediatric subjects.<sup>235</sup> Milrinone is also increasingly used to improve oxygenation in neonates with persistent pulmonary hypertension who are unresponsive to therapy with nitric oxide.<sup>240</sup> Animal studies have shown that IV or inhaled milrinone enhances the response of the pulmonary vasculature to iloprost and prostacyclin.<sup>241,242</sup>

### Enoximone

Enoximone is a phosphodiesterase inhibitor that has been used extensively in Europe but is not currently available in the United States. Its properties are similar to those of the other members of its class.<sup>222,243</sup> Improvements in indirect indices of cardiac function, such as mixed venous oxygen saturation, ventricular filling pressures, and systemic arterial blood pressure, were observed in infants treated with enoximone after cardiac surgery. In addition, the length of hospital stay was reduced.<sup>244</sup> Enoximone was also useful to support cardiac function and potentially reduce PVR in children after cardiac transplantation.<sup>245</sup>

### Digoxin

Digoxin remains the most frequently administered oral inotropic agent. Its efficacy in children with congestive heart failure due to large left-to-right shunts has been questioned. The clinical picture in such children often improved without echocardiographic evidence of increased contractility, and frequently progressive ventricular dilatation was observed.<sup>246,247</sup> Use of digoxin to improve RV dysfunction due to pulmonary hypertension or as part of a multimodal therapy during the interstage phase for infants with single ventricle physiology has also been debated.<sup>248</sup>

Digoxin has both direct and indirect effects. Its direct effects are mediated by inhibition of the membrane sodium-potassium ATPase and thereby outward sodium ion flux. The resulting increased intracellular sodium concentration stimulates the membrane sodium-calcium exchanger, producing increased intracellular calcium and positive inotropic effect. The indirect effects of digoxin are mediated by stimulation of the parasympathetic nervous system. The parasympathetic effects of digoxin result in slowing of atrial and AV node conduction. The drug can also be used to slow down the ventricular response in atrial flutter and

atrial fibrillation and to treat supraventricular tachycardia (SVT) (see later discussion).

Because digoxin has a slow distribution phase after oral administration and a long elimination half-life (up to 1 to 2 days in neonates and young infants), a loading dose is usually administered (see Table 16-8). Renal dysfunction can significantly prolong the elimination half-life. Therapeutic digoxin levels are between 0.5 and 2.0 ng/mL. IV and oral dosing regimens are the same, although the onset of electrophysiologic effects from IV dosing is much more rapid (5 to 20 minutes).

Many drugs interact with digoxin and influence its pharmacokinetics. It should be assumed that almost any drug administered along with digoxin can affect the absorption and clearance, usually necessitating a reduction in dose.<sup>249,250</sup> The likelihood of digoxin toxicity increases with serum concentrations greater than 3 ng/mL.<sup>251,252</sup> Symptoms of toxicity include drowsiness, nausea, and vomiting. Various conduction abnormalities and SVT are the most frequent cardiac rhythm manifestations of digoxin toxicity in infants and young children. Older children and adults are more likely to experience AV block, ventricular dysrhythmias, junctional tachycardia, and premature ventricular contractions. Hypokalemia, specifically intracellular potassium depletion (often a result of longstanding diuretic use), exacerbates the proarrhythmogenic effects of digoxin.

### CALCIUM

The role, mechanisms of action, and potential for deleterious consequences of IV calcium continue to be controversial.<sup>253</sup> It is the ionized calcium concentration that is important for myocardial function. Calcium is a positive inotrope, particularly when it is administered in the presence of ionized hypocalcemia. It may also improve ventricular contractility when LV function is depressed by halothane,  $\beta$ -adrenergic blockade, or disease (e.g., sepsis).<sup>254,255</sup> In the presence of a normal myocardium and normal ionized calcium concentrations, the effects of IV calcium on contractility are much more modest.<sup>256</sup> Extracellular calcium levels also play an important role in the regulation of peripheral vascular resistance. A calcium-sensing receptor (CaSR) has been identified on vascular cell walls.<sup>257</sup>

There is evidence in adults that the primary effect of calcium administered after cardiac surgery is to increase SVR and mean arterial pressure with little or no effect on intrinsic myocardial contractility.<sup>253,258</sup> In fact, the increase in afterload, if not accompanied by a corresponding increase in contractility, may only serve to decrease stroke volume and cardiac output. Calcium may cause or exacerbate reperfusion injury and cellular damage by mechanisms that include activation of calcium-dependent proteases and phospholipases and organelle damage due to cellular calcium overload.<sup>259,260</sup> These concerns are particularly relevant in children immediately after cardiac surgery. IV calcium may also attenuate the  $\beta$ -adrenergic effects of concurrently administered epinephrine.<sup>263</sup>

The role of IV calcium administration in neonates and young infants, both alone and after cardiac surgery, is more complicated. Preterm and term neonates have erratic calcium handling and are prone to ionized hypocalcemia.<sup>261,262</sup> The neonatal myocardium is more sensitive to ionized hypocalcemia than the adult myocardium, owing to reduced intracellular calcium stores, immaturity of sarcoplasmic reticulum calcium-handling mechanisms, and greater dependency on transmembrane calcium flux for excitation-contraction coupling.<sup>263</sup> Furthermore, the need to administer

substantial volumes of citrated and albumin-containing blood products (both of which bind calcium) and other fluids after cardiopulmonary bypass increases the likelihood of ionized hypocalcemia.<sup>264</sup> The most prudent approach includes awareness of the greater dependency of the immature myocardium on extracellular calcium, monitoring of ionized calcium concentrations, and careful administration to maintain normal, or at most mildly increased, ionized calcium concentrations. This approach is particularly needed in neonates and in those with diminished LV function. Administration of large bolus doses of calcium immediately on reperfusion of the heart after a period of ischemia is probably ill advised because of the potential to exacerbate reperfusion injury and even to cause myocardial contracture.

Extravasation of calcium can cause local venous irritation and significant tissue necrosis. Although it has been suggested that calcium gluconate may cause less harm in this regard than calcium chloride, we recommend that both forms be administered via a centrally positioned catheter whenever possible. Both forms of calcium increase ionized calcium concentrations similarly when equal amounts of elemental calcium are administered.<sup>265</sup> Calcium may cause significant slowing of AV conduction and should be administered cautiously in children with sinus bradycardia or junctional rhythm. Care must also be exercised when administering calcium to children who are receiving digoxin, particularly in the presence of concurrent hypokalemia, because IV calcium exacerbates the potential for digoxin-induced dysrhythmias in this setting.

### TRIIODOTHYRONINE

Triiodothyronine hormone ( $T_3$ ) is essential for the maturation of sarcolemmal calcium channels, myosin, actin, and troponin. In addition, hypothyroid rats demonstrate reduced numbers of  $\beta$ -receptors and reduced density of stimulatory secondary messenger protein with an increase in inhibitory secondary messenger protein density.  $T_3$  is mostly produced by monodeiodination of thyroxine. This process is inhibited by surgery, hypothermia, catecholamines, propranolol, and amiodarone; therefore, postoperative  $T_3$  levels are often reduced.<sup>266-268</sup>

$T_3$  replacement therapy acts via two pathways, intranuclear and extranuclear. Intranuclear effects include an increase in mitochondrial density and respiration, an increase in contractile protein synthesis, and an upregulation in  $\beta$ -adrenoceptors. Extranuclear effects include an improvement in glucose transport, increased stimulation of L-type calcium channels with subsequent calcium mobility, and increased efficiency in calcium reuptake with subsequent improvement in diastolic relaxation.

Endocrine function is compromised after cardiac surgery. Infants younger than 3 months of age with low  $T_3$  concentrations on intensive care admission after cardiac surgery have a more complicated intensive care course. Low cortisol concentration is common in the early postoperative period but is not associated with postoperative complications.<sup>269</sup> A randomized, double-blind, placebo-controlled study of  $T_3$  administration in children undergoing simple or complex cardiac surgery demonstrated that myocardial function was better and length of stay in the intensive care unit was decreased in the  $T_3$  group.<sup>270</sup>  $T_3$  improved contractility without any associated increase in oxygen consumption. In addition, the  $T_3$  group demonstrated no delay in recovery of thyroid function secondary to exogenous administration. The dose of  $T_3$  used was 2  $\mu\text{g}/\text{kg}$  on day 1 followed by 1  $\mu\text{g}/\text{kg}$  on days 2 through 12. Many of the follow-up studies have been flawed by small numbers and significant patient heterogeneity,

and routine postoperative  $T_3$  replacement therapy remains controversial.<sup>271-274</sup>

### CALCIUM-SENSITIZING AGENTS

#### Levosimendan

Calcium-sensitizing agents represent a relatively new class of drugs with inotropic properties. Levosimendan is one of the best studied drugs in this class. Although its mechanism of action is not entirely clear, it seems to maintain the calcium-binding site of troponin C in its active conformation. This shifts the calcium binding-concentration relationship toward increased binding (i.e., more binding at reduced intracardiac calcium concentrations). Contraction is thereby enhanced for a given cytosolic calcium concentration. In contrast to other types of inotropic agents, myocardial contractility is greater with minimal increase in oxygen demand. The concept of increasing the sensitivity to calcium rather than the cellular calcium concentration is also attractive because it reduces the deleterious effects of increased calcium concentrations on oxygen consumption, mitochondrial function, and activation of various calcium-dependent proteases and phospholipases (e.g., during ischemia-reperfusion).

Levosimendan has also been shown to stimulate membrane and mitochondrial potassium-sensitive ATP ( $K_{\text{ATP}}$ ) channels. The former dilates both the coronary and the peripheral vasculature. Opening mitochondrial  $K_{\text{ATP}}$  channels is likely to be an important mechanism of pharmacologic (and anesthetic) preconditioning and potential cytoprotection. Interestingly, and for reasons that are not entirely clear, levosimendan has either no effect or a positive effect on lusitropy (diastolic relaxation). At much larger doses than clinically used, it does inhibit phosphodiesterase III. Compared with other inotropic agents (e.g., dopamine, amrinone, milrinone), its efficacy as a positive inotrope is maintained in the depressed myocardium. Both its mechanism of action and experience thus far indicate limited, if any, potential to stimulate arrhythmias.<sup>275</sup>

Clinical effects include improved cardiac output, reduced ventricular filling pressures, and decreased PVR during the acute treatment of adult patients with either stable or decompensated heart failure.<sup>276-279</sup> However, mortality studies failed to show any improvements in short- or long-term prognosis for acute heart failure with levosimendan compared to dobutamine or placebo.<sup>280</sup> Other investigations demonstrated improved cardiac performance after cardiectomy and bypass, including beneficial responses in adult patients who appeared to be poorly responsive to other inotropes.<sup>281-286</sup> Beneficial effects were also found with levosimendan pretreatment directly before bypass.<sup>287</sup>

Current recommendations suggest a 6- to 12- $\mu\text{g}/\text{kg}$  loading dose followed by an infusion of 0.05 to 0.2  $\mu\text{g}/\text{kg}/\text{min}$ . The drug's elimination half-life is approximately 1 hour. There is at least one metabolite that has prolonged (approximately 80 hours) effects, and this may, in part, account for observations of sustained benefit after discontinuation of the drug.<sup>288</sup> There are limited data available regarding its use in children or immature animal preparations.<sup>289-297</sup> One study in a relatively small, heterogeneous group of inotrope-dependent children with acute or end-stage heart failure demonstrated significant reductions in the use of inotropes in both groups and improved ejection fraction in those with acute heart failure.<sup>294</sup> Another study compared milrinone and levosimendan in children after congenital cardiac surgery and concluded that levosimendan is at least as effective as milrinone.<sup>291</sup> These early data and the drug's mechanism of action suggest the need for further study in children and a likely

indication for use in infants and children with decreased myocardial performance from a variety of causes, including cardiac surgery, myocarditis, and sepsis.<sup>298</sup>

### B-TYPE NATRIURETIC PEPTIDE AND NESIRITIDE

B-type natriuretic peptide (BNP) and its N-terminal precursor (NTpBNP) are members of the natriuretic peptide family. These peptides are released from the heart in response to pressure and volume overload and play an important role in maintaining fluid balance and hemodynamic stability. BNP is secreted from cardiac ventricles in response to increased stimulation of cardiac stretch receptors and increased wall tension. It acts mainly via natriuretic peptide receptors (NPRs) that are present in large vessels and kidneys. Once stimulated, NPRs promote diuresis, natriuresis, and vasodilation and inhibit the renin-angiotensin-aldosterone system. BNP is used as a marker for heart failure in adults and as a monitor for the response to anticongestive heart failure therapies.<sup>299</sup> These markers are also increasingly used to diagnose cardiovascular disease in neonates, infants, and children. The concentrations of NTpBNP are often markedly increased immediately after birth but decrease during the first week of life. Age-adjusted cut points and reference values have been suggested.<sup>300,301</sup> Currently, it is unclear whether these biomarkers can significantly improve diagnostic accuracy or even serve as a prognostic tool.<sup>302</sup>

Nesiritide is a recombinant form of BNP and therefore acts via NPRs to promote diuresis, natriuresis, and vasodilation. Early investigations in the adult population suggested that nesiritide may be beneficial for patients with decompensated heart failure; it seemed to improve cardiac output, reduce pulmonary capillary occlusion pressure, and dilate arterial and venous vessels with only minimal increase in HR or myocardial oxygen consumption.<sup>303-305</sup> However, a recent multicenter study found no significant advantages of nesiritide and only recommended its use as an individualized case-based therapy.<sup>306</sup> Although nesiritide reduces mean arterial pressure in children after cardiac surgery, more extensive studies are required before its usefulness and safety in children can be determined.<sup>307-313</sup>

### β-BLOCKING AGENTS

There are several indications for the use of β-blockers in children, including control of hypertension (both acutely in a perioperative period and chronically), treatment of cyanotic spells and RVOTO in tetralogy of Fallot, reduction of LVOTO in hypertrophic cardiomyopathy, control of HR in thyrotoxicosis and pheochromocytoma, and control of SVT (see later discussion).<sup>314-318</sup> In contrast to the situation in adults, the use of β-blockers to treat chronic heart failure in children is controversial.<sup>319</sup> Important distinctions include β-receptor subtype selectivity, variability in half-life and metabolism, and intrinsic sympathomimetic activity. Even “selective” β-blockers lose their selectivity at increased plasma concentrations.

#### Propranolol

Propranolol is one of the most frequently used β-blockers in children. Typical oral doses start at 0.25 to 0.5 mg/kg every 6 hours, titrated every 3 to 5 days; the usual dose is 2 to 4 mg/kg/day. A sustained-release form is available for older children who are able to swallow pills. IV propranolol is administered at doses of 0.01 to 0.1 mg/kg over several minutes; this may be increased if necessary (maximum dose 1 mg in infants, 3 mg in children). Sinus bradycardia and hypotension can be serious

complications, particularly in infants or after IV administration. Propranolol may also cause conduction disturbances at the level of AV node and worsen pump function in congestive heart failure. Other important adverse effects include fatigue, depression, and lethargy. Interactions with the β<sub>2</sub>-receptor may exacerbate bronchospasm and predispose children to hypoglycemia.<sup>320</sup> Propranolol is primarily metabolized in the liver. Significant population variability in its kinetics has been noted. Metabolism is also affected by factors that alter hepatic blood flow and hepatic metabolic enzyme activity. Its major metabolite, 4-hydroxypropranolol, is also active.<sup>315</sup>

#### Atenolol

The use of atenolol has been increasing in children.<sup>318,321,322</sup> Compared with propranolol, it is more selective for the β<sub>1</sub>-adrenergic receptor subtype; the elimination half-life is 8 to 12 hours. There is little hepatic biotransformation, and there are no active metabolites. The typical starting dose is 0.8 to 1.5 mg/kg/day in one or two doses daily, with an upper limit in the range of 2 mg/kg/day. No IV form is available. Atenolol does not cross the blood-brain barrier, so some of the limiting adverse effects common to propranolol are absent. At large doses, β<sub>1</sub> selectivity is probably lost, leading to the potential to exacerbate bronchospasm and hypoglycemia.

#### Esmolol

Esmolol is a relatively selective β<sub>1</sub>-adrenergic blocker with several unique features. Its onset is fast, it can easily be titrated to a desired end point, and its effects are rapidly terminated via metabolism by red blood cell and plasma esterases.<sup>323,324</sup> The drug has been particularly useful for the acute control of perioperative hypertension and for treatment of supraventricular tachyarrhythmia (see later discussion). Loading doses between 100 and 500 μg/kg given over 1 to 5 minutes are followed by maintenance infusions of 50 to 100 μg/kg/min. If the desired response is not achieved, the infusion rate is then typically doubled every 5 minutes until a desired response is achieved.

Specific data on pediatric dosing are limited at present.<sup>325</sup> One study investigated the pharmacokinetics of esmolol therapy after an episode of stimulated or spontaneous SVT. The results were similar to the findings in the adult population.<sup>326</sup> A maximum loading dose of 500 μg/kg and infusion rates of 250 to 300 μg/kg/min are currently suggested. A major potential adverse effect of esmolol is hypotension, particularly during bolus therapy. As noted earlier, esmolol rapidly distributes and has a very small elimination half-life (7 to 10 minutes) that is unaffected by organ blood flow or disease. Therefore, hypotension is usually short-lived, but therapy with vasopressors may occasionally be required until it resolves.<sup>327</sup>

#### Labetalol

Labetalol has nonselective β-adrenergic blocking properties and is also a selective α-adrenergic receptor blocker. The ratio of α- to β-blockade efficiency is 1:3 and 1:7 after oral and IV administration, respectively. The primary use of labetalol in children is to control hypertension. The drug has been given intravenously to treat hypertensive crisis, to control hypertension after aortic coarctation repair, and as an adjunct to induce controlled hypotension during surgery.<sup>328-331</sup> Typical doses are 0.1 to 0.4 mg/kg given every 5 to 10 minutes until the desired effect is achieved with infusions of 0.25 to 1 mg/kg/hr. The elimination half-life of labetalol is 3 to 5 hours.

### Carvedilol

Carvedilol is a newer nonselective  $\beta$ -blocker with additional vasodilatory and also some antioxidant properties.<sup>332,333</sup> The ratio  $\beta_1$  to  $\alpha_1$  blockade is 1.7:1. It is primarily used for the treatment of heart failure. In adults, significant benefit has been demonstrated, including reduced mortality, reduced hospital stay, improved New York Heart Association (NYHA) functional class, and a somewhat reduced progression of the clinical disease.<sup>334</sup> However, a randomized, double-blind, placebo-controlled, multicenter study of children and adolescents with symptomatic systolic heart failure found no significant differences in outcome between carvedilol and placebo during an 8-month follow-up period.<sup>335</sup> Carvedilol may have differential effects based on ventricular morphology, and further studies are necessary.<sup>336-339</sup> A retrospective review of the initial experience with carvedilol therapy in children showed that adverse effects—mainly dizziness, headaches, and hypotension—were common (>50%) but well tolerated.<sup>340</sup> The ideal dose in children has not yet been determined. Pharmacokinetic simulation studies suggest that larger doses<sup>341</sup> are appropriate, although clinical experience in small patient populations favors smaller doses.<sup>339</sup>

### VASODILATORS

Vasodilators are used in children to control blood pressure during and after surgery, to treat systemic and pulmonary hypertension, and to decrease afterload on either the systemic or the pulmonary ventricle, thereby improving pump function. Vasodilators are also given during cardiopulmonary bypass to reduce SVR, improve regional perfusion, and facilitate rapid and even core cooling and rewarming.

Vasodilators can be divided in several different pharmacologic groups. Direct-acting nitrovasodilators such as sodium nitroprusside and nitroglycerin are among the most commonly used cardiovascular medications. These drugs directly relax vascular smooth muscle to cause vasodilation. Hydralazine is another direct-acting smooth muscle vasodilator that is occasionally given to children to reduce blood pressure. Selective  $\alpha$ -adrenergic blockers, such as phentolamine and phenoxybenzamine, are occasionally used to reduce blood pressure and SVR in the perioperative period. The classic indication is the treatment of pheochromocytoma, but they are also frequently given during hypothermic cardiopulmonary bypass. Ventricular “remodeling” and long-term blood pressure control is often achieved with angiotensin-converting enzyme (ACE) inhibitors. Prostaglandin  $E_1$  ( $PGE_1$ ) is a direct-acting vasodilator primarily used to maintain the patency of the ductus arteriosus in duct-dependent circulations. In contrast, prostacyclin and inhaled nitric oxide are vasodilators with relatively selective effects on the pulmonary vasculature. Commonly used vasodilators and antihypertensive agents are summarized in Table 16-9.

### Sodium Nitroprusside

The primary indication for sodium nitroprusside is the rapid and reliable reduction of afterload and blood pressure before, during, and after a wide variety of procedures. For example, it is used to control intraoperative and postoperative hypertension in children with aortic coarctation and other forms of LVOTO. The reduction in afterload may improve performance of a dysfunctional ventricle, particularly in combination with a positive inotropic agent.<sup>342,343</sup> The ability of nitroprusside to

**TABLE 16-9** Antihypertensives and Vasodilators\*

Drug	Intravenous Dose	Comments
Propranolol	0.01-0.1 mg/kg slowly	Nonselective $\beta$ -blockade; bradycardia, hypotension, worsening of myocardial pump function; atrioventricular block; hypoglycemia; bronchospasm; depression; fatigue
Labetalol	0.1-0.4 mg/kg per dose; 0.25-1.0 mg/kg/hr infusion	Nonselective $\beta$ -blockade; selective $\alpha$ -blockade; ratio of $\alpha$ - to $\beta$ -blockade is 1:7 for intravenous form; doses (0.1 mg/kg) can be repeated every 5-10 minutes until desired effect is achieved; side effects are similar to those of propranolol.
Esmolol	100-500 $\mu$ g/kg loading dose (over 5 minutes); 50-250 $\mu$ g/kg/min infusion	Relatively selective $\beta$ -blockade; short elimination half-life (7-10 minutes); hypotension, especially during bolus administration; if less than desired response after 5 minutes, can repeat or double bolus dose, followed by doubling infusion rate; non-organ-based metabolism by plasma and red blood cell esterases; infusion concentrations >10 mg/mL may predispose to venous sclerosis; dilute infusion at high rates increases risk of volume overload.
Sodium nitroprusside	Start at 0.5-1.0 $\mu$ g/kg/min infusion; maximum 6-10 $\mu$ g/kg/min	Potent direct smooth muscle relaxation; dilates both arteriolar resistance and venous capacitance vessels; hypotension potentiated by hypovolemia, inhalation anesthetics, other antihypertensives; variable pulmonary vasodilation; potential cyanide toxicity; reflex tachycardia; check cyanide and thiocyanate levels if >4 $\mu$ g/kg/min is infused or drug is used longer than 2-3 days.
Nitroglycerin	0.5-10 $\mu$ g/kg/min infusion	Direct smooth muscle relaxation; predominantly dilates venous capacitance vessels, modest effects on arterial resistance at larger doses; weak antihypertensive effects; variable pulmonary vasodilation; used to facilitate cooling and rewarming during cardiopulmonary bypass.
Phentolamine	0.05-0.1 mg/kg dose; 0.5-5 $\mu$ g/kg/min infusion	Selective $\alpha$ -blocker, produces mainly arteriolar vasodilation; some direct vasodilation with mild venodilation.
Enalaprilat	5-10 $\mu$ g/kg per dose q8-24hr	Long duration of effect; angioedema, renal failure, hyperkalemia; potential problematic hypotension with anesthetic agents (see text)
Hydralazine	0.1-0.2 mg/kg bolus q6hr	Maximum 20 mg/dose; direct-acting smooth muscle (predominantly arteriolar) vasodilation; long effective half-life; tachyphylaxis; reflex tachycardia; lupus-like syndrome; drug fever; thrombocytopenia
Prostaglandin $E_1$	0.05-0.1 $\mu$ g/kg/min infusion	Direct smooth muscle relaxation, relatively specific for ductus arteriosus; variable pulmonary and systemic vasodilation; apnea in neonates

\*All drugs should be started in the lower dose range and titrated to effect.

successfully treat pulmonary hypertension is variable and may be age dependent.<sup>344-348</sup>

Sodium nitroprusside is an extremely potent vasodilator that acts directly on smooth muscle to cause dilation.<sup>349,350</sup> Its effects reduce cardiac preload as well as afterload. Onset of effect is fast (within minutes), and offset is similarly rapid; the effect ends within 1 to 2 minutes after termination of the infusion. Because of its potency, it should always be administered via an infusion pump in conjunction with continuous direct arterial pressure monitoring. The starting dosage is 0.5 to 1  $\mu\text{g/kg/min}$ . This can be increased to achieve the desired effect. The hypotensive effects of nitroprusside are potentiated by hypovolemia, inhalation anesthetics, and drugs that inhibit the reflex responses to direct vasodilation (e.g., increase in sympathetic tone, renin release), such as propranolol and ACE inhibitors.

Adverse effects of sodium nitroprusside include cyanide and thiocyanate toxicities, rebound hypertension, inhibition of platelet function, and increased intrapulmonary shunting. Rebound hypertension is most likely caused by activation of the aforementioned reflex mechanisms. It can usually be avoided by slowly tapering the infusion rather than abruptly discontinuing it. Toxicity may occur when more than 10  $\mu\text{g/kg/min}$  of sodium nitroprusside is administered, if tachyphylaxis develops within 30 minutes, or if there is immediate resistance to the drug. A blood cyanide concentration of approximately 500  $\mu\text{g/dL}$  has been associated with death in a child.<sup>351</sup> Cyanide and thiocyanate toxicities are rare but may be more likely in neonates and young infants and in those with impaired hepatic or renal function.<sup>351,352</sup>

Cyanide is produced from the metabolism of sodium nitroprusside. Free cyanide is then conjugated with thiosulfate by rhodanase in the liver to produce thiocyanate. A major mechanism of cyanide toxicity is binding to cytochrome oxidase in the mitochondrial electron transport chain, which prevents mitochondrial respiration and ATP production. Signs of toxicity include tachyphylaxis and an increase in mixed venous oxygen saturation and metabolic acidosis. In children who have received prolonged (>24 hours) or large-dose infusions of nitroprusside and in those with organ dysfunction, it may be advisable to measure blood cyanide concentrations.<sup>353-357</sup> Serum thiocyanate concentrations may also be measured. Thiocyanate concentrations may increase if renal function is abnormal. Central nervous system (CNS) dysfunction can occur when thiocyanate concentrations reach 5 to 10  $\text{mg/dL}$ . Treatment of cyanide toxicity consists of IV infusion of sodium nitrite, 6  $\text{mg/kg}$  (maximum dose 300  $\text{mg}$ ) over 5 minutes, and sodium thiosulfate, 250  $\text{mg/kg}$  or 7  $\text{g/m}^2$  (maximum dose 12.5  $\text{g}$ ) over 15 minutes. In children with abnormal renal function in whom stimulating the production of thiocyanate from thiosulfate may be contraindicated, administration of hydroxocobalamin has been recommended.<sup>357a,357b</sup>

### Nitroglycerin

Nitroglycerin is primarily a venodilator that acts on venous capacitance vessels. It has a substantially smaller effect on arteriolar smooth muscle, and its ability to attenuate an increased PVR is variable. Compared with nitroprusside, it is a poor antihypertensive agent. It has a short half-life and no significant toxic metabolites. Similar to nitroprusside, it may increase intrapulmonary shunting and cause platelet dysfunction. Nitroglycerin is typically administered in doses of 0.5 to 3.0  $\mu\text{g/kg/min}$ . Effects occur within 2 minutes after nitroglycerin is started and resolve within 5 minutes after discontinuation. Mild decreases in blood pressure may be observed at doses exceeding 2 to 3  $\mu\text{g/kg/min}$ .

In case of prolonged simultaneous infusions of nitroglycerin and nitroprusside, methemoglobin and cyanmethemoglobin levels can accumulate.<sup>358</sup>

Nitroglycerin is frequently used during cardiopulmonary bypass to facilitate rapid and effective cooling and rewarming and to improve tissue blood flow. Nitroprusside and nitroglycerin differ substantially with regard to their effects on the microcirculation. Because nitroprusside primarily reduces arteriolar tone and dilates precapillaries, it decreases microvascular blood flow and tissue perfusion more than nitroglycerin does, particularly in the presence of reduced arterial blood pressure (e.g., during cardiopulmonary bypass).<sup>359</sup> In contrast, nitroglycerin dilates precapillaries and postcapillaries with equal efficacy, thereby maintaining stable or enhanced capillary perfusion.<sup>360,361</sup>

### Phentolamine and Phenoxybenzamine

Both phentolamine and phenoxybenzamine are  $\alpha$ -adrenergic blocking agents with little selectivity for  $\alpha$ -receptor subtypes. Their primary effect is to decrease resistance on the arterial side of the circulation, although both possess weak venodilating capabilities. Phentolamine is usually administered by infusion at 0.5 to 5  $\mu\text{g/kg/min}$ , whereas phenoxybenzamine is administered orally initially 0.2  $\text{mg/kg}$  once daily, then slowly increased every 4 days by 0.2  $\text{mg/kg/day}$ . The usual maintenance dose is 0.4 to 1.2  $\text{mg/kg/day}$  divided in three doses. The elimination half-life of phenoxybenzamine is much greater than that of phentolamine. Some cardiovascular centers have found the potent arteriolar dilating effects of phenoxybenzamine and its prolonged elimination half-life to be advantageous, especially to provide adequate vasodilation during deep hypothermic cardiopulmonary bypass.<sup>362-366</sup>

### Angiotensin-Converting Enzyme Inhibitors

ACE inhibitors are administered to children with increasing frequency.<sup>367-369</sup> In the perioperative setting, they are given to control blood pressure after aortic coarctation repair or to relieve LVOTO. In addition, ACE inhibitors are given on a more long-term basis to reduce afterload on the systemic ventricle and to improve ventricular performance in children with congestive heart failure or single ventricle physiology.<sup>248,370</sup> Among the growing number of ACE inhibitors, captopril, enalapril, and lisinopril are most often used in children, although data in children are scant. Adverse effects common to all ACE inhibitors include angioedema, acute renal failure, and hyperkalemia; case reports of significant complications have been published.<sup>371,372</sup> Cyanosis and coadministration of furosemide were shown to be independent risk factors for acute kidney injury in children undergoing cardiac surgery who were treated with ACE inhibitors.<sup>373</sup>

The contribution of ACE inhibitors to anesthetic-induced hypotension remains controversial.<sup>374-377</sup> Angiotensin receptor-blocking agents such as losartan and lisinopril can produce significant and refractory hypotension with standard anesthetic induction techniques.<sup>378</sup> Because of the potential risk of significant and refractory hypotension, which is usually unresponsive to volume expansion and requires substantial vasoconstrictor treatment, it is our practice to discontinue long-acting ACE inhibitors 1 day before surgery.

### Captopril

Captopril has a relatively brief elimination half-life (<2 hours); it is metabolized in the liver and then excreted by the kidney.<sup>379</sup> Oral dosing in neonates is 0.05 to 0.1  $\text{mg/kg}$  every 8 to 24 hours,

titrated up to 0.5 mg/kg every 6 to 24 hours. Infants initially receive 0.15 to 0.3 mg/kg every 6 to 8 hours. This can be titrated toward a maximum dose of 6 mg/kg/day in four divided doses. Older children may receive 0.3 to 0.5 mg/kg every 6 to 12 hours. The brief duration of effect, necessitating more frequent dosing, has led to increased use of the longer-acting ACE inhibitors (enalapril and lisinopril) in children.

### **Enalapril**

Enalapril is metabolized in the liver to its active form, enalaprilat. Enalapril is the only ACE inhibitor currently available in the United States that has an IV formulation. It can be given orally, once or twice daily, with daily doses ranging between 0.1 and 0.5 mg/kg. The IV dose is 0.005 to 0.01 mg/kg/dose, one to three times a day.<sup>367</sup> Both enalapril and lisinopril are eliminated by the kidney. The duration of their hypotensive actions averages 24 hours but can extend to 30 hours.

### **Losartan**

Losartan blocks selectively angiotensin II type 1 (AT1) receptors. In children, it is used mainly in the treatment of proteinuria and hypertension associated with renal disease and seems to be well tolerated.<sup>380-383</sup>

### **Hydralazine**

Hydralazine was frequently used in the past for long-term blood pressure control in children, but has been largely replaced by ACE inhibitors. In contrast to its effect in adults, its ability to decrease pulmonary hypertension in children was disappointing.<sup>384</sup> Hydralazine directly relaxes smooth muscle without known effects on receptors. It reduces cardiac afterload but may cause significant reflex tachycardia. With long-term use, it may also cause fluid retention, requiring concurrent administration of a diuretic. Oral dosing is in the range of 0.75 to 1 mg/kg/day divided in two to four doses and is slowly increased over 3 to 4 weeks to a maximum dose of 5 mg/kg/day for infants and 7.5 mg/kg/day for children. In the perioperative setting, it is occasionally used intravenously to control blood pressure and reduce afterload. IV doses are administered as a bolus of 0.1 to 0.2 mg/kg not to exceed 20 mg. The effects of IV hydralazine on PVR are variable.<sup>384,385</sup> Tachyphylaxis to the antihypertensive effects of IV hydralazine may occur. Important side effects include a drug-related fever, rash, pancytopenia, and lupus-like syndrome. The elimination half-life of the drug is approximately 4 hours, but the effective biologic half-life may be substantially longer due to significant binding of the drug to vascular smooth muscle.<sup>386</sup>

### **Prostaglandin E<sub>1</sub>**

The major indication for PGE<sub>1</sub> is to establish or maintain patency of the ductus arteriosus in infancy. It is best able to reopen a closing ductus in neonates up to 1 to 2 weeks of age but may occasionally be effective even in older infants.<sup>19,387</sup>

Ductal patency is important and often lifesaving for duct-dependent circulations—those in which either the lower body is supplied by right-to-left ductal flow (e.g., interrupted aortic arch, critical aortic stenosis, HLHS) or the PDA is the sole provider of pulmonary blood flow (e.g., pulmonary atresia, tricuspid atresia, severe tetralogy of Fallot). Adverse effects of PGE<sub>1</sub> include systemic hypotension, apnea, increased risk of infection, leukocytosis, gastric outlet obstruction, and CNS irritability.<sup>388-390</sup> PGE<sub>1</sub> infusions are usually begun at 0.05 µg/kg/min and may be increased to 0.1 µg/kg/min or more. The risk of apnea may be

related to the infusion rate. Tracheal intubation and ventilation are often required with infusion rates greater than 0.05 µg/kg/min.<sup>391,392</sup> Prophylactic treatment with aminophylline was found to be effective in reducing the apnea risk.<sup>393</sup> PGE<sub>1</sub> has also been used to treat primary or acquired pulmonary hypertension with varying degrees of success.<sup>394-397</sup>

### **Inhaled Nitric Oxide**

An important development in the treatment of pulmonary hypertension is inhaled nitric oxide gas, which can be delivered directly to the pulmonary circulation. Nitric oxide is an endothelium-derived relaxing factor that acts on guanylate cyclase in vascular smooth muscle.<sup>398</sup> Endogenous nitric oxide is produced by endothelial cell nitric oxide synthase. Nitric oxide synthases convert the amino acid L-arginine into nitric oxide and the byproduct L-citrulline. Nitric oxide then diffuses into the subjacent vascular smooth muscle. It produces relaxation by acting on smooth muscle guanylate cyclase to produce cyclic guanosine monophosphate (cGMP), which acts on a series of protein kinases and reduces intracellular calcium levels to inhibit muscle contraction (see Fig. 36-1 in Chapter 36). Nitric oxide diffusing in the other direction from the endothelial cell into the blood vessel lumen can decrease the adhesiveness of white blood cells and platelets. Nitric oxide in the blood is rapidly bound by oxyhemoglobin, which is then oxidized to methemoglobin. From this reaction, nitric oxide is inactivated and nitrite and nitrate are released in the blood. Red blood cell methemoglobin is subsequently reduced back to hemoglobin. The rapid binding and inactivation of nitric oxide in the blood means that inhaled nitric oxide has a minimal effect on the systemic circulation and functions as a very specific pulmonary vasodilator.

Significant reductions in PVR from inhaled nitric oxide have been demonstrated in adults with mitral stenosis, in neonates with persistent pulmonary hypertension of the neonate, in lung transplant recipients, and in children after surgical repair of a variety of CHDs.<sup>399-403</sup> The efficacy of inhaled nitric oxide is in large part related to the ability to deliver it into the alveolus, which is in close proximity to the pulmonary vascular smooth muscle.

Inhaled nitric oxide has found several indications in children with CHD. In the cardiac catheterization laboratory, it is used to assess the reactivity of the pulmonary vasculature in children with pulmonary hypertension. In this use, it can help distinguish between children with fixed pulmonary vascular obstructive disease and those with a reversible component to pulmonary hypertension, thereby facilitating therapeutic management and operative planning.<sup>404-406</sup>

In the postoperative period after the repair of CHD, nitric oxide can be used to reduce PVR and improve cardiopulmonary performance.<sup>407,408</sup> Experience thus far suggests that children with two ventricles who have increased LA pressure or its pathophysiologic equivalent (e.g., mitral stenosis, severe congestive heart failure, cardiomyopathy, large left-to-right shunt, TAPVR) are more likely to respond to nitric oxide in the postoperative period. On the other hand, children with single ventricle physiology often show no or only minimal improvements in pulmonary blood flow and oxygenation after nitric oxide. Some children who do not respond to nitric oxide immediately after cardiopulmonary bypass in the operating room demonstrate significant reductions in PVR with nitric oxide several hours later. Nitric oxide is administered in concentrations of 1 to 80 ppm in oxygen via a special delivery device attached to the ventilator or oxygen delivery system. Inspired gas is monitored for toxic nitrogen

oxides, and during long-term therapy with nitric oxide, blood methemoglobin concentrations should be assessed on a regular basis.<sup>409</sup>

### Prostanoids

Members of the prostacyclin and prostaglandin families are often classified as *prostanoids*. All prostanoids are potent vasodilators and inhibitors of platelet aggregation. Since the 1980s, they have been used in the treatment of PA hypertension and are part of the official treatment guidelines,<sup>410,411</sup> even though they are not selective pulmonary vasodilators. Common side effects include flushing, hypotension, headache, jaw pain, skin rash, nausea and diarrhea, and nonspecific musculoskeletal pains. Tolerance can develop over time, requiring increasing doses.<sup>412</sup> In the United States, only three prostanoids are currently approved by the Food and Drug Administration (FDA): epoprostenol (Flolan), treprostinil (Remodulin), and iloprost (Ventavis). Beroprost is an oral prostacyclin analogue that is licensed in Japan and still being investigated.

#### Epoprostenol (Flolan)

Continuous IV infusion of epoprostenol has been used effectively for many years in children with PA hypertension of any cause. It improves hemodynamics by reducing PA pressure, increasing cardiac output, increasing oxygen transport, and improving symptoms such as exercise capacity and dyspnea.<sup>413</sup> It has been used with excellent results in the treatment of primary pulmonary hypertension and irreversible acquired pulmonary hypertension in CHD; in children awaiting heart, lung, or heart-lung transplantation; in children with primary pulmonary hypertension; in neonates with persistent pulmonary hypertension; and in pulmonary hypertensive crises.<sup>414-420</sup> The fact that children who were initially nonresponders may respond after prolonged use of nitric oxide suggests that its mechanism of action involves a degree of remodeling, although no absolute mechanism has been elucidated.

Unfortunately, epoprostenol is chemically unstable at room temperature and has an elimination half-life of only 1 to 2 minutes; it requires continuous IV infusion via a central venous catheter and a specific delivery system. Rapid and unintended decreases in the rate, dislodgments or occlusions of the central venous catheter, or pump malfunctions can lead to severe and life-threatening rebound pulmonary hypertension.<sup>421,422</sup> The infusion is usually started at 1 to 2 ng/kg/min and gradually increased over several months to doses between 30 and 80 ng/kg/min. In patients with pulmonary venous disease, IV epoprostenol can worsen the pulmonary edema; it can also increase the ventilation/perfusion mismatch in patients with pneumonia and thereby negatively affect oxygenation. In the acute setting, epoprostenol is increasingly used in the inhaled form to benefit from the selective pulmonary vasodilation and reduction of ventilation/perfusion mismatch.<sup>412,423-425</sup> Some centers have used inhaled epoprostenol as an alternative to the rather expensive nitric oxide, although the currently available delivery systems are far from ideal and may alter the delivered tidal volumes.<sup>412</sup>

#### Treprostinil (Remodulin)

Treprostinil was first introduced in 2002, initially only for continuous subcutaneous infusion, but later also for IV infusion in patients who could not tolerate the pain at the subcutaneous infusion site. The hemodynamic effects are similar to those of epoprostenol, with fewer adverse effects.<sup>426-429</sup> IV infusions of

treprostinil are started at 1 to 2 ng/kg/min and slowly increased over several weeks to 40 ng/kg/min, occasionally even higher doses (80-120 ng/kg/min). One pediatric study confirmed the effectiveness of IV treprostinil in children.<sup>430</sup> Since 2009, inhaled treprostinil has been used for long-term outpatient management. Because of the relative short half-life, it must be administered every 6 hours.<sup>431-434</sup>

#### Iloprost (Ventavis)

Iloprost, approved by the FDA in 2004, is another prostaglandin I<sub>2</sub> analogue that can be delivered intravenously or via an ultrasonic nebulizer. It has a very brief elimination half-life of 15 to 20 minutes and requires frequent nebulized treatments (six to nine times each day). In adult studies, iloprost was shown to be beneficial in patients with PA hypertension of any cause, idiopathic PA hypertension, or chronic thromboembolic pulmonary hypertension. These patients demonstrated improvements in hemodynamics and in subjective parameters such as quality of life scores.<sup>435,436</sup> Studies in children are scarce and have involved only small numbers of patients, although numerous case reports are encouraging.<sup>412,437-443</sup> When iloprost and nitric oxide were compared in children with CHD, the two agents produced similar effects.<sup>444</sup> In one study, combination therapy using both systemic and inhaled prostacyclin analogues showed promise.<sup>445</sup> An animal study in lambs demonstrated an enhanced effect of prostacyclin and iloprost when combined with milrinone.<sup>242</sup>

#### Beroprost

Beraprost sodium is an oral prostacyclin analogue that is chemically more stable and has a prolonged elimination half-life but nevertheless requires dosing three to four times per day, reaching its peak blood concentration at 30 minutes. Two double-blind studies showed no significant long-term benefit, but there may still be a role for this drug in combination therapy, because improvements have been observed in the exercise capacity of children with idiopathic PA hypertension.<sup>446,447</sup> Case reports of successful long-term treatment with beraprost and of combination therapy using oral beraprost and inhaled prostacyclin have been published.<sup>445,448-450</sup>

### Endothelin Receptor Antagonists

Endothelin 1 is a potent vasoconstrictor that is thought to be a key factor in the pathogenesis of PA hypertension. There are two known receptors on which it acts: endothelin A and endothelin B. Endothelin A receptors are present on smooth muscle cells, and agonist action causes vasoconstriction; endothelin B receptors are present on endothelial cells, and agonist action causes both relaxation and vasoconstriction through different pathways. In addition, endothelin B receptors are involved in the clearance of endothelin.

Bosentan is an oral, nonselective endothelin-receptor antagonist. Adult studies have shown long-term benefit in patients with PA hypertension. Bosentan can cause abnormal liver function tests, although to date no severe liver dysfunction has been reported in adults.<sup>451-455</sup> Two studies in children showed both short-term reduction in PA pressure and PVR and longer-term improvement in symptoms and stabilization of the disease process.<sup>413,456</sup> In addition, three studies have suggested that the dose for children weighing more than 10 kg could largely follow adult guidelines, with the total daily dosage not exceeding 125 mg. There is growing evidence, although few controlled studies, suggesting that bosentan is an effective and well-tolerated

therapy in children. Compared with the results in adult studies, hepatic dysfunction was less frequently reported.<sup>457-459</sup>

### Sildenafil

Sildenafil is a selective inhibitor of phosphodiesterase type 5, the isoform that is responsible for hydrolysis of cGMP in the pulmonary vasculature. By preventing the breakdown of cGMP, sildenafil increases cGMP concentrations and potentiates the pulmonary vasodilation caused by endogenous nitric oxide.<sup>460-462</sup> It has a longstanding track record in the adult population.<sup>463-467</sup> In children, sildenafil is currently used as an adjunctive agent during weaning from nitric oxide and also in the treatment of PA hypertension.<sup>46,468-470</sup> A Cochrane review of the efficiency and safety of sildenafil in the treatment of neonates with persistent pulmonary hypertension found only two eligible trials with a small number of children, prompting a recommendation for further studies.<sup>471,472</sup> Oral therapy begins with 0.25-0.5 mg/kg every 4 to 6 hours with increasing doses as tolerated.<sup>473-475</sup> The IV use of sildenafil for postoperative pulmonary hypertension in children with CHD is currently under investigation.<sup>476</sup> The benefit of combining oral sildenafil with inhaled iloprost for the treatment of severe pulmonary hypertension has also been demonstrated.<sup>477</sup>

### ANTIARRHYTHMIC AGENTS

Antiarrhythmic agents have been traditionally categorized according to the Vaughan Williams classification, which is based on the presumed primary mechanism of action. For example, class I agents are sodium channel blockers. They are also called membrane-stabilizing agents because of their ability to decrease the excitability of the plasma membrane. Class I drugs can be subdivided into class IA, IB, or IC agents depending on their effects on the cardiac action potential (Table 16-10). Many antiarrhythmic drugs have multiple mechanisms of action and are therefore difficult to classify. Commonly used IV antiarrhythmic agents for children are described in Table 16-11.

#### Procainamide

Procainamide is one of the most commonly used class IA agents in children. It has sodium channel and moderate potassium channel blocking activities (class III effect). Its major effect is to delay repolarization. This effect is more pronounced at faster HRs. IV procainamide is used to treat SVT associated with the Wolff-Parkinson-White syndrome, atrial flutter, and ventricular dysrhythmias unresponsive to lidocaine.<sup>478-481</sup> It may also be effective in postoperative junctional ectopic tachycardia.<sup>482,483</sup>

Procainamide is the only class IA agent that is still clinically used in children, mainly as a short-term IV therapy. A loading dose of 3 to 10 mg/kg is given over 30 to 60 minutes to infants younger than 1 year of age. Older children receive IV bolus doses of 5 to 15 mg/kg given over 30 to 60 minutes. After the bolus dose, an infusion is usually started at 20 to 80 µg/kg/min. Infusion rates in excess of 100 µg/kg/min are occasionally necessary, particularly in infants. Infusion rates are adjusted to achieve procainamide plasma levels of 4 to 10 µg/mL.<sup>484</sup> The levels should be measured 2 hours after each rate change. It is recommended to stop the infusion if hypotension occurs or the QRS widens by more than 50%. Procainamide can have substantial negative inotropic effects, which may be more pronounced in the ischemic/reperfused or otherwise damaged myocardium.

Procainamide is metabolized in the liver to *N*-acetyl procainamide (NAPA), which has significant class III antiarrhythmic

**TABLE 16-10** Vaughan Williams Classification of Antiarrhythmic Drugs

Class	Mechanism	Examples
I	Sodium channel blockers	
	IA Increase length of action potential	Procainamide Quinidine Disopyramide
	IB Decrease length of action potential	Lidocaine Mexiletine Phenytoin
IC	No effect on length of action potential	Flecainide Propafenone
II	β-Blockers	Propranolol Atenolol Metoprolol Esmolol
III	Potassium channel blockers	Amiodarone Sotalol Bretylium Ibutilide Dofetilide Dronedarone
IV	Calcium channel blockers	Verapamil Diltiazem
V	Other or unknown mechanism	Adenosine Digoxin Magnesium sulfate

Data from Vaughan Williams EM. A classification of antiarrhythmic actions reassessed after a decade of new drugs. *J Clin Pharmacol* 1984;24:129-47; and Fuster V, Ryden LE, Cannom DS, et al. ACC/AHA/ESC 2006 guidelines for the management of patients with atrial fibrillation: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines and the European Society of Cardiology Committee for Practice Guidelines (Writing Committee to Revise the 2001 guidelines for the management of patients with atrial fibrillation). Developed in collaboration with the European Heart Rhythm Association and the Heart Rhythm Society. *Circulation* 2006;114:e257-354.

effects.<sup>485</sup> Biotransformation of procainamide and NAPA is based on genetic acetylator status (slow versus fast acetylators). In the past, procainamide and NAPA serum concentrations were added, with a therapeutic goal of 10 to 30 µg/mL. Today, only procainamide plasma concentrations are monitored. Oral procainamide therapy is complicated by unreliable absorption, the need for frequent dosing, potential proarrhythmogenic effects, and a wide spectrum of adverse effects. Typical doses are 15 to 50 mg/kg/day, divided every 4 to 6 hours. A sustained-release form (administered every 8 to 12 hours) is available for older children.

The majority of procainamide-related adverse effects depend on the plasma concentration and the duration of therapy. A systemic lupus erythematosus-like syndrome is common, manifested as fevers, pleural effusions, pericarditis, arthralgias, myalgias, and rashes. A considerable number of children demonstrate positive antinuclear antibodies with chronic therapy, but they do not necessarily require discontinuation of the therapy.

#### Lidocaine

Lidocaine is a member of the class IB antiarrhythmic agents, which include mexiletine and phenytoin. Proarrhythmogenesis is less common with class IB agents. In addition to blocking fast sodium channels, they also reduce the duration of both the action potential and repolarization.<sup>484</sup> As with class IA agents, the effects of these agents may be greater at faster HRs. Lidocaine primarily affects cells inferior to the AV node. It produces its

**TABLE 16-11 Intravenous Antiarrhythmic Agents**

Agent (Vaughan Williams Class)	Dose	Comments
Procainamide (IA; sodium $\pm$ potassium channel blockade; antivagal effects)	Infant (<1 year): 3-10 mg/kg loading dose over 30 minutes Child (>1 year): 5-15 mg/kg loading dose over 30 minutes All ages, infusion rate: 20-80 $\mu$ g/kg/min	Used to treat SVT due to WPW, atrial flutter, junctional ectopic tachycardia (with patient hypothermia), lidocaine-resistant ventricular dysrhythmias; hypotension and negative inotropy; lupus-like syndrome.
Lidocaine (IB; sodium channel blockade; speeds repolarization)	1 mg/kg bolus; then 20-50 $\mu$ g/kg/min	Used for ventricular dysrhythmias; CNS toxicity (apnea, seizures, abnormal sensations).
Phenytoin (IB)	1-3 mg/kg q5min up to 15 mg/kg loading dose, then 5-10 mg/kg divided q6hr	Drug must be infused slowly (>30 minutes) due to potential hypotension; antidysrhythmic profile similar to that of lidocaine; may be useful to treat digoxin-induced dysrhythmias.
Propranolol (II; $\beta$ -adrenergic blockade; sodium channel blockade also)	0.01-0.1 mg/kg slowly	Nonselective $\beta$ -blockade; used mainly to treat SVT; bradycardia, hypotension, worsening of myocardial pump function; AV block; hypoglycemia; bronchospasm; depression; fatigue.
Esmolol (II; B-receptor blockade)	100-500 $\mu$ g/kg loading dose (over 5 minutes); 50-250 $\mu$ g/kg/min infusion	Used to treat SVT; relatively selective $\beta_1$ blockade; short elimination half-life (7-10 minutes); hypotension, especially during bolus; if less than desired response after 5 minutes, can repeat or double bolus dose, followed by doubling infusion rate; non-organ-based metabolism by plasma and red blood cell esterases; infusion concentrations >10 mg/mL may predispose to venous sclerosis; dilute infusion at high rates increases risk of volume overload.
Amiodarone (III; prolongs repolarization; adrenergic and calcium blockade)	1-2.5 mg/kg bolus over 5-10 minutes (total loading dose up to 5-6 mg/kg); 5-15 mg/kg/24-hour infusion	Used for resistant reentrant atrial and ventricular dysrhythmias; may be useful for postoperative junctional ectopic tachycardia; hypotension with bolus IV administration; bradycardia; AV block; rare proarrhythmia and torsades de pointes; pulmonary fibrosis; hypothyroidism; controversial association with acute perioperative lung injury.
Bretylium (III)	5 mg/kg; then 10 mg/kg q15min (maximum 30 mg/kg total)	Use limited to ventricular tachycardia resistant to other therapies during cardiopulmonary resuscitation; hypotension. (No longer marketed in the United States.)
Verapamil (IV; calcium channel blockade)	0.1-0.3 mg/kg bolus (maximum 5 mg)	Used for SVT in older children and adults; potential for hypotension and asystole contraindicates use in children <1 year of age; bradycardia; AV block; may increase ventricular response rate in some children with WPW.
Adenosine	0.05-0.1 mg/kg rapid bolus followed by flush; may repeat with doses increasing in increments of 0.05 mg/kg q2min (maximum dose 0.25 mg/kg or 12 mg, whichever comes first)	Increases potassium channel flux and inhibits slow inward calcium current; causes transient sinus bradycardia and AV block; transient hypotension; rarely causes ventricular ectopy or atrial fibrillation; bronchospasm; used to terminate SVT; used diagnostically to transiently produce AV block. Reduce dose by 50% in heart transplant patients or if given through a central line.
Digoxin	Total digitalizing dose (TDD)*: Premature: 15-25 $\mu$ g/kg Neonate (<1 month): 20-30 $\mu$ g/kg Infant (<2 years): 30-50 $\mu$ g/kg Child (2-5 years): 25-35 $\mu$ g/kg Child (>5 years): 15-30 $\mu$ g/kg Child (>10 years): 8-12 $\mu$ g/kg	TDD given in divided doses: $\frac{1}{2}$ TDD followed by $\frac{1}{4}$ TDD q8-12hr $\times$ 2; slows sinus node and decreases AV node conduction; used to slow ventricular response in atrial flutter and fibrillation and may also treat junctional tachycardia or SVT; variable effect on accessory pathways; long half-life (24-48 hours) that is prolonged by renal dysfunction; numerous drug interactions; toxicity includes SVT, AV block, ventricular dysrhythmias; toxicity symptoms include drowsiness, nausea, vomiting; toxicity exacerbated by hypokalemia.
Magnesium sulfate	25-50 mg/kg bolus; maximum single dose 2 g; 30-60 mg/kg/24-hour infusion	May be first-line therapy for torsades des pointes; also used for refractory ventricular tachycardia and ventricular fibrillation; hypotension and respiratory depression may accompany IV bolus dosing—IV calcium is an antidote.

AV, Atrioventricular; CNS, central nervous system; IV, intravenous; SVT, supraventricular tachycardia; WPW, Wolff-Parkinson-White syndrome.

\*Daily maintenance dose varies by age; consult pharmacy or cardiologist.

greatest effects on cells with the longest duration of action potential and thereby balances the ventricular repolarization.

Because of its rapid hepatic metabolism, lidocaine is available only in an IV formulation. It is indicated for the emergency treatment of ventricular dysrhythmias. Lidocaine is initially

administered as an IV bolus of 1 mg/kg that can be repeated once within 5 to 10 minutes. Standard lidocaine infusion rates range from 20 to 50  $\mu$ g/kg/min.

The major side effects of lidocaine administration are well known to anesthesiologists. They primarily consist of CNS

toxicity, which typically occurs at plasma concentrations in excess of 6 to 8  $\mu\text{g/mL}$ . Mental status changes, abnormal taste or other sensations, apnea, and seizures may occur. In children with reduced cardiac output and impaired hepatic clearance, lidocaine doses should be reduced. The administration of lidocaine to children with atrial tachydysrhythmias or prolongation of the QT interval can increase the ventricular response rate.<sup>486</sup>

### Phenytoin

Phenytoin shares many similarities to lidocaine in terms of its antiarrhythmic effects, which are also restricted primarily to tissues inferior to the AV node and the bundle of His. Phenytoin primarily binds to sodium channels, maintaining them in the inactivated state. Very large concentrations may also affect calcium channels and automaticity. This drug is useful in treating refractory ventricular arrhythmias and especially digoxin-induced dysrhythmias.<sup>487,488</sup>

IV loading with phenytoin is achieved by a bolus dose of 1 to 3 mg/kg. For treatment of status epilepticus, higher loading doses (10–15 mg/kg) are used. IV maintenance is 5 mg/kg/day divided in two to three doses. IV phenytoin must be administered extremely slowly (>30 minutes) owing to the potential for hypotension. The oral dose in infants and older children is 5 mg/kg/day given every 12 hours, after a total loading dose of 15 mg/kg that has been divided over 6 hours. Other typical adverse effects are well described from its use as an antiepileptic medication and include gingival hyperplasia, aplastic anemia, ataxia, and nystagmus. Phenytoin should be avoided in patients who are pregnant or who may become pregnant because of its significant teratogenic profile (fetal hydantoin syndrome).

### Flecainide and Propafenone

Flecainide and propafenone are class IC agents. As such, they have potent sodium channel blocking activity. In adults, flecainide is used to treat various tachyarrhythmias, and it has a special role in the pharmacologic cardioversion of recurrent atrial fibrillation in patients with normal hearts (“pill in a pocket”).<sup>489,490</sup> Flecainide has also been extensively evaluated in children.<sup>491–498</sup> It blocks activated slow sodium channels but exerts less of an inhibitory effect on potassium channels. It appears to reduce the refractory time and decrease the automaticity in His-Purkinje cells. In contrast, the duration of the action potential and refractory period is prolonged in ventricular muscle, resulting in a greater duration of the QRS complex.

Oral dosing of flecainide may be more reliable when it is calculated on the basis of body surface area. Typical dosages in infants are in the range of 80 to 90 mg/m<sup>2</sup>/day, given in two doses (40 to 45 mg/m<sup>2</sup> every 12 hours). Older children receive 100 to 110 mg/m<sup>2</sup>/day (50 to 55 mg/m<sup>2</sup> every 12 hours). Loading doses are not used. Serum elimination half-life is age dependent: approximately 1 day in neonates, 12 hours in infants younger than 6 months of age, and 8 to 12 hours in older children and adults. Therapeutic trough concentrations are believed to be in the range of 200 to 1000 ng/mL. Alterations in diet can markedly affect drug absorption with oral dosing. IV flecainide is available outside the United States. A dose of 1 to 2 mg/kg given over 5 to 10 minutes has been used. Continuous infusions are not given because of its prolonged elimination half-life.

Flecainide has mild to moderate negative inotropic effects. Substantial proarrhythmogenic effects have been observed in children with atrial tachydysrhythmias or significant abnormalities of myocardial anatomy and function. Proarrhythmia was

considerably increased in adult patients who received flecainide after myocardial infarction.<sup>499</sup> In children and adults with paroxysmal SVT, a slow but incessant SVT may result on initiation of therapy. As a result, it is recommended to closely monitor these patients when initiating therapy with flecainide. The efficiency and safety of class IC antiarrhythmic agents in children with an abnormal or damaged myocardium are unclear; many pediatric electrophysiologists would avoid these drugs in children with severe myocardial dysfunction, myocardial injury (e.g., immediately postoperatively), right- or left-sided hypertrophy e.g., tetralogy of Fallot, or aortic stenosis.<sup>479,500</sup>

The effects and risks of propafenone are similar to those discussed for flecainide. Propafenone can also control dysrhythmias that arise from automatic mechanisms and can be used to treat postoperative junctional ectopic tachycardia. Oral propafenone is administered at 200 to 600 mg/m<sup>2</sup>/day divided into three doses (for children under 15 kg, 10–20 mg/kg/day and for children over 15 kg, 7–15 mg/kg/day). IV propafenone is not available in the United States. An IV loading dose of 0.2 to 1.0 mg/kg should be given slowly over 10 minutes. The initial dose may be doubled to achieve a maximum 2 mg/kg total loading dose. Infusion rates of 4 to 7  $\mu\text{g/kg/min}$  have been reported.<sup>501–506</sup>

Significant hypotension can occur with a bolus of propafenone. Hypotension has been attributed primarily to its negative inotropic effects. Like flecainide, propafenone is probably contraindicated in children with significant structural or metabolic myocardial abnormalities, such as those related to severe pressure or volume overload, ischemia-reperfusion, or myocardial infarction. In addition, propafenone has the potential for proarrhythmogenic effects. Propafenone is extensively metabolized in the liver, with significant interindividual variability. Its reported elimination half-life ranges from 4 to 18 hours. Serum concentrations of propafenone do not correlate well with the clinical response.<sup>507</sup>

### $\beta$ -Blockers

$\beta$ -Blockers are class II antiarrhythmic agents. Mechanism of action, relevance of subtype selectivity, metabolism, and other features are described in the section on vasoactive drugs. Here we focus on their indications as antiarrhythmic agents. In children, propranolol, atenolol, and esmolol are the most frequently used  $\beta$ -blockers.<sup>318</sup>

#### Propranolol

Propranolol is probably the most widely studied  $\beta$ -blocking agent in children.<sup>508</sup> Its primary indication is the acute control of SVT. In addition to nonselective  $\beta$ -blockade, propranolol has effects on the sodium channels and at high concentrations on calcium channels as well. It seems that conduction tissues of neonates are more sensitive to the drug than those of older children and adults.<sup>488,509</sup>

#### Atenolol

Atenolol is a commonly used, longer-acting  $\beta$ -blocker.<sup>510,511</sup> It has more selective effects on  $\beta$ -adrenergic receptors, although the risk of bronchospasm may not be completely eliminated with this drug. Atenolol does not cross the blood-brain barrier, which may be a reason for its lower incidence of depression, fatigue, and malaise compared with propranolol.<sup>322,512</sup>

#### Esmolol

Esmolol is increasing in popularity for the control of perioperative tachydysrhythmias in children.<sup>479</sup> Esmolol acts predominantly

on the sinus and AV nodes. It does not appear to have significant antiarrhythmic effects in the His-Purkinje or ventricular conducting tissues. Pharmacokinetics and the efficacy to terminate SVTs were found to be similar in children and adults.<sup>326</sup>

### Class III Agents

The primary class III agents are amiodarone, sotalol, bretylium, and ibutilide. They prolong depolarization and therefore increase refractoriness. All of these drugs have numerous other properties, including membrane-stabilizing effects, calcium channel blockade, and adrenergic blockade.

#### Amiodarone

In addition to prolonging refractoriness, amiodarone has sodium channel blocking and noncompetitive  $\alpha$ - and  $\beta$ -adrenergic receptor blocking properties. It may also interfere with potassium channels and inhibit the release of myocardial norepinephrine. Oral amiodarone is absorbed quite slowly from the gastrointestinal tract and is metabolized in the liver to an active metabolite, desethylamiodarone. Because of its high lipid solubility and large volume of distribution, tissue concentrations are maintained for 2 to 3 months after discontinuation of therapy. There are increasing data demonstrating the efficacy and safety of oral and IV amiodarone for the treatment of dysrhythmias in infants and children.<sup>513-517</sup> In addition to resistant reentrant atrial and ventricular dysrhythmias, amiodarone may be effective in treating postoperative junctional ectopic tachycardia.<sup>518-520</sup> Amiodarone, in a dose of 5 mg/kg IV push, is also indicated for shock-resistant arrhythmias during cardiopulmonary resuscitation in infants and children.<sup>521</sup>

The loading dose for oral amiodarone is 10 to 15 mg/kg/day for 5 to 10 days. After the loading dose, long-term oral dosing is 2 to 5 mg/kg once daily. IV amiodarone is usually given in boluses of 1.0 to 2.5 mg/kg, reaching a total of 5 to 6 mg/kg, with each bolus administered over 5 to 10 minutes. In children with resistant dysrhythmias, the average loading dose was 6.3 mg/kg, with 50% of children requiring a continuous amiodarone infusion of 10 to 15 mg/kg/day.<sup>515,522</sup>

Hypotension is the most significant acute adverse effect of IV amiodarone therapy. The effects of amiodarone may be synergistic with those of other agents that depress sinus node and AV node function. Important cardiac dysrhythmias include bradycardia and AV block. Proarrhythmogenic effects and torsades de pointes may occasionally occur. Long-term oral amiodarone therapy can lead to progressive and irreversible pulmonary fibrosis; these patients are usually monitored with pulmonary function tests at regular intervals.<sup>523,524</sup> The high iodine content of amiodarone can affect thyroid function, resulting in either hyperthyroidism or hypothyroidism. Other effects include drug deposits in the cornea, skin photosensitivity, and chemical hepatitis with increased liver transaminases. Coadministration of amiodarone with other antiarrhythmic agents may result in significant increases in the plasma concentrations of the other drugs.<sup>513,515</sup>

The incidence of perioperative organ dysfunction in children who receive either acute or long-term amiodarone therapy is controversial. A syndrome with similarities to the adult respiratory distress syndrome has been described, particularly in children exposed to high inspired oxygen concentrations who are undergoing thoracic surgery or cardiopulmonary bypass.<sup>525-528</sup> This finding led to the recommendation that amiodarone be discontinued for several weeks before elective surgery.<sup>529</sup>

Subsequent studies failed to demonstrate a significantly increased incidence of injury to lungs or other organs in children undergoing surgery while receiving amiodarone. Because it is most frequently given to children with severe and life-threatening cardiac rhythm disturbances, the current recommendation is to continue amiodarone up to the time of surgery. However, it may be wise to attempt to limit the inspired oxygen concentration and other factors that may predispose the children receiving amiodarone to free radical and inflammatory injury.<sup>530</sup>

#### Dronedarone

Dronedarone is a new, non-iodinated analogue of amiodarone which was developed to reduce the iodine-associated adverse effects of chronic amiodarone therapy. Like amiodarone, it inhibits sodium, potassium, and calcium currents. It is mainly indicated for maintenance of sinus rhythm in patients with atrial fibrillation but is still undergoing investigations regarding its long-term safety profile.<sup>489,531-533</sup> Pediatric data are not yet available.

#### Sotalol

Sotalol, a newer agent available in the United States, is a class III antiarrhythmic that also acts as a nonselective  $\beta$ -blocker. At small doses, the  $\beta$ -adrenergic blocking effects predominate; at larger doses, the class III effects become more significant. Sotalol is indicated for a number of refractory tachydysrhythmias. Current oral dosing recommendations for children start at target doses of 2 and 4 mg/kg in neonates, 3 and 6 mg/kg for children up to 6 years, and 2 and 4 mg/kg, divided into three doses, for children older than 6 years of age.<sup>534</sup> The major adverse effects of sotalol include mild cardiodepression due to its  $\beta$ -blocking ability and prolongation of the QT interval and torsades de pointes due to its class III effects.<sup>535</sup> It should be avoided in children with asthma, heart failure, renal dysfunction, or QT interval prolongation. Sotalol may be used as an alternative to amiodarone in some children who are unable to tolerate the adverse effects associated with amiodarone. Adult studies have shown that sotalol is not as effective for pharmacologic conversion of atrial fibrillation compared to other strategies or medications, but it can be indicated for maintenance of sinus rhythm after an episode of atrial fibrillation, especially for patients with coronary artery disease.<sup>490</sup> It has also been recommended as an alternative to amiodarone for postoperative atrial fibrillation in cardiac patients, but for prophylaxis and rate control pure  $\beta$ -blockers are still preferred.<sup>536-538</sup> The pediatric experience with sotalol is steadily increasing, but most studies have been limited by small numbers.<sup>318,479,539-543</sup>

#### Bretylium

Bretylium has limited use in children, being primarily indicated during cardiopulmonary resuscitation for the treatment of ventricular tachycardia resistant to other therapies.<sup>544</sup> The IV dose of bretylium is 5 mg/kg given as a bolus. Bretylium does have significant hypotensive properties and therefore should be given slowly in children with hemodynamically stable ventricular tachycardia. The total dose should not exceed 30 mg/kg. Bretylium is no longer available in the United States and has been removed from the current advanced cardiac life support algorithms, but it may be available in other countries.

#### Ibutilide

Ibutilide is one of the more recently released intravenous class III antiarrhythmic drugs. It prolongs repolarization by increasing

the slow inward sodium current and by blocking the late rectifier current. It can be given intravenously and has a fast onset. Ibutilide is currently indicated for the rapid pharmacologic conversion of atrial fibrillation and atrial flutter, although it may be more efficacious for the latter. As with other class III drugs, ibutilide can prolong the QT interval and can cause associated polymorphic ventricular tachycardia (torsades de pointes, which occur in 5% to 8% of adults).<sup>545,546</sup> Because the elimination half-life of ibutilide is approximately 6 hours, the current recommendation is to observe children for several hours after an IV administration of this drug. Studies to date have used a bolus dose of 10 to 25 µg/kg administered over 10 minutes, which may be repeated once. Ibutilide has been successfully used in children with CHD<sup>547</sup> and in children with accessory pathways.<sup>548</sup>

### **Dofetilide**

Dofetilide is another new class III antiarrhythmic drug that has been approved for treatment of atrial fibrillation and flutter.<sup>490</sup> It prolongs the effective refractory period by selectively blocking the rapid component of the delayed rectifier potassium current. The major adverse effect is the potential for torsade de pointes due to QT prolongation.<sup>549</sup> Dofetilide is currently available only for oral administration; IV formulations are still under investigation. It has been successfully used in adult patients with CHD, but pediatric data are still missing.<sup>550</sup>

### **Verapamil**

Verapamil is a member of the class IV antiarrhythmic agents, the calcium channel blockers. Its primary action is depression of sinus node and AV node function.<sup>551</sup> Oral doses range from 4 to 8 mg/kg/day divided into three doses. A sustained-release preparation is available for older children. IV doses range from 0.1 to 0.3 mg/kg with a maximum dose of 5 mg. The most important side effect of verapamil occurs in children younger than 1 year of age, in whom IV administration can cause severe hypotension and asystole.<sup>552</sup> In fact, the drug is now contraindicated in infants (<1 year of age) because of this complication. Other side effects include bradycardia, AV block, and increased ventricular response in some children with Wolff-Parkinson-White syndrome.

Verapamil has been shown to be effective in terminating most SVTs in older children and adults.<sup>479,553,554</sup> Verapamil is also used to relieve outflow obstruction in hypertrophic cardiomyopathy<sup>555</sup> and as an antihypertensive in some children. The negative inotropic and AV conduction effects of verapamil are potentiated by β-blockers and anesthetic agents.<sup>556,557</sup> IV calcium and β-adrenergic drugs such as isoproterenol have been given to reverse the depressive effects of verapamil and other calcium channel antagonists.<sup>558,559</sup>

### **Adenosine**

IV adenosine has markedly changed the therapy for SVTs. Its electrophysiologic effects are multiple and include increased potassium channel flux and decreased slow inward calcium current. These effects result in sinus bradycardia and transient AV block and are mediated primarily by stimulation of the A1-puriner receptor subtype. Its onset of action is within 10 to 20 seconds. Bradycardia, AV block, and hypotension last an additional 10 to 30 seconds.

The best response to adenosine is achieved when it is rapidly administered into the central circulation. The initial central venous dose is 50 µg/kg and the initial peripherally

administered dose is 100 to 150 µg/kg given as a rapid bolus, followed by a fluid bolus given via a syringe to flush the medication into the circulation. If this is unsuccessful or the effect is not sustained, the procedure can be repeated with a double dose (up to a maximum of 300 µg/kg). In adults, the starting dose is 6 to 12 mg.<sup>560,561</sup> Adenosine can also be used as a diagnostic tool to differentiate between SVT and other dysrhythmias. The slower HR caused by the transient AV conduction block often allows the recognition of specific electrocardiographic features, such as delta waves in Wolff-Parkinson White syndrome.<sup>562</sup>

Other than the noted electrophysiologic changes, the major side effect from adenosine is transient hypotension. In children with an antegrade-conducting accessory pathway, adenosine can induce atrial fibrillation with a rapid ventricular response. Therefore, it should be used only in an appropriate setting with electrocardiographic monitoring and available resuscitation equipment.<sup>563</sup> Dipyridamole and diazepam may inhibit the metabolism or cellular redistribution of adenosine. Either drug can significantly potentiate the effects of adenosine, resulting in more prolonged hypotension and AV node blockade.<sup>564</sup> Children with transplanted hearts can demonstrate prolonged bradycardia and asystole in response to adenosine. The denervated heart is extremely sensitive to the AV node blocking effects. It is recommended that the initial dose be reduced by 50% in these children.<sup>139</sup> This can be very important in the cardiac catheterization laboratory, where wire-induced supraventricular arrhythmias are common during surveillance biopsies. Adenosine has been reported to cause bronchospasm in children both with and without known reactive airway disease. It is usually mild and, if necessary, can be treated with IV aminophylline, which directly counteracts the receptor-mediated effects of adenosine.

### **Digoxin**

Digoxin has antiarrhythmic as well as positive inotropic effects. Its basic pharmacology and therapeutic dosing were discussed earlier in the section on vasoactive drugs. As an antiarrhythmic agent, digoxin slows both atrial and AV node conduction. It slows the ventricular response in atrial flutter and fibrillation and may be used to treat children with junctional tachycardia and SVT.<sup>318,479</sup> Digoxin can have an unpredictable effect on the refractory period of accessory pathways<sup>565,566</sup> and is therefore relatively contraindicated in children with Wolff-Parkinson-White syndrome or other forms of SVT with accessory pathways. Digoxin easily crosses the placenta and remains the primary treatment for termination of fetal SVT.<sup>567-569</sup>

The dosing of digoxin in infants and children must be undertaken with care. Infants have greater myocellular concentrations of digoxin than adults do.<sup>246,570-572</sup> The dosing schedule of digoxin, based on age, is shown in Tables 16-8 and 16-11. IV and oral dosing are essentially the same. The onset of effect is more rapid with IV dosing (5 to 10 minutes) than with oral dosing (1 to 2 hours). The elimination half-life of digoxin is prolonged, approaching 1 to 2 days in young infants. Significant renal dysfunction and congestive heart failure can extend the elimination half-life. There are no active metabolites of digoxin. Therapeutic digoxin concentrations are 0.7 to 2.0 ng/mL. To properly measure the blood concentration of digoxin, blood should be obtained either just before a dose or at least 6 hours after the preceding dose.

Cardiac injury (e.g., ischemia-reperfusion, myocarditis) may increase the sensitivity to digoxin. Toxicity is more likely in children whose plasma concentrations exceed 3 ng/mL.<sup>251</sup> Signs

of toxicity include proarrhythmia, nausea, vomiting, and drowsiness. Infants and young children frequently manifest digoxin toxicity as SVT and AV node conduction disturbances, whereas adults are more prone to ventricular arrhythmias, premature ventricular contractions, AV blocks, and junctional tachycardias. Hypokalemia exacerbates the risk of digoxin toxicity. Many drugs interact with digoxin. As a rule, the administration of other drugs may require a reduction in the digoxin dosing.

### Magnesium Sulfate

Magnesium plays an important role in many biologic processes. The catalytic actions of more than 300 enzymes, including those for ATP and DNA synthesis, depend on the presence of the  $Mg^{2+}$  ion, the physiologically active form. Myocardial conduction and contractility, transmembrane calcium flux, potassium transport, vascular smooth muscle tone, coronary reactivity, and nitric oxide synthesis are all regulated by magnesium. Only 1% of the total body magnesium is extracellular; 60% is found in bones and 39% is intracellular, especially in muscle cells. This distribution explains why serum levels of magnesium may be normal despite an underlying intracellular deficiency. Of the extracellular magnesium, 55% is in the active ionized form. Ionized magnesium is a better predictor of the intracellular magnesium status; age-specific reference values have been published.<sup>573-574</sup>

Magnesium sulfate is currently used for the correction of hypomagnesemia, for management of seizures and hypertension, for bronchodilation during status asthmaticus, and in the treatment of life-threatening arrhythmias. It is especially valuable in the treatment of long QT syndromes and torsades de pointes.<sup>575,576</sup>

More recently, prophylactic magnesium supplementation during pediatric cardiopulmonary bypass has been advocated to reduce the incidence of postoperative junctional ectopic tachycardia.<sup>577,578</sup>

The IV dose is usually 25 to 50 mg/kg over 10 minutes (0.2 to 0.4 mEq/kg), with a maximum single dose of 2 g. This dose can be repeated every 6 to 8 hours depending on renal function and serum concentrations. Because magnesium is excreted solely by the kidneys, renal insufficiency requires increasing the intervals between doses to avoid toxicity. The normal serum concentration of magnesium is 1.5 to 2.5 mEq/L. Levels greater than 5 to 7 mEq/L can lead to increasing CNS and cardiac depression,

initially manifested as loss of deep tendon reflexes and muscle weakness, potentially leading to respiratory depression and cardiac arrest (at levels >15 to 20 mEq/L). IV calcium directly antagonizes magnesium-induced toxicity.

### ACKNOWLEDGMENTS

We wish to thank Avinash C. Shukla, James M. Steven, Francis X. McGowan, Jr., Paul R. Hickey, Robert K. Crone, and Susan L. Streitz for their prior contributions to this chapter.

## Summary

THIS CHAPTER REVIEWS THE equipment and strategies for cardiopulmonary bypass (CPB) in infants and children, focusing on how they differ compared with CPB in adults. We will review the effects of CPB on the key organ systems and discuss specific management issues that occur in daily practice.

## Basic Aspects of Cardiopulmonary Bypass

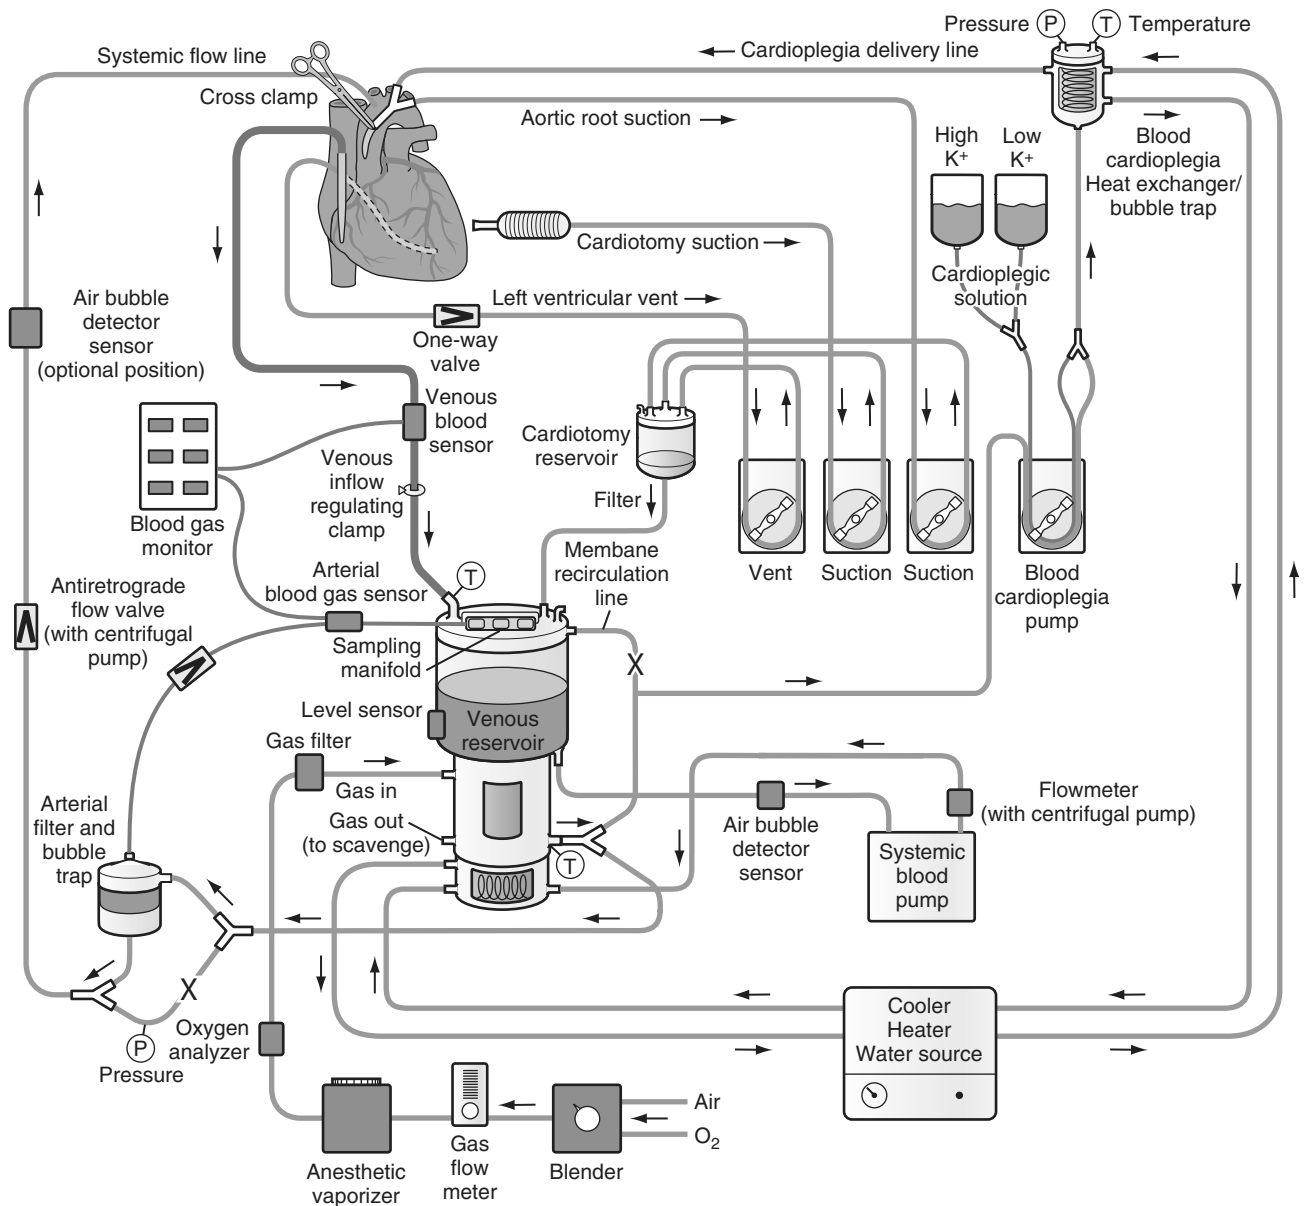

The basic principles of CPB remain unchanged from when they were first introduced in the 1950s: the CPB machine assumes the functions of the heart and lungs during the time necessary to complete either an intracardiac or an extracardiac repair. A basic bypass circuit (Fig. 17-1) consists of an oxygenator, heat exchanger, and venous reservoir; pump heads for perfusion, cardiotomy suction, and cardioplegia; and appropriate tubing, cannulas, and monitoring and alarm devices.<sup>1</sup> Major differences exist between pediatric and adult CPB, stemming from anatomic, metabolic, and physiologic differences in these age groups (Table 17-1).

## THE CIRCUIT AND CANNULAS

Unfortunately the circuit size cannot be reduced proportionately to the patient's size; this disproportion commonly leads to hemodilution and dilutional coagulopathies in children. The surgical procedures require extremes of temperature, hemodilution, and changes in flow rates. Because of the smaller size cannulas and higher flow rates (150 to 200 mL/kg/min) in infants and children, cannulas assume a much more important management issue than in adults. Shear stress is significant in small cannulas and is several-fold greater than needed for activation of blood cells and platelets, leading to a disproportionately exaggerated systemic inflammatory response syndrome (SIRS).

## Bypass Circuit

Technical advances in the field of oxygenator construction and size, and reduction of priming volumes to as low as 45 mL for neonatal oxygenators, have allowed marked reductions of circuit volumes over the past decade. Also, tubing sizes can be reduced to  $\frac{3}{16}$ -inch diameters, which, in combination with shorter length

**FIGURE 17-1** Schematic diagram of a cardiopulmonary bypass circuit. This scheme depicts a membrane oxygenator with integral hard-shell venous reservoir and external cardiomy reservoir. Many circuits have the cardiomy reservoir, venous reservoir, and oxygenator integrated into one single unit. The systemic blood pump may be either a roller or centrifugal pump. Most pediatric venous cannulations are bicaval with two separate venous cannulas instead of the single venous cannula depicted here. Carbon dioxide can also be added to the inspired gas to facilitate pH-stat blood gas management. Arrows indicate direction of flow; P, pressure sensor; T, temperature sensors; X, placement of tubing clamps. (From Hessel EA, Hill AG. Circuitry and cannulation techniques. In: Gravlee GP, Davis RF, Kurusz M, Utley JR, editors. *Cardiopulmonary bypass: principles and practice*. 2nd ed. Philadelphia: Lippincott Williams & Wilkins; 2000, p. 69-97.)

tubing, allows reduction of priming volumes to the range of 100 to 150 mL for neonates. A summary of the Texas Children's Hospital sizing chart is shown in Table 17-2.

#### Heparin Coated Versus Noncoated Circuits

Young children are more susceptible to the adverse effects of CPB than adults, and the inflammatory response to CPB may have serious consequences for neonatal and pediatric patients.<sup>2,3</sup> This is in part related to the surface area of the CPB circuit, which is large relative to the child's blood volume when compared with an adult's blood volume. For example, a 3-kg neonate with a blood volume of 90 mL/kg has a total blood volume of

approximately 270 mL, and with an average priming volume in many centers of 350 mL, the CPB circuit volume thus causes greater than 100% dilution. A 70-kg adult with 70 mL/kg blood volume has an approximately 5000-mL blood volume, and with a CPB circuit prime of 1500 mL, this results in less than 33% dilution. Contact of blood with the surface of the circuit also plays an important role for activation of coagulation and fibrinolysis. Heparin-coated biocompatible bypass systems reduce this activation in children weighing less than 10 kg undergoing CPB.<sup>4</sup> They also have been shown to reduce the activation of factor XII and the complement system.<sup>5,6</sup> This results in less production of kallikrein and bradykinin, which in turn reduces

**TABLE 17-1** Comparison of Pediatric Versus Adult Cardiopulmonary Bypass

	Child	Adult
Hemodilution	3-15× adult	Moderate
Perfusion pressure	30-40 mm Hg	Moderate (>50-80 mm Hg)
	Wide flow rates (0-200 mL/kg/min)	Narrow range (CI 2.0-2.4 L/m <sup>2</sup> /min)
Blood gas management	pH-stat (PCO <sub>2</sub> 20-80 mm Hg or greater)	α-stat (PCO <sub>2</sub> 30-45 mm Hg)
Cannulation techniques	Variable	Predictable
Aortopulmonary collaterals		Uncommon
Temperature ranges	Variable	DHCA occasionally
Glucose management		Predictable
Inotropic response	Negative	Positive
Perfusion circuit	Per kilogram weight	Standard
Parameters	Hematocrit often >55%-60%	
	PO <sub>2</sub> 40-80 mm Hg	±
	SaO <sub>2</sub> 75%-85%	
	Ultrafiltration (MUF/CUF)	±Ultrafiltration

CI, Cardiac index; CUF, conventional ultrafiltration; DHCA, deep hypothermic circulatory arrest; MUF, modified ultrafiltration.

**TABLE 17-2** Cardiopulmonary Bypass Circuit Prime Volume and Constituents at Texas Children's Hospital

Patient Weight	Prime Volume	Prime Constituents
<8 kg	350 mL	Whole blood or PRBC + FFP + crystalloid prime*
8-15 kg	650 mL	100 mL albumin 25% ± PRBC + crystalloid prime*
15-25 kg	900 mL	100 mL albumin 25% + crystalloid prime*
15-25 kg	1200 mL	Crystalloid prime*

FFP, Fresh frozen plasma; PRBC, packaged red blood cells.

\*Crystalloid prime: ½ normal serum + Plasmalyte + CaCl<sub>2</sub> + KCl.

the secretion of tissue plasminogen activator from endothelial cells. One study has documented more bleeding with the use of a conventional, non-heparin-coated circuit compared with a heparin-coated circuit.<sup>6</sup> Overall, children operated on while supported with heparin-coated circuits have a significant reduction in inflammatory mediator release and fewer consequences thereof, such as prolonged postoperative ventilation and stay in the intensive care unit (ICU).<sup>7</sup>

### CARDIOPULMONARY BYPASS PUMPS

The two pumps used most commonly for CPB are roller pumps and centrifugal pumps. Roller pumps have the advantages of simplicity, low cost, ease and reliability of flow calculation, and the ability to pump against high resistance without reducing flow.<sup>8</sup> Disadvantages include the need to assess occlusiveness, spallation of the inner tubing surface (potentially producing

particulate arterial emboli), capability for pumping large volumes of air, and ability to create large positive and negative pressures. Compared with roller pumps, centrifugal pumps offer the advantages of less air pumping capabilities, less ability to create large positive and negative pressures, less blood trauma, and virtually no spallation. Disadvantages of centrifugal pumps include higher cost, the lack of occlusiveness (creating the possibility of accidental patient exsanguination), and afterload-dependent flow that requires constant flow measurement. In the setting of short-term CPB for cardiac surgery, it remains uncertain whether the selection of a roller pump over a centrifugal pump, or of any specific centrifugal pump over another, has clinical importance. Pulsatile perfusion may prove to be beneficial in the future, but further outcome data and technical improvements are needed.<sup>9</sup>

### CARDIOPULMONARY BYPASS PRIME

The optimal priming fluid in cardiac surgery is a topic of enduring debate. Crystalloid solutions, colloids, and mixtures of both are used. Children appear to benefit from a colloid prime. If crystalloid is used for priming, it should not contain lactate or dextrose because CPB induces a metabolic acidosis<sup>10</sup> that has been shown to be iatrogenic and not splanchnic in origin.<sup>11</sup> The addition of lactate to the prime increases postoperative serum lactate concentrations and should be avoided.<sup>12</sup> Hyperchloremic metabolic acidosis is the second contributing component of a metabolic acidosis on CPB. This is often only detected by measuring the strong ion difference via the Stewart approach to the acid-base homeostasis.<sup>13</sup> Both acidifying events are attenuated by the dilutional hypoalbuminemia induced by the administration of the pump prime. Because a hyperchloremic acidosis of a mild degree seems to be well tolerated and not associated with a poor outcome, no intervention seems necessary. Understanding the nature of CPB-associated acidosis, however, is likely to prevent unnecessary investigations or interventions.

The avoidance of dextrose is especially important during complex repairs using deep hypothermic cardiac arrest in which the risk of neurologic injury is substantive. The additives in banked blood, namely, glucose in citrate-phosphate-dextrose (CPD) storage solutions, also need to be considered as a source of glucose (together with the increased plasma concentrations of potassium in stored blood). We use a balanced electrolyte solution, such as Plasmalyte, for the crystalloid component of our prime.

The proportionally large volume of the bypass circuit compared with the child's blood volume has a significant impact on the coagulation factors and cellular components. Platelet count decreases and coagulation factors, including fibrinogen, are diluted after bypass; these factors may contribute to a coagulopathy. The fibrinogen concentration at the end of bypass has been shown to correlate with the 24-hour chest drainage in children weighing less than 8 kg.<sup>14</sup> This is seen more frequently in infants and neonates in whom an average decrease in plasma concentrations of hemostatic proteins by 56% immediately on initiation of bypass can be observed.<sup>15</sup> Overall, younger age represents the single most important risk factor for coagulopathy and bleeding complications.<sup>16</sup>

One approach to the just-mentioned problems is the addition of whole blood to the circuit prime. Proponents cite two advantages: (1) improved hemostasis and (2) a decreased SIRS with less edema formation and less organ dysfunction. One study has disproved these perceived advantages; the investigators found that the use of fresh whole blood increased perioperative fluid

requirements, leading to a longer duration of mechanical ventilation and ICU stay than in the single component group.<sup>17</sup> The only advantage found by their study was the lesser number of donor exposures, a problem we try to overcome by matching packed red blood cells (PRBCs) and fresh frozen plasma (FFP) from the same donor.<sup>18</sup> In addition, whole blood is frequently not available. An alternative approach is the use of FFP in the prime.<sup>19</sup> Other investigators found that the use of FFP led to greater fibrinogen concentrations at the end of surgery. On average, children in the FFP group needed 1.3 fewer donor exposures and tended to need fewer PRBCs. The lower donor exposure was primarily because of fewer transfusions of cryoprecipitate.<sup>19</sup> FFP may be safely substituted by 5% albumin in the prime in children with less complex repairs and acyanotic lesions.<sup>20</sup> Whenever possible, we prefer fresh blood less than 5 days old. Fresh PRBCs are presumably more balanced metabolically than stored PRBCs; the former contain less potassium, a greater concentrations of glucose, reduced concentrations of lactate, and a greater pH.<sup>21</sup> Also postoperative morbidity increases with increasing age of red blood cells.<sup>22</sup> Pulmonary complications, acute renal failure, and increased infection rates were among the main complications associated with increased red blood cell storage time. As far as potassium levels and acid-base balance are concerned, PRBC priming can be safely performed with stored PRBCs if the priming solution is circulated for 20 minutes before the initiation of CPB.<sup>23</sup>

Depending on the size and age of the child, and the complexity of the repair, a target hematocrit is chosen. Based on the child's blood volume and the prime volume, homologous blood is added using the following calculation:

$$\begin{aligned} \text{Prime PRBC volume} = & [\text{Target hematocrit}] \\ & [\text{Patient blood volume} + \text{Prime volume}] \\ & - [\text{Patient PRBC volume}] \end{aligned}$$

The average prime volume of the circuits we use is shown in Table 17-2. Other prime additives are heparin, antifibrinolytics, antiinflammatory agents (corticosteroids), antibiotics, vasodilators, and, sometimes, diuretics (mannitol, furosemide). At the end of the case and before separation from bypass, blood gas analysis is done to ensure that the electrolytes (including calcium and magnesium ions), glucose, and hematocrit are within a desired range. Acid-base changes and sodium concentration are corrected with sodium bicarbonate, and residual lactate is washed out with the help of the hemofiltration.

## ANTIFIBRINOLYTIC AGENTS (SEE CHAPTER 18)

### Aprotinin

Inhibitors of serine proteases regulate and prevent uncontrolled activation of thrombin, coagulation factors, complement products, kallikrein, trypsin, elastase, and cathepsin among others of these potent enzymes. Of the serine protease inhibitors, the broad-spectrum agent aprotinin is the most widely studied in both experimental and clinical settings. Aprotinin is derived from bovine lung. It inhibits plasmin, kallikrein, trypsin, and other proteases, resulting in both antiinflammatory and antifibrinolytic effects and maintenance of glycoprotein homeostasis.

The first use of aprotinin in pediatric cardiac surgery was reported in 1990<sup>24</sup>; a high-dose regimen was administered to 28 children at increased risk of bleeding. This population included those undergoing transposition of the great arteries or reoperations, and children with endocarditis. No reduction in blood loss

or drainage was observed; there were no adverse effects, and chest closure time was reduced.

Despite the high cost of aprotinin, follow-up studies have had more favorable results and its use has been shown to reduce overall costs, with decreased patient charges as a result of reduction in the number of blood products used, operative time, duration of postoperative ventilation, and hospitalization.<sup>25,26</sup> This was confirmed in a recent comparative analysis amongst antifibrinolytic medications.<sup>27</sup> However, this benefit was observed only in complex repairs and the use of a high-dose regimen.<sup>28</sup> The lesser effect of a low-dose regimen may be attributable to the dilutional effects in pediatric surgery compared with the adult population.<sup>29</sup> Pediatric lung transplantation has been studied as a potential target group for aprotinin use.<sup>30</sup> As in most high-risk groups, a significant benefit was found for children with repeat operations (defined as repeat sternotomies or repeat transplantations), either with a high- or a low-dose regimen. This is consistent with our experience. Also, in general, infants younger than 6 months of age and those with repeat sternotomies seem to get a particular benefit from a high-dose regimen of aprotinin<sup>31</sup> compared with reduced doses, despite greater drug costs. Economic studies have shown a cost-effective benefit of aprotinin in repeat cardiac procedures.<sup>25,26</sup>

Aprotinin seems to have an influence on the inflammatory response to CPB in children.<sup>32</sup> Less time mechanically ventilated postoperatively<sup>33</sup> and an improved PaO<sub>2</sub>/FiO<sub>2</sub> (ratio of arterial oxygen concentration to the fraction of inspired oxygen, or P/F ratio) as an indicator of an attenuated reperfusion injury of the lung with the use of aprotinin have been reported.<sup>34</sup> The clinical relevance of its antiinflammatory action remains unclear but points toward significant antiinflammatory properties.

Although a standard dosing regimen has yet to be defined in children, pediatric studies have demonstrated decreases in operative time post CPB, exposure to donor blood, and postoperative chest tube drainage with the use of aprotinin.<sup>33</sup> In vitro plasma concentrations of aprotinin have been related to antifibrinolytic and antiinflammatory activity at concentrations of 50 to 125 kallikrein inhibitor units (KIU)/mL and 200 KIU/mL, respectively.<sup>25,35,36</sup> Anaphylactic and anaphylactoid reactions may occur with aprotinin, and a test dose should be given before administration of the loading dose or addition of aprotinin to the CPB circuit. In a retrospective review of 681 children, reactions occurred in 1% of first exposures, 1.3% of second exposures, and 2.9% of more frequent exposures.<sup>37</sup>

We used aprotinin for complex neonatal repairs, such as arterial switch operations or Norwood procedures, as well as for most reoperative procedures and organ transplantations.<sup>38,39</sup> Because of safety concerns in adults, the drug is currently unavailable in the USA and Europe. The decision to withdraw the drug was based on data that were obtained entirely from adults, who present with a different profile of complications following cardiac surgery than do children. Aprotinin has been shown to be safe and efficient in the neonate.<sup>40</sup> Furthermore, serious questions have been raised regarding the statistical method used in the sentinel study that questioned the safety of aprotinin. Aprotinin continues to be used in Australia and New Zealand and has been reintroduced for adult coronary artery bypass graft surgery in Canada. Currently, the FDA in the United States is reevaluating the role of aprotinin in anesthesia. Our dosing regimen is weight based, with 60,000 KIU/kg as a loading dose and in the pump prime. Aprotinin is started before the incision and blood levels are maintained with a continuous infusion of 7000 KIU/kg/hour; this is

discontinued just before leaving the operating room. Regimens based on body surface area are also used, along with a CPB prime dose based on priming volume designed to achieve a plasma level above 200 KIU/mL. An example is  $0.85$  to  $1.7 \times 10^6$  KIU/m<sup>2</sup> loading dose, and into the CPB prime, and  $2.0$  to  $4.0 \times 10^5$  KIU/m<sup>2</sup>/hour infusion.<sup>25</sup>

### The Lysine Analogues: Aminocaproic Acid and Tranexamic Acid

Despite meticulous surgical technique, it is still frequently difficult to achieve adequate hemostasis after CPB, particularly in neonates.  $\epsilon$ -Aminocaproic acid (EACA) and tranexamic acid (TXA) are analogs of the amino acid lysine. They exert their antifibrinolytic effect by interfering with the binding of plasminogen to fibrin, thereby preventing the activation of the active plasmin. TXA may also improve hemostasis by preventing plasmin-induced platelet activation. Both TXA and EACA exercise some antiinflammatory properties but not to the same extent as aprotinin. In one study, the use of EACA reduced bleeding postoperatively in 25 of 71 children undergoing cardiac surgery on CPB and was found to benefit only the children with cyanotic heart disease.<sup>41</sup> The EACA loading dose was 75 mg/kg followed by an infusion of 15 mg/kg/hour; an additional 75 mg/kg was added to the CPB prime. Because the effective dose of EACA is unknown, another study used a regimen of 150 mg/kg bolus followed by an infusion of 30 mg/kg/hour of EACA. Intraoperative blood loss was reduced, but postoperative blood loss was not different between treatment arm and placebo.<sup>42</sup> Blood coagulation measured with a thromboelastograph showed less fibrinolysis with EACA.

EACA compares favorably with TXA; a beneficial effect has been reported only in children with cyanotic heart disease.<sup>43</sup> Those with acyanotic defects or undergoing repeat sternotomies had no benefit from TXA. Their dosing regimen, however, was only 50 mg/kg as a single bolus before incision. In children, the TXA plasma concentration between the post bolus peak and the end of CPB has an 80% decline when a continuous infusion is not used.<sup>44</sup>

In conclusion, though less efficient than aprotinin, TXA and EACA are equally effective in reducing perioperative blood loss in pediatric cardiac surgery.<sup>45</sup> Given their safety profile, they may be even more appealing in the future. Further studies are needed to delineate their pharmacokinetic profiles and their efficacy. We use EACA based on simulation results from a study by Ririe and coworkers.<sup>46</sup> An initial loading dose of 75 mg/kg over 10 minutes and a maintenance infusion rate of 75 mg/kg/hour is used with 75 mg/kg placed in the pump to maintain serum concentrations above the therapeutic concentration (assumed to be 130  $\mu$ g/mL) in more than 95% of children.

## Special Coagulation and Hematologic Problems

### HEPARIN-INDUCED THROMBOCYTOPENIA

The use of unfractionated heparin for anticoagulation for CPB in adults produces antiheparin antibodies in 25% to 50% of patients within 10 days postoperatively. In a small minority of these patients, high-titer IgG platelet-activating antibodies form and make immune complexes with heparin and platelet factor 4 (PF4).<sup>47</sup> This results in activation of platelets (via their Fc receptors) and formation of procoagulant platelet microparticles,

leading to thrombin generation and thrombosis. Thus, the major problem in heparin-induced thrombocytopenia (HIT) is thrombocytopenia several days after heparin exposure accompanied by thrombosis, often in major vessels or structures. HIT appears to be less common, of milder course, and probably underrecognized in neonates and children. About 1% of children exposed to CPB have PF4 antibodies when tested before their second CPB, and actual HIT is much less common.<sup>48</sup> When HIT is suspected, either PF4 enzyme-linked immunosorbent assay or a functional assay for HIT can be used to make the diagnosis; if positive, no further heparin should be given. If CPB is necessary, alternatives, such as the direct thrombin inhibitors argatroban, lepirudin, and bivalirudin, may be used. None of these agents is approved for use in children for anticoagulation for CPB, but case reports and small series have documented their successful use when HIT is diagnosed.<sup>49-51</sup> The partial thromboplastin time (PTT), activated clotting time (ACT), and a specialized clotting time called the *ecarin clotting time* can be used to follow anticoagulation with these agents, but there is no reversal agent for them. Thus, treatment of post-CPB bleeding involves administration of blood products and coagulation factors as well as recombinant factor VIIa (see later discussion).

### ANTITHROMBIN III DEFICIENCY

Heparin produces anticoagulation by combining in a 1:1 ratio with antithrombin III (ATIII), which then binds to and inhibits thrombin, leading to anticoagulation. Of adult patients, 4% to 13% have a resistance to normal doses of heparin for CPB; most instances occur because of a partial deficiency of ATIII, rendering heparin less effective at producing anticoagulation.<sup>52</sup> In children this is often unknown, and the first suspicion of ATIII deficiency may occur when the standard heparin dose of 300 to 400 units/kg fails to adequately anticoagulate before CPB, that is, the ACT remains less than 300 seconds. The usual response is to apply another dose of heparin from a different vial and remeasure the ACT, but if the ACT is still not adequately prolonged, a diagnosis of ATIII deficiency may be suspected. Infants less than 6 months of age and children with congenital heart disease have decreased ATIII concentrations.<sup>53</sup> Therefore, heparin may not achieve adequate anticoagulation, and disorders in hemostasis and thrombosis and an exaggerated inflammatory response may occur. In this case, blood can be sent for ATIII levels, but to proceed with CPB, the ATIII must be increased. This can be accomplished in two ways: (1) by supplementing ATIII with recombinant ATIII, 75 units/kg, and ensuring that the ACT is adequately prolonged before proceeding with CPB, or (2) by adding FFP (which has ample levels of ATIII) to the CPB prime or administering it to the child.<sup>52,54</sup>

### RECOMBINANT FACTOR VIIa FOR MASSIVE HEMORRHAGE

Recombinant factor VIIa (rFVIIa) was originally approved for use in patients with hemophilia who possess inhibitors to factors VIII or IX, and was shown to be effective at treating bleeding in these patients at doses of 90  $\mu$ g/kg (see Chapter 10).<sup>55</sup> Endogenous factor VII circulates at low concentrations in the plasma. At a site of tissue or blood vessel injury, tissue factor (TF) is exposed, and the extrinsic coagulation pathway is activated by the binding of factor VII to TF, resulting in the activation of factor X to factor Xa, leading to the generation of thrombin from prothrombin, with further activation of platelets and the coagulation cascade.<sup>56</sup> High concentrations of rFVIIa result in major activation of the extrinsic pathway at the site of injury, theoretically without

resulting in systemic hypercoagulability. However, thrombotic complications are increased after its use. rFVIIa also activates platelets, adding to the potential benefit of this agent in significant hemorrhage. Thus, this therapy seems attractive for the treatment of surgical bleeding. A recent analysis of factor VII concentrations during pediatric cardiac surgery recommended that it be used to treat postoperative coagulopathies that were resistant to conventional therapy, when no identifiable surgical cause of bleeding could be determined.<sup>57</sup>

Because of its high cost, and the paucity of data in children undergoing cardiac surgery, rFVIIa should be reserved for life-threatening hemorrhage unresponsive to other measures. A dose of 45 to 90 µg/kg, repeated every 2 hours, can be used. rFVIIa cannot produce hemostasis alone and should only be administered after the transfusion of sufficient amounts of platelets, plasma, and fibrinogen to form the substrate for hemostasis.

### SICKLE CELL DISEASE

Sickle cell disease (SCD), one of the most common hemoglobinopathies among patients of African-American or West Indian origin (with a prevalence of 0.2% to 0.3% in that population), results from the substitution of valine for glutamic acid in position 6 of the β-hemoglobin chain. Normal adult hemoglobin is referred to as HbA, whereas hemoglobin containing the mutant β-hemoglobin chains is referred to as HbS. SCD is represented by a homozygous genotype (HbSS) with fractional concentrations of HbS in the range from 70% to 90%. Sickle cell trait, on the other hand, is a heterozygous manifestation (HbAS) with a prevalence of 8% to 10% in the same population. The definitive diagnosis of any sickle cell hemoglobinopathy is confirmed by hemoglobin electrophoresis (see Chapter 9).

Children with SCD are at a particular risk for perioperative complications.<sup>58,59</sup> Sickling can be triggered by hypoxia, dehydration, acidosis,<sup>60</sup> hypothermia, stress, and infections. Hypoxia induces opening of a Ca<sup>2+</sup>-activated K<sup>+</sup> channel (Gardos channel) that causes intracellular dehydration.<sup>61</sup> Chain formation occurs and leads to increased blood viscosity with vaso-occlusion. Opening of the Gardos channel is an important mechanism of sickle cell dehydration, which is temperature dependent, with greater potassium efflux at lower temperatures.<sup>62</sup> Shrinkage of sickle erythrocytes may also result from activation of a K<sup>+</sup>/Cl<sup>-</sup> cotransport pathway under acidotic conditions.<sup>63</sup> Activation of this pathway can be blocked by increasing the abnormally low level of intracellular magnesium in sickle erythrocytes. The use of magnesium and hydroxyurea in the perioperative period therefore seems to be beneficial.<sup>64</sup>

CPB, particularly for more complex surgical procedures, may involve periods of low flow or even circulatory arrest, as well as hypothermia with consequent local vasoconstriction, hypoxemia, and acidosis. There is some evidence that CPB can be safely undertaken in SCD.<sup>65</sup> Flow conditions are an important determinant of sickle erythrocyte adherence to endothelium. Under low-flow conditions sickle cell adhesion to endothelium increases with contact time in the absence of endothelium activation or adhesive proteins, whereas under venular flow conditions sickle cell adhesion occurs only after endothelial activation. During CPB, both low-flow conditions and endothelial activation may occur. Multiple triggers of sickling are likely to occur during CPB, and close attention should be paid to the conduct of all aspects of bypass.

In the past, routine exchange transfusion has been recommended to prevent these complications.<sup>66</sup> More recent experience

provides evidence that not all children require an exchange transfusion.<sup>67</sup> The growing evidence of the harmful effects of blood transfusion adds to the need to carefully reconsider routine exchange transfusion.<sup>68</sup> For uncomplicated bypass surgery without periods of cardiac arrest, the omission of exchange transfusion has led to good outcomes.

Guidelines have been proposed for the perioperative management of children with sickle cell disorders.<sup>67</sup> It is essential to avoid hypothermia using tepid or warm CPB in its stead; blood transfusion only for a decrease in hematocrit to less than 20%; maintenance of intravascular volume and body temperature while on CPB; the avoidance of vasopressors; the use of postoperative multimodal pain therapy; and early incentive spirometry to prevent pulmonary complications.<sup>69</sup> In our practice, we utilize cerebral near-infrared spectroscopy (NIRS) to help determine an acceptable hematocrit for the individual child.

For children undergoing hypothermia, successful management with<sup>70</sup> and without<sup>71</sup> partial or complete exchange transfusion on bypass has been reported. Exchange transfusion can be performed preoperatively or on initiation of CPB.<sup>72</sup> For exchange transfusion during CPB, the extracorporeal circuit is primed with blood and the usual components. When CPB is commenced, the child's blood volume is drained into storage bags and separated. The platelet-rich plasma is reinfused at the end of CPB, and the concentrated sickle cells are discarded. Platelet and plasma sequestration in conjunction with exchange transfusion reduces the need for postoperative transfusion and protects the platelets from the negative effects of CPB.<sup>73</sup>

There seems to be no consensus as to a suitable target HbS level. Reducing the absolute level of HbS may be of greater benefit than achieving a particular ratio of HbA to HbS because the remaining sickle-prone cells are still at risk for sickling.<sup>74</sup> In SCD, exchange transfusion has been shown to favorably affect cerebral tissue oxygenation.<sup>75</sup> Exchange transfusion will decrease both the proportion and absolute amount of HbS, but it does not remove every cell that may sickle; it may also have favorable effects on hypoxic pulmonary vasoconstriction.<sup>75</sup> In this context, these children may benefit from continuous hemofiltration to reduce inflammatory mediators and improve pulmonary recovery.<sup>76</sup> Inhaled nitric oxide also has been suggested as an adjunct for the prevention of sickle cell crisis. It may improve the binding of oxygen, thereby reducing the formation of sickle cells; reduce pulmonary hypertension; and improve pulmonary function without adverse effects on normal hemoglobin.<sup>77</sup>

## A Perspective on Blood Preservation: Cardiopulmonary Bypass in Jehovah's Witness Patients

Jehovah's Witnesses differ from other religious groups in their conscious objection to decline the therapeutic infusion of blood and blood components. They uniformly refuse the transfusion of red blood cells, and some individuals also refuse platelets and plasma, as well as predisposed autologous blood. Individual choices that can be made are the acceptance of fractions of blood, such as albumin and globulins, dialysis, cell salvage, and acute normovolemic hemodilution.

Acute isovolumic reduction of hemoglobin down to 5 g/dL is tolerated in healthy individuals under anesthesia and does not appear to reduce tissue oxygenation significantly.<sup>78</sup> Reduction of oxygen delivery to 7 to 8 mL/kg/min under resting conditions

does not lead to an oxygen debt and is compensated by increased extraction, an increase in cardiac index, and a subsequent decrease in systemic vascular resistance.<sup>79,80</sup> In a retrospective study of the tolerance of reduced hemoglobin concentration in Jehovah's Witness patients, the hemoglobin concentration of those who died was less than 5 g/dL.<sup>81</sup> A safe limit of hemodilution in children has not been established. One report showed that hemodilution up to 50% in acyanotic children appears to be safe.<sup>82</sup> In cyanotic children, however, the limit was estimated to be around 40%. If this level of hemodilution is exceeded, hemodynamic instability and inadequate oxygen transfer can occur. Evidence suggests that hematocrit levels of 21.5% in infants on CPB leads to significantly worse psychomotor developmental outcome, compared with 27.8%.<sup>83</sup>

The most important and simplest way to avoid transfusion in the setting of cardiac surgery is to limit blood loss. Unnecessary and reduced amounts of blood sampling help to preserve blood.<sup>84</sup> Pharmacologic agents, such as aprotinin and tranexamic acid, reduce the risk of perioperative blood loss.<sup>85</sup> Hormonal stimulation of erythropoiesis with preoperative recombinant erythropoietin is another strategy acceptable to Jehovah's Witnesses. The administration of erythropoietin in the cardiac surgery setting has been shown to reduce the risk of exposure to allergenic blood.<sup>86</sup> However, the associated increase in hematocrit with erythropoietin use may be potentially thrombogenic and could lead to an increase in the incidence of perioperative venous thromboembolism. The cost of using erythropoietin can be large, and cost analysis suggested that its use in cardiac surgery was not cost effective.<sup>87</sup>

Intraoperative recovery of blood with a cell salvage device is also acceptable to many Jehovah's Witnesses. This involves the removal by suction of blood from the operative field followed by washing, filtering, and return of red blood cells to the patient. A randomized controlled trial of intraoperative cell salvage in cardiothoracic surgery has demonstrated a reduction in red blood cell transfusion and an increase in postoperative hemoglobin.<sup>88</sup>

Acute normovolemic hemodilution involves the preoperative removal of a volume of blood from the patient with the simultaneous administration of crystalloid or colloid to maintain circulating volume.<sup>89</sup> The collected blood is then reinfused during the operation. Some Jehovah's Witnesses find this process acceptable, especially if the access line is maintained in continuity with the patient. Acute normovolemic hemodilution has other advantages, including lower costs, because the blood does not need compatibility testing; reduced possibility of administrative error; and a saving in patient time (see Chapter 10). The development of artificial red cell substitutes could potentially abrogate the need for compatibility testing, as well as vastly reduce infection risks, with none of the immunomodulatory side effects of allogeneic blood.<sup>90</sup> Some of these products would also be acceptable to Jehovah's Witness families. Substitutes include perfluorocarbons, hemoglobin solutions, intramolecular cross-linked hemoglobin, and liposome encapsulated hemoglobin. None of these has reached clinical practice. Lastly, autologous retrograde priming has been used in Jehovah's Witness patients and can further reduce the hemodilutional effects of the prime.<sup>89,91</sup>

In the great majority of adult patients, open-heart surgery can be performed without administration of blood or blood components. In children and small infants weighing less than 5 kg, bloodless open-heart surgery is more complicated. Preoperative iron supplementation (6 mg/kg/day) and erythropoietin (200 to 400 U/kg/wk) have been used successfully to augment preoperative hemoglobin levels.<sup>92</sup>

Modern bypass circuits allow the reduction of priming volumes to less than 200 to 300 mL. Main components that are amenable to volume reduction on a regular circuit are the size and length of the lines, small oxygenators and arterial filters, and priming the hemofilter for modified ultrafiltration with blood from the venous line after CPB. Line volumes, for example, may vary from 1.73 mL per 10 cm of a  $\frac{3}{16}$ -inch tubing to 0.75 mL per 10 cm of a  $\frac{1}{8}$ -inch tubing. The limiting factor, however, is the necessary flow. For a  $\frac{3}{16}$ -inch arterial line, a maximum flow of 1.8 L/min was established as the point at which the Reynolds number reaches a value of 1000, indicating a change to turbulent flow. Modified ultrafiltration at the end of CPB through a fluid warmer line to prevent heat loss or continuous ultrafiltration has been used. The venous line and the reservoir are emptied before discontinuation of bypass, the field is suctioned, and all blood is retransfused through the arterial line. Decannulation is achieved and protamine is given as usual. Crystalloid cardioplegia solution should be evacuated from the field by an external sucker to prevent dilution of the pump volume.

Postoperative care involves minimal blood sampling, and only on special indications. Noninvasive monitoring allows uncomplicated weaning from the ventilator.<sup>93</sup> The first report of successful outcomes in Jehovah's Witness children with congenital cardiac defects was in 1985<sup>94</sup>; 110 children older than 6 months of age successfully underwent operation, with a perioperative mortality rate of 5.3%. Only one death was attributed to blood loss. A weight less than 5 kg is considered by some as a contraindication for open-heart surgery and palliative procedures were advocated in the past.<sup>95</sup> For some lesions, however, no palliation is possible. The development of miniaturized circuits, preoperative optimization, use of high-dose aprotinin, vacuum-assisted drainage to allow smaller tubing and cannula sizes, as well as the use of modified ultrafiltration, enabled the safe expansion of surgery into the neonatal population. Individualized heparin level-based anticoagulation management further results in a reduction of coagulation problems, blood loss, and transfusion requirements.<sup>96</sup> The addition of desmopressin, 0.3  $\mu$ g/kg, also not proven, is thought by some to improve platelet activity and stimulate the release of von Willebrand factor after protamine infusion.

All of the aforementioned considerations are important in approaching the Jehovah's Witness patient; however, at Texas Children's Hospital, Jehovah's Witness children are not treated differently with regard to blood transfusion practice than any other child. Cerebral NIRS is utilized to help determine the safe hemoglobin level for the individual child at all phases of surgery. Consent for blood transfusion in this situation is a complicated issue, because the legal status of children is different from that of an adult. Each institution must develop a legal informed consent process for blood transfusion for Jehovah's Witness children, in consultation with local legal authorities, social work and ethic groups, and representatives of the Jehovah's Witness faith. Currently we have a release of liability form for the parent to sign stating that he or she requests that blood products not be used, but that acknowledges they may be needed to treat his or her child. The parent further agrees to release and hold harmless the physicians and hospital for any liability associated with blood transfusion. This form was developed in conjunction with the local Jehovah's Witness church representatives, and in our practice this has been accepted by more than 95% of parents and has obviated the need for more extreme measures, such as temporary

child protective services custody during the perioperative period, which was our former practice.

## Myocardial Protection

Myocardial protection during cardiac surgery has evolved over the years. Melrose and colleagues introduced the concept of chemical cardioplegia in 1955.<sup>97</sup> Before the popular use of chemical cardioplegia, topical cardiac hypothermia was used. In the late 1970s and early 1980s, the concept of cold hyperkalemic blood cardioplegia was introduced.<sup>98</sup> Potassium concentrations in cardioplegic solutions ranging from 12 to 30 mEq/L are typically used to achieve cardiac standstill within 1 to 2 minutes under hypothermic conditions, with higher concentrations (or longer induction times) required for normothermic conditions. Myocardial edema after bypass and global ischemia can be reduced by a number of strategies that involve modifying the conditions of delivery and composition of cardioplegia solutions as they affect the movement of intracellular and interstitial fluid. In contrast to studies in adults, most studies conducted in neonates have shown little difference between blood and crystalloid cardioplegia.<sup>99,100</sup> Hypothermia also decreases myocardial oxygen consumption. The benefits of this approach appear to be optimal at myocardial temperatures between 24° C and 28° C. However, there is growing evidence that warm, intermittent blood cardioplegia may be advantageous to either cold crystalloid or cold blood cardioplegia.<sup>101</sup> The benefits of blood cardioplegia are more pronounced in younger, cyanotic children who require longer aortic cross-clamping. For acyanotic children, the cardioplegic technique is probably not as critical.<sup>102</sup> Avoidance or reduction of myocardial edema occurs by limiting the pressure of cardioplegia infusions and by providing moderately hyperosmolar cardioplegia solutions that contain blood. Buffering the acidosis that results from ischemia is achieved by including tromethamine, histidine-imidazole, or both in the cardioplegia solution. Close management of myocardial calcium balance to avoid extremes of intracellular hypercalcemia or hypocalcemia, especially during reperfusion, is very important.<sup>103,104</sup> The addition of magnesium may solve this dilemma by preventing damage from higher cardioplegic calcium concentrations by its action as a calcium antagonist.<sup>104,105</sup> This prevents mitochondrial calcium overload as a consequence of reperfusion injury. Magnesium also prevents the influx of sodium into the postischemic myocardium, which is exchanged for calcium during reperfusion.

Every cardiac program has its own philosophy regarding cardioplegia and myocardial protection. At Texas Children's Hospital, plain crystalloid cardioplegia is used. The prime blood gas and electrolytes should mimic physiologically the child's arterial blood gas as closely as possible. If whole blood or packed cells are added to the prime, the target hemodilution range should be 28% to 30%; the prime should be recirculated continuously and warmed between 35.0° C and 36.5° C before initiation of bypass. In neonates and infants, albumin is added to the cardioplegic solution to maintain an appropriate colloid osmotic pressure. This may decrease edema formation of the arrested heart. In children undergoing circulatory arrest, long cross clamp times, and large pump suction return cases, 20 mg/kg methylprednisolone is used, up to a maximum of 500 milligrams, to reduce the production of inflammatory mediators that result in myocardial dysfunction. Table 17-3 summarizes the Texas Children's Hospital protocols for cardioplegia and myocardial protection.

## Phases of Cardiopulmonary Bypass

Surgical cases requiring CPB are divided into several basic phases.

### PRE-BYPASS PERIOD

This phase begins with surgical incision and lasts through initial dissection and preparation for cannulation. During this period transesophageal echocardiography (TEE) is performed to confirm the diagnosis and establish a basis for post-bypass comparison.

### CANNULATION AND INITIATION OF BYPASS

After sternotomy and mediastinal dissection, the aorta is cannulated, along with either the right atrium, if single venous drainage is planned, or the superior and inferior venae cavae for bicaval venous drainage. A large dose of heparin (300 to 400 units/kg) is administered intravenously, and the adequacy of anticoagulation is measured using the ACT *before initiating CPB*. The target ACT is usually 480 seconds. High ACTs are maintained during CPB with the addition of heparin to the prime as needed, because larger doses of heparin lead to a reduced degree of consumptive coagulopathy, which translates into reduced blood product therapy requirements.<sup>96</sup> Other methods of measuring anticoagulation include the Hepcon system (a plasma heparin concentration assay), which may allow for more accurate titration of heparin and protamine dosages.<sup>106</sup> The thromboelastogram may also be used as a baseline measure of the coagulation system and then may be repeated during bypass, with heparinase added to more objectively assess each child's anticipated need for coagulation products.<sup>107</sup> An improved preservation of the hemostatic system with subsequent reduction of blood loss and a reduction in transfusion requirements has been demonstrated after maintenance of high heparin levels during CPB.<sup>108</sup> The additional maintenance of high ATIII concentrations may further contribute to a reduction of hemostatic activation.<sup>109</sup>

In most centers, bicaval cannulation is used for all but the smallest children (less than 2 kg) to prevent venous return from interfering with the surgical field. A gradual transition to full CPB is then performed to minimize myocardial stress, using a prime that has essentially the same composition as the child's blood with regard to temperature, pH, calcium, potassium, and hematocrit. CPB flows of 150 mL/kg/min are used for infants weighing less than 10 kg, and 2.4 L/min/m<sup>2</sup> is used for children weighing more than 10 kg. Flow rates may be reduced during periods of hypothermia (see later), although many centers now prefer to maintain greater flows throughout the bypass period. Misplaced cannulas can lead to significant morbidity. Obstruction of the inferior vena cava (IVC) by a misplaced IVC cannula can lead to increased venous pressure, which causes ascites and decreased perfusion pressure in mesenteric, hepatic, and renal vascular beds. Misplacement of the cannula in the superior vena cava can result in cerebral edema from inadequate venous drainage and a subsequent reduction in cerebral blood flow, potentially resulting in ischemia. Arterial cannula misplacement can also occur. If the cannula inadvertently slips beyond the takeoff of the right innominate artery, preferential perfusion to the left side of the brain can be observed. This can be detected on the NIRS monitor, which may be an important monitor, particularly in pediatric cardiac surgery.<sup>110</sup>

The presence of any anomalous systemic-to-pulmonary shunts can lead to shunting of blood away from the systemic circulation, through the pulmonary circuit, and then through the venous

**TABLE 17-3** Cardioplegia Solution

Cardioplegia Base Solution (385 mL)				Note: Following the initial dose, cardioplegia is to be delivered every 20 minutes during the cross clamp period unless otherwise indicated by the surgeon. The perfusionist will remind the surgeon of the need for cardioplegia and keep track of the time. Because of the nature of the surgical procedure, it may be necessary to deliver cardioplegia directly into the coronary ostia via a hand-held delivery system. In this case the surgeon will direct the perfusionist. Close attention should be paid to the delivery line pressures.

cannula to the CPB machine. Thus, the systemic perfusion is shunted away from the body in a futile circuit back to the CPB machine. Anatomic lesions where such shunting can occur include an unrecognized patent ductus arteriosus and large aortopulmonary collaterals, as found in pulmonary atresia. Bypass flow needs to be increased to compensate for these shunts.

### COOLING PHASE

Systemic cooling is used for nearly every case. Hypothermia is classified as mild (30° C to 36° C), moderate (22° C to 30° C), or deep (17° C to 22° C). In general, lower temperatures are used for more complex operations that carry a greater potential for requiring periods of low-flow bypass or circulatory arrest. Cooling is primarily achieved extracorporeally through the heat exchanger

in the bypass circuit, although some surgeons also request that ice be applied to the head to prevent rewarming during the circulatory arrest.

### AORTIC CROSS CLAMPING AND INTRACARDIAC REPAIR PHASE

The aorta is cross clamped, with the heart then rendered asystolic after infusion of cardioplegia solution into the aortic root.

### DEEP HYPOTHERMIC CIRCULATORY ARREST OR SELECTIVE CEREBRAL PERFUSION PHASE

If circulatory arrest is to be used, it is initiated after a slow cooling period of at least 20 minutes, and an attempt is made to limit the total duration of deep hypothermic circulatory arrest (DHCA)

to less than 40 minutes. Special bypass techniques (see later) have been developed to avoid the necessity of using DHCA and may also be performed during this time.

### REMOVAL OF AORTIC CROSS CLAMP AND REWARMING PHASE

After completion of the intracardiac repair and de-airing of the heart, the aortic cross clamp is removed, allowing reperfusion of the myocardium. Optimally, normal sinus rhythm and myocardial contractility are restored during this time, while the child is slowly rewarmed. During rewarming, surgery is completed, inotropic and vasoactive agents are started, and ventilation begins. Hemofiltration and blood transfusion are used to achieve the desired hematocrit. Left atrial and/or pulmonary artery monitoring lines, if indicated, are placed at this time, as are temporary atrial and ventricular pacing wires. If the child is incompletely rewarmed before separation from CPB, a significant afterdrop with precipitous post-bypass reduction in core body temperature can occur. This can lead to vasoconstriction, shivering, increased oxygen consumption, and acidosis. However, postischemic hyperthermia can lead to delayed neuronal cell death.<sup>111</sup> Mild degrees of hypothermia and certainly the avoidance of hyperthermia are essential in the perioperative period.<sup>112</sup> In children, rectal temperature mostly reflects peripheral temperature. One study showed that the temperature of the foot was more sensitive than the temperature of the hand.<sup>113</sup> Another study revealed that for anatomic or physiologic reasons, temperature gradients in the toes develop more readily than those in the fingers.<sup>114</sup> Several endpoints have been proposed, such as nasopharyngeal temperatures greater than 35.0° C, bladder temperature greater than 36.2° C, or skin temperatures greater than 30° C<sup>115,116</sup>; we use an endpoint of 35.5° C rectal temperature.<sup>117</sup>

### SEPARATION FROM BYPASS

The child's core body temperature, hematocrit, and metabolic parameters should be optimized before attempting separation from CPB. Careful observation for left-sided air, confirmation with the TEE, and concurrent inspection of electrocardiogram (ECG) changes should continue throughout the weaning process, with the child in the Trendelenburg position and the aortic root vented. While fluid volume is gradually added to the child by reducing the outflow to the venous reservoir until optimal filling pressures are achieved, CPB flow is then slowly reduced to zero. If inotropic support is anticipated to separate from CPB, infusions should be prepared before beginning separation.

### POST-BYPASS PERIOD

This phase lasts until chest closure and transfer to the ICU have been accomplished. During this time, modified ultrafiltration (MUF) may be performed for 10 to 15 minutes after cessation of CPB. Cardiac function and the quality of the surgical repair are assessed via TEE, and, if found to be satisfactory, protamine is administered to neutralize residual heparin. The usual dose of protamine is 1.0 to 1.3 mg/100 units of heparin given at the onset of bypass. Limiting protamine to this dose prevents an overdose with its associated effects on platelet function (reduction of the interaction of glycoprotein Ib receptor interaction with von Willebrand factor).<sup>118</sup> If the ACT remains increased or prime blood is given back to the child, an additional 25% of the initial dose of protamine is added and the ACT is rechecked. However, particularly in infants, the administration of protamine and the persistent treatment of a suspected

incomplete heparin reversal should not distract and delay the treatment of other commonly associated post-bypass coagulopathies, such as thrombocytopenia, platelet dysfunction, and other coagulation factor deficiencies.

Protamine reactions occur much less frequently in children younger than 16 years of age, approximately 1.76% to 2.88%.<sup>119</sup> Independent risk factors are a female gender, a larger protamine dose, and smaller heparin doses. Type I reactions or effects during administration are rare and adding calcium does not change the hemodynamic consequences of injection.<sup>120</sup> Fortunately, severe anaphylactic reactions (type II) or catastrophic pulmonary vasoconstriction (type III) are rare but have been observed by us and others.<sup>121</sup> Administering the protamine over no less than 5 minutes reduces the severity and precipitous nature of any protamine reaction.

Unstable neonates and small infants may have their sternums temporarily left open, with surgical closure planned 24 to 72 hours later when cardiac function has improved and myocardial edema diminished.

Because CPB can have a multitude of adverse physiologic effects, attempts are made to minimize both the duration of CPB and ischemic (aortic cross clamp) time; thus, as much of the surgery as possible is performed outside of these phases. In general, physiologic responses to bypass are more extreme with decreasing age and size of the child. The neonate experiences a greater degree of hemodilution on bypass and colder temperatures on bypass and frequently requires longer aortic cross clamp times, all of which can result in a greater inflammatory response. Table 17-4 summarizes clinical management issues during the major phases of CPB.

## Particular Aspects of Management on Cardiopulmonary Bypass

### pH-STAT VERSUS $\alpha$ -STAT MANAGEMENT

Some degree of hypothermia is used for nearly every cardiac operation to slow the metabolism and oxygen consumption of all organs, particularly the brain and heart.<sup>122</sup> During cooling, the carbon dioxide contained in blood becomes more soluble and its partial pressure decreases. The PaCO<sub>2</sub> sensed by the body decreases as body temperature decreases, with the result that at a core temperature of 17° C to 18° C, if pH and PaCO<sub>2</sub> have not been corrected for temperature, the body experiences a pH of about 7.6 and PaCO<sub>2</sub> of 15 to 18 mm Hg (Fig. 17-2).<sup>123</sup> This very low PaCO<sub>2</sub> causes cerebral vasoconstriction, particularly during the cooling phase of bypass, which in turn leads to less cerebral blood flow, less efficient brain cooling, and less cerebral protection at a given temperature.<sup>124</sup> Because blood samples are normally heated to 37° C before measurement of pH, PaCO<sub>2</sub>, and PaO<sub>2</sub>, the use of pH-stat management indicates that blood gases are being corrected for the child's actual body temperature by increasing the PaCO<sub>2</sub> during bypass, as it is measured at 37° C, so that the body experiences a PaCO<sub>2</sub> of approximately 40 mm Hg and a pH of 7.4 at all temperatures. Conversely,  $\alpha$ -stat management means not correcting the blood gases for temperature, as if the child's blood was always at 37° C, with the goal of pH 7.4 and PaCO<sub>2</sub> 40 mm Hg. In the early days of CPB, pH-stat was used to preserve cerebral blood flow at all ages.<sup>123</sup> Subsequently, in the 1970s and 1980s, randomized controlled studies in adults undergoing CPB confirmed that acute, post-CPB neurologic problems were worse with the use of pH-stat management.<sup>125</sup>

**TABLE 17-4 Checklist for Bypass Management****Before CPB**

1. Check temperature; maintain normothermia during induction and preparation.
2. Supplement premedication.
3. Ensure noninvasive monitoring: blood pressure, ECG, pulse oximetry, stethoscope.
4. Perform inhalational induction after preoxygenation; intravenous induction, if cannula is in place.
5. Peripheral intravenous placement(s)
6. Neuromuscular blockade and ventilation
7. Intubation and mechanical ventilation according to shunt lesion (CO<sub>2</sub>, O<sub>2</sub> control)
8. Monitoring:
  - a. Arterial line and central venous line
  - b. ECG electrodes
  - c. Bladder catheter
  - d. Temperature probes
  - e. TEE probe (in infants >3 kg)
9. Positioning
10. Deepening of anesthetic level
11. Antifibrinolytics and corticosteroids, as indicated
12. Heparin, 300-400 U/kg, before arterial cannulation
13. Check activated clotting time >400 seconds.
14. Supplement anesthetics on initiation of bypass.

**During CPB**

1. Stop ventilation and drips when full flow is reached.
2. Inspect head perfusion.
3. Evaluate quality of perfusion (perfusion pressure, central venous pressure, diuresis, arterial blood gases, temperature gradient).
4. Prepare for separation.
  - a. Drips (inotropic drugs, calcium)
  - b. Pacemaker
  - c. Blood products
5. Set and control temperature and rewarming (heating blanket, room temperature).
6. Zero transducers
7. Check arterial blood gases in preparation for discontinuation of CPB; correct abnormalities.
8. Suction and ventilate.

**After CPB**

1. Separate when
  - a. Temperature >35.5° C
  - b. Stable rhythm or pacing
  - c. Heart contracting well
2. Fine-tune blood pressure; consider direct blood pressure measurement for hypotension at the aortic cannula; volume  $\pm$  drips.
3. Consider modified ultrafiltration.
4. Check arterial blood gases.
5. Evaluate with transesophageal echocardiography for residual defects.
6. Give protamine, 1-1.3 mg/100 IU of initial heparin.
7. Check activated clotting time and arterial blood gases.
8. Chest closure and recheck arterial blood gases.
9. Transport to the intensive care unit.

CPB, Cardiopulmonary bypass; ECG, electrocardiogram; TEE, transesophageal echocardiography.

$\alpha$ -Stat management was, therefore, adopted for both adult and pediatric CPB. However, studies in a neonatal pig model have challenged this conclusion, proving that neurologic outcomes, both behavioral and neuropathologic, are significantly worse when  $\alpha$ -stat management is used in infants.<sup>124,126</sup>

Advantages of pH-stat CPB have been shown to include:

- A decreased brain metabolic rate<sup>127</sup>
- An increased rate of brain cooling and reperfusion,<sup>128</sup> thereby providing better protection through more even and faster cooling and rewarming secondary to increased CBF<sup>128,129</sup>
- Molecular effects of altered PaO<sub>2</sub> and pH, including changes in cerebral oxygenation and brain enzyme activity, as well as decreased brain electrical activity<sup>129-131</sup>
- Decreased oxyhemoglobin affinity<sup>132</sup>
- Increased cortical oxygenation before arrest (through hypercapnic capillary vasodilation) and decreased oxygen metabolic rate, providing slower deoxygenation compared with  $\alpha$ -stat management (approximately 10 vs. approximately 7 minutes).<sup>124,133</sup> Cortical anoxia occurs at 36 minutes versus 24 minutes for  $\alpha$ -stat management.

In cyanotic infants with aortopulmonary collaterals, pH-stat management results in significantly improved brain oxygenation as measured by near-infrared cerebral oximetry.<sup>134</sup> A retrospective study of 16 infants revealed worse neurodevelopmental outcomes with  $\alpha$ -stat management.<sup>135</sup> In a randomized prospective trial of pH- versus  $\alpha$ -stat management in 182 infants younger than 9 months of age, there was a strong trend toward improved outcomes with pH-stat management, including earlier return of electroencephalographic activity, fewer seizures, and improved psychomotor development index.<sup>136</sup> One study examined the effects of  $\alpha$ -stat and pH-stat on developmental and neurologic outcomes after deep hypothermic CPB in infants.<sup>137</sup> Psychomotor Development Index scores of 110 patients did not differ significantly between the groups ( $P = .97$ ). The results of the Mental Development Index scores were dependent on diagnosis. In all but the ventricular septal defect subgroup, the pH-stat group did not have statistically greater Mental Development Index scores. Abnormalities on the electroencephalogram ( $P = .77$ ) and neurologic examination ( $P = .70$ ) were similar with the two methods of blood gas management. The authors concluded that the use of  $\alpha$ -stat or pH-stat strategy is not consistently associated with improved or impaired early neurodevelopmental outcomes in infants undergoing deep hypothermic CPB.<sup>137</sup> One reason for the differing results between pediatric and adult studies is that cerebral emboli are more common in the adult population because of the presence of atherosclerotic plaques, which cause microembolic infarcts, and the increased cerebral blood flow produced by pH-stat management, which leads to a greater number of cerebral emboli in adults. Emboli occur much less frequently in children, and the primary cause of neurologic injury from CPB in children is hypoxic-ischemic.<sup>138</sup> Thus, the increased cerebral blood flow observed on CPB with pH-stat management lessens this risk in children. Interestingly, this putative mechanism has been recently challenged by a study involving a controlled microembolic load and DHCA in pigs that revealed that pH-stat was still associated with improved outcomes when compared with  $\alpha$ -stat.<sup>139</sup> pH-stat also improves oxygen delivery by counteracting the pH- and hypothermia-associated leftward shift in the oxyhemoglobin dissociation curve. Studies have also revealed a decrease in peak postoperative troponin levels, reduced ventilator dependence, and reduced ICU stays with pH-stat versus  $\alpha$ -stat.<sup>140</sup> Most programs specializing in surgery for

a greater hematocrit on CPB is the finding that greater transfusion of blood products in the intraoperative, and early postoperative periods, is associated with longer duration of mechanical ventilation in infants undergoing two-ventricle repairs.<sup>147</sup> Additional studies are required to optimize strategies for the use of blood products in infants and children undergoing CPB.

### FLOW RATES ON BYPASS

The traditional practice in many institutions has been to decrease CPB flows, particularly during hypothermia, to reduce the volume of blood returning to the surgical field and allow more efficient completion of the surgery, particularly in small infants. This concept has been questioned in recent years owing to the inability to determine the safe low-flow bypass rate in the individual child. One report studied 28 neonates who underwent arterial switch operation with  $\alpha$ -stat blood gas management during CPB.<sup>148</sup> At 14° C to 15° C, bypass flow was sequentially reduced from 150 mL/kg/min to 50 mL/kg/min, and then further decreased in increments of 10 mL/kg/min until circulatory arrest was begun (to 0 mL/kg/min). All neonates had detectable cerebral blood flow by transcranial Doppler at CPB flows above 20 mL/kg/min, but one had no detectable perfusion at 20 mL/kg/min, and eight had none at 10 mL/kg/min, leading the authors to conclude that 30 mL/kg/min was the minimum acceptable flow in this population. A neonatal pig model determined that, at normothermia, bypass flows of at least 150 to 175 mL/kg/min were necessary to ensure full oxygenation of all end organs and tissues.<sup>149</sup> Clinical studies of a high-flow bypass strategy, which included flows of 150 mL/kg/min at all phases of bypass except during DHCA, minimal use of DHCA, and  $\alpha$ -adrenergic receptor blockade with phenoxybenzamine to produce long-duration systemic vasodilation, demonstrated excellent short- and long-term clinical and neurodevelopmental outcomes, with no child scoring outside normal ranges for testing performed at a mean age of 9 years.<sup>150</sup> This strategy also has led to excellent early results for the Norwood operation, with an early perioperative survival of 83% for cases carried out from 1993 to 1999.<sup>151</sup> During the same era, one report documented that 26.7% of arterial switch children had neurologic abnormalities and 55% had at least one abnormal area on neurodevelopmental testing (performed at a mean of 10 years) when DHCA and low-flow bypass had been used.<sup>151</sup>

Vasoconstriction and increased vascular resistance, resulting in uneven regional organ perfusion, are among the undesired side effects of CPB. Endogenous catecholamine production and the alkaline  $\alpha$ -stat CPB technique, if used, are responsible for these effects. To be able to run full flow during hypothermic CPB without significant hypertension, vasodilators are often used. Agents currently used to provide systemic vasodilation and more even cooling and rewarming include phentolamine, nitroprusside, or nitroglycerin. Phenoxybenzamine, which is no longer available, was used as part of a treatment strategy after stage 1 palliation for hypoplastic left heart syndrome, and has been associated with improved outcome.<sup>152,153</sup> Phenoxybenzamine was more effective than sodium nitroprusside in improving peripheral circulation, as shown by temperature gradients intraoperatively.<sup>154</sup> Greater CPB flows are associated with an improved oxygen delivery, which can improve patient outcome.<sup>155</sup>

Phentolamine is a nonselective competitive  $\alpha_1$  and  $\alpha_2$  catecholamine receptor blocker. It has a half-life of 19 minutes and is eliminated mainly by the kidneys. Through postsynaptic  $\alpha_1$  and  $\alpha_2$  receptor inhibition it has a vasodilating and hypotensive

effect that can improve cardiovascular parameters and metabolic acidosis during CPB management.<sup>156</sup> In children receiving phentolamine, increasing lactate concentrations at the end of the CPB period show a steady state toward the end of the surgery, whereas lactate continues to rise in patients who did not receive phentolamine.<sup>156</sup> These findings suggest that the use of phentolamine limits lactic acid production during the hypothermic period and aids the disposal of lactic acid from tissues. Seelye and associates called the physiologic state after hypothermia the "oxygen debt repayment" period in infants.<sup>157</sup> Although it has a beneficial effect on CPB management, the potential harmful effects of phentolamine, especially on the brain, have still not been fully elucidated. One study provided evidence that phentolamine increases S100B protein and a parameter indicative of altered cerebrovascular resistance, the pulsatility index in the middle cerebral artery, in infants given phentolamine during open-heart surgery.<sup>158</sup>

Nitroprusside has been used as an easily titratable agent with  $\alpha$ -adrenergic receptor-blocking capacity. One study examined the effect of perioperative sodium nitroprusside application in 25 neonates undergoing an arterial switch operation for transposition of the great arteries.<sup>159</sup> In comparison to the pre-bypass values, a similar increase in the concentration of S100B protein was found 2 hours after the termination of CPB in the sodium nitroprusside-treated and nontreated neonates, which decreased over the subsequent 48 postoperative hours. However, significantly reduced post-bypass serum levels of S100B protein were found in the sodium nitroprusside-treated group after 24 and 48 hours of treatment.

Nitroglycerin has been used with the same success. The only proven benefit over other agents is its nitric oxide donation capacity.<sup>160</sup> In Japan, high-dose chlorpromazine has been used as part of a low-resistance strategy during CPB for the Norwood procedure.<sup>161</sup>

We routinely use phentolamine, 0.1 to 0.2 mg/kg, to provide normal CPB flow and mean arterial pressure in the range of the diastolic pressure. If hypotension develops during bypass, the flow should be increased up to 150% of predicted; also one should examine the acid-base status in conjunction with cerebral oxygenation and mixed venous saturations. Often, severe hemodilution with oxygen debt is the cause and should be treated as such. After exclusion, we treat the hypotension carefully with vasoconstrictors, knowing that normal systemic pressures will not restore splanchnic hypoperfusion<sup>162</sup> and that vasoconstrictors will often lead to a greater base excess. Excessive  $\alpha$ -adrenergic receptor blockade can be antagonized by vasopressin.<sup>163</sup> One study demonstrated that vasoconstrictor treatment results in more sodium bicarbonate to treat the acidosis and is associated with a later time to extubation and return of bowel function.<sup>164</sup> In conclusion,  $\alpha$ -adrenergic receptor blockade during bypass should be considered because of its benefits for tissue perfusion, but carefully executed and balanced against potential drawbacks afterwards.

### CONVENTIONAL ULTRAFILTRATION AND MODIFIED ULTRAFILTRATION

Ultrafiltration involves placing a hemofilter (similar to those used for continuous arteriovenous or venovenous hemofiltration in the ICU) in the CPB circuit and has become the standard of care for nearly all programs that specialize in surgery for congenital heart defects.<sup>165</sup> Conventional ultrafiltration (CUF) is performed during CPB, with the filter placed between the

arterial and venous sides of the CPB circuit. The hemofilter has thousands of fibers with pores, which allow water, electrolytes, and small molecules to be filtered out of the blood. Suction is applied to the hemofilter on CPB, and an ultrafiltrate of plasma is produced. Advantages of ultrafiltration include the ability to increase the hematocrit, fibrinogen, plasma proteins, and platelet count,<sup>166,167</sup> without necessitating further blood transfusion, the ability to remove excess free water and sodium (which contribute to excess intravascular volume, tissue edema, pulmonary and myocardial edema), as well as the ability to correct acid-base and electrolyte imbalances, and to remove small molecules, such as interleukins and tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) in particular,<sup>168</sup> which are involved in the post-bypass inflammatory process.<sup>169,170</sup> This improves systolic and diastolic function of the myocardium and reduces endothelial dysfunction in the systemic and pulmonary vasculature.<sup>170,171</sup> Pulmonary function is better preserved, probably owing to a slight reduction in interleukin 6 (IL-6) and thromboxane B<sub>2</sub>,<sup>172</sup> even though this is not a consistent finding in the literature.<sup>173,174</sup> Endothelin-1, another mediator of pulmonary damage and hypertension, was not reduced by any filtration method.<sup>174</sup> Clinically, however, any ultrafiltration method seems to benefit children, especially those undergoing complex repairs, neonates, and children with preexisting pulmonary hypertension.<sup>173</sup>

Modified ultrafiltration (MUF) is performed for 10 to 15 minutes immediately after the conclusion of CPB. It can be performed in an arteriovenous manner with a hemofilter placed between the aortic cannula and the IVC cannula, or in a venovenous fashion using bicaval cannulation or an internal jugular venous catheter.<sup>175</sup> It was developed in 1991<sup>176</sup> as an alternative method to reduce the side effects of CPB. CUF during bypass is often limited by the minimal venous reservoir levels and requires the addition of crystalloid or colloid to be able to continuously remove cytokines during ultrafiltration. During MUF, blood passes out of the aorta, through the hemofilter, and is returned through the IVC cannula. The theoretical advantage of MUF over CUF is that only the child's blood volume is filtered, yielding a more efficient system for achieving the goals just outlined. The disadvantages are that the child remains heparinized, and body temperature may decrease during the process (unless the circuit is modified to include the heat exchanger).<sup>177</sup> It also requires extra time, an aortic cannula is needed that can obstruct the aorta in small infants, and acute intravascular volume shifts may occur at a time when the child is prone to hemodynamic instability. Opposite to the expected effects of fluid removal, MUF actually increases arterial pressures despite decreasing filling pressures and improving myocardial performance.<sup>178</sup>

There is increasing evidence that the use of ultrafiltration reduces bypass-related postoperative morbidity. Outcome studies have demonstrated that ultrafiltration improves myocardial and pulmonary function, lessens tissue edema, allows faster weaning from mechanical ventilation, and decreases the need for inotropic support.<sup>179</sup> In that aspect it may be as efficient as the perioperative application of steroids.<sup>180</sup> The reduction of inflammatory transmitters is only temporary, because the levels of cytokines are similar after 24 hours.<sup>181</sup>

Although each method has its proponents, and some centers perform both techniques in the same children, controlled comparative studies revealed no difference in outcome between MUF and CUF.<sup>179,182</sup> We routinely use a balanced ultrafiltration technique for all cases on CPB because it removes fluids and cytokines, as well as reduces lactate, which can aggravate reperfusion injury.<sup>183</sup>

## Pre-Bypass Anesthetic Management

The objectives of the anesthetic management of children before bypass include maintenance of normal sinus rhythm and ventricular function and avoidance of extreme increases in heart rate, ventricular contractility, and pulmonary vascular resistance (PVR). The duration of the pre-bypass period varies greatly, particularly in children who have had previous surgeries, and maintaining hemodynamic stability for prolonged periods of time can often be challenging. Adequate anesthetic depth should be ensured to avoid increases in sympathetic stimulation and hypercyanotic spells, and temperature homeostasis should be maintained to avoid cardiac arrhythmias, especially when the duration of the pre-CPB surgical dissection is protracted. For children undergoing repeat sternotomy, blood products with an appropriate-capacity blood warmer should be readily at hand in case of emergent need.

Neonates and children who have been receiving total parenteral nutrition preoperatively receive an infusion of 5% or 10% dextrose before CPB, with frequent monitoring of glucose concentrations to avoid hypoglycemia or hyperglycemia. Older children receive Plasmalyte, a balanced electrolyte solution, at a reduced maintenance rate, allowing the administration of 5% albumin, if necessary, for volume augmentation.

The placement of purse-string sutures before cannulation, as well as the actual cannulation of the great vessels before CPB, can often precipitate arrhythmias, hypotension, and arterial desaturation, especially in small infants and children. It is common for volume replacement to be necessary during placement of the cannula; if the aortic cannula is already in place, it is our practice to coordinate the administration of fluid volume between the anesthesiologist and perfusionist while the surgeon completes cannulation. Calcium chloride (10 mg/kg) is also frequently useful to support hemodynamics at this time.

## Anesthesia on Cardiopulmonary Bypass

### CHANGES IN PHARMACOKINETICS

The initiation of CPB introduces additional volume to the intravascular space (hemodilution). This greatly affects drug distribution, plasma concentrations, and elimination. The major factors responsible for this are hemodilution and altered plasma protein binding,<sup>184</sup> hypotension, hypothermia,<sup>185</sup> pulsatility,<sup>186</sup> isolation of the lungs from the circulation, and uptake of anesthetic drugs by the bypass circuit.<sup>187,188</sup> Drugs in the blood exist in the free (unbound and therefore the active form) or plasma bound (inactive form bound to protein, e.g., albumin) forms and therefore are subject to marked changes with alterations in plasma protein levels. CPB alters all these factors, which makes description of pharmacokinetic parameters during CPB problematic. The greatest changes occur within 5 minutes of initiation of CPB. The addition of the prime volume immediately reduces the protein concentration, and the ratio of bound-to-free drug in the circulation changes. A reduction in red blood cell concentration occurs, and this reduces the free drug concentrations. This will reduce the amount of drug available for interaction with the receptors. Most studies show a reduction in total drug concentration in plasma with little change in unbound drug concentration over time, whereas on CPB other than the transient (less than 5 minutes) reduction at initiation of CPB<sup>189</sup> it would appear that the greatest risk for unwanted "lightening of anesthesia" is within this time frame, and additional doses of

fentanyl, muscle relaxant, and midazolam are generally administered just before or with the onset of CPB. The explanation for why unbound drug concentrations are sustained during CPB is that the volume of distribution for most anesthetic agents is large relative to the volume of the CPB prime and serves as a huge reservoir for drug after intravenous administration. A decrease in the plasma concentrations of medications as a result of hemodilution shifts drugs down their concentration gradient from tissue to plasma. Hypothermia contributes to the changes in plasma concentrations primarily by depressing enzyme function and slowing the metabolism of medications. Drug metabolism is diminished during hypothermia; enzyme activity is approximately halved for every 10° C reduction in temperature. This may increase the free drug available for binding. When normothermia is reestablished, reperfusion of tissues might lead to washout of drug sequestered during the hypothermic CPB period. This may explain the secondary increases in plasma concentrations of opioids reported during the rewarming phase. pH-stat management also affects the degree of ionization and protein binding of certain medications, leading to increased unbound drug. During CPB, the lungs are out of circuit and medications that are taken up by the lungs (e.g., opioids) are sequestered during CPB. These medications are released when systemic reperfusion is established and concentrations are transiently increased. The volume of distribution of many drugs is expanded because of the priming volume of the bypass circuit, especially with neonates and small infants, where the priming volume is often greater than the child's blood volume. Finally, medications may be taken up by various components of the CPB circuit itself.

### CHANGES IN PHARMACODYNAMICS

The pharmacodynamic effects of anesthetic agents are affected primarily via the central nervous system, which undergoes major changes during CPB. For example, hypothermia during CPB reduces anesthetic requirements. Hypothermia causes a host of other effects, including decreases in receptor affinity (e.g., decreased opioid receptor affinity<sup>190</sup> and nicotinic acetylcholine receptor sensitivity<sup>191</sup>), enhanced effects of neuromuscular receptor blocking drugs at the neuromuscular junction,<sup>192,193</sup> and alterations in tissue blood flow that may affect the response to catecholamines.<sup>194</sup>

CPB also affects the degree of ionization and protein binding (hence free or unbound drug concentrations) of weak acids and bases, as well as the electrolyte balance achieved by the blood gas management strategy used during CPB. Plasma concentrations of calcium, magnesium, and potassium decrease during CPB,<sup>195,196</sup> and these changes may lead to muscle weakness, dysrhythmias, and digitalis toxicity. The number of receptors available for interaction with a ligand will determine the subsequent magnitude of a drug effect. A reduction in the number of cardiac receptors has been observed in congestive heart failure, and defects in receptor transduction, as well as impairment of synthesis and reuptake of norepinephrine occur.

Administration of  $\beta$ -adrenergic agonists in this condition has been associated with further reductions in  $\beta$ -receptor numbers, with diminished pharmacologic effect. Removal of  $\beta$ -adrenergic blockade may lead to  $\beta$ -adrenergic receptor upregulation and increased adrenergic responsiveness.<sup>197</sup> Changes in receptor density and function may occur very quickly and have been observed to occur during cardiac surgery. Many perfusionists, under the direction of the anesthesiologist, can also administer

inhalation agents via a separate vaporizer mounted on the bypass machine. Anesthetic requirements decrease with systemic hypothermia,<sup>198</sup> but as rewarming is initiated, additional anesthetic drugs, including a benzodiazepine, are added to the pump to ensure that amnesia is maintained. Further work is required to elucidate the mechanisms and clinical implications of these acute changes in receptor density and function.

## Special Techniques

### MANAGEMENT OF DEEP HYPOTHERMIC CIRCULATORY ARREST

In the early days of cardiac surgery and CPB, hypothermia was used to improve intracardiac surgical exposure. In 1950, Bigelow and colleagues were the first to show that hypothermia decreases the metabolic rate.<sup>199</sup> Since then, we have discovered other advantages of hypothermia, including decreases in the inflammatory response of CPB,<sup>200</sup> decreases in blood loss,<sup>201</sup> myocardial protection,<sup>202</sup> and neuroprotection.<sup>203</sup> The last effect relates primarily to the decrease in the metabolic rate (by approximately 64%) that is achieved by cooling from 37° C to 27° C. The disadvantages of DHCA include a prolongation of CPB and a greater tendency toward postoperative bleeding.<sup>204</sup> Postoperative recovery, however, is not prolonged by hypothermia.<sup>205</sup> The rate of wound infection is uninfluenced by hypothermic bypass.<sup>206</sup>

Hypothermia during cardiac surgery gained widespread acceptance only after the development of a heat exchanger that could be integrated into the CPB machine in 1959.<sup>207</sup> Deep hypothermic circulatory arrest involves cooling the child's body temperature during CPB to 17° C to 18° C, stopping the bypass machine, draining the blood from the child into a venous reservoir, and removing the cannulas from the heart. After the first reports of DHCA in the 1960s, this technique gained popularity in the 1970s and 1980s because the bloodless field it provided, thus facilitating complex intracardiac and aortic repairs in neonates and small infants,<sup>208</sup> as well as reducing myocardial edema. However, it soon became evident that DHCA was associated with neurologic morbidity. Choreoathetosis, seizures, coma, and hemiparesis were all noted, especially with prolonged (>60 min) DHCA. The incidence of these acute morbidities seemed to increase when  $\alpha$ -stat management became the accepted standard in many centers. Long-term adverse neurodevelopmental outcomes have also been associated with long periods of DHCA, including abnormalities in mental development and in fine and gross motor skills.<sup>209</sup> The Boston Circulatory Arrest Study is a remarkable achievement in which 155 neonates undergoing the arterial switch operation from 1988 to 1992 were studied, with follow-up complete to 8 years of age.<sup>210</sup> The CPB protocol in those years included  $\alpha$ -stat management, routine hemodilution to a hematocrit of 20%, and the absence of an arterial filter on the CPB circuit. A DHCA time of greater than 40 minutes was associated with a significant increase in adverse long-term neurologic outcomes (Fig. 17-3). Although the 40-minute cutoff is now well-accepted in surgery for congenital heart defects, a number of changes have subsequently been made to bypass protocols. Results from animal experiments using a neonatal pig model of DHCA, as well as data from the Boston Circulatory Arrest Study, led to the following recommendations for increasing the child's safety margin when using DHCA:

- Hematocrit of 30% should be the target.<sup>83</sup>
- Systemic hypothermia should be achieved slowly, over no less than 20 minutes.<sup>211</sup>

Variable	Cut-point estimate (minutes)	95% lower confidence limit (minutes)
Full-scale IQ	42	27
Verbal IQ	41	23
Performance IQ	47	31
Average achievement	43	4
Grooved pegboard	35	13
Mayo test for apraxia	40	29
Combined analysis (overall six outcomes)	41	32

**FIGURE 17-3** Safe duration of circulatory arrest. From the Boston Circulatory Arrest Study, 155 8-year-olds underwent arterial switch operation for D-transposition of the great arteries as neonates. Bypass protocol used  $\alpha$ -stat pH management, with hematocrit of 20% and temperature of 18° C. Above 40 minutes DHCA, both mental and physical performance test scores decreased significantly. (From Wypij D, Newburger JW, Rappaport LA, et al. The effect of duration of deep hypothermic circulatory arrest in infant heart surgery on late neurodevelopment: the Boston Circulatory Arrest Trial. *J Thorac Cardiovasc Surg* 2003;126:1397-403.)

- pH-stat blood gas management should be used, at least for cooling (Fig. 17-4).<sup>124,126</sup>
- Core body temperatures of 17° C to 18° C should be used, and ice bags should be applied to the head.<sup>212</sup>
- DHCA should be divided into periods of less than 20 minutes, allowing a reperfusion period of at least 2 minutes between each segment of DHCA, to improve neurologic outcome.<sup>213</sup>
- Low-flow CPB is better than DHCA. Selective regional cerebral perfusion may be better than full body low-flow CPB.<sup>214</sup>
- Normoxemia should be maintained to decrease exacerbation of brain injury after DHCA.<sup>215</sup>

Neurologic monitoring (see later discussion) may be useful in the individual child to aid in determining the safe duration of DHCA.<sup>124,216</sup>

Although there are situations in which DHCA must be used, many surgeons are avoiding it whenever possible, minimizing its duration and dividing the periods of its use, or using alternate methods, such as selective cerebral perfusion (see the following discussion).

**FIGURE 17-4** Cortical oxygen saturation ( $SO_2$ ) during deep hypothermic circulatory arrest in pH-stat and  $\alpha$ -stat groups. The cortical  $SO_2$  half-life during arrest was significantly greater in the pH-stat than in the  $\alpha$ -stat group. Mean  $\pm$  SD, eight animals per group. \* $P < .05$  between groups. (From Kurth CD, O'Rourke MM, O'Hara IB. Comparison of pH-stat and alpha-stat cardiopulmonary bypass on cerebral oxygenation and blood flow in relation to hypothermic circulatory arrest in piglets. *Anesthesiology* 1998;89:110-8.)

## REGIONAL CEREBRAL PERFUSION

To avoid the use of DHCA, several novel CPB techniques have been developed. The purpose of these techniques is to allow perfusion of the brain during critical periods of surgery, such as aortic reconstruction during the Norwood operation.<sup>217,218</sup> These techniques are collectively referred to as selective cerebral perfusion. Regional cerebral perfusion (RCP) is one variation in which a small Gore-Tex graft of 3 to 4 mm is sewn onto the innominate artery before initiation of CPB and is then used as the aortic cannula during CPB (Fig. 17-5). During aortic reconstruction, snares are placed around the brachiocephalic vessels and CPB flow is decreased, with only the brain receiving perfusion via the right carotid artery during this period. In this way, a bloodless operative field is achieved, just as if DHCA was being performed, yet the brain is still receiving blood flow and oxygen, theoretically increasing protection from hypoxic ischemic brain injury. Another potential advantage of this technique occurs in neonates, who frequently have extensive arterial collaterals between the proximal branches of the aorta and the lower body via the internal mammary and long thoracic arteries. In this instance, the use of selective cerebral perfusion also provides some blood flow to the lower body, protecting renal, hepatic, and gastrointestinal systems from hypoxic damage as well.<sup>219</sup> This protection is, however, incomplete and RCP at 25° C is no more protective than DHCA.<sup>220</sup> Also, the ongoing perfusion prolongs the effective bypass time, leading to more cytokine release and capillary leakage, with worse pulmonary function, more weight gain, and decreased right ventricular function.<sup>221</sup>

Despite the theoretical advantages of selective cerebral perfusion and a study demonstrating that selective cerebral perfusion does provide oxygenated blood flow to both cerebral hemispheres,<sup>222</sup> no long-term outcome studies have been performed that prove it is superior to standard techniques. This may in part be related to the novelty of this procedure. Neurologic monitoring has been used to determine the flow rate that is necessary during RCP.<sup>222,223</sup> We use 40% to 50% of full flow and adjust it according to brain saturation or Doppler measurements,

**FIGURE 17-5** Selective cerebral perfusion for the Norwood stage I palliation for hypoplastic left heart syndrome. Arterial inflow for bypass is provided by a small polytetrafluoroethylene graft sewn to the right innominate artery. Instead of deep hypothermic circulatory arrest, flow is provided to the brain at low rates, while the brachiocephalic vessels and descending thoracic aorta are snared, providing a bloodless operating field. (From Pigula FA, Nemoto EM, Griffith BP, Siewers RD: Regional low-flow perfusion provides cerebral circulatory support during neonatal aortic arch reconstruction. *J Thorac Cardiovasc Surg* 2000; 119:331-339.)

maintaining baseline saturation before the onset of RCP. If a left radial arterial line or a femoral arterial line (or umbilical arterial line) is in place, an abdominal perfusion pressure of about 12 mm Hg, which correlates with radial artery pressures of 25 to 30 mm Hg, is the goal.<sup>222</sup>

## Effects of Cardiopulmonary Bypass

### CARDIAC EFFECTS

In addition to myocardial ischemic injury secondary to aortic cross clamping, several other factors can contribute to perioperative myocardial dysfunction. The first is entrainment of air into the coronary arteries, which frequently occurs during weaning from bypass.<sup>224</sup> Despite meticulous de-airing of the heart, air may enter the right coronary artery, producing ischemia that is heralded by a pale myocardium, poor contractility, and ST-segment elevation of the ECG. Should this occur, appropriate management involves remaining on CPB, increasing perfusion pressure, and “milking” the air through the coronary arteries, allowing time for recovery of the ECG and ventricular function before attempting to wean from bypass. Surgical factors, such as reimplantation of coronary arteries with possible resultant ischemia or residual surgical defects, can also occasionally contribute to myocardial dysfunction.

The inflammatory response to CPB (see later discussion) has important implications for cardiac function.<sup>225</sup> This systemic response results in a capillary leak syndrome, which in turn leads to accumulation of edema fluid in interstitial and extravascular

spaces, including the myocardium.<sup>226</sup> Myocardial edema can contribute to post-CPB myocardial dysfunction by impairing diastolic function and causing mechanical limitation of cardiac filling and outflow in small infants whose sternums have been closed. Additionally, myocardial edema has been implicated as a causative factor in the frequent decline in myocardial function that occurs 6 to 12 hours after conclusion of CPB. Inflammatory mediators also affect the responsiveness of the myocardium to catecholamines by interfering with their binding to the cell surface receptors,<sup>227</sup> rendering exogenously administered drugs, such as dopamine and epinephrine, as well as the child’s endogenous catecholamines, less effective at increasing cardiac output in the perioperative period.

Mechanisms for prevention and treatment of myocardial dysfunction include the use of ultrafiltration and antiinflammatory drugs, such as corticosteroids and aprotinin.<sup>228,229</sup> The prophylactic use of noncatecholamine inotropic agents, such as milrinone, has also been shown to prevent low cardiac output syndrome in infants, even if cardiac function is adequate in the immediate postoperative period.<sup>230</sup>

### SYSTEMIC AND PULMONARY VASCULATURE EFFECTS

The inflammatory response to CPB often produces mediators that directly increase pulmonary and systemic vascular resistance. These include interleukins, leukotrienes, and endothelin.<sup>231</sup> Indeed, when pulmonary artery pressure is measured directly, it is often significantly increased immediately after bypass, even if surgical results are optimal. This increase can be extremely detrimental in children with large left-to-right shunts, those undergoing cardiac transplantation secondary to dilated cardiomyopathy, and those undergoing bidirectional cavopulmonary anastomosis, where right ventricular output depends on maintaining low PVR. Prevention and treatment of increases in PVR include maintaining an adequate depth of anesthesia, ventilating with 100% oxygen, and judicious use of hyperventilation. Milrinone will increase right-sided heart output via its actions as both an inotropic agent and a pulmonary vasodilator. When PVR is significantly increased, inhaled nitric oxide is often used to assist in the early postoperative period.<sup>232</sup> Although effective, its cost is not inconsequential, and because PVR almost always decreases with time, nitric oxide is generally reserved for selected cases of pulmonary hypertension. Other simpler, less expensive treatments include oral or intravenous sildenafil<sup>233,234</sup> and inhaled nebulized prostacyclin.<sup>235</sup>

### PULMONARY EFFECTS

The lungs are not ventilated during CPB and are usually totally collapsed by intention, with the ventilator circuit disconnected, especially in small infants. This leads to significant atelectasis. The lungs are also at least partially ischemic during the bypass period, resulting in decreased production and alveolar levels of surfactant after CPB.<sup>236</sup> In addition, reperfusion injury (pulmonary edema or hemorrhage after a sudden increase in pulmonary flow) can also occur after creation of a systemic-to-pulmonary artery shunt or pulmonary artery unifocalization. Inflammatory mediators liberated by the bypass run, also predispose to increases in smooth muscle tone and resistance, and can result in bronchospasm.<sup>237</sup>

In addition to complement, endotoxins and certain cytokines can also activate neutrophils and attract them toward sites of inflammation.<sup>238</sup> In animal studies, endotoxin-induced lung injury can lead to rapid (within 45 minutes) accumulation of

**FIGURE 17-6** Leukocytes, endothelial cells (EC), and humoral inflammatory mediators have been shown to play an important role in the cardiopulmonary bypass-induced lung injury. Complement (C) activation and complement-independent mechanical injury activates leukocytes, which, in their turn, secrete several inflammatory mediators, such as proteases and cytokines. Complement, cytokines, and ischemia-reperfusion also activate endothelial cells. Endotoxin, probably released from intestinal bacteria, exerts similar effects on leukocytes and endothelium. This process leads to disruption of endothelial and epithelial integrity and allows albumin, plasma, and activated leukocytes to enter the interstitial and alveolar space, causing tissue edema and reducing pulmonary compliance and blood oxygenation. AAM, Arachidonic acid metabolites; ICAM-1, intercellular adhesion molecule 1; IL, interleukin; IS, interstitial space; M, monocyte; Mg, macrophage; MPO, myeloperoxidase; N, neutrophil; NO, nitric oxide; O<sub>2</sub>-DFR, oxygen-derived free radicals; P, platelet; PAF, platelet-activating factor; PDGF, platelet-derived growth factor; Pn, pneumocyte; TGF, tumor growth factor; TNF, tumor necrosis factor. (From Asimakopoulos G, Smith PL, Ratnatunga CP, Taylor KM. Lung injury and acute respiratory distress syndrome after cardiopulmonary bypass. *Ann Thorac Surg* 1999;1107-15.)

neutrophils within lung capillaries. Activation of neutrophils, with upregulation of adhesion molecules, neutrophil adhesion to the endothelium of lung vessels, and endothelial damage through proteases, appears to be the main step of the underlying pathophysiologic mechanism (Fig. 17-6). Macrophages play an important role in the evolution of the inflammatory acute lung injury

through the secretion of cytokines, cytotoxic metabolites, and chemoattractants for leukocytes. At the clinical level, acute respiratory distress syndrome (ARDS) is often only one part of multiorgan failure, and lung injury should be seen as part of a more general state of systemic inflammation. The reported prevalence of ARDS after CPB in adults is 0.5% to 1.7%; the incidence in

children is unknown. Interestingly, general hypothermia at 28° C failed to prevent the loss of ATP and the accumulation of lactate in lungs.<sup>239</sup> Other methods that aim to protect the lungs during CPB, such as continuous lung perfusion, pneumoplegia, and nitric oxide ventilation at lung reperfusion, prevent more severe hemodynamic deterioration and preserve reactivity of the pulmonary vasculature, but fail to prevent pulmonary dysfunction.

The severity of pulmonary dysfunction after CPB can be measured via changes in the alveolar-arterial oxygenation gradient, intrapulmonary shunt, degree of pulmonary edema, pulmonary compliance, and PVR. Treatment of pulmonary atelectasis includes careful reinflation of the lungs when weaning from bypass (by administering several vital capacity breaths), gentle but thorough suctioning of the tracheal tube, and prophylactic use of inhaled bronchodilators before separation from CPB. Using these measures, pulmonary function has been shown to improve immediately in most children with large left-to-right shunts, with the duration of CPB seemingly having little effect on pulmonary outcomes.<sup>240</sup> Thus, CPB itself has little effect on pulmonary function in most children. There is still an occasional child, however, who experiences classic “pump lung” ARDS, caused by the factors noted earlier. Treatment is supportive as for anyone with ARDS.

#### NEUROLOGIC MONITORING AND EFFECTS OF CARDIOPULMONARY BYPASS ON THE BRAIN

Cerebral monitoring can help to detect those children who are at risk for neurologic sequelae after bypass, promptly recognize and treat changes in cerebral blood flow/oxygenation, evaluate the effect of therapeutic interventions on cerebral physiology, optimize brain protection during the vulnerable periods of CPB, and potentially improve short- and long-term neurologic outcomes.<sup>241</sup>

The cerebral NIRS monitor measures brain tissue oxygenation. This device noninvasively measures the cerebral tissue oxygen saturation and displays a numerical value for the cerebral regional oxygen saturation (rSO<sub>2</sub>), the ratio of oxyhemoglobin to total hemoglobin in the light path. rSO<sub>2</sub> is a measure of local microcirculatory oxygen supply-and-demand balance and is reported on a scale from 15% to 95%. It has been assumed from anatomic models that 75% of the cerebral blood volume in the light path is venous and 25% is arterial. One study verified this in children with congenital heart disease by directly measuring the jugular venous bulb and arterial oxygen saturations and comparing these with the cerebral oxygen saturation measured with NIRS.<sup>242</sup> The actual ratio in children varied widely, but on average the venous to arterial ratio was 85 : 15. All devices measure both the arterial and venous blood oxygen saturations. Accordingly, this device does not provide a measure of the jugular venous bulb oxygen saturation (SjvO<sub>2</sub>). A corollary of this is that maneuvers that increase arterial oxygen saturation (e.g., increasing FiO<sub>2</sub>) increase cerebral oxygenation as measured by these devices, although the SjvO<sub>2</sub> may remain unchanged. In a study of 40 infants and children with congenital heart disease who were undergoing cardiac surgery or catheterization, NIRS correlated poorly with SjvO<sub>2</sub> measurements, except in infants younger than 1 year of age.<sup>243</sup> In contrast, in a study of 30 children undergoing cardiac catheterization, NIRS correlated very well with SjvO<sub>2</sub> ( $r = .93$ ).<sup>244</sup> These data suggest that NIRS is a useful indicator of trends in cerebral oxygenation in individual infants and children. NIRS values also correlate with long-term neurodevelopmental outcomes in infant heart surgery. In a prospective study of 104 two-ventricle repairs, low rSO<sub>2</sub> in the intraoperative period did

not correlate with death or major morbidity.<sup>245</sup> However, when these children underwent neurodevelopmental testing at 1 year of age, lower average and minimum rSO<sub>2</sub> in the 60 minute period immediately after CPB correlated with worse psychomotor development index scores. Low rSO<sub>2</sub> also correlated with remote ischemic changes on brain MRI at 1 year of age.<sup>246</sup>

#### Neurologic Monitoring for Low-Flow Hypothermic Bypass

Transcranial Doppler (TCD) ultrasonography has been used to determine the threshold of detectable cerebral perfusion during low-flow CPB. *TCD velocities reveal trends or changes in cerebral blood flow and not absolute values.* One report studied 28 neonates undergoing the arterial switch operation using  $\alpha$ -stat blood gas management.<sup>148</sup> Their study suggested that NIRS and TCD may be useful to determine the minimum acceptable bypass flow rate for an individual neonate during low-flow hypothermic bypass. Blood flow becomes insufficient at bypass flow rates less than 30 mL/kg/min.<sup>148,247</sup> Inadequate blood flow to the brain during this technique could be undetected without such monitoring, and low-flow bypass may confer no advantage to the brain over DHCA in some children. Long-term outcome studies of this monitoring strategy are not available.

#### Neurologic Monitoring for Deep Hypothermic Circulatory Arrest

Despite clinical and experimental evidence that periods of DHCA that exceed approximately 40 minutes are associated with an increased risk of adverse long-term neurologic and developmental outcomes, this technique is still widely used in surgery to correct congenital heart defects. Recent recommendations for improving outcome after DHCA, based on both animal and clinical studies, were described previously. During DHCA, rSO<sub>2</sub> predictably decreases to a nadir 60% to 70% (relative change) below baseline values obtained before bypass. The nadir is reached at 10 to 20 minutes, after which there is no further decrease.<sup>248</sup> At this point, it appears that there is no additional oxygen uptake by the brain. Several studies suggest the potential for near-infrared cerebral oximetry to determine the safe conduct and duration of DHCA in the individual child. In a study of infants and children undergoing surgery with bypass and DHCA, three children with low rSO<sub>2</sub> developed acute postoperative neurologic changes—seizures in one, and prolonged coma in two.<sup>248</sup> In these three children, the increase in rSO<sub>2</sub> after the onset of CPB was much less (average 3% relative increase vs. 33% increase in children without neurologic deficit) and the duration of cooling before DHCA shorter than in the remaining 23 children who did not develop neurologic changes. In a neonatal pig model, the timing of the nadir of rSO<sub>2</sub> values during DHCA correlated with neurologic outcome: a more prolonged period without oxygen uptake by the brain correlated with a greater incidence of adverse neurologic outcome. The maximum safe duration at 17° C without additional brain oxygen uptake was 30 minutes.<sup>142</sup> Interestingly, this time period correlates with clinical and experimental studies, suggesting that 40 minutes is the safe duration for circulatory arrest (see Fig. 17-3). When circulatory arrest is initiated at greater temperatures (e.g., 25° C), the rSO<sub>2</sub> decreases more rapidly, and the nadir is achieved sooner, than at lower temperatures.<sup>249</sup> Reperfusion results in an increase in rSO<sub>2</sub> to levels observed at full bypass flow before DHCA, with a subsequent decrease during rewarming. Based on these data, our current practice is to reperfuse after the NIRS nadir has been reached for a period of 20 to 25 minutes.

### Neurologic Monitoring for Regional Cerebral Perfusion

RCP (also known as selective cerebral perfusion or antegrade cerebral perfusion) uses a polytetrafluoroethylene (PTFE) graft or a small aortic cannula as arterial inflow to the right innominate artery for neonatal aortic surgery, such as the Norwood stage operation or aortic arch advancement. The other brachiocephalic vessels and descending thoracic aorta are snared, resulting in a bloodless operating field. The brain is perfused through the right innominate and right vertebral arteries only. This approach significantly reduces or eliminates the use of DHCA for these operations and preserves brain perfusion, potentially improving neurologic outcome. Initial descriptions of this technique used the pressure in the radial artery or a predetermined bypass rate of 25 to 30 mL/kg/min as an estimate for the bypass flow during RCP without neurologic monitoring. When flow rate was estimated on the basis of NIRS monitoring in individual children, it was determined that 20 to 25 mL/kg/min was required.<sup>217</sup> However, NIRS was applied only to the right side of the skull (i.e., brain), the same side as the sole arterial inflow. Using a pH-stat blood gas strategy for RCP, we noted that the majority of our children had an  $rSO_2$  of 95% (the maximum reading on the  $rSO_2$  scale) when we used the left radial artery pressure of 20 to 25 mm Hg as the target for bypass flow. These children were theoretically at risk for excessive cerebral perfusion. Therefore, we performed a study using both NIRS and TCD of the right cerebral hemisphere, to determine if TCD could be used as a guide to RCP flow rate.<sup>222</sup> Bypass flow rate was adjusted to achieve a cerebral blood flow volume within 10% of baseline (e.g., TCD was used to determine necessary flow). The estimated flow rate, 63 mL/kg/min (range, 24 to 94 mL/kg/min), proved to be significantly greater than that estimated in the earlier studies. This flow rate did not correlate with the pressure in the right or left radial artery. The  $rSO_2$  was well maintained in all children, leading us to conclude that TCD was a useful monitor to ensure adequate but not excessive cerebral blood flow during RCP. Because RCP perfuses the brain through a single arterial inflow vessel, questions have arisen about the adequacy of cerebral blood flow and oxygenation to the left cerebral hemisphere. Although the circle of Willis is expected to be intact without stenoses in neonates, 10% of healthy full-term neonates exhibit deviations from normal flow patterns. Two studies concluded that although cerebral blood flow and oxygenation were adequate to both cerebral hemispheres in neonates during RCP, bilateral monitoring, at least of NIRS, may be warranted.<sup>222,250</sup>

### SYSTEMIC INFLAMMATORY RESPONSE SYNDROME

In cardiac surgery, SIRS is thought to result from four main sources of injury: (1) contact of the blood components with the artificial surface of the bypass circuit, (2) ischemia-reperfusion injury, (3) endotoxemia, and (4) operative trauma. Inflammatory cytokines, together with endothelial activation and endothelial-leukocyte interactions, appear to play an important role in the induction of this systemic inflammatory response.

Exposure of blood to the artificial materials in the bypass circuit—plastics, polypropylene oxygenator fibers, and metal suction devices—initiates a cascade of inflammatory responses, including activation of the complement system, the kallikrein system, and the coagulation system.<sup>226</sup> As a result, interleukins, tumor necrosis factor, endotoxin, heat shock protein, and many other inflammatory mediators are released into the circulation. Leukocyte activation also results in secretion of inflammatory mediators, such as proteases and cytokines (e.g., TNF- $\alpha$  and

IL-1), which are secreted early in the evolution of the inflammatory process. This chemokine-mediated increased leukocyte activation constitutes an important link in the chain of the propagation of the inflammatory response (see Fig. 17-6).

This inflammatory response is counterbalanced by a complex system of inhibitors, such as IL-10 and soluble cytokine receptors.<sup>251</sup> Also, the inflammatory response of the neonate may be more exaggerated than that of the infant or older child,<sup>252</sup> justifying a more aggressive approach to its modulation in the neonate (see later discussion).

A number of novel treatments have been studied, including monoclonal antibodies for inflammatory products, such as complement, endotoxin, and tumor necrosis factor. Although theoretically attractive, no clinical difference has been noted with any of these treatments.

Effective treatments used every day in the operating room and ICU include:

- Use of corticosteroids<sup>253</sup>
- Ultrafiltration<sup>228</sup> (see earlier discussion)
- Aprotinin<sup>229</sup> (see earlier discussion)
- Leukocyte depletion<sup>254</sup>: leukocyte-depleted blood in prime and in-line arterial filter; initiate bypass using normoxic management (FIO<sub>2</sub> of 21%) in severely cyanotic infants.

Corticosteroids interrupt the inflammatory response at several levels by entering cell nuclei and changing the rate of transcription of inflammatory molecules. Increasing evidence suggests that glucocorticoids act by regulating transcription or translation of antiinflammatory cytokines, such as IL-10, and altering expression of other proteins, such as endothelin-1 and inhibitor NF- $\kappa$ B.<sup>255,256</sup> Because these processes take time to develop, the effects of corticosteroids are not immediate, taking up to several hours.<sup>257</sup> Thus, the common practice of adding corticosteroids to the CPB prime will not fully prevent the inflammatory response<sup>258</sup>; to be effective, corticosteroids may need to be administered 4 or more hours before the onset of CPB.<sup>259</sup>

Despite these theoretical advantages of using corticosteroids to modulate the inflammatory response, a recent large discharge database review of over 46,000 infants and children, in which 54% did receive corticosteroids, demonstrated no difference in mortality. Using propensity score matching the authors concluded that corticosteroids were associated with greater length of hospital stay, greater rate of infection, and greater use of insulin. There was no difference in duration of ventilation. Steroids conferred no significant benefit; conversely in the simpler surgery categories, there was increased morbidity with these drugs.<sup>260</sup> Although inflammatory activation from CPB definitely occurs, and it would seem intuitive that this would lead to worse outcomes in those patients with excessive inflammation, in contemporary practice, the correlation of the magnitude of this response and length of ICU stay and blood product administration, is statistically significant, but clinically modest, accounting for only 4% to 9% of the difference in these variables, in a large study of infants undergoing two-ventricle repairs.<sup>261</sup>

### COAGULATION EFFECTS

Blood coagulation is frequently abnormal after CPB for several reasons. The inflammatory cascade activates the coagulation system, resulting in factor consumption and fibrinolysis, which, in turn, breaks down existing blood clots, leading to increased bleeding.<sup>16</sup> Treatment is adequate heparinization, reversal with protamine, and the use of an antifibrinolytic to inhibit fibrinolysis and improve platelet function.<sup>33</sup> In addition, the smaller

the child, the greater the dilution of clotting factors by the bypass prime, and the greater the risk for low concentrations of clotting proteins and fibrinogen postoperatively. Platelets are also degranulated and consumed by the CPB circuit, leading both to low platelet counts and nonfunctioning platelets.<sup>16</sup> The smaller the infant, the greater the duration of bypass, and the more complicated the surgery, the greater the incidence of coagulopathy after bypass. Efforts to minimize the post-bypass coagulopathy in infants includes priming the CPB circuit with fresh whole blood for small infants, if available, or packed cells plus fresh frozen plasma (FFP) if fresh whole blood cannot be obtained.<sup>19,262</sup> Treatment involves administration of platelets to small infants as the first line of therapy, followed by the replacement of fibrinogen and FFP to replace clotting factors. If these factors are not effective after correcting coagulation parameters, such as platelet count, prothrombin/PTT, fibrinogen, and thromboelastogram, then surgical bleeding may be the cause and surgical reexploration may be warranted.<sup>263</sup> Factor VIIa has also been used as a last resort in children who have significant post-bypass bleeding unresponsive to standard measures.<sup>56</sup>

### HEPATIC, RENAL, AND GASTROINTESTINAL EFFECTS

The liver, kidneys, and gastrointestinal tract, like the brain and heart, may be rendered ischemic by prolonged CPB, DHCA, or low cardiac output syndrome. Renal function is compromised on CPB. This is manifested by the appearance of proteinuria and impaired tubular cellular function immediately after CPB. Renal dysfunction from ischemia is also common. Low urine output may occur secondary to secretion of antidiuretic hormone, a response to surgical stress. However, the latter appears to be transitory and usually resolves spontaneously.<sup>264</sup> The incidence of acute renal dysfunction after surgery with bypass to correct congenital heart defects is 17%, ranging from 0.7% for arterial septal defect closure to 59% for arterial switch operations.<sup>265</sup> Deep hypothermic cardiac arrest subjects the kidney to additional ischemia reperfusion injury.<sup>266</sup> Acute renal failure after CPB is uncommon in children, with fewer than 3% requiring dialysis perioperatively.<sup>265,267</sup> Infants who undergo cardiac surgery routinely receive diuretics or a peritoneal dialysis catheter, the latter prophylactically in some instances.<sup>268,269</sup> Although some have attributed the improved survival with early peritoneal dialysis to the prevention of fluid overload, others have attributed it to a more rapid clearance of CPB-induced proinflammatory cytokines.<sup>270</sup> Further study is required to clarify the mechanism of action of early peritoneal dialysis. In our center, neonates and children with a complex heart defect usually receive peritoneal dialysis immediately postoperatively to prevent fluid overload.

Recovery of hepatic and gastrointestinal function follows hemodynamic recovery, but may require several days. Therapy is mainly supportive. Splanchnic and renal perfusion can be monitored noninvasively using somatic oximetry. Somatic oxygenation may predict renal dysfunction and predict organ failure. Interventions based on the somatic NIRS may improve outcome.<sup>271</sup>

### IMMUNE SYSTEM EFFECTS

Leukocytes are activated by the CPB circuit, although their numbers may be depleted by leukocyte filters, which are sometimes used to attenuate the inflammatory response. Despite the theoretical possibility that this may increase the risk of infection or neutrophil dysfunction, this has not been observed in published studies or clinical practice.<sup>272</sup>

### ENDOCRINE SYSTEM EFFECTS

The magnitude of the inflammatory and endocrine responses after cardiac surgery depends in part on the duration of the surgical procedure and CPB.<sup>273</sup> In children undergoing brief operating times, postoperative blood concentrations of cortisol, adrenocorticotrophic hormone, and  $\beta$ -endorphins are significantly greater than those in children undergoing prolonged operation times. In contrast, the serum concentrations of the proinflammatory cytokines IL-6, IL-1 $\beta$ , and TNF- $\alpha$  are similar in the two groups. Adrenocorticotrophic hormone and cortisol concentrations correlated positively with the blood concentrations of IL-1 $\beta$ , IL-6, and TNF- $\alpha$  in the group of children with prolonged operation times.

The plasma concentrations of both epinephrine and cortisol increase after cardiac surgery.<sup>274</sup> In children, pre- and post-bypass cortisol and norepinephrine increase significantly during isoflurane anesthesia when 2  $\mu$ g/kg of fentanyl is used rather than 25, 50, 100, or 150  $\mu$ g/kg.<sup>275</sup> No significant increase in the blood concentrations of these hormones occurred with any of the fentanyl doses of 25  $\mu$ g/kg or greater. In addition to cardiovascular stability, continued use of larger doses of opioids during bypass minimizes the stress responses and stabilizes hemodynamics during and after bypass, but may delay recovery.<sup>276</sup> Also, growth hormone, glucose and insulin, lactate, glutamate, aspartate, and free fatty acid concentrations increase after cardiac surgery, whereas total triiodothyronine concentrations decrease.<sup>277</sup> Limiting the amount of opioids balances the negative effects of inflammation and stress with the opportunity to fast-track children's recovery after surgery for congenital heart disease.<sup>278,279</sup>

## Transport to the Intensive Care Unit

Extreme vigilance is required during transfer of the child from the cardiac operating room to the ICU. Monitoring of ECG, arterial, venous, and atrial pressures, and end-tidal CO<sub>2</sub> and pulse oximetry must be maintained continuously; the battery charge of the monitor and the infusion pumps should be checked beforehand to prevent monitor failure and interruption of the infusions of vasoactive medications. Resuscitation drugs, airway equipment, and blood products should accompany the child to the ICU. Before leaving the operating room, a report should be given to the ICU staff. Children who are transported with tracheal tubes in situ are usually ventilated manually during transport via a Jackson-Rees circuit, with either 100% oxygen or, for those who require a FIO<sub>2</sub> less than 1.0, an oxygen-air blender. For children who require nitric oxide, a respiratory therapist should assist with transport to ensure that no interruptions in therapy occur and that a smooth transfer occurs in the ICU as well. On arrival in the ICU, vital signs are confirmed, all monitoring devices are transferred sequentially to the ICU monitors and rechecked to ensure they are in working order, and a detailed report is given to the ICU staff.

## Summary

Cardiopulmonary bypass is a necessary technique for intracardiac and major extracardiac surgery on the great vessels. CPB induces a multitude of physiologic and inflammatory derangements, but, through extensive experience and research, these ill effects can be largely mitigated by a number of evidence-based strategies. Therefore, outcomes after CPB have improved dramatically, and CPB is no longer a barrier to accomplishing complex surgery to correct congenital heart defects, even in neonates.

- One hundred thirteen infants randomized to a target hematocrit of 20% (actual 21.5%) versus 30% (actual 28%) on CPB had lower neurodevelopmental outcome scores at 1 year of age: 82 on the Psychomotor Development Index of the Bayley Scales of Infant Development with lower hematocrit versus 90. The children with lower target hematocrit also had a greater incidence of scores more than 2 SD below the mean (29% vs. 9%).*
- Miller BE, Mochizuki T, Levy JH, et al. Predicting and treating coagulopathies after cardiopulmonary bypass in children. *Anesth Analg* 1997;85:1196-202.
- This is the classic article describing the reasons for post-CPB bleeding in infants and children. Platelet defects are the most important cause and the first blood*

*product to administer; hypofibrinogenemia is the second most important, and fibrinogen is the next most important blood product, with fresh frozen plasma ineffective or possibly worsening bleeding.*

- Newburger JW, Jonas RA, Soul J, et al. Randomized trial of hematocrit 25% versus 35% during hypothermic cardiopulmonary bypass in infant heart surgery. *J Thorac Cardiovasc Surg* 2008;135:347-54.
- Perioperative hemodynamics during hypothermic cardiopulmonary bypass and developmental outcome and brain magnetic resonance imaging at 1 year were evaluated. Hemodilution to hematocrit levels of 35% compared with those of 25% had no major benefits or risks overall among infants undergoing two-ventricle repair. Developmental outcomes at 1 year of age in both randomized groups were below those in the normative population.*
- Wypij D, Newburger JW, Rappaport LA, et al. The effect of duration of deep hypothermic circulatory arrest in infant heart surgery on late neurodevelopment: the Boston Circulatory Arrest Trial. *J Thorac Cardiovasc Surg* 2003;126:1397-403.
- Neurodevelopmental outcomes were assessed with a battery of 6 tests in 155 8-year-olds who had a neonatal arterial switch operation using a-stat bypass management, hematocrit of 20% on bypass, and varying duration of DHCA at 18° C. Neurodevelopmental outcomes were not adversely affected for the group as a whole until the DHCA time exceeded 41 minutes (95% lower confidence limit 32 minutes).*
- Wypij D, Jonas RA, Bellinger DC, et al. The effect of hematocrit during hypothermic cardiopulmonary bypass in infant heart surgery: results from the combined Boston hematocrit trials. *J Thorac Cardiovasc Surg* 2008;135:355-60.
- In this combined review of 271 infants, analysis was undertaken of the effects of hematocrit level at the onset of low-flow cardiopulmonary bypass. A hematocrit level at the onset of low-flow cardiopulmonary bypass of approximately 24% or higher was associated with higher Psychomotor Development Index scores and reduced lactate levels.*

Failure of Hemostasis Associated with Cardiac Surgery	Factor VIIa
<b>Medications Used for Hemostasis</b>	<b>Summary</b>
Blood Products	
Platelets	

**BLEEDING IS AN INEVITABLE CONSEQUENCE** of surgery and trauma. Provided the coagulation processes are normal, a meticulous hemostatic surgical technique is usually adequate to achieve hemostasis for most surgical procedures. If, however, the degree of injury is more extensive, major blood loss can occur, particularly if there is a coexistent deficiency of the normal coagulation process. It has been appreciated since the early part of the 20th century that transfusion of fluids and human (allogeneic) blood can prevent many of the adverse effects of blood loss. Despite this, it is important to appreciate the risks and limitations of transfusion; red cell concentrates alone will fail to correct any existing coagulopathy and the immunologic and pathophysiologic adverse effects of exogenous stored blood products are now well known.

This chapter will examine specific treatments aimed at correcting coagulopathy and at reducing the requirement for transfusion of blood products by encouraging hemostasis. Although similar, these objectives are not the same. During many types of surgery, *in vitro* tests may only demonstrate mild coagulation defects, and yet the use of hemostatic medications may reduce blood loss and obviate the need to transfuse red cells.<sup>1,2</sup> In the absence of these medications, bleeding itself is often unlikely to be life-threatening. In comparison, severe coagulopathic bleeding is, by its nature, life-threatening. Transfusion of blood products cannot be avoided and the hemostatic medications used are often the blood products themselves. Fundamentally, the equation of risk and benefit is very different in these two situations. In the former case, benefit will occur if the risk reduction associated with the avoidance of blood products is greater than any risk from the medication itself. In the latter case, the use of medications that carry a high risk of causing adverse effects is more acceptable if the aim is to prevent death from uncontrolled bleeding. As an example of this, aprotinin has been largely rejected for use during adult cardiac surgery as a strategy to reduce transfusion,<sup>3</sup> whereas use

of recombinant factor VIIa (almost certainly a more "hazardous" drug) is still considered appropriate for the treatment of life-threatening bleeding.

Avoidance of transfusion of human blood products seems to be a fundamentally good notion. However, many common ideas about the potential harm of transfusion may be mistaken. A national audit of the serious hazards of transfusion (SHOT) in the United Kingdom reported 3239 adverse events over a 10-year period; this is only 0.013% of all blood transfusions.<sup>4</sup> These adverse events were more common in infants, but were only reported in 0.037% of infants given transfusions. The true incidence of events is likely to be more common because of underreporting, though many of these "events" were procedural errors not associated with actual harm. It is clear that the risk of immediate harm directly attributable to transfusion is exceptionally low. The risk of direct transmission of infection (the most feared risk in the public perception) is particularly small; the risk of transmission of HIV from transfusion of blood in the UK is 1 in 5 million, and no child has contracted a viral infection from transfusion in the last 4 years.<sup>4</sup> The greatest hazard of immediate harm is of a mistake leading to transfusion of incompatible blood.<sup>5</sup> However, subtle negative effects of transfusion on children's outcomes may be considerably more important.<sup>6</sup> Transfusion of blood may lead to deterioration in pulmonary function and immunologic effects that predispose children to infection. In addition, if the objective of transfused red cells is to boost tissue oxygenation by improving oxygen carrying capacity, then transfused blood is less effective than the child's own blood for this function.<sup>7</sup> Additional considerations include the increasing costs of transfused blood products, the logistical difficulties of maintaining a secure blood supply (in both well-resourced and less well developed health systems), substantially greater risks of transfusion (in poorly developed

health systems), and the possibility of new, unrecognized infective agents entering the blood supply.

There are 2.3 million transfusions each year (37 per 1000 population) in the UK; 4.2% are given to children under 18 years of age (7.1 per 1000) and 1.7% to infants (52 per 1000). An audit of pediatric blood transfusion from Australia revealed 41% of blood transfused was given perioperatively,<sup>8</sup> and blood was transfused during 6.3% of instances of anesthesia. The majority of units were used during heart surgery (58% of perioperative use) while a very small minority, 4% were used during major trauma surgery. Heart surgery (on and off bypass), craniostomy surgery, and liver transplantation were all commonly associated with blood transfusion. The epidemiology of major bleeding is less certain. Reports of blood use may be misleading (e.g., neonates undergoing cardiac surgery to correct congenital defects may receive few blood units despite significant bleeding), and blood is also used for purposes such as priming the bypass circuit. Observational studies have reported very heavy blood loss associated with heart surgery in children, with increased (per kg) blood loss in smaller children and more complex surgery.<sup>9,10</sup> Cardiac surgery can probably be considered the main cause of major blood loss in children and will account for most severe bleeding events in children less than 1 year of age.

In this chapter we review the physiology of normal coagulation and how this is deranged in situations likely to be encountered by the pediatric anesthesiologist, particularly during cardiopulmonary bypass and massive transfusion situations. We will demonstrate the importance and limitations of newer physiologic models of coagulation for the understanding of bleeding. The management of major bleeding (with the exception of the off-label use of factor VIIa) has been largely unchanged for many years. Newer approaches are now emerging, although at the time of this writing, robust evidence of risk and benefit is not available.

## Physiology of Coagulation

The understanding of coagulation has shifted greatly in the last few years. The “traditional” model, which emphasizes the importance of a cascade of proteolytic enzymes has given way to the “cell based” model of coagulation that emphasizes the importance of cellular elements in coagulation and presents coagulation as a complex web of interactions rather than a linear process.<sup>11,12</sup>

To achieve effective hemostasis, a platelet plug must form at the site of vessel injury. In addition, the procoagulant factors need to remain localized to the injured site to avoid widespread clotting activation. This is achieved through changes at the cell surface and localization of the procoagulant reactions on the surfaces of specific cells. Different cells possess different procoagulant and anticoagulant properties; these are incompletely understood, but platelets and cells bearing tissue factor (TF) are central to the process. Intact endothelium is also vital to normal control of coagulation, as it keeps these different procoagulant components apart and modifies coagulation through expression of inhibitory proteins such as thrombomodulin. The described phases of coagulation are overlapping and involve initiation, amplification, and propagation.<sup>12</sup>

### INITIATION

Coagulation is initiated by a membrane-bound lipoprotein called tissue factor. This is usually expressed on subendothelial

**FIGURE 18-1** Initiation. The TF/VIIa complex on the tissue factor-bearing cell activates factors IX and X. The factor Xa/Va complex, known as the “prothrombinase” complex, forms small amounts of thrombin (factor IIa). (Reproduced from Hoffman M. Remodeling the blood coagulation cascade. *J Thromb Thrombolysis* 2003;16:17-20.)

TF-bearing cells, such as stromal fibroblasts; in the absence of vessel injury it is separated from the vessel lumen. After injury, a complex is formed between TF and factor VIIa (TF/VIIa), which activates factors IX and X. Factor Xa, in association with cofactor Va, forms “prothrombinase” complexes on the surface of the TF-bearing cell, which activates a small amount of thrombin (factor IIa)<sup>12</sup> (Fig. 18-1). The purpose of this small generation of thrombin and Xa is to activate platelets and factors V and VIII.

Tissue factor pathway inhibitor (TFPI) and antithrombin III (ATIII) provide a localizing function on factor Xa by inhibiting any factor Xa that becomes dissociated from the TF-bearing cell. Factor IXa is not localized to the cell in the same way.

Low levels of IX and X activation occur in the absence of tissue injury without causing clot formation. The process only leads to amplification when damage to the vasculature allows intravascular platelets and a complex formed by factor VIII and von Willebrand factor (VIII/vWF) to adhere to the extravascular TF-bearing cells.<sup>11</sup>

### AMPLIFICATION

Small quantities of thrombin are generated on the TF-bearing cells. This sets up the subsequent propagation phase, during which thrombin is generated in large quantities (Fig. 18-2). This thrombin has many major functions:

- Activation of platelets, exposing receptors and binding sites for clotting factors
- Activation of cofactors V and VIII on the activated platelet surface, thereby releasing vWF to mediate additional adhesion and aggregation at the injury site
- Activation of factor XI to XIa<sup>13</sup>
- Activation of factor XIII (fibrin stabilizing factor) and promotion of fibrin crosslinking
- Cleaving fibrinopeptides A and B from fibrinogen (forming fibrin)

### PROPAGATION

Propagation occurs on the surface of activated platelets that are recruited to the site in large numbers. Activated factor IX (from both initiation phase and provided by factor XI on the platelet) binds to VIIIa. The resultant IXa/VIIIa complex activates factor X on the platelet surface. This factor Xa associates with factor Va

**FIGURE 18-2** Amplification. Small amounts of thrombin (factor IIa) set the stage for large-scale generation of thrombin in the propagation phase. Small amounts of thrombin activate platelets, as well as other important coagulation enzymes and cofactors. (Reproduced from Hoffman M. Remodeling the blood coagulation cascade. *J Thromb Thrombolysis* 2003;16:17-20.)

**FIGURE 18-3** Propagation. Factor Xa is formed locally by the VIIIa/IXa complex on the surface of the activated platelet. The resulting Xa/Va prothrombinase complex causes a burst of thrombin (factor IIa) generation. (Reproduced from Hoffman M. Remodeling the blood coagulation cascade. *J Thromb Thrombolysis* 2003;16:17-20.)

and forms the prothrombinase complex. The prothrombinase complex causes a “burst” of thrombin generation to cause clotting via fibrinogen (Fig. 18-3).<sup>11</sup>

This sequence explains why children with hemophilia bleed despite having a normal TF/VIIa complex; the factor Xa during the initiation phase is broken down by ATIII and TFPI if it dissociates from the TF-bearing cell. It is therefore unable to activate the “burst” of thrombin generation that normally occurs in this propagation phase. The factor Xa needs to be generated on the platelet itself via the IXa/VIIIa complex.<sup>11</sup>

Of note, an alternative pathway is initiated by contact factors (XII, XI, prekallikrein, and high-molecular-weight kininogen [HMWK]). It is of no physiologic importance in terms of coagulation activation; however, it provides important acceleration

loops through feedback activation of factors VIII, IX, and XI<sup>14</sup> and is important in fibrinolytic and inflammatory pathways.<sup>15</sup>

### CLOT INHIBITION

The clot is confined to the site of injury by direct and indirect thrombin inhibitory systems. The direct system comprises ATIII,  $\alpha_2$ -macroglobulin, and heparin cofactor II (HCII). ATIII and HCII activities are accelerated in the presence of heparin.

Several indirect systems inhibit thrombin, such as the protein C-protein S-thrombomodulin (TM) and the TFPI systems. Thrombin binds to TM on the surface of intact endothelial cells and can no longer cleave fibrinogen to form fibrin. The TM/thrombin complex is neither able to activate platelets nor activate factors V and VIII. Instead, this complex activates protein C, which binds to the cofactor protein S and inactivates factors Va (on the surface of endothelial cells and platelets) and VIIIa.<sup>11,14</sup> TFPI bound to endothelial surfaces can form complexes with factor Xa that inhibit factor VIIa. Thrombin generation is therefore inhibited.<sup>14</sup>

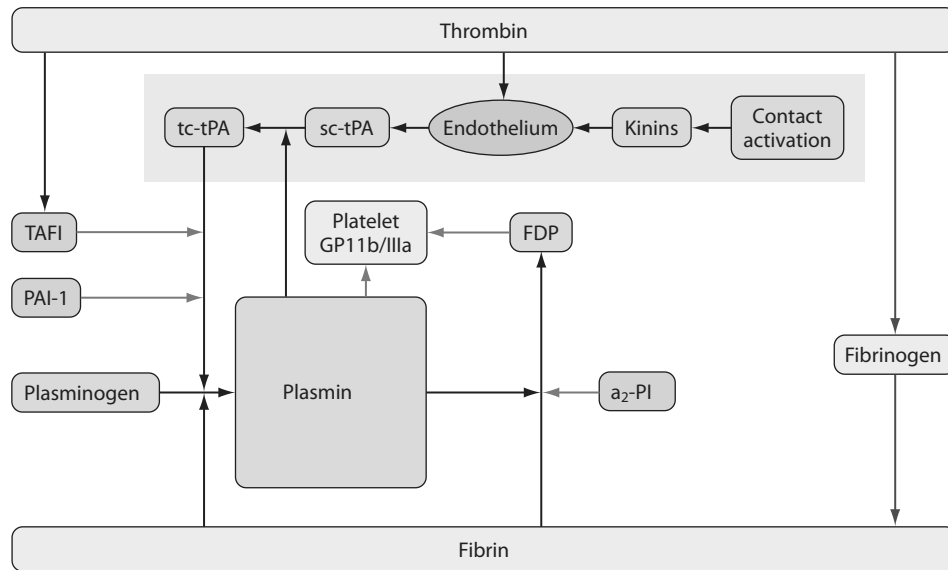

### FIBRINOLYSIS

Fibrinolysis (the breakdown of fibrin into soluble degradation products) is mediated by the proteolytic enzyme, plasmin. Plasmin is formed from an inactive zymogen, plasminogen, which is produced in the liver. This process is controlled by activators and inhibitors. The principal plasminogen activators are tissue plasminogen activator (tPA) and urokinase (uPA). Although overlap exists between the functions of these activators, they have distinct physiologic roles. uPA is primarily involved in a wide variety of extracellular processes, including remodeling of tissues. tPA is the major intravascular activator of fibrinolysis and is discussed in more detail later.<sup>16</sup> The main inhibitory proteins are plasminogen activator inhibitor-1 (PAI-1), antiplasmins ( $\alpha_2$ -PI and  $\alpha_2$ -macroglobulin), and thrombin activated fibrinolysis inhibitor (TAFI)<sup>17</sup> (Fig. 18-4).

As well as cleaving fibrin, plasmin metabolizes a number of other proteins, including the platelet receptor for fibrinogen (glycoprotein IIb/IIIa) and fibrinogen.<sup>18</sup> In addition, plasmin accelerates its own production by metabolizing the conversion of single chain plasminogen activators to more active two-chain versions. The action of plasmin on fibrin produces a series of degradation products some of which convey anticoagulant properties; this effect is achieved by preventing polymerization of fibrinogen and by inhibition of platelet function.

tPA is released by vascular endothelium of small blood vessels. Release is increased in the presence of stimuli such as trauma, endotoxins, ischemia, or normal exercise. This effect is mediated via contact activation (through the kallikrein system) and also by a series of other substances, including thrombin. Once released, tPA is rapidly metabolized by the liver with a half-life of approximately 5 minutes.<sup>17</sup> Fibrin binds both plasminogen and tPA and greatly accelerates the conversion of plasminogen to plasmin (facilitating its own degradation, but also localizing the process to areas of clot). An alternative mechanism for plasminogen activation by tPA exists through binding to receptors expressed by certain cells (endothelium, white cells and some tumor cells); the importance of this in health or disease is unclear.

Excessive fibrinolysis can directly result from excess production of fibrin, as in disseminated intravascular coagulation. This is termed secondary hyperfibrinolysis and in this context the fibrinolysis is considered beneficial because it prevents

**FIGURE 18-4** The main fibrinolytic pathway, leading to the breakdown of fibrin into fibrin degradation products (FDP). It is initiated by release of tissue plasminogen activator (tPA) from endothelial cells in response to contact activation (shaded area). Plasminogen needs to be bound to fibrin in order to allow conversion to plasmin. sc-tPA and tc-tPA refer to single- and (more active) two-chain tPA, respectively. Endogenous fibrinolysis inhibitors are shown in blue boxes: TAFI is thrombin activated fibrinogen inhibitor, PAI-1 is plasminogen activator inhibitor, and  $\alpha_2$ -PI is  $\alpha_2$  plasmin inhibitor. Interactions with the coagulation system are shown by red arrows.

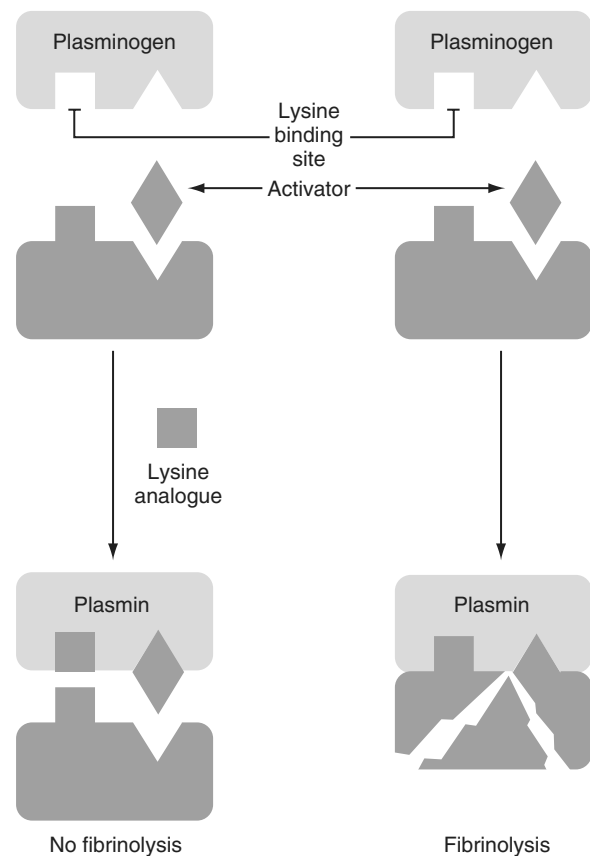

widespread vascular occlusion. Therapy is directed at replacement of consumed clotting factors, inhibition of excessive coagulation, and treatment of the underlying cause. Primary hyperfibrinolysis can occur during cardiac bypass, massive blood loss, trauma, and liver transplantation.<sup>19</sup> During the anhepatic stage of liver transplant surgery, there is hyperfibrinolysis because of failure to metabolize tPA. On reperfusion of the liver, a further surge of tPA occurs that can take several hours to return to normal. In coagulopathic patients, reduced thrombin formation may lead to reduced production of TAFI (important in inhibition of membrane bound plasmin), whereas conversion of single- to two-strand tPA by plasmin may further sustain the process. Individual susceptibility is likely to be important and may have a genetic component.<sup>20,21</sup>

Two groups of drugs are used clinically to inhibit fibrinolysis:

1. Synthetic lysine analogues, e.g., tranexamic acid (TXA) and  $\epsilon$ -aminocaproic acid (EACA).
2. Protease inhibitors (e.g., aprotinin).

Synthetic lysine analogues are fairly specific inhibitors of plasminogen activation, working by competitively binding to lysine-binding sites on the plasminogen molecule (Fig. 18-5). This blocks the binding of plasminogen to fibrin; a required step for the conversion of plasminogen to plasmin by plasminogen activators.<sup>22</sup> At larger doses, they may have additional effects through direct inhibition of plasmin; this includes inhibition of the plasmin mediated effects on platelets.

Aprotinin is a less specific inhibitor of proteolytic enzymes; it has actions on the kallikrein-kinin (contact) system, as well as enzymes involved in coagulation and fibrinolysis. In addition, aprotinin may be associated with greater preservation of platelet function, as well as an antiinflammatory effect. This wider spectrum of effects from aprotinin may have additional benefits over the antifibrinolytic lysine analogues. Some additional effects may not necessarily be of benefit; for example, the contact system may have protective effects against ischemic reperfusion injury that are inhibited by aprotinin.<sup>15</sup>

**FIGURE 18-5** Diagrammatic representation of the mode of action of the synthetic lysine analogues tranexamic acid and  $\epsilon$ -aminocaproic acid. (Reproduced from Mahdy AM, Webster NR. Perioperative systemic haemostatic agents. Br J Anaesth 2004;93:842-58.)

## Developmental Coagulation

The hemostatic system in the neonate rapidly matures towards that of the adult (see also Chapter 9).<sup>23-25</sup> One must consider how the coagulation system matures in the child to interpret coagulation tests and use appropriate modalities to manipulate hemostasis *in vivo*.

All fetal coagulation factors are produced independently of the mother; fibrinogen starts to be formed as early as 5.5 weeks gestation, and blood can clot at 11 weeks. The introduction of microassays in the 1980s allowed for the determination of reference ranges for the coagulation factors beginning at 19 weeks gestational age.<sup>14,23,24</sup> In general, there are four fundamental differences between the coagulation systems in the infant and the adult<sup>26</sup>:

- Concentrations of components of the hemostatic system
- The turnover rate of various components of the coagulation cascade
- The rate of synthesis
- Differences in the overall ability to generate and regulate the key enzymes: thrombin and plasmin

Despite the upregulation of coagulation factors at birth, the vitamin K-dependent factors II, VII, IX, and X in the neonate are only 50% of adult values; this leads to a slightly prolonged prothrombin time (PT) or international normalized ratio (INR).<sup>14</sup> The contact factors HMWK, prekallikrein, and factors XI and XII are also approximately 50% of adult values.<sup>14,26</sup> The reduced contact factors account for a disproportionately prolonged activated partial thromboplastin time (aPTT). The reduced concentration of factors at birth is probably explained by the reduced synthesis of factors by the liver; however, concentrations increase rapidly, reaching approximately 80% of adult values by 6 months of age.<sup>14,27</sup>

In contrast, the plasma concentrations of fibrinogen and factors V and VIII at birth are similar to those in adults, although the fetal form of fibrinogen differs in structure from that of the adult. The physiologic significance of this is not clear.<sup>28</sup> Concentrations of vWF in the first 2 months of life are greater than those in adults.<sup>29</sup>

The inhibitor systems of coagulation also differ from adults. At birth, plasma protein C and S are 35% of adult values, although the fetal forms of the proteins differ from the adult forms. The concentration of protein C does not reach adult values until adolescence. Neonatal concentrations of ATIII and HCII are 50% of adult values; they reach adult concentrations by 6 months of age. The  $\alpha_2$ -macroglobulin value, however, is increased at birth and remains increased throughout childhood; it is postulated that this may be one of the mechanisms that protects young children from thromboembolic complications.<sup>30</sup>

Finally, thrombin generation *in vitro* is reduced in children to approximately 75% of adult values,<sup>30</sup> but there is difficulty in interpreting the apparent discrepancy between the sufficient hemostasis seen *in vivo* and these *in vitro* laboratory thrombin generation assays. It still remains to be clarified whether neonates and children are more susceptible to bleeding<sup>14</sup>; however, the risk of thromboembolic complications appears to increase with age.<sup>30</sup>

Despite reduced plasma concentrations of many procoagulant and anticoagulant proteins in infants, there still appears to be an effective hemostatic balance; healthy fetuses, neonates, and children do not suffer excessive hemorrhage in the presence of minor challenges. This is consistent with the thromboelastogram (TEG) studies of healthy children younger than 2 years of age; no

defects in coagulation were noted using this test compared with adults, indicating an intact hemostatic system.<sup>31</sup> Another TEG study reported that infants younger than 1 year of age with complex congenital heart disease have an intact and balanced coagulation–fibrinolytic system but at a “lower level” than healthy children. This has been interpreted as a reduction in hemostatic potential with less reserve.<sup>32</sup>

## GENETICS OF BLEEDING

The hemophilias are a group of genetic diseases that cause excessive bleeding, often in response to minor trauma. von Willebrand disease and hemophilia A are the most common variants (see also Chapter 9), associated with low levels of von Willebrand factor and factor VIII respectively. A wide range of single gene defects resulting in deficiencies of single clotting proteins or regulatory proteins have now been described. A further group of single gene disorders may result in thrombophilic disorders, associated with abnormalities of inhibitory proteins.

Unexplained variation has been observed in bleeding between apparently similar patients in the absence of specific factor deficiency. The causes of this variation are likely to be multifold according to nuances of surgical technique and subtle difference in disease process and therapy. It might appear counterintuitive that genetic factors have a significant role in acquired bleeding resulting from surgery; however, recently there has been increased interest in the interplay of genetic and environmental factors in the progress of acquired diseases. The genetics of most clotting proteins has been described, and common variations within populations have been revealed for some. Of these, a common polymorphism of PAI-1 has been well described. PAI-1 is an important endogenous inhibitor of fibrinolysis, and deficiency is associated with increased bleeding.<sup>33</sup> The *G5/G5* polymorphism is common (about 20% in European populations) and is associated with lower levels of PAI-1. It has been linked (though not consistently) to bleeding after heart surgery and to increased benefit from use of antifibrinolytics.<sup>20,21</sup> Should these findings be substantiated, then PAI-1 may still be an exceptional example. In general, the influence and consequences of genetic determinants of bleeding are likely to be more subtle. In infancy an additional factor in the mix may be the relationship between developmental and genetic factors. Many clotting proteins are present in infants as isoforms distinct from those in adults. This implies a different gene expression in the young. It is possible that understanding genetically determined variations in bleeding will increase our understanding of bleeding and, perhaps, allow us to guide therapy for the individual patient. The practical applications of such techniques, however, remain speculative.

## Coagulopathy and Major Surgery

Bleeding is an inevitable consequence of invasive surgery. Severe bleeding can be associated with derangement of coagulation, which may increase the severity of bleeding or, alternatively, may put the child at risk for thrombosis. These two adverse events are not mutually exclusive: patients who bleed more and who demonstrate coagulopathic bleeding may also be at increased risk of thrombosis.

Coagulation changes during major surgery and bleeding are complex<sup>34</sup> and depend on the clinical context in which bleeding occurs. Coagulation changes that occur in surgical patients have some similarities to those who present after severe trauma; however, the balance of pathophysiologic factors is likely to be

very different. The factors underlying these coagulation changes include:

- **Dilution.** Components of the coagulation system are lost in shed blood. The volume of blood lost is then replaced by crystalloid, colloid, or blood products lacking these components, leading to progressively smaller concentrations of these coagulation components. To some degree such changes are balanced, as the concentration of coagulation inhibitors also falls. In addition, coagulation components may be produced or released in response to trauma, which limits the reduction in concentration. To complicate this issue, a reduction in the concentration of one component of the coagulation system may not have the same clinical effect as the same reduction of another component. For example, substantial decreases in the concentration of many clotting proteins will not result in severe bleeding, while even modest decreases in platelet numbers or in the fibrinogen concentration may be significant (see also Chapter 10).
- **Effect of tissue damage.** Extensive interactions occur between inflammatory and coagulation pathways. Inflammation following trauma to tissues can be linked to excess activation of fibrinolytic pathways (resulting in excess bleeding) and to activation of procoagulant pathways (resulting in increased risk of thrombosis).
- **Physiologic derangement associated with blood loss.** Acidosis, hypothermia, and hypocalcemia are associated with excess bleeding.<sup>35</sup> Hypothermia will result in a general slowing of proteolytic enzyme activity, reduced fibrin synthesis, and reduced platelet function. These effects are largely reversible on rewarming. Acidosis is associated with a marked reduction in activity of coagulation proteins.<sup>36</sup> These effects are not fully reversed by correcting acidosis. The degree to which coagulation changes reflect acidosis itself or reflect other underlying factors is unclear. During major bleeding, calcium ion concentration should be monitored and replaced as needed.
- **Effects of treatment.** The use of some synthetic colloids may worsen bleeding to an extent greater than might be expected by dilution. The use of hydroxyethyl starch leads to increased risk of coagulation abnormalities and of acute kidney injury when compared to albumin, gelatins, or crystalloids. Whether differences exist in coagulation effects between different starches is controversial.<sup>37-39</sup> Caution should be exercised in the use of starches in children at risk of coagulation problems, and in larger volumes.
- **Use of specific techniques during surgery.** The important effects of cardiac bypass and anticoagulation are discussed later. Liver transplant surgery (see also Chapter 29) and major trauma (see also Chapter 38) are discussed in detail elsewhere in this book.

## Alterations in Hemostasis during Pediatric Cardiac Surgery

### ROUTINE ANTICOAGULATION Heparin

Heparin remains the most effective anticoagulant used to facilitate cardiopulmonary bypass (CPB).<sup>40</sup> The binding of heparin to lysine sites on ATIII causes a conformational change in ATIII. This results in an increase in ATIII potency; the inhibition of thrombin and factors IXa, Xa, XIa, and XIIa are increased by a factor of 1000.<sup>41,42</sup> In infants ATIII levels are low until 3 to

6 months of age and other heparin cofactors, in particular,  $\alpha_2$ -macroglobulin may have greater importance. However neonates requiring surgery for congenital heart disease have unusually reduced concentrations of all major heparin cofactors, and this may explain the greater concentrations of thrombin production in these patients.<sup>43</sup>

Heparin therapy is most frequently guided by the activated clotting time (ACT). The ACT is an inexpensive and rapid on-site test in which a small sample of blood is mixed with a coagulation activator, such as Celite, kaolin, or diatomaceous earth. The ACT is the time to produce a stable clot, with a normal value being between 80 and 140 seconds. A number greater than 400 seconds is required for CPB.

There are limitations to the use of the ACT; first, the ACT is altered by hypothermia, hemodilution, platelet activation, activation of the hemostatic system, and aprotinin therapy.<sup>44,45</sup> Accordingly, it does not accurately reflect the heparin concentrations. One study found that as soon as children go on CPB, the heparin concentrations decreased by 50% as a result of hemodilution, even though the ACT doubled.<sup>46</sup> Second, in the bleeding child, the ACT is unable to differentiate between bleeding resulting from excess heparin or from other acquired hemostatic defects.<sup>46</sup> The gold standard for measurement of heparin concentration is considered to be the antifactor Xa assay; however, this test remains too cumbersome for routine clinical use. A further method is protamine titration, which has been available as a point-of-care test for some years (Medtronic Hepcon HMS Plus, Medtronic, Minneapolis, USA). In adult patients, use of this system has been shown to lead to reduced thrombin formation<sup>47</sup>; however, the accuracy of the device has been questioned.<sup>48</sup> Reduced bleeding and reduced thrombin generation in children has been demonstrated with the use of this system, whereas other studies have demonstrated reduced thrombin formation<sup>22,49</sup> in infants. A trial in small infants was terminated early when increased bleeding and increased length of stay was demonstrated in children in whom the Hepcon device was used.<sup>49</sup> The device underestimated heparin concentration in this group, leading to excess dosing of heparin and inadequate reversal with protamine. After modification of their protocol, use of the device demonstrated reduced bleeding, length of stay, and reduced thrombin formation compared to standard treatment.<sup>49</sup> Agreement between protamine titration, measures of heparin concentration, and laboratory measures has been demonstrated, but the Hepcon devices tended to underestimate heparin concentrations in infants.<sup>50</sup>

A common feature of the pediatric studies using the Hepcon device is increased heparin use compared to regimes based on units/kg dosing or ACT. This is consistent with other studies of traditional dosing regimes. Using common pediatric heparin regimens (300 units/kg before CPB, then 100 units/kg to keep the ACT above 450 sec), 50% of children on CPB had low levels of heparin (less than 2 units/mL).<sup>46</sup> It is suggested that reduced heparin concentrations during CPB is a major factor responsible for activation of coagulation and fibrinolysis. It is likely that widely used regimens for dosing of heparin in children lead to inadequate dosing, and that units/kg dosing fails to allow for important pharmacokinetic (PK) and pharmacodynamic (PD) differences in children.

Even effective dosing of heparin does not completely abolish the production of thrombin. Low-grade ongoing thrombin production leads to ongoing activation of the coagulation cascade, platelets, fibrinolysis, and the endothelium. The continued

thrombin generation and activity during CPB reflects the inability of the heparin-ATIII complex to inactivate fibrin-bound thrombin or to inhibit thrombin-induced platelet activation.<sup>51</sup> Theoretically, direct thrombin inhibition may be free of these limitations. Practically, the use of the current generation of thrombin inhibitors (such as hirudin and bivalirudin) is limited because of a lack of effective monitoring and reversal. Currently few reports exist of the use of hirudin in children, although it would be indicated in children in whom heparin use is not possible.<sup>52</sup>

Adverse effects of heparin are uncommon; hypotension can result from a reduction in calcium ions or, rarely, anaphylaxis. A benign transient decrease in the platelet count can occur. Heparin-induced thrombocytopenia is a rare but life-threatening prothrombotic condition.

### Reversal of Anticoagulation with Protamine

Protamine is a positively charged polypeptide derived from salmon sperm. It neutralizes heparin by forming an ionic bond with heparin. The resultant complex is removed by the reticulo-endothelial system. The most appropriate dosing regimen has yet to be determined. Current dosing used in pediatric practice fails to take into account the range of concentrations of heparin that occurs in infants and children.<sup>40,49</sup> The administered heparin dose is often used to guide the dose of protamine; however, it is unclear how this should be modified by various factors, such as additional doses of heparin administered (to prime or during bypass), duration of bypass, techniques (e.g., ultrafiltration), or developmental coagulation differences in children.<sup>53</sup>

Excessive protamine has been associated with catastrophic pulmonary hypertension and hemorrhagic pulmonary edema. It is also known that protamine can be associated with coagulation abnormalities; an increasing ACT occurs at a protamine-heparin ratio of 2.6:1, and platelet aggregation occurs with a minimal excess in protamine.<sup>54</sup> Although some studies on titrating protamine regimens in adults demonstrated encouraging results in terms of reduced bleeding,<sup>55</sup> others failed to demonstrate differences in transfusion requirements.<sup>56</sup>

The clearance of protamine is greater than that of heparin, and "heparin rebound" is described as tissue-bound heparin redistributes.<sup>40</sup> The diagnosis of residual heparin effect or heparin rebound is challenging. The ACT is not a specific measure of excessive heparin and is also poor at detecting heparin at low concentrations (less than 0.5 unit/mL).<sup>57</sup> The aPTT and PT are similarly nonspecific and may be increased after CPB in the absence of heparin.<sup>58</sup> An unmodified TEG does not reliably detect heparin rebound if the heparin concentration is small.<sup>59</sup> The sensitivity of these tests may be improved by performing similar tests in parallel and comparing the results, such as a reptilase time (unaffected by heparin), or by eliminating residual heparin in vitro with heparinase or protamine. Protamine titration can be used to guide protamine dose in children; however, in infants protocols will require modification (50% higher than calculated dose).<sup>49</sup> In practice most anesthesiologists continue to give protamine empirically at a protamine-heparin ratio of between 1 and 1.3 to 1.

### FAILURE OF HEMOSTASIS ASSOCIATED WITH CARDIAC SURGERY

Complex abnormalities occur in the coagulation system in cardiac surgery, owing to the profound surgical insult, hypothermia, acid-base disturbance, blood transfusion, anticoagulants, CPB

**TABLE 18-1** Causes of Excessive Bleeding after Pediatric Cardiac Surgery

#### Preoperative Causes

Liver immaturity  
Congenital coagulopathy  
Poor nutrition  
Cyanotic congenital heart disease  
Drugs: prostaglandin E<sub>1</sub>, aspirin, clopidogrel

#### Intraoperative Causes

##### *Surgical Insult*

Inadequate surgical hemostasis before bypass  
Inflammatory cascade, fibrinolysis, etc.

##### *Cardiopulmonary Bypass*

Inflammatory cascade  
Ongoing fibrinolysis  
Increased vascular permeability  
Capillary damage

##### *Hemodilution*

Platelet reduction  
Clotting factor reduction  
Fibrinogen reduction

##### *Complement activation*

Platelet abnormality  
Fibrinogen reduction  
Disseminated intravascular coagulation

#### Post Cardiopulmonary Bypass

Inadequate surgical hemostasis  
Acidosis  
Hypothermia  
Hypocalcemia  
Excessive blood transfusion and clotting factor dilution  
Inadequate reversal of heparin with protamine  
Excess protamine  
Inadequate reversal of heparin in transfused pump blood

(contact activation, platelet dysfunction, and hemodilution), and in some cases, deep hypothermic cardiorespiratory arrest. In addition children and infants with congenital heart disease may have preexisting coagulation defects or be taking medications that affect coagulation before surgery (Table 18-1).

Antiplatelet drugs such as aspirin or clopidogrel may exacerbate bleeding. The clinician must balance the risk of perioperative bleeding against the risk of drug discontinuation when deciding if and when to withhold the drug before surgery. In most cases aspirin can be safely discontinued 5 days before surgery. Prostaglandin E<sub>1</sub> can inhibit platelet aggregation, acting in synergy with endothelial cell-derived factors (nitric oxide and prostacyclin) at clinically relevant concentrations,<sup>60</sup> although this effect was too subtle to detect in vitro using the TEG.<sup>32</sup> It is usually not possible to stop the prostaglandin E<sub>1</sub> infusions, because neonates are dependent on its use to maintain ductal patency. For elective surgery in children on oral anticoagulant therapy, it is usually possible to transfer to heparin before surgery. An INR of less than 1.5 is usually considered acceptable for surgery. If urgent correction of anticoagulants is required, prothrombin complex concentrates, together with vitamin K, are more effective than FFP.<sup>61</sup> FFP should only be used if prothrombin complex concentrates are not available.

In the child with cyanotic congenital heart disease, hemostasis is further impaired because of polycythemia, low platelet count and altered function, reduced factors V, VII, and VIII, and increased fibrinolysis.<sup>32,62</sup> The degree of derangement is related to the degree of cyanosis.<sup>63</sup> Preexisting coagulopathy may also occur in children with severe underlying illness or poor nutritional status.

Despite improvements in design and materials of the CPB circuit, abnormal activation of the coagulation and fibrinolytic systems persist. The normal balance of coagulation and fibrinolysis is particularly delicate in children, and more susceptible to exogenous perturbations.<sup>64</sup> Shortly after CPB is established in children, all hemostatic protein concentrations are decreased (to a variable degree) as a result of dilution.<sup>65</sup> Because of the relative volume of the circuit in relation to the size of the child, it is not surprising that the magnitude of the effect of hemodilution is greater than in adults.<sup>46</sup>

Reductions in coagulation factor concentrations after cardiac surgery contribute to bleeding in adult cardiac patients,<sup>66</sup> and a reduction in platelet count is well described on initiation of bypass. In adults, the platelet count is reduced on CPB by approximately 50%.<sup>67</sup> This is also attributed primarily to dilution, although other factors include organ sequestration, mechanical disruption, and adhesion to the circuit.<sup>68</sup> A relatively greater reduction will occur in smaller children, although newer combined filter and oxygenators should considerably reduce the circuit volume and, hence, the degree of dilution. Significant platelet dysfunction also occurs.<sup>46,69</sup> Low platelet counts have been strongly associated with increased bleeding.<sup>10,31,70</sup>

Further activation of platelets and denaturing of plasma proteins will occur at interfaces between blood and air, or on contact with extravascular tissue. CPB pump suction and spilling of blood into the pericardium will further contribute to coagulopathy. Greater coagulopathy is also seen during prolonged bypass and when deep hypothermic circulatory arrest is employed.<sup>71</sup>

The major mechanism for activation of the coagulation cascade during CPB is thought to be the “extrinsic” TF pathway, which is activated as a result of surgical trauma and inflammation.<sup>42,72,73</sup> Inflammatory mediators such as tumor necrosis factor (TNF) and interleukin-1 induce expression of TF on endothelial cells and monocytes. The “intrinsic” coagulation system is also activated when factor XII is adsorbed onto the surface of the CPB circuit, causing activation of complement, neutrophils, and the fibrinolytic system via kallikrein.<sup>42</sup> Although the intrinsic system has little role in initiating coagulation, activations of kinins will lead to increased fibrinolysis and inflammation.<sup>15</sup>

The blood loss in the first 24 hours after cardiac surgery can vary between 15 and 110 mL/kg, although the risk of excessive blood loss is greatest among those weighing less than 8 kg, younger than 1 year of age, and children undergoing complex surgery.<sup>10</sup> The common preoperative and intraoperative risk factors for excessive bleeding are summarized in Table 18-2.

Blood loss and transfusion requirements in pediatric cardiac surgery vary inversely with age; neonates bleed more and receive more products per kilogram than any other age group.<sup>74</sup> There are some correlations between coagulation tests before and during CPB and postoperative blood component transfusion requirements, although the sensitivity and specificity of the tests are not sufficient to justify routine coagulation tests while on CPB. Of all the tests, a platelet count of less than 108,000/mm<sup>3</sup> while on CPB yielded the greatest sensitivity (83%) and specificity (58%) for predicting excessive blood loss.<sup>70</sup>

**TABLE 18-2 Common Predictive Factors for Bleeding**

Preoperative	Intraoperative
Age <1 year or weight <8 kg	Individual surgeon
High hematocrit	Complex surgery
Congestive heart failure	Low platelet count during CPB
Repeat sternotomy	Prolonged CPB
Congenital and preoperative acquired coagulopathy	Duration of hypothermia on CPB
Cyanotic congenital heart disease	Deep hypothermic cardiac arrest

## Medications Used for Hemostasis

The pathophysiology of coagulopathies and bleeding in children during surgery are complex, and the etiology is multifactorial (see Table 18-1). No single blood component or drug treatment can reverse the abnormal clotting profile. Initially an attempt should be made to identify causes of bleeding that can be remedied by surgical interventions. The anesthesiologist should attempt to ensure adequate reversal of heparin and restore normal physiologic variables, such as body temperature, serum [Ca<sup>2+</sup>], and acid-base balance. In the postoperative period, platelets, and other blood products, such as fresh frozen plasma (FFP) and cryoprecipitate, remain the mainstay of treatment for excessive bleeding.<sup>75</sup> Blood products (see also Chapter 10) are briefly discussed here, primarily within the context of pediatric heart surgery.

### BLOOD PRODUCTS

Frequently it is necessary to administer blood products on a largely empirical basis; laboratory tests describe only parts of the coagulation process<sup>32</sup> and are practically too slow to direct the anesthesiologist in real time as to the requirement for blood components. The TEG is a dynamic whole-blood test that is frequently used as a near-patient test to assess clot elasticity properties and, hence, more precisely delineate the bleeding and homeostasis profile. The role of TEG during pediatric heart surgery has been recently reviewed.<sup>76</sup> The use of treatment algorithms based on TEG can limit transfusion of blood products in adults<sup>77-81</sup> and children.<sup>82</sup> In children, it may not be appropriate to use protocols originally designed for adults. An alternative approach has recently been proposed.<sup>76</sup>

### PLATELETS

Platelet dysfunction and thrombocytopenia are common after cardiac bypass in infants. Hence, in the presence of bleeding, transfusion of platelets is logical. Coagulation variables that relate to platelet number and function (such as TEG maximum amplitude) are corrected by infusion of platelets, and clinical experience indicates that platelet transfusion reduces bleeding. This has been confirmed in a small study of children after cardiac surgery.<sup>31</sup> A platelet count of less than 108,000/mm<sup>3</sup> has been identified as a predictor of bleeding, whereas clot strength measured by TEG reduces steeply at platelet counts below 120,000/mm<sup>3</sup>. The current recommendation of targeting a platelet count of approximately 100,000/mm<sup>3</sup> appears to be logical. It would also appear

reasonable to use platelets for the initial treatment of presumed coagulopathic bleeding (in the absence of specific clotting tests).

### FRESH FROZEN PLASMA

The case for use of fresh frozen plasma (FFP), either as empirical treatment of bleeding, or guided by coagulation tests, is considerably weaker than for platelets. The use of FFP in cardiac surgery is based on the observation that the concentration of clotting factors are often low in bleeding patients, especially in the period following bypass. The PT (with its derived measure, INR) is the most common test used to detect the presence and gauge the severity of clotting factor-deficient coagulopathy. Unfortunately, observation studies have shown that the PT correlates poorly with clinical bleeding, and that transfusion of plasma often achieves no measurable change in the INR, nor is of any known clinical benefit (particularly if the INR was only marginally raised to less than 1.7).<sup>83</sup> Despite this, FFP is frequently transfused in the absence of either bleeding or significantly raised PT.<sup>84</sup> Administration to patients with higher PT values will be more effective in correcting clotting tests, however large volumes may be required,<sup>83</sup> even in the absence of ongoing loss of clotting factors. The situation is further complicated, in that coagulation tests that are initially normal will deteriorate during severe bleeding.

A systemic review of the use of FFP to treat or prevent bleeding resulting from acquired coagulopathy failed to demonstrate benefit, although the trials examined were small, used a wide range of outcomes, and were conducted in heterogeneous populations.<sup>85</sup> In a small observational study of children undergoing heart surgery, a number of patients had coagulopathic bleeding after transfusion of platelets; if these patients were then given FFP, the bleeding increased, whereas if cryoprecipitate was given bleeding decreased.<sup>31</sup>

It is possible that the lack of efficacy may be related to the dose of FFP used. The dose of FFP most frequently recommended (10 to 15 mL/kg)<sup>84,86</sup> may be inadequate to restore factor concentration.<sup>83</sup> Of note, dosage of plasma is inexact. Hence, interinstitution practices differ considerably in defining both a threshold INR for prophylactic plasma administration and the actual dosage of plasma prescribed.<sup>87</sup>

Modeling of FFP administration in major trauma suggests that larger doses (30 to 40 mL/kg) may be required to increase or maintain factor concentrations<sup>88</sup>; however, administration of such a large volume is often undesirable in the absence of severe ongoing bleeding. Addition of FFP to the bypass circuit or during modified ultrafiltration may allow administration of much larger doses; benefit appears to be confined to younger children.<sup>89,90</sup> It is always important to document the specific reasons for FFP administration.

### CRYOPRECIPITATE

Not all coagulation factors are of equal importance during bleeding. Fibrinogen is present in much greater concentrations than other clotting factors, and while other factors are mainly involved in initiating or amplifying thrombin formation, fibrinogen is a substrate for the production of fibrin. Deficiencies of fibrinogen are reflected in reduced strength of clot and are associated with increased bleeding.<sup>91</sup> Cryoprecipitate is the most concentrated fibrinogen replacement widely available, with a fibrinogen concentration 4 to 8 times that of FFP; however, a unit of cryoprecipitate contains less fibrinogen than a unit of FFP, and multiple cryoprecipitate units will be required in larger patients. One

cryoprecipitate unit for each 10 kg should raise fibrinogen concentration by 0.5 to 1.0 g/L. As well as fibrinogen, cryoprecipitate is a source of von Willebrand factor and factors VIII and XIII, although the clinical significance of this to bleeding is unclear. Cryoprecipitate has been effective in treating bleeding resistant to platelet concentrates alone during pediatric heart surgery.<sup>31</sup>

### FRACTIONATED HUMAN BLOOD PRODUCTS

Products such as FFP or cryoprecipitate can be considered as only crudely purified blood products. It is possible to produce more refined products containing high concentrations of only a single clotting protein or relatively standardized concentrates of selected proteins. Examples of these are prothrombin complex concentrates and fibrinogen concentrate (e.g., Riastap, CSL Behring, King of Prussia, Pa., USA; Haemocomplettan P, CSL Behring, Marburg, Germany). These products are human blood products produced from pooled plasma; they are presented as a powder requiring reconstitution for use. They do not require freezing or cross matching, which simplifies their supply, storage, and administration. Risk of viral transmission should be low<sup>92</sup> because of sourcing of plasma from low-risk populations, pooling of plasma from many individual donors (reducing viral load resulting from a single infected donor), and pasteurization. Although the effect of pasteurization on prion infection is less certain, the risk of transmission would be expected to be similarly low. Recombinant factor concentrates (as opposed to factor concentrates of human origin) are increasingly available and avoid cross infection. One such agent, recombinant activated factor VII (rVIIa), is discussed later in this chapter (see also Chapter 10). Although the agents discussed in this section are used in a similar way to traditional factor supplementation to reestablish near physiologic concentrations, rVIIa is used very differently to produce factor levels greatly in excess of "normal."

Prothrombin complex concentrates (PCCs) are mixtures of factors II (prothrombin), VII, IX, and X, plus the coagulation inhibitors Protein S and C. They are indicated when urgent reversal of oral anticoagulation (with warfarin or related drugs) is required. Dose is specific for each make of PCC, and is dependent on the child's INR and the target for correction (generally an INR of 1.5). Older reports of lack of efficacy or risk of thrombosis probably relate to older brands of PCCs with low levels of factor VII or of inhibitors.<sup>93</sup> PCCs are more efficacious than FFP for warfarin reversal.<sup>61</sup> They have also been used in other causes of acquired coagulopathy and bleeding, including after adult heart surgery.<sup>94,95</sup> Potentially these products are superior to FFP in such situations; however, routine use for treatment of acquired bleeding in children (other than reversal of warfarin) cannot be recommended until further evaluation is conducted. Dosing in this situation is also uncertain.

The importance of fibrinogen depletion in coagulopathy and bleeding has been increasingly appreciated.<sup>96,97</sup> It has also been recognized that traditional cut-off values for supplementation of fibrinogen during bleeding (1.0 g/L) are likely to be too low and that further advantage can be gained from higher targets; possibly as high as 2.0 g/L. This may be difficult to achieve with traditional blood products. FFP contains only physiologic concentrations of fibrinogen and only modest increases may be achieved, while cryoprecipitate will require administration of product from several donors to achieve significant increases in fibrinogen concentration (especially in larger patients). Human fibrinogen concentrate has been available in continental Europe for some time and has recently been licensed within the United Kingdom and

the United States for treatment of congenital fibrinogen deficiency. Unlike cryoprecipitate, they contain only fibrinogen and a direct comparison in other forms of coagulopathy has not been made. Recent reports have demonstrated advantages to its use in adult cardiac surgery and other causes of bleeding.<sup>98,99</sup> Reports of its use in children with acquired coagulopathy are limited. Combining use of fibrinogen concentrates with rapid measurement of fibrinogen concentration (using modified TEG) is an attractive approach.<sup>100</sup>

The most obvious use for fibrinogen concentrates is as an alternative to cryoprecipitate. Their apparent safety and ease of administration may, however, make other applications possible. A small randomized study comparing prophylactic administration of fibrinogen concentrate to placebo in adult cardiac patients demonstrated a reduction in bleeding.<sup>99</sup> Alternatively, it has been proposed that targeting larger fibrinogen concentrations with these agents may reduce the requirement for platelet transfusion. Animal work has demonstrated the effectiveness of this approach in models of bleeding and thrombocytopenia.<sup>101</sup> The product of fibrinogen concentration and platelet count may be a better predictor of bleeding in children than either measure alone.<sup>91</sup> If the concentration of fibrinogen is high, the amplitude of TEG recordings can be normal, even in the absence of platelets. In vivo, it would be expected that there are limits to this phenomenon; at some point, platelets are required for formation of clot. Such an approach requires proper clinical evaluation before being more widely adopted. Recombinant fibrinogen in fibrin sealants is currently undergoing phase II trials, although widespread availability of systemic recombinant fibrinogen is still some years away.<sup>102</sup> With proper assessment, recombinant fibrinogen has the potential to greatly alter the management of severe bleeding and coagulopathy.

Deficiency of factor XIII during and after cardiopulmonary bypass has been described, although the importance of this finding is uncertain.<sup>103-105</sup> Supplementation with human or recombinant factor XIII has been demonstrated to reduce bleeding after adult heart surgery, although possibly only in the presence of factor deficiency.<sup>104,106,107</sup> The action of factor XIII is to

catalyze the formation of cross bridges between fibrin molecules. It also has a wider function in promoting fibroblast proliferation, and it has been used in the treatment of chylothorax after pediatric heart surgery (with possibly only minor benefit).<sup>108</sup> Recombinant factor XIII is currently being considered for approval by the FDA, and wider availability may lead to greater use of this agent. Evidence to support widespread use is currently not available.

## PHARMACEUTICAL AGENTS TO REDUCE BLEEDING

Blood products are, in most cases, effective at treating coagulopathic bleeding, but may be associated with deleterious effects on the patient. Drug use is aimed at reducing bleeding and blood product requirements. These drugs are principally the two classes of antifibrinolytics:

1. Synthetic lysine analogues, such as EACA and TXA (see Fig. 18-5)<sup>106</sup>
2. Protease inhibitors (aprotinin)

More recently rVIIa has been employed as a rescue therapy for severe bleeding unresponsive to traditional therapy using blood products. Desmopressin has also been used in the past and is discussed later.

### The Effectiveness of Synthetic Antifibrinolytics during Pediatric Heart Surgery

A meta-analysis comparing TXA and placebo in children undergoing heart surgery<sup>2</sup> concluded that antifibrinolytics reduced bleeding and that TXA was as effective as aprotinin. Figure 18-6 shows a summary of the studies included in this meta-analysis<sup>109-116</sup>; the figure has been updated to include a more recent trial.<sup>115</sup> There were 1061 children entered into nine studies, and results demonstrated a mean reduction in bleeding of approximately 14 mL/kg (95% confidence interval [CI] of 12.7 to 15.6 mL). This is a clinically useful reduction in blood loss. The meta-analysis also demonstrated a small reduction in transfusion of red blood cells with use of TXA.

Data concerning more clinically important outcomes (e.g., reexploration or “life-threatening” hemorrhage) are lacking.

**FIGURE 18-6** A forest plot of trials of synthetic antifibrinolytic drugs (ε-aminocaproic acid [EACA] and tranexamic acid [TXA]) to reduce bleeding during pediatric heart surgery. Number in parentheses after each study refers to reference from main text. \*Study is from The All Indian Institute of Medical Science. (Forest plot generated using Review Manager (RevMan) Version 5.1. Copenhagen: The Nordic Cochrane Centre; The Cochrane Collaboration, 2011.)

Analyses have a high degree of statistical heterogeneity ( $I^2 = 78\%$ ), indicating differences in the populations, interventions, or study methodology.<sup>115-117</sup> This makes pooling of results less valid and makes it impossible to exclude factors that could introduce bias to conclusions. The patients and protocols are clinically variable with differing drugs, dosing regimens and patient populations. Only 163 of the patients did not have cyanotic heart disease; data on 6-hour blood loss was available for 144 of these children and did not demonstrate a significant reduction in bleeding (mean reduction 1.8 mL/kg, 95% CI of -0.8 to 4.5 mL/kg).<sup>115-117</sup> The majority of studies come from a single institution (The All India Institute of Medical Science),<sup>111-114</sup> and these patients represented a specific population undergoing relatively late correction of cyanotic disease. Polycythemia, and presumably severe cyanosis, was common, with a mean hemoglobin concentration of 19 g/dL.

Another feature of the studies<sup>115-117</sup> is that only one study recruited infants less than 2 months of age.<sup>116</sup> The mean age of patients was 40 months. This may be important, because the fibrinolytic system in neonates differs from adults; plasminogen levels are about 50% of adult values, plasminogen activation occurs more slowly, and levels of inhibitor (PAI-1) are normal.<sup>25</sup> This may make neonates relatively resistant to fibrinolysis. In turn, this may mean that antifibrinolytic medication is less effective, although in vitro experiments using neonatal plasma do not demonstrate a difference in the ability of synthetic antifibrinolytics to inhibit fibrinolysis.<sup>118,119</sup>

In conclusion, current pediatric data support the use of synthetic antifibrinolytics in cyanotic children older than 2 months of age, but data supporting more widespread use are unclear. While there is substantial evidence to support the use of these drugs in adults,<sup>120</sup> extrapolation of conclusions to children is uncertain and has implications with regard to drug development.<sup>121</sup> If it can be demonstrated that there are similarities for both the disease process (e.g., hyperfibrinolysis as a contributor to hemorrhage) and drug effect at different age groups (e.g., hyperfibrinolysis reduction), then adult data for efficacy could more reliably be used in children. Hyperfibrinolysis is most likely part of an inflammatory response to cardiopulmonary bypass and would be expected to occur in children (other than neonates) in a similar way to adults. It would also be expected that antifibrinolytic drugs function in a similar way in children and adults. It seems reasonable to extrapolate adult data of efficacy to children. A more difficult question is whether this reduction in bleeding is worthwhile when balanced against adverse effects (discussed later). Small children have more bleeding (relative to body weight) compared to adults. This does not in itself imply that an intervention to reduce bleeding will have greater effect in children. It has been suggested that factors other than fibrinolysis make a greater contribution to bleeding in children.<sup>91</sup>

### SYNTHETIC ANTIFIBRINOLYTIC MEDICATIONS

There is considerable uncertainty about the dose of these drugs. A recent survey of pediatric cardiac anesthetists in the UK demonstrated a 50-fold variation in TXA dose used during surgery (from a single dose of 5 mg/kg to a cumulative dose of 250 mg/kg).<sup>122</sup> In the studies summarized in Figure 18-6 there was also wide variation.

Rational dosing of a drug is determined by its PK and how the resulting plasma (or tissue) concentration translates to a clinical effect (PD). TXA has a volume of distribution (Vd) of 9 to 12 L in adults. The drug is water soluble and poorly protein

bound. Most of the drug is excreted unchanged by the kidneys, so the dose should be reduced in renal failure. The terminal elimination half-life is about 2 hours,<sup>123</sup> although CPB will affect this. In adults a loading dose of 12.5 mg/kg followed by 6.5 mg/kg/hour with 1 mg/kg added to the pump prime maintains the concentration of TXA greater than 52.5 µg/mL.<sup>124</sup> However, neonates and infants will be expected to have a relatively larger Vd and a greater change in Vd with initiation of CPB. In addition, clearance will be reduced in neonates because of renal immaturity. The effects of the surgical insult, CPB, hypothermia, ultrafiltration, and fluid resuscitation on the PK and PD of TXA remain to be established.

The target concentration of TXA is not clear. A plasma concentration of greater than 100 µg/mL will produce complete inhibition of fibrinolysis in vitro, however a concentration of 30 µg/mL accounts for most of the pharmacologic effect of the drug.<sup>125</sup> It is difficult to translate these in vitro effects into clinical dosing recommendations. Dosing regimens that involved multiple doses were more effective than a larger single bolus at the start of cardiac surgery, in terms of sternal closure time, blood loss, and blood product requirement, despite similar total doses.<sup>113</sup> The administration of a loading dose (50 mg/kg repeated on bypass) in addition to an infusion of 15 mg/kg/hour achieved mean tranexamic concentrations above 100 µg/mL, although concentrations may be below this concentration after bypass.<sup>126</sup> This dosing regimen reduced bleeding compared with placebo, and greater tranexamic concentrations were associated with less bleeding (although this does not demonstrate causality). Dosing regimens using a smaller total dose (30 to 50 mg/kg in divided doses) have also been effective. A detailed PK study of TXA in children undergoing heart surgery is currently under way and may help to improve decision making about dosing.

The use of EACA during surgery to correct a congenital heart defect was first described in 1969.<sup>127</sup> The dose of EACA is based on a small PK study in children undergoing heart surgery.<sup>128</sup> Most of the drug is excreted unchanged by the kidneys, while about 35% of EACA undergoes hepatic metabolism. The terminal elimination half-life is 1 to 2 hours.<sup>129</sup> Children have a greater weight-adjusted clearance and Vd compared with adults before, during, and after CPB. Consequently, larger doses are used in children: 75 mg/kg over 10 minutes, 75 mg/kg in the CPB circuit, and 75 mg/kg/hour as an infusion. This regimen maintains concentrations of EACA above the presumed "therapeutic" concentration of 260 µg/mL.<sup>128</sup> While the target concentration is not clear, this triple-dosing regimen appears to be clinically effective in children. One study (using three doses of 100 mg/kg EACA before, during, and after CPB) demonstrated a reduction in postoperative blood loss, reduced blood and platelet transfusion requirements, and reduced reexploration rate compared with control subjects.<sup>114</sup> The PK have not been studied in infants and neonates.

### Adverse Effects of Synthetic Lysine Analogues

As with any drug used to promote hemostasis, the most worrisome complication is thrombosis. This is likely to be a particular concern in cardiac surgical patients because of vascular anastomoses, conduits, and indwelling lines. Thrombosis is also a potential concern for those patients on extracorporeal support.

Patients following any major surgery or trauma can be hypercoagulable and at risk of thrombosis. Unlike aprotinin, the lysine analogues (TXA or EACA) have not shown an increased risk of renal, cardiac, or cerebral events in adult cardiac surgery patients.<sup>130</sup>

Several meta-analyses in adults concluded that prophylactic lysine analogues in cardiac surgery did not increase the incidence of thromboembolic complications.<sup>120,131,132</sup> However, thrombosis has been reported in nonsurgical hypercoagulable states.<sup>133</sup> Despite occasional anecdotes, there is no clear-cut evidence that the incidence of thrombosis is increased with either of the lysine analogues. Both TXA and EACA appear to have a very low incidence of other serious adverse effects, such as anaphylaxis.

The most common acute adverse effect of EACA is hypotension, usually associated with rapid intravenous (IV) administration. Rash, nausea, vomiting, weakness, retrograde ejaculation, myopathy, and rhabdomyolysis have been less frequently reported and are associated with longer-term use.<sup>123</sup> EACA is teratogenic and therefore contraindicated in pregnancy.

Rapid IV administration of TXA can cause hypotension. Oral administration can be associated with gastrointestinal adverse effects. In an adult study, prolonged infusion was associated with renal dysfunction.<sup>134</sup> There is a possible association between TXA and seizures (without any neurologic injury). TXA is found in the cerebrospinal fluid following IV administration (though at concentrations much lower than in plasma),<sup>135</sup> and when applied directly to an animal's brain can initiate seizures. Two observational studies (one in children) have reported an association with seizures<sup>136,137</sup>; however, the incidence of seizures (in both those treated and not treated) was much greater than that which occurred at the authors' institutions. The significance of this association is unclear.

#### SERINE PROTEASE INHIBITOR: APROTININ

The use of aprotinin has become a source of considerable controversy since publication of data that appeared to demonstrate increased morbidity and mortality with its use in adults undergoing heart surgery.<sup>3,130</sup> This is discussed further, later, but has led to a reduced availability of the drug in most countries. If aprotinin remains available, the decision to continue to use it must rest on a balance of the benefits (principally reduction in bleeding) and uncertain risks. More precisely, one must consider how this risk-benefit balance compares with that of the synthetic antifibrinolytics, which have more certain risk profiles.

#### Effectiveness of Aprotinin for Reducing Bleeding

Two meta-analyses demonstrated that aprotinin reduces bleeding and volume of red cell transfusion in children undergoing heart surgery.<sup>2,138</sup> However, similar difficulties arise for studies of synthetic antifibrinolytic drugs: statistical heterogeneity, suboptimal methodology, varied dosing regimes, different study populations, and small, underpowered studies. In particular, most studies are extremely small: 12 of these studies (67%) had less than 50 children in total and only one study had more than 100 children. A meta-analysis of studies in adult patients detailed 107 studies and a total of 11,000 patients.<sup>120</sup> There were 94 trials (just less than 10,000 patients) that examined aprotinin use in cardiac surgery. Risk of blood transfusion, volume of blood transfused, volume of blood loss, and requirement for reexploration were all reduced. As with lysine analogues, similar caveats exist with extrapolation of adult data to pediatrics. It appears a reasonable conclusion that aprotinin is effective at reducing blood loss during cardiac surgery and that this conclusion also applies to children. Importantly, there is evidence for efficacy in neonates, where a controlled trial demonstrated reduced blood loss, exposure to allogeneic blood products, and reexploration after arterial switch procedures.<sup>139</sup> A further randomized trial of aprotinin in

neonates was terminated early (because of the concerns about toxicity in adults), but it failed to show any advantage in indices of bleeding or postoperative recovery.<sup>140</sup>

#### Secondary Benefits of Aprotinin

While synthetic antifibrinolytics are selective inhibitors of fibrinolysis, aprotinin is a less specific inhibitor of proteolytic enzymes.<sup>15</sup> Proteolytic enzymes are important mediators of inflammation via contact activation and the complement system; it is postulated that aprotinin may exert a beneficial antiinflammatory effect. A number of studies have demonstrated a reduction in markers of inflammation; however, other studies have failed to demonstrate this effect.<sup>141</sup> A recent trial demonstrated reduced inflammatory markers postoperatively in infants treated with aprotinin in comparison to infants treated with TXA.<sup>142</sup> A further small study in older children undergoing mainly low complexity surgery failed to demonstrate any effect of aprotinin on a series of inflammatory markers compared to control.<sup>143</sup> There are no convincing clinical data to show any benefit from an antiinflammatory action of aprotinin. A trial designed to detect a reduction in ventilation days (as a marker of organ dysfunction) in neonates was terminated before an adequate number of patients had been recruited to identify a significant effect.<sup>140</sup>

#### Adverse Effects of Aprotinin

There is great concern about the adverse effects of aprotinin in adult patients. This followed the publication of an observational study in adults with acute coronary syndromes, which concluded that rates of renal failure, serious intravascular thrombosis (myocardial infarction and stroke), and of death (at 5 years) were increased if aprotinin was used.<sup>3,130</sup> The rate of these complications was not increased with the use of synthetic antifibrinolytics, whereas all agents appeared effective for reducing bleeding. This was followed by the early termination of a large randomized trial (BART trial), comparing synthetic antifibrinolytics and aprotinin (in "high risk" adults undergoing heart surgery), when interim analysis showed an increased mortality in the group treated with aprotinin.<sup>144</sup> Excess deaths appeared to result from heart failure and myocardial infarction. Rates of renal failure were not increased in those treated with aprotinin, although an increase in plasma creatinine was common. The relative risk of death in adults treated with aprotinin compared to those treated with either TXA or EACA was 1.53 with a 95% CI of 1.06 to 2.22. Data on bleeding in this study were inconclusive, although they suggested a small benefit for aprotinin for preventing severe bleeding. The conclusion of these papers was that aprotinin should not be used in the patient populations studied. This has led to differing responses from drug regulators and pharmaceutical companies in different countries. The drug is effectively unavailable in a number of countries; it has remained available in the UK on a restricted, named patient basis.

The implication of these studies for children and young adults with congenital heart disease is controversial. The use of aprotinin has reduced dramatically within the UK.<sup>122</sup> An important large observation series (over 30,000 patients) demonstrated no increased risk of death or dialysis in children,<sup>145</sup> and there was a significant reduction in length of stay for those undergoing reoperation. The main cause of death reported in adult patients was from stroke and myocardial infarction. Although thrombotic complications do occur in children, the pathogenesis and underlying risk factors are very different from those in adults (especially in adults with ischemic heart disease). Renal failure occurs in

children after high-risk operations, and may share pathogenic factors with postoperative renal failure in adults; aprotinin accumulates within renal tissue and affects local autoregulation of blood flow in response to ischemia. The evidence is unclear as to whether aprotinin causes any more than temporary derangement of renal function tests in adults or children. A further retrospective series demonstrated no increase in the incidence of renal failure in neonates when corrected for confounding variables.<sup>146</sup>

As with many polypeptides, anaphylactic reactions can occur with aprotinin. The reported incidence of adverse reactions in children varies, but the largest reported experience with aprotinin found 1 reaction from 2202 primary exposures (0.05%) and 6 reactions from 453 reexposures (1.3%). There have been no severe reactions to aprotinin since 1998 and this is attributed to the elimination of its use in recently exposed patients.<sup>147,148</sup> Studies report the incidence and severity of reaction to be less than that of adults. This may be due to the immature neonatal immune system.<sup>149</sup> It has been recommended that:

- Test dose and initial loading dose are not given until it is possible to rapidly initiate CPB (package insert).
- Aprotinin is avoided within 12 months of previous exposure (FDA recommendation).

### Dosing of Aprotinin

The lack of clarity regarding the efficacy of aprotinin in children may reflect differing doses used in clinical studies. Aprotinin rapidly redistributes into the extracellular space after IV administration. It is metabolized in the proximal renal tubules and eliminated in a biphasic pattern: a distribution half-life of 40 minutes and an elimination half-life of 7 hours.<sup>129,150</sup> A PK study of aprotinin in children undergoing CPB examined aprotinin concentrations after administration of weight-based dosing (25,000 KIU/kg bolus pre-CPB, 35,000 KIU/kg in CPB prime, and 12,500 KIU/kg/hour infusion).<sup>151</sup> Although there was considerable variation in plasma concentration of aprotinin, there was a correlation between concentration and weight at 5 minutes after administration and 5 minutes after cardiopulmonary bypass. This study can provide one possible explanation as to why there are such inconsistent results from aprotinin trials in children. Using a dose-per-weight regimen, the smaller children may fail to achieve therapeutic concentrations of aprotinin, in terms of plasmin inhibition and the possible antiinflammatory effects (a low concentration of aprotinin, e.g., less than 200 KIU/mL, would be insufficient to inhibit contact activation on the CPB circuit). This is consistent with greater clearance (expressed as per kilogram) in children (see also Chapter 6, Fig. 6-4). To achieve target concentrations, aprotinin should be given according to nonlinear functions (e.g., body surface area or an allometric  $\frac{3}{4}$ -power model; see Chapter 6), as opposed to the linear dose per kilogram. This would result in a 2.5 times greater dose in neonates than would otherwise be given.<sup>48</sup> A recent qualitative literature review suggested that an initial loading dose of at least 30,000 KIU/kg is required, followed by an infusion. The pump prime dose should be based on the volume of the pump rather than the weight of the child.<sup>149</sup>

### WHICH ANTIFIBRINOLYTIC DRUG FOR PEDIATRIC CARDIAC SURGERY?

A meta-analysis of trials in adult patients demonstrated no difference between EACA and TXA. Aprotinin was more effective than either TXA or EACA, and although that effect appeared

marginal, only aprotinin was demonstrated to reduce the risk of reoperation.<sup>120</sup> Direct comparison between TXA and EACA has demonstrated no difference in children.<sup>112,152</sup> Low-dose aprotinin (10,000 KIU/kg followed by 10,000 KIU/kg/hour) has been compared with EACA (100 mg/kg on induction, 100 mg/kg in the pump prime and 100 mg/kg on weaning CPB).<sup>110</sup> There was a reduction in postoperative blood loss and in transfusion requirements in both groups compared with control but no significant difference between the two drugs. These data are difficult to interpret because substantially larger doses of aprotinin are frequently used in current practice. More recently, TXA (100 mg/kg before, during, and after CPB) was compared with aprotinin (30,000 KIU after induction, 30,000 KIU in the pump, and 30,000 KIU after weaning off bypass). There was a reduction in the time to sternal closure, transfusion requirements, and blood loss compared with control, but no significant difference between the two drugs. When the two drugs were combined at the same doses, they showed no additional benefit.<sup>109</sup> A recent retrospective study confirmed these findings.<sup>153</sup>

There remains uncertainty about the comparative effectiveness of lysine analogues and aprotinin; data suggest that there are no differences or only marginal differences. The choice of antifibrinolytic will, therefore, depend on the adverse effect profiles and cost. The incidence of important adverse effects is also uncertain. Both mechanistically and from the available data it would appear that the recent “safety” concerns about aprotinin in adults may not be applicable to children. A more certain risk of aprotinin is anaphylaxis with repeated exposure. This is a concern because many pediatric cardiac patients (and a large proportion of those at a increased risk of severe bleeding) will undergo repeat surgery. The greater cost of aprotinin will also be difficult to justify in the absence of clear advantage over lysine analogues. In the absence of further studies, it is the authors’ conclusion that if an antifibrinolytic is indicated, lysine analogues are preferred over aprotinin.

### USE OF ANTIFIBRINOLYTIC DRUGS IN NONCARDIAC SURGERY

A recent trend has been towards increased use of antifibrinolytic drugs (especially TXA) during noncardiac surgery; principally major orthopedic surgery (e.g., spinal instrumentation, see also Chapter 30) and craniofacial surgery (see also Chapter 33). Aprotinin is less commonly used because of reduced availability and the safety concerns discussed previously.

There are 27 trials that have examined the use of TXA during orthopedic surgery in adults<sup>120</sup>; they report a 50% reduction in the relative risk of requiring a blood transfusion. There was a reduction in the incidence of total blood loss of over 400 mL in 20 of these trials. Almost all these studies were conducted in adults undergoing major joint replacement surgery. In one study of adults ( $n = 147$ ) undergoing posterior spinal fusion, TXA reduced total blood loss by 25%; however, the reduction in blood products transfused was not statistically significant.<sup>154</sup> The popularity of antifibrinolytic use during scoliosis surgery in children and adolescents is reflected in two surveys, which show use in 70% to 80% of hospitals.<sup>155,156</sup> It is unclear whether this use is mostly confined to higher-risk cases; however, in the authors’ institution TXA is currently used during all scoliosis surgery as part of a program aimed at reducing the use of blood products. Two meta-analyses have examined this question (looking at 6 and 7 studies, respectively); no individual study had more than 45 patients.<sup>2,157</sup> These meta-analyses conclude that antifibrinolytic

drugs reduce bleeding and volume of red cells transfused. To date there has been no single prospective trial that compares different antifibrinolytics. A retrospective comparison of TXA and EACA appeared to show superiority of TXA; however, doses used were not comparable.<sup>158</sup> The two meta-analyses failed to establish any difference between the drugs.<sup>2,157</sup> It is also not possible to determine whether reported benefits hold for all children undergoing scoliosis repair. Bleeding is greater in children with secondary scoliosis (including patients with Duchenne muscular dystrophy),<sup>159</sup> those with hemostatic disorders, and in those undergoing more extensive surgery; these might, therefore, be expected to see a greater advantage in terms of bleeding reduction. At least one study examined children with idiopathic scoliosis and demonstrated a reduction in blood loss with use of aprotinin (see also Chapter 30).<sup>160</sup> As with cardiac studies there is a considerable range in the dose of drug used; in a survey of practice in the UK, TXA dose ranged from three- to fivefold, whereas in published trials, the dose varied 10-fold.<sup>155</sup>

Antifibrinolytics are also used widely in craniostomies surgery. In a survey of North American practice, they were used in 20% of hospitals for strip craniotomy, rising to 30% for more complex repairs.<sup>161</sup> Four small trials (total 141 children) have addressed the use of these agents for this indication; three using TXA<sup>162-164</sup> and one using aprotinin.<sup>165</sup> All of these trials have demonstrated reductions in blood transfused and in bleeding. A recent publication demonstrated a greater than 50% reduction in the volume of blood transfused and in the proportion of children transfused (70% vs. 37%).<sup>162</sup> Although all these studies were relatively small, it would appear likely that antifibrinolytics produce a useful reduction in blood loss for craniostomies surgery.

#### ANTIFIBRINOLYTIC MEDICATION AND TRAUMA

There is no evidence in children concerning the use of antifibrinolytic medications to treat massive hemorrhage following trauma. The CRASH 2 study (a blinded randomized control trial of over 20,000 patients) demonstrated a reduction in mortality with TXA in adult trauma patients with, or at risk of, significant hemorrhage; mortality was reduced from 16% to 14.5%.<sup>166</sup> Mortality due to bleeding was reduced from 5.7% to 4.9%. No difference was seen in rates of vascular occlusive events. Despite the size and complexity of the study, it appears to have been properly randomized and blinded. It is difficult to see an explanation for the reduction in mortality, other than a reduction in bleeding. It is therefore likely that TXA can be efficacious in the treatment of established bleeding (at least in the context of trauma). Ideally, further studies would be required to establish the effectiveness of TXA in the treatment of established bleeding of other causes in children; however, it is unlikely a controlled trial of pediatric trauma would be large enough to be adequately powered. In the absence of such studies, and in the absence of definite evidence of toxicity, it would be reasonable to consider TXA as part of the treatment of established *severe* bleeding resulting from trauma or surgery. Some caution is required, and given the uncertainty concerning dosing, it would be premature to recommend the widespread use of the drug in young children. When used, it should be reserved for severe bleeding; for example, bleeding requiring treatment with non-red cell blood products. An important caveat to this is that administration greater than 3 hours after injury appeared to increase mortality.<sup>167</sup> The significance of this is unclear; however, such late administration should be avoided.

#### AUTHORS' RECOMMENDATIONS FOR USE OF ANTIFIBRINOLYTICS

There are 2260 children and more than 25,000 adults who have been recruited into trials that investigated antifibrinolytics during surgery. As a result, we can conclude that these drugs reduce bleeding during a variety of surgeries. However, the dose remains uncertain, important adverse effects unclear, the choice of drug open to question, and their effectiveness in different patient subgroups and clinical situations debatable. Further studies should be designed very carefully to address these questions. Establishing the safety of interventions, in particular with respect to uncommon but devastating complications, is a particular challenge. In the absence of this data it is not possible to make solid recommendations. One of the author's current practice is as follows:

- Antifibrinolytics are used routinely during heart surgery in children with cyanotic heart disease; especially in the presence of polycythemia, reduced saturations for a prolonged period, or iron deficiency.
- Antifibrinolytics are used during other cardiac procedures in children to help reduce the use of blood products. Greater benefit is likely (but not proven) in children with greater tendency to bleeding, including smaller children (when prolonged bypass times are anticipated) and repeat surgery.<sup>115,168</sup>
- Consideration is given to use of antifibrinolytics during other major noncardiac procedures in children to help reduce the use of blood products
- Synthetic antifibrinolytics are used in preference to aprotinin, outside of well-conducted trials.
- TXA is used in high dose: 50 mg/kg bolus followed by 15 mg/kg/hour infusion (plus if cardiac bypass is used an additional 50 mg/kg to the CPB pump). Infusion is continued until significant bleeding has stopped up to 4 hours postoperatively.
- EACA is not used by the authors, however, an appropriate dose would be 75 mg/kg bolus followed by 75 mg/kg/hour (plus, if cardiac bypass is used, an additional 75 mg/kg to the CPB pump).
- Synthetic antifibrinolytics are administered during severe bleeding, in the doses given previously; however, in the case of traumatic hemorrhage, they are not given more than 3 hours after the initial injury.

#### DESMOPRESSIN

Desmopressin acetate (1-desamino-8-D-arginine; DDAVP) is a synthetic analogue of vasopressin. The production of desmopressin involves alteration in the chemical structure of naturally occurring vasopressin. In the process, the antidiuretic effect is enhanced and the vasopressor effect is virtually eliminated. Desmopressin is more resistant to enzymatic cleavage, and hence the duration of action is prolonged to 6 to 24 hours.<sup>123</sup> Desmopressin potently causes endothelial release of factor complexes VIII/protein C and VIII/vWf. It has been used in mild hemophilia, von Willebrand disease, coagulopathy of uremia, liver failure, and in adults undergoing cardiac and spinal fusion surgery (see also Chapter 10).

During the early phase of coagulation, platelets bind via the glycoprotein receptor Ib to vWf on the damaged endothelium. IV desmopressin releases vWf, thus enhancing the binding of platelets to damaged endothelium. The maximum effect of desmopressin is observed at a dose of 0.3 µg/kg. It must be given *after* cessation of the extracorporeal circuit to prevent unwanted platelet activation.<sup>48</sup>

Several meta-analyses of its use in adults have been published, the most recent showing that desmopressin was associated with a small reduction in blood loss, but no benefit in terms of repeat sternotomy, proportion of patients requiring transfusion, or mortality.<sup>131</sup> It was also associated with a 2.4-fold increase in risk of myocardial infarction.

In children, desmopressin at 0.3 µg/kg failed to demonstrate any benefit for both non-high-risk<sup>169</sup> and high-risk cardiac surgery.<sup>170</sup> Younger children are not as capable of releasing vWf from endothelial storage sites as are older children, and the maximal release of vWf caused by the operative stimulus cannot be enhanced by desmopressin.<sup>171</sup> Potential adverse sequelae from desmopressin include fluid retention, hyponatremia, tachyphylaxis, tachycardia, and mild hypotension.<sup>172</sup> Desmopressin is not currently recommended in pediatric surgery,<sup>64</sup> although one could postulate that it could be reserved for those with ongoing bleeding with evidence of platelet function abnormalities, such as prolonged bleeding time or decreased maximum amplitude values on a TEG.<sup>173</sup>

### FACTOR VIIA

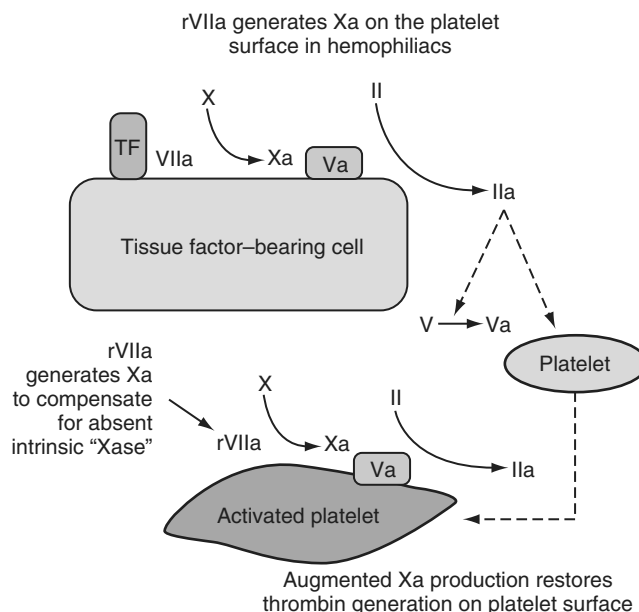

Recombinant activated factor VII (rVIIa) is known to be safe and effective for treatment and prevention of hemorrhage in children with hemophilia who have circulating inhibitors to replacement factors (see also Chapters 9 and 10). It is also used in patients with Glanzmann thrombasthenia refractory to platelet transfusion, and in patients with Factor VII deficiency. Regulatory approval has been granted in Europe and the United States for these conditions.

Off-label use of this drug has grown steadily over the last few years and now accounts for 97% of in-hospital use.<sup>125</sup> This has encompassed a number of indications involving treatment or prevention of acquired bleeding or coagulopathy<sup>174-186</sup> of varying severity. The most common off-label indications are treatment of bleeding related to cardiovascular surgery, trauma, and intracranial bleeds. Off-label use in children is also widespread. One retrospective study recorded 3655 administrations (in 39 U.S. pediatric hospitals over a 7-year period); 46% were in children admitted to a surgical specialty or to a pediatric intensive care unit, over 20% to cardiac surgery or cardiology. Administration was most common in children under 1 year of age.

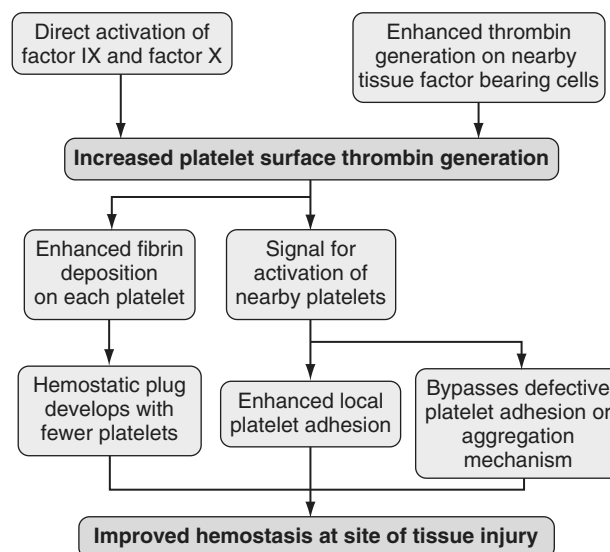

For rVIIa to exert a beneficial action, it must generate a burst of thrombin at the sight of injury. Two mechanisms are likely to work in synergy to produce this. First, the TF pathway described previously is stimulated to augment generation of factor Xa. Second, high concentrations of rVIIa will bind directly to the surface of activated platelets, again activating factor Xa, leading to thrombin production (Figs. 18-7 and 18-8).<sup>187</sup>

Usually such processes will be confined to the site of injury; however, in markedly proinflammatory states, expression of tissue factor on activated monocytes and platelets increases the risk of thrombosis distant from the injury. For this reason rVIIa is contraindicated in disseminated intravascular coagulation and should be used with caution in children on extracorporeal life support.<sup>188</sup> The importance of this to more routine bypass is unknown. The therapeutic effects of factor rVIIa begin at doses up to 10 times greater than physiologic concentrations of the endogenous factor. It is therefore not simply a “replacement” therapy of a deficient factor.<sup>147</sup>

The action of rVIIa is to produce a surge of thrombin; however, because clots comprise fibrin, platelets, and red cells, it is unlikely that rVIIa will be effective in the absence of these

**FIGURE 18-7** Schematic representation of the cell-based coagulation model and the proposed mechanism of how recombinant activated factor VII (rVIIa) can potentially improve coagulation in hemophiliacs. At supraphysiologic concentrations, rVIIa can bind to the phospholipid membranes of activated platelets, where it activates factor X independent of the tissue factor (TF) pathway, causing a large rise in thrombin at the platelet surface. It can therefore compensate for a lack of factor VIII or IX, a possible explanation for its effectiveness in platelet function disorders (From Welsby IJ, Monroe DM, Lawson JH, Hoffmann M. Recombinant activated factor VIIa and the anaesthetist. *Anaesthesia* 2005;60:1203-12.)

**FIGURE 18-8** Theoretical mechanisms by which recombinant activated factor VII could increase thrombin generation and fibrin deposition that may lead to improved hemostasis. (From Welsby IJ, Monroe DM, Lawson JH, Hoffmann M. Recombinant activated factor VIIa and the anaesthetist. *Anaesthesia* 2005;60:1203-12.)

substrates. Measures should be taken to ensure adequate fibrinogen concentration and platelet numbers before giving rVIIa. In addition, factors such as acidosis and hypothermia will reduce the efficiency of rVIIa (although mild to moderate hypothermia has only minor effects *in vitro*).<sup>148</sup> Given the expense of rVIIa,

in addition to doubts over safety, it would appear to be wise to employ more established measures before its use, along with (as dictated by local agreements) consultation with a hematologist.

Evidence that rVIIa will reduce bleeding comes mainly from case reports. Numerous anecdotes appear to demonstrate dramatic reductions in bleeding in apparently catastrophic situations. Demonstrations of even occasional success, in the face of an otherwise hopeless situation, might itself be taken as a good reason to use the drug. Events are rarely, however, that clear cut and rVIIa is often used on patients at much lower risk of bleeding to death. Reported cases of off-label use in anesthesiology and surgical practice range from truly prophylactic use (in high-risk populations before evidence of severe bleeding), to use to control prolonged or severe (but not immediately life-threatening) bleeding, through to compassionate use in immediately life-threatening bleeding after exhaustion of all conventional treatments. The balance of risk and benefit will vary widely within these differing clinical scenarios.

Most controlled trials of rVIIa have focused on prophylaxis use or use in less severe bleeding. There are 26 randomized controlled trials that have examined off-label use of rVIIa, and 5 have focused on surgical use.<sup>150,189-192</sup> A meta-analysis of these trials demonstrated no reduction in mortality and only relatively modest reductions in bleeding and transfusion.<sup>193</sup> A study<sup>190</sup> that examined patients with moderately severe bleeding (more than 200 mL/hr or greater than 2 mL/kg for 2 consecutive hours) following heart surgery in adults reported that although 2619 patients had consented to the trial, only 179 subsequently had sufficient bleeding to be randomized. The results demonstrated a reduction in reexploration, bleeding, and in transfusion requirements. The objective of the trial was to examine the safety of using rVIIa. Unfortunately, the trial was terminated early; although a trend to increased adverse effects was seen, the result was inconclusive. The authors of this study cautioned against wider use before further trials. A single randomized trial ( $n = 76$ ) that examined prophylactic rVIIa administration (40  $\mu\text{g/kg}$ ) in infants undergoing heart surgery,<sup>191</sup> demonstrated neither efficacy nor toxicity in this group. The study was small but larger than several of the adult studies that demonstrated an effect. Whether this demonstrates a genuine difference between adults and infants or is related to the relatively low dose rVIIa used is unclear. The use of rVIIa in children has been recently reviewed.<sup>188</sup>

Concerns about adverse effects of this drug have grown. Two studies have attempted to systematically review the data on toxicity.<sup>194,195</sup> The rate of thrombosis was greater (10.2% vs. 8.7%) in those treated with rVIIa, but this increase was largely confined to the elderly. The second study examined data from observational trials with comparator groups; mortality was not affected by treatment with rVIIa, although the risk of thrombosis was increased in some groups (including adult cardiac patients). Both these reviews combined data from studies on very different patient populations, and some caution is required in their interpretation. The risk of thrombosis in children is uncertain and data inconclusive.<sup>188</sup> Neonates treated with either FFP or rVIIa for similar indications had a similar incidence of thrombosis (7%).<sup>196</sup> Thrombotic complications occurred in 10.8% of children who received off-label rVIIa; the overall mortality in those receiving rVIIa was 34%.<sup>197</sup> It is not possible to know how this was affected by use of rVIIa. It is clear that both thrombotic complications and mortality are common in patients with bleeding serious enough to warrant use of this drug. Use of rVIIa will very likely increase the risk of thrombosis, although the impact

of this (and the benefit of the drug) will vary in different clinical situations.

The dose regimen for off-label use of rVIIa is yet to be firmly established. One of the difficulties is that there is no satisfactory laboratory test to monitor its effectiveness,<sup>198,199</sup> and factor VII activity does not always predict efficacy.<sup>200</sup> Although it is known that the PT, aPTT, and TEG improve after rVIIa is given in liver surgery,<sup>201</sup> they cannot reliably be used to determine a dosing regimen. If the main effect of rVIIa is at the site of injury, clinical observation still remains the best indication of effect.<sup>198</sup> The dose used often closely relates to the dose indicated in hemophilia patients (90  $\mu\text{g/kg}$ ), although in practice doses are often rounded to the nearest vial.<sup>201</sup> Although Warren et al. recommended a lower dose of 40 to 60  $\mu\text{g/kg}$ , a dose of 40  $\mu\text{g/kg}$  has been shown to have no effect.<sup>191</sup> Larger doses of 60 to 90  $\mu\text{g/kg}$  may prove more effective.

The justification to use larger doses is supported by differences in PK. In older children with hemophilia, the terminal elimination half-life of rVIIa is less than in adults (1.3 vs. 2.7 hours), and the clearance is greater (67 vs. 37 mL/kg/hour).<sup>202,203</sup> When prophylactic rVIIa at 100  $\mu\text{g/kg}$  was given to 10 preterm infants between 23 and 28 weeks gestational age every 4 hours for 72 hours, two umbilical artery catheter thromboses were reported and no embolic events or increase in intraventricular hemorrhage rate compared with those not given rVIIa.<sup>204</sup> There were no other treatment-related side effects, despite this large repeated dose, which suggests that a large study in neonates is warranted.

Since the previous edition of this book, there have been a considerable number of publications related to the use of rVIIa. Unfortunately, information, especially that concerning specific indications, remains sparse. It would appear that rVIIa can be effective for the treatment of severe bleeding refractory to other treatments, but it is certainly not universally effective. The risk of thromboembolic complications is substantial in those recovering from severe bleeding, and rVIIa is likely to increase this risk. There seems to be no reason to think that these considerations do not apply to children, although the balance of risk and benefit may be very different in children. It is the authors' current view that rVIIa should only be used for treating life-threatening bleeding that has proved refractory to other treatments. Outside of properly conducted trials, it should not be used for prevention of bleeding, treatment of less severe bleeding, or as an alternative to blood products. Its use should not delay surgical reexploration if indicated. Every attempt should be made to ensure an adequate platelet count, adequate fibrinogen concentration, correction of acidosis, and near normothermia before use.

## Summary

We began this chapter by reviewing the mechanism of coagulation and how this alters during normal development and disease. This understanding of coagulation has led to the development of new treatments, most notably rVIIa.<sup>12</sup> Complex systems such as the coagulation system behave in unanticipated ways and while mechanisms can be found to justify many interventions, not all interventions will bring a clinically useful improvement for the patient. The coagulation model becomes more complicated when we consider the interactions between coagulation and other systems (noticeably the kinin-kallikrein system<sup>15</sup> and other proinflammatory cascades), as well as the effects of transfusion of allogeneic blood products. Mechanistic justifications for use of any treatment are therefore limited. Direct evidence that a

specific treatment brings a benefit to the child is required. Although the evidence available is still lacking, and at times appear contradictory, we have aimed to give clear advice to the practicing anesthesiologist when possible.

The problems of research into this subject are demonstrated by aprotinin studies. Despite relatively large numbers of patients (including children) recruited into trials, many important questions remain incompletely resolved. Concerns over safety in an entirely different population have led to the effective withdrawal of what may (or may not) have been a useful medication in children. Beyond moderate reductions in blood loss, few advantages have been convincingly demonstrated for this drug.<sup>2</sup> For therapies aimed at treatment rather than prevention of bleeding, the challenges of conducting well-designed trials are even greater. Currently, several therapeutic approaches are proposed (rVIIa, fibrinogen concentrates, transfusion protocols based on TEG) that differ from traditional treatment. The requirement for well-conducted trials, with meaningful outcome measures, is greater than ever.

Future Directions

**THE NUMBER OF INFANTS** and children hospitalized with heart failure resulting from congenital or acquired heart disease continues to increase each year; according to a recent analysis of 15 million pediatric hospitalizations in the United States, this number grew by 25% between 2003 and 2006.<sup>1</sup> Failure of the myocardium, despite maximal medical therapy, to provide sufficient cardiac output for adequate support of end-organ perfusion results in the need for mechanical support of the circulation, either as an adjunct to cardiopulmonary resuscitation (CPR) or as a bridge to myocardial recovery or cardiac transplantation. Data from the Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart Failure Trial (REMATCH) demonstrated prolonged survival and increased quality of life in adult patients with end-stage heart failure who received mechanical cardiac support (MCS).<sup>2</sup> Although the number and type of MCS devices available for children remains comparatively limited, particularly for children weighing less than 20 kg in the United States, the use of extracorporeal life support in this population has continued to grow, with a 32% increase in the use of ventricular assist devices (VADs) between 2003 and 2006.<sup>3</sup> Initiatives by the National Heart, Lung, and Blood Institute (NHLBI) supporting the development of MCS devices for infants and children offer promising future alternatives for children.<sup>4</sup>

## Initiation of Mechanical Circulatory Support

### INDICATIONS AND CONTRAINDICATIONS

Mechanical circulatory support in children is most often necessary due to intrinsic failure of the myocardium. Preoperative cardiopulmonary stabilization may be required in children with profound hypoxemia and/or cardiovascular collapse due to hypercyanotic spells, pulmonary hypertensive crises, obstructed total anomalous pulmonary venous return, occlusion of systemic-pulmonary shunts, or cardiogenic shock (Table 19-1). Extracorporeal membrane oxygenation (ECMO) was used to bridge to surgical repair or palliation in 26 children, with 62% surviving to discharge and no observed differences in outcome between single and biventricular patients.<sup>5</sup> ECMO has also been successful in

stabilizing children with refractory dysrhythmias.<sup>6-8</sup> In a retrospective study, ECMO was used in nine infants with a variety of tachy- or bradydysrhythmias, with all nine surviving to discharge.<sup>9</sup> ECMO has also been used to stabilize children in the cardiac catheterization laboratory, both preemptively before high-risk interventional procedures<sup>10</sup> and as a rescue technique for catheter-induced complications, persistent low cardiac output, or hypoxemia.<sup>11</sup>

Postcardiotomy myocardial dysfunction can manifest as either early (inability to wean from cardiopulmonary bypass [CPB]) or late failure (sustained postoperative low cardiac output syndrome), with poor end-organ function, persistently increased plasma lactate concentrations, low mixed venous oxygen saturations, and escalating inotropic support. To maximize survival, it is essential to rule out the presence of residual surgical lesions, coronary insufficiency secondary to surgical manipulation, and mechanical problems (e.g., cardiac tamponade) before initiating MCS.<sup>12</sup> Both ECMO and left ventricular assist devices (LVADs) have been used for postoperative ventricular support in infants with anomalous origin of the left coronary artery from the pulmonary artery trunk (ALCAPA), either as a bridge to recovery or transplant.<sup>13,14</sup> The routine use of MCS after a Stage I Norwood procedure has also been advocated in order to optimize postoperative cardiac output.<sup>15</sup>

Other cardiac pathophysiologic processes, such as acute myocarditis, coronary ischemia, graft rejection after cardiac transplantation, or end-stage heart failure due to chronic cardiomyopathies, dysrhythmias, or congenital heart defects, may also warrant the use of MCS.<sup>16-18</sup> The steadily enlarging population of adults with congenital heart disease who develop heart failure will pose special challenges due to their complex anatomy and prior surgical palliations.

Noncardiac indications for MCS include severe hypothermia, drug toxicity, and near-drowning. ECMO can also provide short-term respiratory support for tracheobronchial reconstruction in infants and children with critical airways, when conventional mechanical ventilation is not feasible or has not been successful.<sup>19</sup> Although septicemia was initially considered a contraindication to MCS, a recent review of 45 children who required ECMO for hemodynamic support due to septic shock reported

**TABLE 19-1** Indications for Mechanical Circulatory Support

<b>Preoperative Stabilization</b>
Severe cyanosis/hypercyanotic spells
Pulmonary hypertensive crises
Myocardial dysfunction
Malignant dysrhythmias
Sepsis
<b>Postcardiotomy Patients</b>
Failure to wean from cardiopulmonary bypass
Late postcardiotomy failure (prolonged low cardiac output syndrome)
Stage I palliation for hypoplastic left heart syndrome
After ALCAPA repair
Malignant dysrhythmias
<b>Bridge to Myocardial Recovery</b>
Acute myocarditis
Cardiomyopathy
Acute cardiac transplant rejection
<b>Bridge to Transplantation</b>
Direct bridge to transplantation
Bridge to bridge (short- to long-term support)
<b>Noncardiac Indications</b>
Near-drowning
Severe hypothermia
Drug toxicity
Critical airway (tracheal stenosis)
Sepsis/shock
ALCAPA, Anomalous origin of the left coronary artery from the pulmonary artery.

a 47% survival to discharge.<sup>20</sup> ECMO can provide a bridge to lung transplantation or retransplantation, and posttransplantation can be used in cases of severe primary graft dysfunction, although survival in these patient groups remains less overall than for other indications.<sup>21-23</sup>

Contraindications to implementation of MCS should be considered on a case-by-case basis and may include advanced multisystem organ failure, significant neurologic damage or intracranial hemorrhage, severe coagulopathy, and/or extreme prematurity. Additionally, the presence of certain chromosomal abnormalities, multiple congenital anomalies, or existing infections may influence decision making. For children who require MCS secondary to a cardiac etiology, due consideration should be given to the likelihood of recovery of myocardial function before instituting support; and if not, whether the child is a suitable candidate for cardiac transplantation.

#### **TIMING AND PREPARATION FOR THE INITIATION OF SUPPORT**

As experience with the use of pediatric circulatory support continues to grow, it has become increasingly evident that early institution of support better preserves end-organ function and maximizes the opportunity for recovery or bridge to transplantation. The following criteria for implementation of MCS have been used in one institution: (1) cardiac index less than 2 with inotropic dependence; (2) poor peripheral perfusion with metabolic acidosis and mixed venous oxygen saturation less than 40%; (3) signs of impending respiratory, renal, or hepatic failure;

**TABLE 19-2** Suggested Clinical Criteria for Mechanical Cardiac Support Implementation

#### **Rapid Circulatory Deterioration (CI <2 L/min/m<sup>2</sup>)**

Inotropic dependence

#### **Critical Peripheral Perfusion**

Development of metabolic acidosis

Mixed venous oxygen saturation <40%

#### **Signs of Renal, Hepatic and Respiratory Failure**

Ventilatory support with increasing FiO<sub>2</sub>

#### **Critically Impaired Myocardial Function on Echocardiography**

High or rapidly increasing B-type natriuretic peptide

Modified from Hetzer R, Potapov EV, Alexi-Meskishvili V, et al. Single center experience with treatment of cardiogenic shock in children by pediatric ventricular assist devices. *J Thorac Cardiovasc Surg* 2011;141:616-23; and Potapov EV, Stiller B, Hetzer R. Ventricular assist devices in children: current achievements and future perspectives. *Pediatr Transplant* 2007;11:241-55.  
CI, Cardiac index.

and (4) increased or rapidly increasing B-type natriuretic peptide (BNP) concentrations (Table 19-2).<sup>24</sup>

During routine preparation for MCS, baseline laboratory hematologic studies should be obtained, including a complete blood cell count (CBC), platelet count, prothrombin time (PT), activated partial thromboplastin time (aPTT), activated clotting time (ACT), plasma hemoglobin, antithrombin III, fibrinogen, and thromboelastogram (TEG). A minimum of two units of packed red blood cells (PRBCs) should be available (preferably cytomegalovirus-negative, leukocyte-reduced, and irradiated), because all such children should be considered potential cardiac transplant candidates (note that the potassium concentration of irradiated PRBCs may be greatly increased, resulting in acute hyperkalemia if administered rapidly) (see also Chapter 10). In infants, ultrasonography of the head is useful before considering institution of MCS. Anesthesiologists are frequently involved during the cannulation procedure, and all arterial and central venous lines, as well as the tracheal tube, should be well secured and the ventilator easily accessible.

The emergent use of ECMO for children during in-hospital cardiac arrest with failure of conventional resuscitation methods has become increasingly common. An analysis of data from the National Registry of CardioPulmonary Resuscitation (NRCPR) database of outcomes from children less than 18 years of age who received extracorporeal cardiopulmonary resuscitation (ECPR) for cardiac arrest that was refractory to conventional CPR demonstrated a 43.7% survival to discharge. Preexisting conditions of septicemia, pneumonia, and renal insufficiency correlated with an increased risk of mortality. Children with a cardiac disease diagnosis showed slightly improved odds of survival to discharge when compared with children without cardiac disease.<sup>25</sup> In a review of pediatric cardiac patients from the Extracorporeal Life Support Organization (ELSO) registry who received ECPR, single ventricle physiology and a history of more complex cardiac surgery were negative predictors of survival.<sup>26</sup> Renal dysfunction, pulmonary hemorrhage, neurologic injury, and the need for additional CPR during ECMO have also been associated with increased mortality.<sup>27</sup>

Acceptable neurologic outcomes have been described in children after CPR of up to 3 hours in duration before institution

of ECMO.<sup>28</sup> The duration of CPR before ECMO cannulation did not differ between survivors and nonsurvivors.<sup>29</sup> Of the children in the ELSO registry who received ECPR, 22% of the 682 developed an acute neurologic injury, with an in-hospital mortality rate of 89%. The risk of neurologic injury in children with cardiac disease in this cohort was reduced.<sup>30</sup>

A dry circuit can be kept ready for rapid deployment, with crystalloid prime used during initiation of support and addition of blood products (PRBCs and fresh frozen plasma) as soon as they become available. During resuscitative efforts before the institution of mechanical support, multiple doses of vasoconstrictors should be avoided, if possible, acidosis should be corrected, and ice may be placed around the head to provide cerebral protection. Ultimately, the restoration of cardiac output, even with a low hematocrit, is the most important factor for successful resuscitation and long-term survival.<sup>31,32</sup>

## Mechanical Circulatory Support Devices

In pediatric practice, the size of the child and the type of support required (cardiopulmonary vs. cardiac) are the most important considerations when choosing an MCS device (Table 19-3). Secondary factors are the indication for, and expected duration of, support and the desired end point: bridge to bridge, procedure (surgery or catheterization), recovery, or transplantation. Certain devices, such as the intra-aortic balloon pump (IABP), ECMO, and centrifugal pump, are best used for short-term support (less than 2 to 4 weeks) and may occasionally serve as a “bridge to bridge” for institution of a long-term mechanical support device.<sup>33</sup>

A VAD may be defined most simply as a mechanical pump attached between the heart and either the aorta or pulmonary artery to circulate blood when one or both ventricles are no longer capable of adequately maintaining circulation. In short, a VAD is a pump supporting a failing ventricle, whether right, left, or biventricular (BiVAD). Isolated ventricular dysfunction with adequate oxygenation, as seen in acute myocarditis, acute rejection after cardiac transplantation, or dilated cardiomyopathy, is the ideal cardiac pathology for VAD support. ECMO, on the other hand, provides full cardiopulmonary support and may be preferable to VAD support for children with pulmonary hypertension, complex congenital heart lesions involving intracardiac shunts, severe hypoxemia, or respiratory failure (Fig. 19-1).

### SHORT-TERM SUPPORT

#### Intra-Aortic Balloon Pump

IABPs are support devices with a balloon ranging from 2.5 to 20 mL in size mounted on a 4.5F to 7F catheter that may be inserted either via the femoral artery or, in infants, via the ascending aorta. The balloon inflates during diastole, forcing blood toward the heart and increasing blood flow to the coronary arteries, and deflates before systole, decreasing ventricular afterload. Cardiac output is augmented by 10% to 20%, whereas left atrial, left ventricular end-diastolic, and pulmonary artery pressures are all decreased.

Anatomic contraindications to the use of an IABP include patent ductus arteriosus, aortic insufficiency, aortic aneurysm, and recent aortic surgery. Technical limitations in children consist of size constraints, the increased distensibility and compliance of the aorta, and the difficulty of synchronizing pump function with an infant or child's rapid heart rate,<sup>34</sup> although use of M-mode echocardiography-timed IABP in infants and children to assist with cardiac synchronization has been described.<sup>35</sup> IABP use in

**TABLE 19-3 Mechanical Circulatory Support Devices: Advantages and Disadvantages**

Device	Advantages	Disadvantages
ECMO	No patient size limitations Cardiopulmonary support Central or peripheral cannulation Relatively inexpensive Extensive pediatric experience	Short-term support Increased bleeding and thromboembolic complications More complex circuit Nonpulsatile flow No patient mobility Need for trained personnel
Centrifugal VAD	No patient size limitations Right, left, or biventricular support Simpler setup than ECMO Less anticoagulation than ECMO Better ventricular unloading than ECMO	Short-term support No respiratory support Nonpulsatile flow No patient mobility Direct cannulation of the heart required
Thoratec	Pulsatile flow Right, left, or biventricular support Extubation/ambulation possible	BSA >1.2 m <sup>2</sup> Sternotomy required for implantation
Berlin Heart Excor and Medos HIA-VAD	No patient size limitations Pulsatile flow Right, left, or biventricular support Extubation/ambulation possible Long-term support possible	Not currently available in the United States Sternotomy required for implantation
MicroMed DeBakey Child VAD	Noiseless pump No compliance chamber No artificial valves Fewer moving parts Small blood-to-device interface Long-term support possible	BSA >0.7 m <sup>2</sup> Only left ventricular support

an adult patient with Fontan physiology and severe ventricular failure has been reported, with improvement in end-organ function and successful weaning.<sup>36</sup> IABP support must be initiated early, while ventricular function is still capable of sustaining adequate cardiac output,<sup>37</sup> because the balloon pump only augments, and does not replace, ventricular output. It can only support the left ventricle.

#### Extracorporeal Membrane Oxygenation

Whereas adults generally have isolated left ventricular failure, children more often require cardiopulmonary support due to hypoxemia, pulmonary hypertension, or concurrent right ventricular failure. For infants and children who require short-term or urgent cardiopulmonary support, ECMO remains the modality of choice. Initially reported for the treatment of cardiac failure in children in the 1970s,<sup>38</sup> ECMO was subsequently used for mechanical support during interhospital transport.<sup>39</sup> Since the ELSO registry began in 1989, ECMO has been the MCS

**FIGURE 19-1** A, Right and left ventricular assist circuits. For biventricular assist, both the right ventricular assist device (VAD) and left VAD circuits are used. B, Venoarterial extracorporeal membrane oxygenation circuits using either a venous reservoir and roller pump, or a centrifugal pump without a reservoir.

modality with the most pediatric usage, with more than 7500 neonates and children using it for cardiac indications.<sup>40</sup>

A typical ECMO circuit is composed of a pump (either a roller pump with a servoregulatory mechanism for controlling circuit flow or a centrifugal pump); a hollow fiber or membrane oxygenator; a heat exchanger; and cannulas (either venoarterial or venovenous). A modified ECMO circuit composed of a heparin-coated circuit, Bio-Medicus centrifugal pump (Medtronic, Minneapolis), hollow fiber membrane oxygenator, flow probe, and hematocrit/oxygen saturation monitor, allowing the circuit to be set up and primed in 5 minutes for rapid resuscitation, has been described.<sup>41</sup> Most hospitals supporting such a service have readily available trained personnel to assist with implementing and maintaining ECMO therapy. Versatility is one of the advantages of ECMO; venoarterial cannulation in postcardiotomy patients may be either transthoracic via the right atrial appendage and aorta, transcervical via the right internal jugular vein and common carotid artery, or femoral via the femoral artery and vein in larger patients. Heparin-bonded circuitry is often used to minimize surface-induced complement activation, platelet dysfunction, and anticoagulation requirements.<sup>42</sup>

Other advantages of ECMO include the lack of patient size limitations, the ability to institute support either in the pediatric intensive care unit or the operating room without the need for CPB, the ability to provide ultrafiltration or hemodialysis for children during mechanical support, and the ability to provide biventricular cardiopulmonary support even in very small children. In a review of 27 children who underwent venoarterial ECMO for cardiac indications, both nonsurgical and postcardiotomy, the overall survival rate was 59%; of these, 56% were undergoing CPR at the time ECMO support was instituted. Of the latter group, 73% survived.<sup>43</sup> Hemodynamic benefits of ECMO include decreased right ventricular preload and pulmonary artery pressures. Due to reentry of blood into the aorta an increase in afterload often occurs and may require pharmacologic afterload reduction therapy, such as milrinone, nitroprusside, hydralazine, or phenoxymethylamine.

Several management options exist for children with single-ventricle physiology and shunt-dependent pulmonary circulation who require ECMO support. The survival rate of 10 children who underwent single-ventricle palliation and subsequently required ECMO support was greater in those in whom the aortopulmonary shunt was left open during ECMO.<sup>44</sup> Adequate alveolar ventilation must be provided, however, and greater ECMO flow rates are generally required to maintain adequate pulmonary and systemic circulations. In children with low pulmonary vascular resistance, pulmonary blood flow may prove to be excessive and limitation of shunt flow with surgical clips may become necessary. Children with single-ventricle physiology have comparable survival rates after ECMO support compared with other cardiac patients.<sup>43</sup> ECMO has been particularly successful in treating children with single-ventricle physiology who develop acute shunt thrombosis or transient depression of ventricular function.<sup>45</sup> Of 44 children with shunted single-ventricle physiology who required ECMO support, the indication for support was the strongest predictor of survival to discharge, with 81% of those cannulated due to hypoxemia surviving, but only 29% of those cannulated for hypotension surviving to discharge.<sup>46</sup> Patients with Fontan physiology who require ECMO have a significantly greater mortality rate (65%), possibly the result of longstanding ventricular dysfunction that is not easily reversible.<sup>47</sup>

Disadvantages of ECMO include complex circuitry, the need for greater levels of systemic anticoagulation than required by VADs, the necessity for both blood prime and frequent transfusions, and decreased pulmonary blood flow. Compared with other support modalities, ECMO circuitry is complex and requires full-time supervision by trained personnel. Left atrial decompression may occasionally be inadequate, requiring either the placement of a left atrial vent or an atrial septostomy. Inadequate unloading of the left atrium can lead to mitral regurgitation and pulmonary edema or hemorrhage, and can also minimize the chances of myocardial recovery when the left ventricle is not sufficiently unloaded. Moderate levels of ventilatory

FIGURE 19-2 Maquet's RotaFlow system. (Courtesy Maquet Cardiovascular, LLC, Wayne, N.J.)

support must be maintained to ensure that well-oxygenated blood is provided to the coronary arteries, and the child must remain intubated and sedated throughout the period of ECMO support.<sup>48</sup>

Although effective for rapid rescue and short-term support, ECMO support is generally maintained only for 1 to 3 weeks before the increasing risk of significant complications limits its usefulness.<sup>49</sup> In children requiring postcardiotomy ECMO support, the need for prolonged support, renal failure, and low pH in the first 24 hours of support have been associated with a higher mortality.<sup>50</sup> A review of combined data between 2004 and 2009 from the ELSO registry and the Organ Procurement Transplant Network database showed that over half the children bridged with ECMO to heart transplant failed to survive to hospital discharge, illustrating that ECMO is not able to reliably provide intermediate to long-term mechanical support to bridge children safely to transplantation.<sup>51</sup> Survivors of ECMO support also have greater rates of neurologic impairment than those supported with VADs, with poorer outcomes noted in younger children with more complex disease.<sup>52</sup>

### Centrifugal Pumps

Currently used centrifugal pumps include the Bio-Medicus Bio-Pump (Medtronic, Minneapolis), CentriMag (Levitronix GmbH, Zurich), RotaFlow (Maquet Cardiovascular, Wayne, N.J.), Capiiox (Terumo Cardiovascular Systems Corporation, Ann Arbor, Mich.) and TandemHeart (CardiacAssist, Inc., Pittsburgh). The CentriMag pump is available as an investigational device only in the US. The term *centrifugal pump* is not always synonymous with VAD, because centrifugal pumps may also be used with an oxygenator to construct an ECMO circuit. Without an oxygenator, they may be used for right, left, or biventricular support (except in infants, when size limitations can preclude the presence of two pumps<sup>53</sup>) and offer the advantage of excellent ventricular unloading and decreased wall stress, optimizing the chances of myocardial remodeling and recovery. Unloading the left ventricle can also decrease left ventricular cavity size and improve septal configuration, resulting in improved tricuspid valve function and right ventricular inflow.<sup>54</sup> When used as a VAD without an oxygenator and heat exchanger, reduced systemic anticoagulation is required, compared with ECMO usage.

Centrifugal pumps offer the advantage of decreased trauma to red blood cells and a less pronounced systemic inflammatory response compared with roller pumps.<sup>55</sup> A centrifugal VAD spins, creating a vortex, with negative pressure at the inlet drawing blood into the cone and positive pressure at the outlet allowing nonpulsatile ejection at the base. The RotaFlow pump (Fig. 19-2) has a rotating mechanism that is levitated in three magnetic fields with one point bearing, allowing laminar flow and reducing mechanical friction, heat production and clotting potential compared to the Bio-Medicus pump.<sup>56</sup> Cardiac output from a centrifugal pump depends on preload, afterload, and the rotational speed of the pump. Because increases or decreases in preload and afterload can affect pump flow without changes in rotational speed, a flow probe is necessary. Excessive negative inlet pressures (hypovolemia) must be avoided because air can be entrained into the circuit.

The TandemHeart system is a low-prime centrifugal pump capable of flows of 0 to 5 L/min, with a hydrodynamic fluid bearing supporting the spinning rotor (Fig. 19-3). Although size requirements (greater than 40 kg) preclude its use in most children, it is advantageous in that it can be placed percutaneously through the femoral vessels, with a transeptal extended flow cannula allowing entry from the femoral vein into the left atrium. The arterial cannula may be placed into the femoral artery, or in patients less than 80 kg, a vascular graft to the femoral artery may be cannulated to avoid lower extremity vascular compromise.<sup>57</sup> A pediatric TandemHeart pump with a priming volume of 4 mL for children from 2 to 40 kg is currently undergoing in vitro testing.<sup>58</sup>

Compared with ECMO, centrifugal pumps are less expensive and can be set up more rapidly, they have reduced priming volumes, and reduced anticoagulation requirements. Disadvantages of centrifugal pumps include the potential for circuit thrombus formation, nonpulsatile flow, and limited duration of usage (usually less than 3 weeks). Excellent outcomes with centrifugal VAD support have been reported in children who required postcardiotomy ventricular MCS of limited duration, such as those with ALCAPA, or ventricular failure due to cardiomyopathy.<sup>59</sup> In addition, fewer post-support neurologic complications were noted in children who received VAD support compared with those who received ECMO for similar indications.<sup>60</sup>

## INTERMEDIATE- TO LONG-TERM SUPPORT

### Pulsatile Pumps

Pulsatile pumps are VADs that facilitate chronic support of the circulation while also allowing tracheal extubation, the use of enteral nutrition, and ambulation for the child. They are paracorporeal and either pneumatically or electromechanically driven. Like centrifugal pumps, pulsatile VADs enjoy several advantages over ECMO: they are simpler in design, less expensive, require lower levels of anticoagulation, and may be used for left, right, or biventricular support of the circulation. Unlike the previously discussed devices, pulsatile pumps are suitable for intermediate- to long-term mechanical circulatory support, but until the advent of the Berlin Heart Excor, their use in infants and children was severely limited by patient size constraints. Internationally, the Berlin Heart Excor and the Medos HIA-VAD pulsatile systems (Berlin Heart GmbH, Berlin, and Medos Medizintechnik AG, Stolberg, Germany, respectively) have been successfully used in children of all ages.<sup>61,62</sup> Insertion of a pulsatile VAD requires the use of CPB and closure of any existing septal defects.

### Thoratec

The Thoratec pulsatile ventricular assist system (Thoratec Corporation, Pleasanton, Calif.) is a pneumatically driven pump with a 65-mL blood sac, Björk-Shiley tilting disc valves, and exteriorized inflow and outflow cannulas (Fig. 19-4). Inflow may be from either the left atrium or left ventricular apex, with outflow to the aorta. Pump output, depending on the cannula size and length,

FIGURE 19-4 **A**, Thoratec pulsatile ventricular assist device. **B**, Thoratec HeartMate II axial pump. (Courtesy Thoratec Corporation, Pleasanton, Calif.)

may vary from 5 to 7 L/min.<sup>63</sup> The Thoratec pulsatile VAD may be operated in three modes: synchronized to the child's underlying heart rate, asynchronous, with a set rate programmed into the device, or fill-to-empty, in which the device fills to a set volume before ejection. Although use of the Thoratec has been described in children as small as 17 kg,<sup>64</sup> the risk of thromboembolic events is greater in smaller children, because lower blood flow in the relatively oversized device can lead to stasis and thrombus formation.<sup>65</sup> Children with congenital heart disease and/or left atrial cannulation are at greater risk for neurologic complications during Thoratec support.<sup>66</sup> The use of a fixed-rate mode, with an increased stroke rate of 80 to 90 per minute and partial stroke volumes, is currently recommended because it is associated with fewer cerebrovascular events. Anticoagulation for the Thoratec VAD initially consists of a heparin infusion, whereas long-term protocols generally use warfarin (Coumadin) and aspirin, with maintenance of an international normalized ratio (INR) of 2.5 to 3.5.<sup>67</sup>

The worldwide experience with the Thoratec paracorporeal VAD in 209 children younger than 18 years of age, ranging from 17 to 118 kg and with a body surface area (BSA) of 0.7 to 2.3 m<sup>2</sup>, has been summarized. Overall survival to discharge was 68%, but subgroups with cardiomyopathies and myocarditis had greater survival rates than did children with congenital heart disease. Device configuration and the type of support used (LVAD vs. BiVAD) were not correlated with negative patient outcomes.<sup>68</sup>

#### Berlin Heart Excor

First used in adults in 1987,<sup>69</sup> the Berlin Heart Excor is a pulsatile, paracorporeal pump currently manufactured in three pediatric sizes (10, 25, and 30 mL) and three adult sizes (50, 60, and 80 mL) (Fig. 19-5, *A*). The pediatric version was first used in 1992<sup>70</sup> and has since been successfully employed in neonates and

infants with a BSA as low as 0.2 m<sup>2</sup>.<sup>61</sup> An investigational device exemption trial was begun in the United States in 2007; before this, the Berlin Heart was used nearly 100 times in North America at 29 different institutions, under compassionate use regulations. A recently published review of 73 of these initial patients (weight 3 to 87.6 kg) revealed a 77% success rate in bridging to either transplant or recovery, with a median support time of 1.6 months. Younger age and the need for BiVAD support were risk factors for increased mortality.<sup>71</sup>

The Berlin Heart Excor design has not changed since 2001, and consists of a pneumatically driven translucent polyurethane pump, trileaflet polyurethane inlet and outlet valves, and silicone inflow and outflow cannulas. All blood-contacting surfaces, including the polyurethane valves, are heparin-coated (Carmeda AB, Upplands Väsby, Sweden). A flexible diaphragm in three layers divides the pump chamber into an air chamber and a blood chamber (Fig. 19-5, *B*), with the two diaphragm layers facing the air chamber serving as driving membranes and the third seamless blood membrane passively moved by the driving membranes.<sup>72</sup> The Berlin Heart Excor has been successfully used to provide univentricular (left or right) or biventricular support, even in infants, and may be operated in a synchronous, asynchronous, or fill-to-empty mode. A rechargeable battery is available that can provide up to 5 hours of independent power supply for adult-sized pumps, but power requirements are greater for pediatric pump operation, owing to the greater flow resistance with small-diameter cannulas and greater pump rates.<sup>73</sup>

Although initial outcomes were not as favorable in infants and children with congenital heart disease,<sup>74</sup> survival rates of 70% have now been reported for children younger than 1 year of age, even those requiring prolonged support. Improvements in survival have been attributed to the development of optimized

**FIGURE 19-5** *A*, Berlin Heart Excor ventricular assist device in pediatric and adult sizes. *B*, A flexible diaphragm in three layers divides the pump chamber into an air chamber and a blood chamber. (From Hetzer R, Potapov E, Stiller B, et al. Improvement in survival after mechanical circulatory support with pneumatic pulsatile ventricular assist devices in pediatric patients. *Ann Thorac Surg* 2006;82:917-25.)

miniaturized apical cannulas, the addition of heparin-coated tubing allowing lower anticoagulation levels, the use of dipyridamole and aspirin after week 1 of support, and continued experience with surgical and intensive care management with use of TEGs and platelet function tests to guide the modification of anticoagulation.<sup>61</sup> In a single-center review of their Berlin Heart Excor experience, comparing the 1990-to-2001 experience with the current era (from 2002 onward), the percent of infants less than one year of age discharged to home after transplantation or weaning increased from 17% in the early era to 93% in the current era. The majority of children successfully weaned from support had a diagnosis of myocarditis, with no long-term complications after removal of the left ventricular cannula reported. Major causes of mortality in both eras were cerebrovascular accidents and multiorgan failure.<sup>24</sup>

Major benefits of Berlin Heart Excor support include the ability to extubate the trachea of children, encourage enteral nutrition, and optimize patient mobility during chronic support. In addition, the transfusion of blood products during MCS is less in children supported with the Berlin Heart Excor when compared with those supported with ECMO. In a study comparing 30 children receiving Berlin Heart Excor support to 34 children on ECMO support, transfusion requirements for platelets, red blood cells, and fresh frozen plasma were significantly less in Berlin Heart Excor patients. The overall mortality rate was also noted to be lower in Berlin Heart Excor patients.<sup>75</sup> Anticoagulation is currently initiated with unfractionated heparin, maintaining aPTT at 60 to 80 seconds. TEG is also used, along with platelet aggregation tests, to monitor the use of aspirin and dipyridamole. Antithrombin III concentrations are closely monitored and substituted if the concentrations fall below 70%.<sup>72</sup> Low-molecular-weight heparin (LMWH), with monitoring of anti-factor Xa concentrations, has been used since 2007.<sup>24</sup> Pump exchange may be necessary if thrombus formation occurs in the valves, although one group reported no complications from this procedure during 15 years of adult and pediatric experience.<sup>76</sup>

### Medos System

The Medos HIA-VAD was first used for children in 1997.<sup>77</sup> The Medos HIA-VAD is a pulsatile, paracorporeal pump available in several different sizes; it differs from Excor in that the left ventricular pumps offer 10% greater stroke volumes than the corresponding right ventricular pumps.<sup>78</sup> Survival has been reported to be 57% in children (ranging in age from less than 1 year to 16 years) awaiting cardiac transplantation.<sup>79</sup>

### Continuous Flow Pumps

Continuous flow pumps can be either axial or centrifugal, depending on the design of the impeller, and are designed to limit the interaction of moving parts. The MicroMed DeBakey VAD Child (MicroMed Cardiovascular, Inc., Houston) is an axial flow device currently available for use in the United States for children 5 to 16 years of age, through a US Food and Drug Administration (FDA) human device exemption. It was first introduced for use in March 2004, making it the first FDA-approved intracorporeal device for provision of left ventricular MCS as a bridge to transplantation in the pediatric population. Children must have New York Heart Association class IV end-stage heart failure that is refractory to medical management, be currently listed for cardiac transplantation, and have a BSA between 0.7 and 1.5 m<sup>2</sup> to be considered candidates for DeBakey VAD Child support. The MicroMed DeBakey VAD Child is

placed via median sternotomy using CPB. A titanium inlet cannula is sutured into the apex of the left ventricle via a circular core ventriculotomy, and a 12-mm gel-weave outflow graft is then anastomosed to the ascending aorta.<sup>80</sup> A percutaneous cable containing the pump power and flow probe cables passes through the skin to the clinical data acquisition system. A separate unit, the "VADPAK," contains a pump controller and two 12-volt batteries in a carrying case that can allow 5 to 8 hours of patient mobility.<sup>81</sup>

The Thoratec HeartMate II (see Fig. 19-4, *B*) is an intracorporeal, axial flow device that has been approved by the FDA for use as bridge-to-transplant and destination therapy in adults. Although recommended for use in patients with a BSA greater than 1.5 m<sup>2</sup>, its use has been reported in adolescents with a BSA as low as 1.3 m<sup>2</sup>. The HeartMate II has a low thromboembolic risk compared to other devices, and anticoagulation is managed using vitamin K antagonism and antiplatelet therapy (aspirin and dipyridamole). The portable system controller is also small enough to wear on a belt, allowing unencumbered movement for several hours, and potentially even discharge home.<sup>82</sup> The VentrAssist (Ventracor Limited, Chatswood, Australia) was another small, implantable, continuous-flow device that had been successfully used in patients with a BSA as small as 1.1 m<sup>2</sup> for prolonged support, allowing both bridge to recovery and to transplantation.<sup>83</sup> Unfortunately this device is currently unavailable.

Like a centrifugal pump, axial pump function depends on the preload and afterload. Decreases in preload can cause emptying and collapse of the ventricle, whereas increases in afterload initially result in reductions in forward flow and ultimately can lead to regurgitant flow. Axial pumps offer several advantages over pulsatile pumps, including their small blood-to-device interface, the lack of a compliance chamber or artificial valves, and fewer moving parts. They are quieter than pulsatile pumps, which is a decided advantage for the child. Axial pumps can also allow some pulsatile flow to occur as the ventricle recovers, and cardiac output can increase in response to increased patient activity. The major disadvantages for children are the continuing size limitations for placement and the fact that the device provides only left ventricular support.

### OUTCOMES

According to the Healthcare Cost and Utilization Project Kids' Inpatient Database, 187 children underwent VAD implantation in 2006 in 67 different U.S. hospitals. High-volume large teaching hospitals reported significantly greater survival rates and reduced costs compared with other institutions.<sup>3</sup> Regardless of the type of MCS chosen, it has become increasingly clear that the indication for and timing of initiation of support are major factors in determining outcome. Universally, survival has been greater in children who required support secondary to acute myocarditis or dilated cardiomyopathy, as compared with children who received support due to congenital heart defects or postcardiotomy failure.<sup>84</sup>

When feasible, VADs offer several major advantages over ECMO. First, the lack of an oxygenator simplifies the circuit, lessening anticoagulation requirements, as well as trauma to blood elements. Second, ECMO-supported patients have been shown to suffer greater rates of neurologic impairment than those supported with VADs, particularly in younger children with more complex heart disease.<sup>52</sup> Additionally, evidence suggests that VAD support provides superior ventricular decompression and physiologic rest, promoting myocardial recovery in children with

acute myocarditis or dilated cardiomyopathy by allowing normalization of ventricular geometry and reverse remodeling.<sup>85-87</sup> A pilot study in children suggests that even short-term LVAD support of 1 to 2 weeks can reverse molecular remodeling.<sup>88</sup>

Children with chronic heart failure awaiting transplantation who experience progressive multiorgan dysfunction have been shown to benefit from the use of pulsatile VADs with potential recovery of pulmonary, renal, and hepatic function.<sup>89</sup> A review of 55 pediatric patients revealed significantly increased survival rates in children who received Berlin Heart Excor support compared with those who received ECMO, despite a mean duration of support that was nearly three times as great in the Excor group.<sup>90</sup> A multiinstitutional study reviewing the outcomes of 99 children bridged to cardiac transplantation with MCS, compared them with 2276 children listed for transplantation during the same era who did not require MCS. Significant findings included a lack of difference in survival rates between VAD-supported and non-VAD-supported children, along with similar survival rates for children who required BiVAD support versus LVAD support. An increasing trend in the number of children undergoing transplantation who required pretransplantation VAD support was also observed, with an increase in the use of long-term MCS devices in the most recent era. Children with long-term devices were significantly more likely to survive to transplantation than those with short-term devices. Ten children were “double bridged” from ECMO to VAD support before transplantation, with nine then undergoing successful transplantation. Not surprisingly, smaller, younger patients and those with congenital heart disease had less successful outcomes.<sup>91</sup>

Use of MCS in single-ventricle patients presents special challenges, particularly in patients with cavopulmonary anastomoses; the reported use of VADs in these patients remains limited compared to ECMO.<sup>47</sup> Ventricular dysfunction in the failing Fontan may be addressed with VAD support of the systemic ventricle as long as pulmonary vascular resistance is not significantly increased.<sup>92</sup> Management of anticoagulation may also prove difficult in this population because of liver dysfunction and coagulation factor abnormalities.<sup>93</sup>

In children with a cardiac etiology for MCS, irrespective of the type of mechanical support employed, if significant improvement in myocardial function has not been observed within 48 to 72 hours of institution of support, the child should be evaluated for potential cardiac transplantation.<sup>94</sup> In the current era, earlier consideration for implementation of mechanical support with a staged approach, first using ECMO installation, with a transition to VAD therapy if necessary, has led to markedly improved survival rates.<sup>24</sup>

## Perioperative Management and Complications of Mechanical Circulatory Support

Successful management of critically ill children on MCS requires the expertise of many groups of practitioners. The Hospital for Sick Children, Toronto, Ontario, developed an Interprofessional VAD Support Team involved in clinical care, education, and family support for patients receiving Berlin Heart MCS. In addition to physicians (cardiac surgeons, cardiac intensivists, heart failure and transplant cardiologists, hematologists and psychiatrists) and nurses (cardiac and critical care), team members

include pharmacists, respiratory therapists, dietitians, social workers, physiotherapists, biomedical engineers, and perfusionists.<sup>95</sup> Development of a team approach and use of interdisciplinary guidelines for care of these children can enhance communication, family support, and outcomes.<sup>96</sup>

### HEMODYNAMICS

During ECMO support, central venous pressure should remain low if adequate venous drainage is being achieved. Left atrial pressure should be closely monitored and can be estimated via echocardiographic evaluation of atrial septal position. An increase in left atrial pressure may indicate incomplete unloading of the left atrium and ventricle, potentially requiring a blade and/or balloon atrial septostomy<sup>97</sup> or surgical placement of a left atrial vent. Anatomic issues, such as the presence of aortopulmonary collateral vessels, aortic insufficiency, or a patent ductus arteriosus, can also result in a persistently increased left atrial pressure.

Increased arterial pressures and systemic vascular resistance during ECMO can be due to large pump flows, but other causes, such as unrecognized seizure activity, inadequate pain or sedation management, and hypothermia, should also be considered. High systemic vascular resistance during ECMO support can be pharmacologically managed. In general, mean arterial pressures should be maintained at a level appropriate to the child's size and body weight.

Unlike ECMO support, support of the left ventricle with a VAD requires maintenance of effective right ventricular output to provide adequate left ventricular preload. Right ventricular failure, pulmonary hypertension, and arrhythmias can all limit left ventricular filling and must, therefore, be aggressively treated.<sup>98</sup> Other potential causes of inadequate left ventricular filling include cannula malposition or low intravascular volume. Evaluation of central venous pressure can be used to evaluate volume status, and serial echocardiograms are useful for ongoing assessment of right ventricular function and estimation of right ventricular and pulmonary artery pressures. Clinical signs of right-sided heart failure include increased central venous or right atrial pressures, hepatomegaly, peripheral edema, and decreasing hemoglobin-oxygen saturations. Right ventricular function can be augmented pharmacologically with drugs such as milrinone or isoproterenol. Increased pulmonary artery pressures are best initially treated by ensuring adequate alveolar ventilation, and subsequently by using inhaled nitric oxide, if necessary. Mechanical issues, such as cardiac tamponade, can also negatively affect hemodynamics and can be diagnosed at the bedside with echocardiography. Inadequate left ventricular decompression can cause resultant increases in left atrial and pulmonary artery pressures and may be treated by augmenting LVAD flow; if necessary, biventricular support can be initiated or the child can be placed on ECMO support.<sup>99</sup>

Children on VAD support often require vasodilators to maintain the low systemic vascular resistance necessary for optimal pump function. Frequently used drugs include sodium nitroprusside, milrinone, hydralazine,  $\beta$ -blockers, angiotensin-converting enzyme inhibitors, and clonidine. Left atrial pressure is optimally maintained at 3 to 4 mm Hg, while allowing some ventricular ejection to avoid stasis. Measurement of systemic mixed venous hemoglobin-oxygen saturation, either continuously via in-line monitoring with a centrifugal VAD, or intermittently with a paracorporeal pulsatile VAD, is also useful to ensure that adequate cardiac output is being delivered.

## RESPIRATORY CONSIDERATIONS

Although ECMO can provide full cardiopulmonary support, the trachea should be intubated and the ventilation continued to avoid atelectasis and to optimize oxygenation of blood returning to the left atrium that will provide coronary artery blood flow. Modest ventilator settings are generally recommended: (1) 10 to 12 mL/kg tidal volume, (2) 5 to 10 cm H<sub>2</sub>O of positive end-expiratory pressure, (3) a rate of 10 to 12 breaths per minute, and (4) a fractional inspired oxygen value of 0.4 or less to avoid oxygen toxicity. Maintenance of adequate ventilation is particularly important in children with single-ventricle physiology with an open systemic-pulmonary shunt. Because of the complexity of the ECMO circuit, mechanical issues, such as oxygenator malfunction, must be considered when increasing hypoxemia occurs. After ruling out oxygenator failure, ECMO flow may be increased or the membrane size may be increased to improve systemic oxygenation.

Children on VADs receive only cardiac support. In the case of centrifugal VAD support, the trachea generally remains intubated and the lungs mechanically ventilated. Paracorporeal pulsatile VADs and implantable VADs, on the other hand, allow children to be weaned to extubation. Anatomic issues, such as an atrial septal defect, should be recognized as potential causes of hypoxemia due to right-to-left shunting.<sup>100</sup> Children who receive left ventricular support via either a centrifugal or pulsatile VAD may also require inhaled nitric oxide to decrease pulmonary vascular resistance and improve right ventricular function.

## HEMATOLOGIC CONSIDERATIONS

Managing the anticoagulation continues to be one of the most challenging clinical issues in caring for children who require MCS, because of the risk of hemorrhage and/or thromboembolic complications.<sup>101</sup> Ongoing hemorrhage around cannulation sites is frequent, particularly for those on ECMO. Of greater concern is hemorrhage in the gastrointestinal tract, the lungs, or, more devastatingly, intracranial hemorrhage; infarctions or thromboembolic events may also occur. Serial ultrasonography of the head may be used to monitor for intracranial bleeding in infants and neonates, and, when possible, computed tomography may be used in older children.

Although ECMO protocols vary at individual centers, ACTs are generally maintained between 180 and 200 seconds via use of a heparin infusion at 10 to 50 units/kg/hour. The use of heparin-bonded tubing can reduce the need for greater ACTs. The hematocrit is generally maintained between 40% and 50%, although efforts are made to limit transfusions, because most such children are potential candidates for cardiac transplantation. When necessary, leukocyte-reduced, cytomegalovirus-negative, irradiated red cells are administered. Platelet counts greater than 100,000/mm<sup>3</sup> and fibrinogen concentrations greater than 100 mg/dL are maintained to minimize bleeding complications.<sup>102</sup> In the presence of continued bleeding, cryoprecipitate and/or fresh frozen plasma may be added to the circuit prime and TEG may be helpful in assisting with appropriate use of blood products. In cases of persistent hemorrhage refractory to blood component administration, recombinant activated factor VII has been shown to significantly decrease bleeding and aid in normalizing the TEG profile,<sup>103-105</sup> although disastrous clotting of circuitry has also been reported with its use.<sup>106</sup> Hemolysis may be monitored by measurement of plasma-free hemoglobin, with increasing concentrations potentially representing the development of thrombus in the circuit.

Without an oxygenator in the circuit, anticoagulation requirements are not as stringent for children on VADs, and their ACTs may be maintained between 140 and 180 seconds. After placement of a Berlin Heart Excor, unfractionated heparin infusions are initially used with a target aPTT of 60 to 70 seconds. The use of argatroban has been described in children with heparin-induced thrombocytopenia type II.<sup>107</sup> Longer term anticoagulation includes the use of LMWH with anti-factor Xa activity monitoring.<sup>108,109</sup> After normalization of the platelet count and function, aspirin and dipyridamole are started, with monitoring via TEG and platelet aggregation tests, with a target activation of 30%. Once a child is tolerating enteral feedings, a transition to warfarin may occur. Although embolic and bleeding complications remain problematic, with this management strategy a marked increase in survival has been noted in children undergoing Berlin Heart Excor support compared to earlier regimens.<sup>110</sup>

Although hemolysis and thrombosis may be less frequent with continuous flow devices, the frequent development of acquired von Willebrand syndrome has been described in adult patients, most likely occurring secondary to the shear stress of the pump, with unfolding and cleavage of the high-molecular-weight multimers of von Willebrand factor. This is also thought to account for the increased incidence of gastrointestinal bleeding noted in these patients, though not all patients with documented acquired von Willebrand syndrome display increased bleeding tendencies.<sup>111,112</sup>

## PREVENTION OF INFECTION

Infection is a constant concern, particularly in children requiring intermediate- to long-term VAD support. Devices with larger surface area and areas of turbulent flow have been correlated with greater infection rates due to increased adherence of blood-borne pathogens; therefore, smaller, fully implantable devices and devices with improved flow dynamics may continue to facilitate decreases in the incidence of infection.<sup>113,114</sup> Devices, such as the Berlin Heart Excor, that facilitate removal of tracheal tubes, indwelling catheters and intravenous lines, and minimize the need for blood transfusions, also offer advantages in minimizing the risk of device-related infections.<sup>75,115</sup> Deep wound complications of inflow and outflow cannulas have been successfully treated with vacuum-assisted wound closure systems.<sup>116</sup>

The use of mechanical support devices can result in immunologic dysfunction, further increasing infection risk.<sup>117</sup> Signs and symptoms of infection can be subtle, and a need for increasing inotropic support to maintain mean arterial pressure can often be a harbinger of infection. Endogenous reactions to infection can also result in activation of the coagulation cascade, increasing the difficulty of anticoagulation management.<sup>118</sup> Many children prophylactically receive antibiotics with gram-positive coverage, as well as oral nystatin for fungal prophylaxis.

## ANESTHETIC CONSIDERATIONS

In preparing for the anesthetic care of infants and children, when ECMO or VAD support is being used or when implementation of MCS is imminent, initial planning centers on two main areas of concern: the child's current status and the location of the proposed procedure (Table 19-4). The need for emergency surgery, the child's condition at the time of surgery, the presence of preoperative multiorgan failure, and the need for CPB with cross-clamping of the aorta have all been shown to increase perioperative risk.<sup>119</sup>

**TABLE 19-4 Anesthetic Considerations**

<b>Preoperative Assessment</b>	
<i>History</i>	
Etiology and duration of cardiac failure End-organ dysfunction Pulmonary Renal Hepatic Neurologic Medications Inotropic/vasoactive support Angiotensin-converting enzyme inhibitors Antiarrhythmic therapy Anticoagulation protocols Sedative drugs Antibiotics Planned surgical procedure Timing of procedure: elective/urgent/emergent	
<i>Laboratory</i>	
Complete blood cell count Electrolytes Liver function studies Blood urea nitrogen, creatinine Coagulation studies Platelet count Prothrombin time/partial thromboplastin time Fibrinogen concentration Activated clotting time Thromboelastogram B-type natriuretic peptide concentration	
<i>Physical examination</i>	
Airway Vascular access, both existing and available Neurologic status Evidence of ongoing hemorrhage Assessment of intravascular volume status	
<b>Intraoperative Management</b>	
<i>Availability of blood products</i>	
<i>Monitoring</i>	
Standard monitors: electrocardiogram, noninvasive blood pressure, end-tidal CO <sub>2</sub> , temperature, peripheral oxygen saturation Assess need for invasive monitoring, arterial or central venous Urine output	
<i>Transesophageal echocardiography</i>	
Presence of septal defects Aortic insufficiency Mitral stenosis Cardiac de-airing Ventricular function	
<i>Management principles</i>	
Avoid abrupt decreases in preload Support right ventricular function, reduce pulmonary vascular resistance Adequate ventilation Inotropic support: milrinone, prostaglandin E <sub>1</sub> Nitric oxide availability Maintain adequate intravascular volume/preload for ventricular assist device Hypotension can be treated with volume or $\alpha$ -adrenergic agonists	
<b>Postoperative Issues</b>	
Transport to intensive care unit Control of ongoing hemorrhage Timing of extubation	

A comprehensive preoperative evaluation of the child is essential, with knowledge of the underlying etiology necessitating MCS and the length of the child's illness, along with evaluation of other potential multiorgan dysfunction, including neurologic, hematologic, renal, hepatic, and pulmonary issues. Review of current drug therapy, particularly the duration and degree of current inotropic support, anticoagulation protocols, sedation regimens, cardiac function, intravascular volume status, and the presence and degree of preoperative hemorrhage, is also necessary. Physical examination should encompass the airway and both current vascular access, as well as the availability of sites for potential vascular access.

Preoperative laboratory evaluation should include CBC with platelet count, electrolytes, blood urea nitrogen and creatinine concentrations, PT and partial thromboplastin time, and liver function tests. Concentrations of BNP, produced in the myocardium, serve as a marker of ventricular overloading and have been shown in adult and pediatric patients with congenital heart disease to correlate with the degree of ventricular dysfunction.<sup>120,121</sup> Serial BNP concentrations in pediatric patients supported with ECMO have also been used to predict clinical outcomes, with greater BNP concentrations noted after termination of ECMO support in nonsurvivors than in children who ultimately survived.<sup>122</sup>

Useful preoperative coagulation data includes recent TEG results, fibrinogen concentrations, and platelet function tests, if available. The most recent echocardiography data and chest radiograph should be reviewed. Blood products, including PRBCs, platelets, cryoprecipitate, and fresh frozen plasma, should be available at the bedside or in the operating room, with provision for continuing supply of products as needed. Appropriate antibiotic prophylaxis should be discussed with the surgeon.

Standard American Society of Anesthesiologists monitoring should be employed before induction of anesthesia. Depending on the child's condition and the type of surgery planned, use of arterial and central venous lines should be considered. In children who have been in the intensive care unit for a prolonged time, or those undergoing current resuscitation, the placement of additional vascular access lines can be quite challenging and may occasionally require surgical assistance. For children already on a mechanical support device, it is important to be aware that VAD ejection is usually asynchronous with the child's underlying heart rate, yielding a discrepancy between the observed electrocardiographic and the arterial line waveform. Multiple peripheral intravenous lines are useful for the administration of volume and blood products. If right VAD support is in place special care must be taken not to entrain air if the great veins are accessed.

For patients undergoing placement of a VAD, etomidate is generally an advantageous drug for induction of anesthesia because it does not result in myocardial depression at clinically relevant concentrations, even in children with severely compromised ventricular function.<sup>123</sup> Judicious doses of opioids and benzodiazepines may be added, while the choice of a neuromuscular blocking agent is often determined by the presence of compromised hepatic or renal function. Adequate depth of anesthesia should be ensured before tracheal intubation, to avoid abrupt increases in pulmonary vascular resistance, particularly in children with marginal right ventricular function. In children undergoing device placement, induction drugs should be given incrementally, because the onset time may be abnormally slow owing to depressed ventricular function. Children may exhibit decreased responsiveness to  $\beta$ -adrenergic agonists due to depletion of myocardial catecholamines.<sup>124</sup> Hypotension on induction of anesthesia and decreased responsiveness to catecholamines may also be observed in children who have been chronically receiving angiotensin-converting-enzyme inhibitors for afterload reduction preoperatively.<sup>125-127</sup> Opioids, benzodiazepines, and neuromuscular blocking agents are generally used for anesthetic maintenance before ECMO cannulation or initiation of CPB for VAD implementation, with the express goal of maintaining adequate cardiac output and resultant systemic perfusion to end organs. Trends in serum lactate concentrations, mixed venous hemoglobin-oxygen saturations, and the presence or absence of metabolic acidosis are useful indices for evaluating the adequacy of cardiac output.

Unless contraindicated by patient size or the presence of gastrointestinal bleeding, a transesophageal echocardiographic (TEE) probe should be placed after the induction of anesthesia, for use throughout the procedure. Initial TEE examination is

important for determining the presence of any intracardiac shunts that would require closing before initiation of MCS. The competence of the aortic valve should also be evaluated, because more than trivial insufficiency can result in recirculation of blood through an LVAD. The mitral valve should also be examined for significant stenosis that could limit left ventricular inflow. After device placement, TEE helps in ensuring that adequate cardiac de-airing has occurred, as well as in ongoing evaluation of ventricular function. TEE is also useful after device placement for monitoring the orientation of intracardiac cannulas and decompression of the left atrium and ventricle after pump activation.

For children undergoing placement of an LVAD, as the venous line from the CPB circuit is occluded, the pump speed will be gradually increased. If LVAD flow (and rate when fill-to-empty mode is used) is less than desired, the major areas of concern are hypovolemia or poor right ventricular function. The right ventricle should be monitored closely for signs of dysfunction or failure. In children with preexisting right ventricular dysfunction, pulmonary vasodilatory agents, such as milrinone, prostaglandin E<sub>1</sub>, or nitric oxide, should be aggressively used to optimize right-sided heart function. Children with low pressures and signs of vasodilatory shock may require infusions of vasopressin, epinephrine, or norepinephrine for circulatory support. In addition, adequate volume loading and VAD output should be ensured.

Tracheal extubation is not an option for those undergoing ECMO or centrifugal VAD support, but children receiving pulsatile VADs or axial pumps may be considered candidates for extubation. Timing of extubation will depend on the child's preoperative condition, degree of preexisting pulmonary dysfunction, duration of the surgical procedure, extent of postoperative bleeding, and maintenance of appropriate hemodynamic parameters.

**FIGURE 19-6** Devices developed under the Pediatric Circulatory Support Program. **A**, The PediPump ventricular assist device showing application for biventricular support. **B**, PedioFlow ventricular assist system. **C**, Penn State infant pediatric ventricular assist device. **D**, Enson's Pediatric Cardiopulmonary Assist System with prototype controller console. **E**, Infant-size pediatric Jarvik 2000 showing thrombus-free bearings after 5 weeks in a lamb animal model. (From Baldwin J, Borovetz H, Duncan B, et al. The National Heart, Lung, and Blood Institute Pediatric Circulatory Support Program: a summary of the 5-year experience. *Circulation* 2011;123:1233-40.)

Not surprisingly, with the steadily increasing use of VAD support in infants and children, a growing demand for anesthesia for noncardiac surgeries during the period of support has also occurred. Transport and care of these children often requires the assistance of respiratory therapists and the availability of a pump specialist. Temporary conversion from warfarin or LMWH to unfractionated heparin infusion should be discussed with the team caring for the patient, including the hematologist, before surgery, and appropriate blood products should be ordered. For children on VAD support, appropriate pump function will continue independently of the induction drugs used, as long as adequate preload is maintained and no acute decrease in systemic vascular resistance occurs. In a series of children with in situ Berlin Heart Excor support undergoing noncardiac surgeries, anesthetic induction with ketamine was found to be less likely to induce hypotension requiring treatment with fluid bolus or  $\alpha$ -adrenergic agonists.<sup>128</sup> Inspection of the pump chamber for wrinkling of the membrane assists in deciding whether the use of a fluid bolus or an  $\alpha$ -adrenergic agonist is more appropriate. In children who are only on LVAD support, care should be taken to avoid increases in pulmonary vascular resistance, as the likeliest cause of decompensation in such patients is right ventricular failure. Nitric oxide and appropriate vasoactive drugs should be readily available for use if needed. When possible, the use of spontaneous ventilation is thought to improve venous return and hemodynamic stability.<sup>57,129</sup>

## Future Directions

The Pediatric Circulatory Support Program (PCSP) of the NHLBI was established to foster development of circulatory support devices suitable for children from 2 to 25 kg. Five contracts were awarded in early 2004 and concluded in 2009, with devices under development including a next-generation ECMO system (Pediatric Cardiopulmonary Assist System, Ension, Inc., Pittsburgh), an implantable VAD (PediPump, The Cleveland Clinic Foundation, Cleveland), an intraventricular pump (Pediatric Jarvik 2000, Jarvik Heart Inc., New York), a pulsatile VAD (Pediatric Ventricular Assist Device, The Pennsylvania State University, Hershey, Pa.), and a miniaturized blood pump (PediaFlow VAD, University of Pittsburgh) (Fig. 19-6). In 2008 the NHLBI requested proposals for the Pumps for Kids, Infants, and Neonates (PumpKIN) program, with three of the five contractors from the NHLBI PCSP program receiving program awards in January 2010. Clinical trials are anticipated to begin in 2013.<sup>130</sup>

Future of Anesthesia in Interventional Cardiology

THE USE OF CATHETERIZATION in the care of children with congenital heart disease (CHD) was first described by Dexter and colleagues in 1947.<sup>1</sup> It has evolved from a physiologic assessment tool to a technique to define anatomic relationships and has become a therapeutic modality. The first interventional procedure, balloon atrial septostomy, was described by Rashkind and Miller in 1966,<sup>2</sup> and since then, the discipline of interventional cardiology has continued to evolve.

As echocardiography and magnetic resonance imaging (MRI) diagnostic capabilities have increased, the need for purely diagnostic cardiac catheterization has declined.<sup>3,4</sup> However, technologic advances and more sophisticated equipment have increased the scope for interventional procedures, and the patient population has changed as more children with CHD are surviving longer. As the surgical management of CHD has evolved, it has introduced a new spectrum of surgical complications. Some surgical operations have been replaced altogether by interventional procedures, and some interventional procedures have facilitated more complex heart surgery.<sup>5</sup> The shifts in practice and population have affected the anesthetic management of these children.<sup>6</sup> Procedures are more diverse, and patients can vary from moribund neonates to healthy adolescents. There are no simple anesthesia recipes for all children and all heart conditions; the type of anesthesia must fit each child and each procedure.

In this chapter, we outline the main procedures performed in interventional cardiology, describe the potential issues and complications faced by anesthesiologists, and address the principles and details of anesthetic techniques.

## Types of Procedures Performed

### DIAGNOSTIC CATHETERIZATION

Diagnostic catheterization allows accurate documentation of pressure and oxygen content from all regions of the circulation. Interpretation of these hemodynamic data allows quantification of the degree of intracardiac shunting and calculation of the vascular bed resistances. This information is necessary to assess the suitability of a child to undergo palliative or reparative surgery for congenital heart lesions. Expected values for hemodynamic variables are listed in Table 20-1. There are no absolute values for these variables, and they vary according to the age of the child. The use of angiocardiology to define anatomy is waning because of the widespread use of noninvasive imaging modalities such as echocardiography, computed tomography, and MRI.

### INTERVENTIONAL CATHETERIZATION

At many centers, interventional catheterization accounts for more than 60% of cardiac catheterization cases.

#### Atrial Septostomy

Atrial septostomy improves mixing of oxygenated and deoxygenated blood at the atrial level in neonates with D-transposition of the great vessels. Children with this disorder are born with ventriculoarterial discordance. The right ventricle pumps deoxygenated blood to the aorta, and the left ventricle pumps oxygenated blood to the main pulmonary artery. Enlargement of the foramen ovale by atrial septostomy improves mixing of oxygenated and

deoxygenated blood, resulting in increased systemic oxygen saturation. This procedure can be performed in the catheterization laboratory with fluoroscopic guidance, or it can be easily and safely undertaken at the bedside in the intensive care unit using echocardiographic guidance.<sup>7</sup> A femoral venous or umbilical venous approach can be used. The drawback with the umbilical venous route is the often-encountered difficulty in traversing the ductus venosus to secure access to the inferior vena cava. The major risks with this procedure are vessel injury, paradoxical embolism, arrhythmia, and cardiac perforation.

### Atrial Septal Defect Closure

With the development of specifically designed closure devices, atrial septal defect (ASD) closure has become one of the most commonly performed endovascular procedures. The technique is intended for closing secundum ASDs, which are defects located in the region of the fossa ovalis. Defects falling outside this area, such as sinus venosus and primum ASDs, are not suitable for percutaneous closure.

To warrant closure, children need to demonstrate clear evidence of volume loading of the right heart structures and a defect that is unlikely to close spontaneously in the short to medium term. The choice of closure device depends on the size and the margins of the defect. The two types of closure devices have either a centering or a noncentering design (Fig. 20-1). The choice of one design over another is based more on the clinician's preference than scientific performance, although the Amplatzer Septal Occluder (AGA Medical Corporation, Golden Valley, Minn.) can close a wider range of defect sizes.<sup>8-10</sup> Daily aspirin in

a dose of 3 to 5 mg/kg is recommended for a minimum 6 months after implantation of either type of device. The main complications associated with ASD closure include vessel injury, cardiac arrhythmia, cardiac perforation, and device embolization.<sup>11</sup> Atrial septal closure devices have also been used to close surgically created fenestrations between the atrium and venous conduits after a Fontan operation. This is undertaken only when the fenestration is no longer required.

### Ventricular Septal Defect Closure

Ventricular septal defect (VSD) closure presents a technically greater challenge than ASD closure and is associated with a greater risk. The VSDs most suitable for device closure are those in the midmuscular septum or those closer to the apex.<sup>12</sup> With further refinement of the implantation technique and equipment, this approach has been undertaken with perimembranous defects.<sup>13,14</sup>

During device closure of VSDs, a snare is placed in the right side of the heart to capture a guidewire that has been passed across the VSD from the left ventricle. The guidewire is brought outside the body to form an arteriovenous rail. The delivery sheath for the VSD device is then advanced over the wire to approach the VSD from the right side of the heart. For anterior and high muscular defects, the wire is best snared and exteriorized through a femoral vein approach, whereas for defects in the middle to low muscular septum, the wire is best snared and exteriorized through a jugular venous approach (Fig. 20-2). Complications include dysrhythmias, blood loss, valve dysfunction, and device embolization.<sup>15,16</sup> At our institution,<sup>17</sup> device closure of perimembranous VSDs with the Amplatzer Membranous VSD Occluder had an unacceptable incidence of complete heart block and is therefore not currently performed. However, other medical units have continued to undertake this intervention, and alternative devices are being developed with the goal of implantation that does not cause complete heart block.

### Patent Ductus Arteriosus Closure

Closure of patent ductus arteriosus (PDA) was the second specific intervention developed for children with CHD, and it continues to be a common procedure performed using techniques that are similar to the original methods pioneered by Rashkind and

**TABLE 20-1** Normal Values in Diagnostic Cardiac Catheterization

Structure	Value (mm Hg)
Right atrium	3-5 (mean)
Right ventricle	20-25/3-5 (systolic/end-diastolic)
Pulmonary artery	12-15 (mean)
Left atrium	7-10 (mean)
Left ventricle	65-110/3-5 (systolic/end-diastolic)
Aorta	65-110/35-65 (systolic/diastolic)

**FIGURE 20-1** Devices for closure of an atrial septal defect. **A**, The Amplatzer Septal Occluder. **B**, The HELEX<sup>15</sup> Septal Occluder. (**A**, Courtesy AGA Medical Corporation, Golden Valley, Minn. **B**, Courtesy W.L. Gore & Associates, Flagstaff, Ariz.).

associates.<sup>18</sup> The customary approach is to perform an aortogram to define the size and geometry of the PDA. Based on this information, a choice is made between using a stainless steel coil or an occluder device.<sup>19</sup> Most interventional cardiologists implant a stainless steel coil to close a small PDA (no greater than 3 mm) using a retrograde or antegrade approach.<sup>20</sup> To lessen the chance of coil embolization during implantation, several techniques can control release of the coils.<sup>21-23</sup> For the larger PDA, most interventional cardiologists implant an occluder device because it lessens the risk of a significant residual shunt. The major risks associated with this procedure are vessel injury and device or coil embolization. Coils are also used to close major aortopulmonary collateral vessels (Figs. 20-3 and 20-4).

**FIGURE 20-3** The coil is used for closure of a patent ductus arteriosus.

### Balloon Dilation and Stent Implantation

Balloon angioplasty techniques are used to dilate stenotic aortic, mitral, tricuspid, and pulmonary valves and stenotic segments of the aorta or of the pulmonary arteries. In neonates, membranous atresia of the pulmonary valve may be crossed with the stiff end of a guidewire<sup>24</sup> or with radiofrequency catheters.<sup>25</sup> After both techniques, the valve is dilated with a balloon that is approximately 120% the size of the annulus. Balloon angioplasty of stenotic pulmonary valves in children beyond infancy is often a curative procedure, whereas balloon valvuloplasty of critical pulmonary stenosis in the neonate often requires intervention again in later infancy. The potential hemodynamic behavior of the child depends on the nature of the lesion. A neonate with duct-dependent critical stenosis and little antegrade flow can tolerate balloon dilation well because there is little disruption of the cardiac output, whereas neonates and infants with less critical stenosis can suffer significant reductions in cardiac output when the balloon is inflated, especially if the ductus arteriosus is not patent. Older children tend to tolerate balloon valvuloplasty surprisingly well,<sup>26</sup> and life-threatening hypotension is uncommon.<sup>27</sup>

In contrast to pulmonary balloon valvuloplasty, aortic balloon valvuloplasty is usually only a palliative procedure, with most children eventually requiring surgery. Balloon dilation of aortic stenosis in the neonate is a high-risk procedure. These infants often present in a low cardiac output state requiring ventilation, inotropic support, and prostaglandin E<sub>1</sub> (PGE<sub>1</sub>) infusion to maintain ductal patency. Catheterization can be complicated by arrhythmias (including asystole), the development of significant aortic regurgitation (which may require surgical intervention), and sudden death due to acute coronary ischemia.<sup>26</sup> The complication rate in older children is less than in younger children, and transient hypotension, bradycardia, and left bundle branch block are commonly reported.

Stents are sometimes implanted across focal areas of persistent stenosis in the systemic and pulmonary circulations. The technique of stent implantation requires great precision in positioning the stent, and the cardiac interventionalist needs to take into account the inevitable shortening that occurs with stent implantation when selecting a device for a particular lesion. The major complication encountered with stent implantation, in addition to those of balloon angioplasty, is stent malposition with the

**FIGURE 20-4** **A**, Lateral angiography demonstrates a patent ductus arteriosus (PDA) (arrow). The PDA lies between aorta and pulmonary artery (arrow). The angiography catheter is in the proximal aorta. **B**, Lateral angiography after closure of the PDA with a coil (arrow). **C**, Lateral fluoroscopy after closure of the PDA with the Amplatz Duct Occlude device. The device (arrow) is in the PDA.

potential for dislodgement. Rarely, late aneurysm formation has been reported after stenting the aorta for coarctation.

### Nonsurgical Pulmonary Valve Replacement

It is more than a decade since Bonhoeffer and colleagues<sup>28</sup> first described the technique of replacing a dysfunctional valve in a right ventricle to pulmonary artery conduit with a catheter-implanted valve. The technology used has matured, and the Melody Valve (Medtronic Inc, Minneapolis, Minn.) is available for use in Europe and is undergoing clinical trials in the United States. The Edwards Sapien Transcatheter Heart Valve (Edwards Lifesciences LLC, Irvine, Calif.) has also been used but is currently not licensed for this indication. Other results<sup>29</sup> have confirmed a high procedural success rate and satisfactory short-term valve function with implantation of the Melody Valve. The need for careful patient selection and for adequate relief of right ventricular outflow tract obstruction at the time of valve implantation are paramount in achieving results comparable to those of surgical replacement of dysfunctional conduits. Unfortunately, most children after tetralogy of Fallot repair with a transannular patch are currently unsuitable for implantation of a stented valve because of an aneurysmal right ventricular outflow tract.

Alternative devices are being sought to overcome these problems and to reduce the size of the delivery systems to enable use of these technologies in younger and smaller children. A novel use of Melody devices in an animal model that replicates the clinical situation of an aneurysmal right ventricular outflow tract has been reported.<sup>30</sup> Implantation of Melody Valves in branch pulmonary arteries appears to favorably reduce the regurgitant fraction in this animal model.

### ELECTROPHYSIOLOGIC CATHETERIZATION

Endocardial catheters that record an electrocardiogram first became available in the early 1960s. Endovascular techniques were developed as an alternative to surgery for certain forms of tachycardia. These therapies initially used direct current energy and subsequently have made use of radiofrequency energy and localized freezing techniques. Tachycardia may be treated by this technique in children with structurally normal hearts and those who have dysrhythmias after surgery for CHD.<sup>26</sup> Ablative procedures account for about 20% of all cardiac catheterization procedures.

The technique requires specialized equipment, specially trained staff, and use of multiple catheters to measure the electrical signals within the heart at any given time. These procedures are often more time consuming than other catheterization procedures. The success of the therapy depends on the mechanism of the tachycardia, the location of the aberrant pathway, and the technique for interrupting the aberrant pathway. Ablation of ectopic foci has a good success rate and small complication rate.<sup>31,32</sup> The main risks with this procedure are heart block, cardiac perforation, vessel injury, and stroke.

### CHOICE OF VESSEL ACCESS

The most common approach for cardiac catheterization is the femoral route. Femoral venous catheterization avoids the risk of pneumothorax, and the vein is easier to access than the internal jugular vein in the unanesthetized child. In children who are likely to have a cavopulmonary shunt placed surgically for palliation, avoiding routine cannulation of the internal jugular vein can decrease the risk of compromising the superior vena cava. However, internal jugular vein access sometimes is

required, such as during VSD closures, investigation of cavo-pulmonary connections in children, and when the cardiac interventionalist is unable to obtain access through the femoral veins. In neonates, the umbilical vein may be used, although it can sometimes be difficult to cross the ductus venosus. Patency of the ductus venosus can be assessed by ultrasound before the procedure to avoid unnecessary manipulation of the umbilical vein. An alternative is transhepatic puncture. This route has been used for temporary access during catheterization and for long-term vascular access.<sup>33</sup>

## Complications and Limitations of Procedures

Interventional cardiology can be associated with significant morbidity and mortality. Complications attributable to the procedure or the physiology of the child occur far more frequently than purely anesthesia-related problems. An important prerequisite for providing quality anesthesia care is understanding the diagnosis and management of anticipated complications. Complications such as tamponade, dysrhythmia, embolism, and rupture may occur suddenly and without warning. The anesthesiologist must be vigilant and maintain communication and rapport with the cardiologist throughout the procedure. The availability of backup from surgeons, cardiologists, and anesthesiologists is preferable, and standard procedures for emergencies should be in place. Some clinicians advocate the availability of cardiopulmonary bypass or extracorporeal membrane oxygenation (ECMO) for children with unanticipated difficulties.<sup>16</sup> Although this type of therapy is available in major referral hospitals, it may not be an option in some centers. Institutions must develop policies regarding the procedures that can be undertaken locally (based on experience and infrastructure) and those that require referral of children to centers that are better equipped to address more complex procedures.

### OVERALL MORTALITY

Despite the increased complexity of interventional procedures, the mortality rate is steadily decreasing. A report from the early 1960s found an overall mortality rate (neonates through to adulthood) of 0.44%,<sup>34</sup> but more recent data show overall mortality rates of 0.08%,<sup>35</sup> 0.14%,<sup>36,35</sup> and 0.39%.<sup>27</sup> All reviews describe a relatively high mortality rate among infants and neonates in particular.<sup>27,36,37</sup> Explanations include a reduced physiologic reserve, presence of uncorrected or partially palliated congenital heart defects, increased risk of obstruction to great vessels and cardiac chambers, and greater susceptibility to catheter-induced damage in infancy.<sup>27</sup> However, neonatal mortality rates are diminishing; one institution reported a decrease from 6.7% to 0.9% during a span of 20 years.<sup>36</sup> The explanations cited for this decrease were noninvasive imaging that reduced the number of neonates who required cardiac catheterization, improved management of the critically ill child, correction of metabolic abnormalities, use of PGE<sub>1</sub>, and use of improved catheters and better support equipment such as temperature control.<sup>36</sup>

### OVERALL MORBIDITY

Complications are frequently categorized as major, minor, and incidental.<sup>27,37</sup> Major complications are potentially life-threatening events that require surgical intervention or are significant permanent lesions resulting from the procedure (e.g., cerebral infarct).

Minor complications are transient and resolve with specific treatment (e.g., transient arterial thrombosis, temporary loss of a pulse or decreased perfusion after arterial puncture). An incidental complication has no effect on the patient's condition and requires minimal or no treatment (e.g., transient hypotension responding to volume infusion, catheter-induced arrhythmia). The incidence of major complications is between 1.4%<sup>37</sup> and 2.6%,<sup>38</sup> and the incidence of minor complications is between 6.8%<sup>37</sup> and 7.5%.<sup>38</sup> The overall complication rate has remained stable for the past 20 years.<sup>38</sup>

Three groups of children are at substantial risk for complications: those who are young, those with low weight, and those undergoing interventional rather than diagnostic procedures; balloon interventions are associated with the greatest risk.<sup>36-38</sup> The incidence of vascular access complications after interventional procedures is three times greater than the rate for diagnostic procedures<sup>36</sup>; this may reflect the use of larger-diameter catheters during interventional procedures than during purely diagnostic procedures. Closure of a PDA and balloon atrial septostomy carries a small overall risk.<sup>27,36</sup>

### VASCULAR COMPLICATIONS

Vascular complications are the most common and broadest category of complications.<sup>36</sup> They may be acute, leading to unexpected hemodynamic instability, or delayed, leading to longer-term morbidity. Many factors contribute to unexpected hemodynamic instability, including the child's condition, blood loss, dysfunction of a valve, arrhythmias, tamponade, vessel rupture, balloon dilation, catheter-induced interruptions in blood flow or coronary perfusion, and device malposition.

#### Arterial Thrombosis and Occlusion

Femoral artery occlusion due to thrombosis is a common complication after femoral cannulation.<sup>36</sup> The true incidence of arterial compromise is unknown,<sup>39</sup> although 32% of infants had compromised blood flow to the leg as measured by Doppler after femoral arterial cannulation in one study.<sup>40</sup> The clinical incidence of arterial compromise is 2.4% to 3.7%.<sup>36,37</sup> Infants undergoing dilational interventional procedures are at a greater risk.<sup>41</sup> The incidence of these complications can be reduced by minimizing the size of the sheath, use of systemic heparinization, and avoidance of arterial entry by using alternative techniques to enter the left side of the heart.<sup>36</sup> Despite the widespread use of intravenous heparin for prophylaxis against arterial occlusion, there is no agreement on the appropriate dosage. Commonly, 50 to 100 IU/kg heparin is used, but schedules vary.<sup>26</sup> Larger doses than these do not reduce the incidence of arterial compromise.<sup>39</sup>

In most cases where the pulse is reduced or absent after catheterization, the occlusion either spontaneously resolves or is managed with anticoagulation or thrombolytic therapy.<sup>36,37,41</sup> Guidelines are available for the management and prevention of femoral artery thrombosis, but advice should be sought from a pediatric hematologist.<sup>42</sup> Although surgical intervention is rarely required, it is most commonly indicated for an arterial tear or avulsion, arterial thrombosis (including iliac arteries), and arterial pseudoaneurysm.<sup>41</sup> Occasionally, despite medical therapy and a well-perfused lower limb, a pulse may be persistently reduced. There is little evidence to predict how and when a reduced pulse may cause delay in limb growth,<sup>36</sup> although cases have been reported.<sup>41</sup> Although femoral cannulation for balloon intervention is associated with vascular compromise of the superficial femoral artery, one small study (43 children between 1 day and

15 years of age) failed to demonstrate significant limb growth discrepancy after a median follow-up of 3.5 years.<sup>43</sup>

### Venous Thrombosis and Occlusion

Although venous thrombosis is a well-known complication of central venous access, the incidence after cardiac catheterization is unclear. Isolated cases of femoral or iliofemoral venous occlusions with limb edema have been published as part of large series,<sup>36,37</sup> in which the incidence of symptomatic venous occlusion was less than 0.3%. All of these children responded to heparin therapy without the need for further intervention.<sup>37</sup> As in arterial thrombosis, the use of smaller catheters and heparin prophylaxis during catheterization procedures may reduce the incidence of venous thrombosis.

### Vessel Rupture, Perforation, and Dissection

Vessel rupture can occur at the site of vessel entry or at the site of intervention. It is a rare but potentially catastrophic event. One death due to intraabdominal hemorrhage after rupture of a femoral vein in a neonate was reported in a series of 4454 catheterizations.<sup>27</sup> Arterial or venous perforation was responsible for four major complications and six minor complications in a series of 4952 procedures, and significant groin hematoma occurred in 25 cases.<sup>36</sup> Femoral artery injuries may require surgical consultation and exploration.

Vessel perforation has occurred at the site of intervention, particularly during balloon interventions. Ruptures have been reported most often after balloon dilation of branch pulmonary arteries,<sup>4,26</sup> but they also have occurred along the ascending aorta and arch after balloon dilation of the aortic valve. Depending on the site of the tear, rupture may cause hemopericardium or hemothorax, or both.<sup>41</sup> Intrapulmonary hemorrhage is usually self-limited. If rupture or hemorrhage occurs, hypertension should be avoided, the trachea should be intubated (if the airway is not already secured), and any circulating heparin should be reversed. Pulmonary artery disruption after balloon dilation may manifest as hemoptysis. Increased blood flow after balloon dilation of pulmonary vessels may lead to unilateral pulmonary edema, which may also present as hemoptysis. Occasionally, arterial dissection,<sup>41</sup> aneurysm, and pseudoaneurysm formation may occur.

### CARDIAC TAMPONADE AND PERFORATION

Cardiac tamponade is an uncommon complication of cardiac catheterization, but when it occurs, it can be responsible for significant morbidity and mortality. The incidence of cardiac tamponade in three large series was 0.1%,<sup>36</sup> 0.04%,<sup>27</sup> and 0%.<sup>37</sup> In one series of 4952 patients, tamponade was responsible for two deaths: one neonate after a balloon atrial septostomy and one 4-year-old child after a recent Fontan procedure for stent insertion in a branch pulmonary artery.

Although tamponade is uncommon, perforation is not. The atrial appendage and right ventricular outflow tract are the sites most commonly perforated,<sup>41</sup> whereas the left ventricle has been punctured less commonly.<sup>42</sup> Perforation of the heart is described during many procedures, including balloon and blade atrial septostomy, balloon dilation of the mitral valve,<sup>4</sup> and attempted radiofrequency perforation of membranous pulmonary atresia.<sup>5</sup>

Signs that suggest a perforation include wires appearing in unexpected places, atypical contrast appearance, lack of a return to baseline blood pressure after catheter-induced tachycardia, and hemodynamic instability. Echocardiography should always be

immediately available to confirm any suspicion of perforation or tamponade. If it occurs, a cannula can be placed in the pericardium to remove blood that can then be returned to the child through the femoral venous catheter. If the tamponade is not controlled with catheter drainage, the cardiac surgeons should be notified and an operating room prepared.

### DAMAGE OR DYSFUNCTION OF A VALVE

Damage to a valve is not particularly common, although it is more likely to occur with a balloon valvuloplasty procedure than with other procedures.<sup>41</sup> The primary complication is creation of excessive regurgitation. The hemodynamic consequences of such a defect are more significant on the systemic side of the circulation than on the pulmonary side.<sup>5,41</sup> The mechanism of injury is most commonly leaflet avulsion during dilation, although the leaflet can be inadvertently perforated by the guide-wire, and there is the likelihood of significant further damage to the leaflet with advancement and inflation of the angioplasty catheter. Emergency repair is occasionally required.<sup>41</sup> Injuries to the atrioventricular valves have rarely been reported. Placement of wires and large sheaths across atrioventricular valves and septal defects can cause severe hemodynamic disturbance. This is particularly true during implantation of VSD occlusion devices.<sup>15,26</sup> ASD and PDA occlusions are less likely to produce significant hemodynamic disturbance.<sup>26</sup> Rarely, the implanted ASD and VSD devices adversely affect the functioning of an atrioventricular valve.

### BLOOD LOSS

Blood loss may be sudden with rupture of vessels, but more often, it is slow and insidious due to multiple blood samples and blood loss associated with catheter exchanges. Anemia may be difficult to detect in a dark room and a covered child. Significant loss is more likely to occur during insertion of a closure device. Blood transfusion was required in 54% of 86 VSD closure devices in one early study.<sup>15</sup> Because interventions have the potential for blood loss, it is reasonable to have a unit of blood and blood administration equipment in the cardiac catheterization laboratory.

### DYSRHYTHMIAS AND THE CATHETERIZATION LABORATORY

Transient dysrhythmias are common during cardiac catheterization.<sup>27</sup> Most dysrhythmias are mechanically induced, and repositioning the wire or catheter usually resolves the dysrhythmia. Other causes of rhythm abnormality include coronary air embolism, electrolyte imbalance, and hypercarbia. Although they are usually minor complications, dysrhythmias are one of the most common causes of major complications, with a frequency of 2.6%<sup>36</sup> to 3.6%.<sup>37</sup> Infants have the greatest incidence of rhythm disturbance. A defibrillator, a pacing device, and antiarrhythmic agents must be present in the cardiac catheterization suite. Doses of any unfamiliar antiarrhythmic drugs should always be double-checked or determined before the procedure with the cardiologist.

### Types of Dysrhythmias

Dysrhythmias may be atrial or ventricular in origin or involve degrees of heart block. Atrial arrhythmias such as supraventricular tachycardia or atrial flutter frequently resolve spontaneously, but persistent atrial dysrhythmias can be treated pharmacologically or with overdrive pacing. They rarely progress to major events.<sup>36,37</sup>

Atrioventricular block occurs in 0.4% of cases, of which one fourth required pacing, although all children were in sinus rhythm by the time of discharge from hospital.<sup>37</sup> First- or second-degree atrioventricular block is well tolerated at all ages. When complete heart block occurs, it usually resolves shortly after the procedure and rarely persists.<sup>36</sup> Device closure for VSD has a high incidence (10.5%) of severe junctional bradycardia or complete heart block, and almost half of these children require pacing or isoproterenol.<sup>15</sup> Transient left bundle branch block has been reported after dilation of the aortic valve.<sup>26</sup>

Overall, the incidence of ventricular tachycardia or fibrillation is approximately 0.2%.<sup>36,37</sup> However, 30% of children who underwent VSD device placement had serious dysrhythmias and hypotension requiring catheter withdrawal, and 8.5% of them had ventricular arrhythmias requiring lidocaine or cardioversion.<sup>15</sup> Even relatively low-risk procedures are associated with dysrhythmias. Balloon atrial septostomy is frequently accompanied by rhythm disturbances. Typically, they are transient, but rarely, they can be permanent or even fatal.<sup>4</sup>

### Cardioversion

Atrial, supraventricular, and ventricular tachyarrhythmias; bradycardias; atrioventricular block; and bundle branch blocks have been described after cardioversion. Factors that influence the incidence of tachyarrhythmias include the underlying rhythm disturbance and cardiac disease, metabolic derangement, drugs (e.g., digoxin), and the strength of shock. Histologic injury to the myocardium is rare when the starting power for cardioversion is set at 0.5 J/kg.<sup>26</sup> Systemic and pulmonary emboli are rare in children compared with adults, for whom the incidence is 1% to 2%. Children with pacemakers are becoming more common, and these patients may require defibrillation. This can be done safely if the electrode pads are placed a distance from the generator and the pacemaker circuits and programming mode are checked afterward.

### CYANOSIS

When cyanosis occurs in the catheterization laboratory, it may be respiratory or circulatory in origin. A transesophageal echocardiographic (TEE) probe can cause desaturation by compressing the bronchi or vessels, pressing on the trachea, or precipitating bronchospasm. These events are more common in children weighing less than 10 kg.<sup>26</sup> Pneumothorax is rare but documented.<sup>37</sup> Hypercarbia, acidosis, excessive positive-pressure ventilation, contrast media, and hypoxia can increase pulmonary vascular resistance, which may lead to increased shunting and cyanosis. Hypercyanotic episodes are frequently observed,<sup>36</sup> particularly in infants with uncorrected tetralogy of Fallot. In one study, 12% of children with tetralogy of Fallot exhibited a hypercyanotic episode within 12 hours of catheterization despite adequate hydration, sedation, and the use of nonionic contrast media.<sup>37</sup>

### EMBOLIZATION

Misplaced devices, fragments of catheters, devices and balloons, thrombi, and air can result in embolization.

#### Device and Balloon

In a 1998 report of 1457 interventional cases, 18 devices embolized; 3 required surgical removal, 8 were removed in the catheterization laboratory, and 7 were of no hemodynamic consequence and were left in situ.<sup>36</sup> Devices that embolized included coils,

duct umbrellas, an atrial defect occlusion device, and endovascular stents.<sup>36</sup> Improvements in device design have reduced the risk for embolization; for example, for ASD devices the risk has decreased from 11.1% to less than 1.1%.<sup>4,44</sup>

Balloon rupture was common in the past, although it rarely produced intimal damage or embolic phenomena.<sup>41</sup> Balloon fragmentation has become uncommon because of technologic improvements in materials and design. To minimize this risk, an inflation device with an attached manometer is recommended to ensure that the pressure does not exceed the burst pressure of the balloon.

### Thrombus or Dislodged Material

Thrombus may be dislodged from devices or catheters, and balloon dilation may dislodge calcium, intimal lining from conduits, and thrombus from surgical systemic-pulmonary shunts.<sup>4</sup>

### Air

Gas emboli may occur in sheaths and catheters, burst balloons, or anesthetic infusion lines. Air embolus (as well as blood loss) is a known risk during interventional procedures in which there are many wire and catheter exchanges.<sup>26</sup> Balloons are dilated with a weak contrast mixture, and in view of the occasional balloon rupture, it is important to ensure all gas bubbles are eliminated from the contrast mix syringe and catheter before dilation is undertaken. Balloons used for flotation tip catheters should be filled with carbon dioxide rather than air to minimize the potential embolic effect if the balloon bursts. All intravenous lines, injections, and infusions must be free of air bubbles because these sources can cause embolic occlusion of arterial vessels, producing cerebral or myocardial ischemia in children with right-to-left mixing. Nitrous oxide should be avoided because it may expand any air embolism.

### CONTRAST TOXICITY

Adverse reactions to intravascular contrast are relatively uncommon, but the anesthesiologist must diagnose and manage a contrast-mediated reaction early in order to minimize morbidity or mortality. Reactions are often classified as idiosyncratic (i.e., unpredictable reactions independent of dose or concentration such as anaphylaxis) or chemotoxic (i.e., related to dose and physiologic characteristics such as osmolality). The pathophysiology of most reactions, however, is complex.<sup>45</sup>

There is reasonable evidence that severe anaphylactoid reactions to contrast media are not immunoglobulin E (IgE) mediated, but this does not explain the increased risk among atopic and asthmatic individuals. Many mechanisms have been proposed, including direct mast cell activation and degranulation, complement activation, inhibition of various enzyme systems, and binding to plasma proteins with conformational change.

#### Acute Reactions

Acute reactions to contrast agents can vary from mild to severe. Flushing, nausea, pruritus, vomiting, headache, and urticaria occur in 1% to 3% of patients receiving nonionic contrast.<sup>46</sup> These reactions are usually mild and self-limiting, requiring no specific treatment. Intermediate effects can manifest as moderate hypotension and bronchospasm and as more severe degrees of the mild reactions. Severe reactions can include convulsions, laryngeal edema, dysrhythmias, and cardiac arrest.

The likelihood of reaction varies with the type of contrast material; low osmolar (nonionic) solutions have considerably

reduced risk. The incidence of severe reactions to high osmolar (ionic) contrast is 0.2% to 0.06%, whereas reaction to low osmolar contrast is five times less common.<sup>45</sup> Reactions are more common when contrast medium is given through an arterial access compared with a venous access. Acute reactions should be managed according to anaphylaxis protocols (i.e., oxygen, intravenous fluid, epinephrine, corticosteroids, and histamine<sub>1</sub>- and histamine<sub>2</sub>-antagonist therapy). Prophylaxis with corticosteroids and antihistamines should be considered only if there is a well-documented history of acute reaction to a nonionic contrast material. If there is a history of reaction to nonionic contrast material, other imaging modalities, such as MRI, should be strongly considered. Occasionally, staining of the myocardium by contrast material has been observed, although this does not appear to confer any significant consequences.<sup>37</sup>

### Delayed Reactions

Delayed reactions to ionic and nonionic media are well described, with an incidence in one study of 8%.<sup>47</sup> Manifestations of these reactions include flulike illness, parotitis, nausea and vomiting, abdominal pain, headache, and rashes. The pathophysiology is unknown. Reactions (e.g., seizures, cerebral edema, electrolyte imbalance) to high- or low-osmolar solutions are possible if given in excessive doses.

### Renal Adverse Reactions and Prevention

The term *contrast media nephrotoxicity* (CMN) refers to an increase in serum creatinine concentration by more than 25% or 0.5 mg/dL within 3 days of receiving intravenous contrast media in the absence of another cause.<sup>45,47</sup> The underlying mechanism of the renal injury is unclear, although it is thought that contrast agents can reduce renal perfusion and are toxic to the tubular cells.

CMN occurs almost exclusively in children with preexisting renal damage. Children with CHD undergoing coronary angiography with low-osmolar contrast media may develop limited glomerular effects and reversible tubular dysfunction, but no long-term effects have been demonstrated. However, any child with reduced renal perfusion (e.g., dehydration, cardiac failure) should be regarded as at risk for CMN. It has been suggested that infants and children who receive more than 5 mL/kg of nonionic contrast agent are at increased risk for CMN.<sup>48</sup>

Many interventions have been given prophylactically to prevent CMN, including normal saline/half-normal saline hydration, administration of *N*-acetylcysteine (NAC), mannitol, theophylline, calcium channel blockers, diuretics, dopamine, dopamine<sub>1</sub> (D<sub>1</sub>) receptor antagonists, endothelin receptor antagonists, atrial natriuretic peptide, angiotensin-converting enzyme inhibitors, and PGE<sub>1</sub>.<sup>49,50</sup> Although preliminary studies with NAC have been promising, no interventions have been more effective than normal saline hydration. To minimize the risk of CMN, the minimal dose of contrast agent should be used.<sup>49,50</sup> When possible, potentially nephrotoxic drugs should be stopped at least 24 hours before the procedure.<sup>51</sup>

Gadolinium-based contrast materials are considered non-nephrotoxic in the normal MRI dose of up to 0.3 mmol/kg.<sup>51</sup> However, there is some evidence that the increased doses required for cardiac angiography may confer adverse renal effects.<sup>52</sup>

### NEUROLOGIC EVENTS

Central and peripheral neurologic damage can occur as a complication of the catheterization procedure. In one prospective study, 0.38% children suffered a neurologic complication, and

the incidence is significantly greater after interventional procedures than diagnostic procedures.<sup>53</sup>

### Central Nervous System

An ischemic cerebrovascular event may occur as a result of embolization, damage to the carotid artery, or acute low cardiac output states causing hypoxic-ischemic encephalopathy.<sup>37,53</sup> Thrombotic emboli may originate from any site in which there is endovascular or endocardial damage from the inner surface of the catheter or an implanted device. Factors that increase the risk during interventional procedures include large catheter size, more numerous vascular punctures, and procedures of increased duration.<sup>53</sup> However, embolic strokes also can follow an unremarkable catheterization procedure. The most common complications after an embolic stroke are convulsion and hemiplegia. Children with this type of stroke usually recover fully.<sup>53</sup> Seizures have been associated with lidocaine toxicity.<sup>54</sup> The outcome is more guarded after hypoxic-ischemic encephalopathy that occurs after a period of reduced cardiac output.<sup>53</sup>

### Peripheral Nervous System

As with any prolonged procedure under general anesthesia, it is crucial to consider pressure areas and traction forces on nerves such as the brachial plexus. Reduced cardiac output states associated with cardiac catheterization can augment the risk. Frequently, the arms are extended above the head to improve the lateral views of the heart. Brachial plexus injury is a risk in these circumstances<sup>26,55</sup> and is an important cause of malpractice lawsuits.<sup>56</sup> At-risk positions should be accepted only if the cardiologist clearly indicates it is required. If it is necessary to bring the arms above the head, the elbows should be flexed and elevated at least 15 cm above the level of the table to minimize traction on the brachial plexus. Head rotation should be minimized.<sup>55,57</sup> Passive movement may help to reduce injury, but it increases the risk of dislodging monitoring equipment or the airway. If such a position is required, it should be documented in the anesthesia record that this was the demand of the cardiologist.

### RADIATION

Radiation poses a risk to the patient and staff. Radiation overexposure can lead to scarring and skin injury, cellular injury, gene mutation, cell death, leukemia, bone cancer, thyroid cancer, and birth defects.<sup>58</sup> The principle with regard to radiation exposure is expressed by the acronym ALARA (or ALARP) which means as low as reasonably achievable (or practical). This principle must be applied in the context of obtaining adequate diagnostic images.

### Radiation Exposure of Patients

Radiation exposure is a particularly important for children because of their greater radiosensitivity compared with adults. Moreover, a greater proportion of their body is irradiated during procedures. Complex interventional procedures require long fluoroscopy times with multiple angiographic or fluoroscopic acquisitions.<sup>59</sup> Children undergoing electrophysiologic studies are particularly at risk for long fluoroscopy times.

When estimating the lifetime risk of cancer from radiation exposure, the child's age and weight need to be considered along with the duration and effective dose of radiation exposure. The risk for adult coronary angiography is 6% per sievert (Sv), and the average dose is about 10 mSv, which gives an increased risk of 0.06%.<sup>60</sup> In contrast, infants require smaller exposures due to

their reduced body weights, but they have an increased sensitivity. An infant has a lifetime cancer risk of 11% to 15% per sievert. If an infant is exposed to approximately 20 mSv (e.g., 1 hour of fluoroscopy and seven digital acquisition runs), the lifetime cancer risk is estimated as 0.03%.<sup>60</sup>

### Radiation Exposure of Staff

Most exposure comes from scatter from the beam entry point on the patient. Lesser amounts come from the x-ray tube and intensifier. The need for staff protection is well established and is accomplished by wearing lead aprons and by using thyroid shields, goggles, and suspended mobile glass lead screens for the head and neck. Operators should have monitoring devices to assess exposure, and only essential personnel should be present in the unprotected area.

### HYPOTHERMIA AND HYPERTHERMIA

The procedure is often prolonged, increasing the need for close temperature monitoring. Children may become hypothermic, which can exacerbate blood loss or dysrhythmias, or they may become hyperthermic, which may exacerbate any neurologic injury. For any procedure that is expected to last more than 1 hour, a forced-air warming device should be used. Central temperature should be measured.

### ENDOCARDITIS

Antibiotic prophylaxis against endocarditis for routine diagnostic cardiac catheterization varies among medical centers. All children scheduled for insertion of implantable devices should receive prophylactic antibiotics during the procedure, and most centers continue to recommend endocarditis prophylaxis for a minimum of 6 months after implantation. Although most centers do not routinely administer antibiotics for angioplasty procedures, there is usually a residual flow disturbance after the procedure that warrants ongoing endocarditis prophylaxis.

### OVERCOMING LIMITATIONS

The main limitation in the use of catheterization techniques in younger or smaller children has been the delay in development of equipment of appropriate size. To overcome this difficulty, clinicians have developed hybrid procedures to permit current catheter-based techniques to be used in infants and small children. Examples of this collaborative approach between surgeon and interventional cardiologist include perventricular closure of muscular ventricular septal defects<sup>61</sup> and hybrid stage 1 palliation for hypoplastic left heart syndrome (i.e., off-pump placement of a PDA stent and creation of an unrestricted ASD).<sup>60</sup>

The next great challenge is to develop equipment and techniques that can be used in conjunction with MRI.<sup>62</sup> This would minimize radiation exposure to children and staff. However, there are significant technical obstacles that need to be overcome before this approach can fully replace catheterization laboratories using ionizing radiation.

## Anesthesia

### WHO AND HOW?

The aims of anesthesia care for pediatric interventional cardiology are to ensure the child is not distressed, to provide optimal conditions for accurate diagnostic measures and successful completion of any intervention, and to manage the complications and significant derangements that may occur in the child's

cardiovascular physiology during the procedure. These aims may require general anesthesia or occasionally may be met with deep sedation.

The care of these children may be provided by a nurse anesthetist, general pediatric anesthesiologist, or specialized cardiac pediatric anesthesiologist, depending on the complexity of the child's condition and qualifications of the practitioner. Because deep sedation can easily merge into general anesthesia, current guidelines sensibly suggest that deep sedation should be supervised by someone skilled at providing anesthesia and sedation.<sup>63</sup> This person should be skilled at resuscitation of children with CHD and must not be the proceduralist. The choice of sedation or general anesthesia and the seniority of anesthesiologist should match the procedure and the child.

Increasingly, there are fewer diagnostic procedures and more interventional procedures. This change is reflected in a shift from sedation to general anesthesia and the expanding role of specialized cardiac pediatric anesthesiologists.<sup>64</sup> Anesthesia providers for these children must have a high level of experience in pediatric anesthesia and a thorough understanding of pediatric cardiology and CHD. They must understand the physiology, the procedure, and the potential complications.

### PREPROCEDURAL ASSESSMENT AND MANAGEMENT

Children scheduled for elective interventional cardiology are often admitted to the hospital on the day of the procedure. Ideally, all children should have an anesthesia assessment at the same time as their preprocedural cardiologic workup. An efficient and complete anesthesia assessment requires good coordination and communication between cardiology and anesthesia units. The anesthesia preoperative assessment should establish the cardiac anatomy and function and determine details of the planned procedure or intervention.

Up to 25% of children with CHD have syndromes or other anomalies that may affect their anesthesia care and require a thorough assessment of all relevant systems. The children might have had previous cardiac surgery or several other interventions. Obtaining intravenous access may be very difficult in some of them. Children with CHD are likely to have undergone anesthesia several times in the past, and the family may be well informed about the child's condition, hospital process, and anesthesia. During the preoperative assessment, it is important to have a discussion about the sedative premedication, parental presence, and the mode of induction of anesthesia (see Chapters 1 and 4).

Interventional cardiology procedures may involve considerable physiologic trespass, and some children may have limited cardiac reserve. They should be in optimal health whenever possible. Intercurrent illness or infection may bias cardiorespiratory diagnostic values, increase the risk of endocarditis, and increase the risk of anesthesia complications such as laryngospasm. The urgency of the procedure, the cardiovascular status of the child, and the extent of the procedure should be considered carefully before proceeding in a child with an intercurrent illness.

### ANATOMY AND FUNCTION

When assessing the anatomy and function, answers to four primary questions may affect anesthesia management:

- Where does the blood go?
- What is the ventricular function?
- How reactive is the pulmonary circulation?
- Is there a fixed or dynamic stenosis?

Answers to these and other questions can help the anesthesiologist determine the optimal approach to management:

- How well is hyperoxia or hypoxia tolerated?
- What will be the effect of increased sympathetic stimulation, vasodilation, or reduction in myocardial contractility?
- What are the likely causes of cardiovascular collapse, and how should they be managed?

Most primary questions can be answered from the record, details of previous surgery, and recent echocardiographic results. Very poor function may be easily discovered in the history and physical examination, but moderate levels of dysfunction may not be offered or easily detected clinically.

Blood should be taken for a hematocrit evaluation and cross-matched for possible rapid transfusion. Premedication may consist of paracetamol for postprocedural analgesia and, if needed, sedation with oral midazolam (0.5 mg/kg) or ketamine (up to 5 mg/kg). Larger doses of sedative premedications may be used to provide more reliable or greater sedation if heavy sedation is mandatory, but large doses may cause delayed recovery or significant sedation after the procedure.

Care should be taken that these children do not become excessively dehydrated. Fasting times should be adequate but not excessive, and in selected children, a preprocedural intravenous line should be started. Topical anesthesia creams can be used if an intravenous induction is planned. To plan optimal anesthesia, the anesthesiologist must understand exactly what the cardiologists are hoping to achieve and what conditions the cardiologist needs.

### THE ENVIRONMENT

Cardiac catheterization laboratories are often remotely located from the main operating room complex, limiting availability of immediate assistance and increasing transport times to and from central recovery areas. Ideally, cardiac catheterization laboratories should be located adjacent to cardiac theaters to facilitate rapid management of complications. For some cases, ECMO and cardiopulmonary bypass circuits should be nearby and immediately available. Blood gas analysis should be rapidly available, and blood should be immediately available for urgent transfusion for interventional procedures such as balloon dilation and device insertion.

The cardiac catheterization laboratory is a hostile environment for anesthesiologists. Access to the child may be limited by the anteroposterior and lateral x-ray cameras, sterile drapes, and radiation protection devices. The x-ray cameras are bulky and may be unexpectedly moved for oblique views, different fields, or greater magnification. The lighting is often subdued to enhance viewing of the radiographs (Fig. 20-5).

Great care must be taken to secure all monitoring and airway devices before draping begins or the x-ray cameras are positioned. Access to the child during the procedure is limited and hazardous. Blind manipulation under the drapes can dislodge monitors or the tracheal tube. Moving cameras are a hazard to the anesthesiologist and may also dislodge anesthesia monitors, the tracheal tube, and the airway circuit.

### THE CARDIAC PATIENT

The management of anesthesia for children with CHD is discussed further in Chapters 15 to 17. Important considerations include the potential for myocardial dysfunction and poor ventricular function reserve. This may be a particular problem in children with hypertrophied right ventricles operating at near-systemic pressures or with volume-loaded dilated ventricles.

**FIGURE 20-5** Typical setup of a catheterization laboratory, showing limited access to a child.

Another important consideration is pulmonary hypertension and the reactivity of the pulmonary circulation. Pulmonary resistance is particularly important in several situations:

- Patients may have increased reactivity, such as in neonates or children with primary pulmonary hypertension.
- Children may have chronically increased pulmonary artery pressures and minimal right ventricular reserve.
- Children may have balanced circulations, such as after a Norwood procedure, in which increases or decreases in pulmonary vascular resistance may lead to spiraling hypoxia or systemic ischemia and acidosis.
- Children may have low-pressure pulmonary circulations, such as cavopulmonary shunts or after Fontan surgery.

### CHOICE OF ANESTHESIA

The choice of anesthesia should be determined by the three factors linked to the aims stated earlier. The ideal anesthesia prescription should achieve the following:

- Ensure the child is not distressed
- Provide optimal conditions for accurate diagnostic measures or successful completion of any intervention
- Minimize any risk inherent in children with abnormal cardiovascular physiology

Many anesthetic agents and techniques have been used in pediatric interventional cardiology. To some extent, the choice is determined by the procedure and the pathology.

### Sedation

The difference between deep sedation and general anesthesia is imprecise and controversial, especially for small children in whom consciousness and memory are harder to measure (see Chapters 45 and 47). When considering the suitability of sedation or general anesthesia, several issues are important:

- Does immobility need to be guaranteed?
- What will be the level of stimulation?
- Do oxygen and carbon dioxide tensions need to be controlled?
- What will be the cardiovascular effects of the anesthetic agents?
- How likely is significant physiologic trespass?
- What will be the duration of the procedure?

Sedation is associated with a degree of movement that may make some procedures difficult or potentially dangerous, such as in device placement or balloon dilation. Stimulating procedures such as balloon dilation may make smooth sedation difficult. Sedation is poorly tolerated if the arms need to be placed above the head for long periods or if the procedure is prolonged. As for any other procedure, sedation for interventional cardiology is unwise if the child has obstructive sleep apnea or airway abnormalities. If significant cardiovascular complications are likely due to the procedure or the status of the child, control of the airway with general anesthesia may be safer. For all children, if sedation is used, there must be provision for rapid and expert transition to general anesthesia.

Sedation techniques have evolved over the past 2 decades, resulting in much more effective and titratable strategies today. Since the 1950s, the classic lytic cocktail, consisting of intramuscular meperidine, promethazine, and chlorpromazine, has been the standard for sedation.<sup>65</sup> However, this cocktail has a high incidence of failure and oversedation, and is associated with sterile abscess formation.<sup>66</sup> Oral ketamine and midazolam provide more reliable sedation, but occasionally, respiratory support is required.<sup>67</sup> In theory, intravenous ketamine is an excellent choice for sedation because it provides a stable or increased heart rate and blood pressure and has little or no effect on pulmonary vascular resistance. However, prolonged recovery, vomiting, and dysphoric reactions may be problematic.<sup>68</sup> Intravenous ketamine has been successfully used alone or in combination with midazolam<sup>69</sup> or propofol.<sup>70</sup> Propofol is also widely used for sedation, but compared with ketamine, it causes a greater reduction in systemic blood pressure and systemic vascular resistance, with no effect on pulmonary vascular resistance. This may increase a right-to-left shunt, or in diagnostic procedures, it may attenuate the gradient across a stenosis, making the decision to dilate the stenosis more difficult.<sup>68,71,72</sup> Compared with propofol sedation, a combination of ketamine with propofol produces similar sedation with less cardiovascular depression.<sup>73</sup> Dexmedetomidine has been proffered for sedation of children undergoing cardiac catheterization, although it may not provide sufficient sedation by itself.<sup>74</sup> When combined with ketamine, dexmedetomidine was inferior to propofol and ketamine.<sup>75</sup>

In sedated children, local anesthesia with the use of a topical cream may facilitate venous access.<sup>76</sup> Spinal anesthesia has been described as an alternative to sedation or general anesthesia in high-risk infants younger than 6 months of age when the procedure is expected to take less than 90 minutes.<sup>77</sup>

Sedation is often used to avoid the potential effects of general anesthesia on diagnostic measures. However, as the diagnosis shifts to intervention, this argument assumes less relevance. Deep sedation may be associated with significant respiratory changes<sup>67,78</sup> and hypoxia<sup>72</sup> in some children. These changes can have as much effect on the circulation as general anesthesia, limiting the theoretical advantage of sedation. General anesthesia and sedation may alter hemodynamics and intracardiac shunts.<sup>67,72</sup>

### General Anesthesia

If general anesthesia is required for diagnostic procedures, the aim should be to maintain normal levels of inspired oxygen and arterial carbon dioxide, a low intrathoracic mean pressure, and minimal direct hemodynamic effects. Positive-pressure ventilation more easily maintains the target carbon dioxide concentrations than spontaneous ventilation, but it decreases preload to the pulmonary and systemic atria, increases afterload on the right

ventricle, and decreases afterload on the left ventricle; especially if the mean intrathoracic pressure is increased. If the child can maintain adequate oxygenation and normal carbon dioxide tension during sedation or general anesthesia, spontaneous ventilation is often preferred.

No general anesthetic agent is definitely superior to others. Using physiologic and theoretical arguments, there is evidence for and against inhalational and intravenous anesthesia, but no outcome studies have provided strong evidence for either technique. Great care should be taken to avoid myocardial depression or vasodilation associated with excessive doses of inhalational or intravenous anesthetics. For this reason, some argue against inhalational induction, although it can also be argued that the use of total intravenous anesthesia is unwise given the wide variability in children's responses. Nitrous oxide should be avoided if there is an element of reversible pulmonary hypertension and to avoid expansion of gas bubbles.

Etomidate may have a role in children with significant compromise because it has little hemodynamic effect on systemic or pulmonary pressures or resistances.<sup>79</sup> Remifentanyl may offer an advantage in cardiac procedures because of the short, context-sensitive half-time that allows rapid awakening on completion of the procedure, although it is an opioid and lacks the sedation qualities of other medications. Concerns remain about the possible risks of bradycardia, hypotension, and chest wall rigidity with this opioid.<sup>80,81</sup> In some cases, postprocedural sedation may offer an advantage in reducing patient movement, thereby reducing the risk for dislodging a clot on the catheter or at the catheterization site.

Opioids are not usually needed for postoperative analgesia after interventional cardiology procedures, and they may contribute to postanesthesia nausea and vomiting. Adequate infiltration with local anesthesia around the femoral vessels can significantly limit the degree of stimulus and should not impair ease of vessel access. However, earlier reports of local anesthetic toxicity in children undergoing cardiac catheterization led to a moratorium on the use of local anesthetics in the cardiac catheterization laboratory in some centers.

Radiofrequency ablation procedures may be protracted and require an immobile child. They may also precipitate arrhythmias, requiring defibrillation. For these reasons, general anesthesia is preferred. General anesthetic agents have effects on conduction that may affect the generation of preexcitation and automatic tachycardia. Good clinical data are scant; however, it appears that for preexcitation, isoflurane and sevoflurane have little effect at less than 1 minimal alveolar concentration (MAC), whereas propofol and opioids have no demonstrable effects at any dose. In contrast, automatic tachycardia may be suppressed by large doses of opioids, propofol or dexmedetomidine.<sup>82</sup> In a prospective, randomized trial, isoflurane- and propofol-based anesthesia resulted in a similar duration of anesthesia and effectiveness of ablation.<sup>83</sup> Because of the protracted time course of these procedures, a forced-air warming device is indicated to maintain thermal homeostasis. Esophageal ulceration and atrio-esophageal fistula have been reported in up to 3% of patients undergoing these procedures, particularly when excessive energy is applied during ablation (e.g., more than 25 W for extended periods).<sup>84</sup> We recommend using energy levels less than 25 W during the ablation and to monitor the esophageal temperature by inserting an esophageal temperature probe to the level of the mid-esophagus. Position of the stethoscope may be verified by injecting contrast dye in the bulb of the stethoscope.

## Principles of Technique

Attention to detail is essential for providing safe anesthesia for children with reduced ventricular reserve and critical pulmonary circulations. The most frequent error precipitating adverse events is providing inadequate anesthesia. Hemodynamic consequences of light anesthesia, such as hypoxia due to laryngospasm, are poorly tolerated in children with pulmonary hypertension. Hypoxia or hypercapnia may lead to increasing pulmonary vascular resistance, which may increase the shunt and further worsen the hypoxia. Increased pulmonary hypertension may also lead to significant decreases in pulmonary compliance, further increasing hypoxia and precipitating a downward spiral.<sup>85</sup> Another cause of adverse outcomes is the use of unfamiliar anesthesia techniques. For example, it is imprudent to use remifentanyl for the first time in a child with primary pulmonary hypertension. Although there are theoretical grounds to support the use of one drug or another, the most important principle of anesthesia in children with CHD is to carefully use techniques that are reliable and familiar. This reinforces the need for these children to be anesthetized only by those with sound knowledge and experience with the physiology of the CHD and the planned procedures. Careful anesthesia entails attention to preprocedural anxiolysis, fluid management, full monitoring, expert assistance, and taking extra time to deliver anesthetic drugs slowly or in incremental doses to avoid overpressure or excessive blood levels. A useful approach is to transduce the cardiologist's arterial access onto the anesthesia monitor. This can be accomplished with a slave connection or by adding a second stopcock to the system with a second transducer for the anesthesia monitor.

The procedures often involve long periods of very little painful stimulation with occasional painful moments such as a sheath change or balloon dilation. These moments can be anticipated if good communication is maintained between the cardiologist and the anesthesiologist. During dilation of the aortic arch or aortic valve, it is prudent to have an arterial line (preferably a right radial line) to allow continuous blood pressure monitoring. Dilation of arterial or venous vessels is quite painful and may cause coughing or significant discomfort if the child is only sedated.

TEE is increasingly used as part of diagnostic procedures or during device placement. Because TEE can be painful, it requires a deeper plane of anesthesia with the addition of opioids or neuromuscular blockade, or both. TEE requires a tracheal tube to provide a patent airway, and care must be taken to hold the tube securely during manipulations of the TEE probe because the manipulations and gel required can easily dislodge the tracheal tube.

Coughing and straining on extubation may increase the risk of bleeding. For this reason, deep extubation may be preferred. The advantages of deep extubation must be balanced with the risks of hypoxia and hypercapnia and loss of airway control or laryngospasm that may ensue if the tracheal tube is removed before the child is fully awake. Postoperative delirium and restlessness can increase the risk of bleeding. Children should have sufficient analgesia to prevent postoperative distress. This is usually provided with paracetamol and local anesthetic infiltration.

Reliable intravenous access is essential in these children to provide rapid resuscitation. Using leg veins may not be ideal if the femoral veins are occluded with thrombosis or catheters.

Similarly, pulse oximetry and noninvasive blood pressure cuffs should not be placed on the legs.

## FUTURE OF ANESTHESIA IN INTERVENTIONAL CARDIOLOGY

Anesthesia for interventional cardiac catheterizations will become more challenging as new interventions are developed for sicker children and as more cardiology procedures are performed in combination with open surgery or MRI. More children are likely to need anesthesia instead of sedation, and specialist pediatric cardiac anesthesiologists will be spending an increasing proportion of their time in interventional cardiology suites.

Altered Respiratory Mechanics	Congenital Anomalies of the Coronary Arteries
Pulmonary Hypertension	Single Ventricle
Endocarditis Prophylaxis	<b>Summary</b>

ADVANCES IN THE PAST SEVERAL DECADES have dramatically altered the natural history of congenital heart disease (CHD). These refinements have resulted in decreased morbidity and mortality for affected children and improvements in quality of life. As life expectancy continues to increase and survival rates further improve, an escalating number of children with CHD will need to undergo noncardiac surgery or other procedures unrelated to their heart disease. Because the trend continues to be for earlier cardiac surgery, children with CHD who have undergone palliative treatment or repair represent the main patient group that an anesthesiologist is likely to encounter during elective or emergent noncardiac surgery. In some cases, children may require noncardiac surgery before undergoing procedures to address their cardiovascular disease. In others, the condition may not require or be amenable to surgical intervention. The care of children with CHD is becoming more common in all diagnostic and surgical settings.

A wide spectrum of extracardiac anomalies has been described in children with CHD.<sup>1-5</sup> A great incidence of chromosomal syndromes and genetic disorders is associated with CHD, and

the reported prevalence of associated malformations ranges between 10% and 33%.<sup>6-8</sup> The organ systems most often affected include musculoskeletal, central nervous, renal-urinary, gastrointestinal, and respiratory. Although many extracardiac malformations are relatively minor and have limited or no clinical implications, many children with CHD have significant noncardiac comorbidities.<sup>9</sup> These pathologic and disease processes may necessitate surgical intervention. Other routine ailments and conditions may affect these children and require diagnostic procedures and surgical care.

The challenges of caring for children with CHD are magnified by the diversity of structural malformations, each with specific physiologic perturbations, hemodynamic consequences, and severity. This is further complicated by the variety of medical and surgical management strategies available. Most children require an individualized approach to anesthetic care.<sup>10-12</sup>

Clinical outcomes for CHD depend on the nature of the anatomic abnormalities and the possibility of successful palliation or correction.<sup>13</sup> The primary goal of palliative surgery is to

favorably influence the natural history of the defect and decrease the likelihood of the severe consequences of the disease. However, children continue to have abnormal cardiovascular anatomy and physiology, and their abnormal circulation is associated with an increased risk of perioperative adverse events.<sup>14-17</sup>

Reparative, corrective, or definitive procedures are expected to improve hemodynamics and cardiac function while minimizing long-term ill effects of an abnormal circulation, improving the overall clinical outcome. Although the pathology might have been surgically treated, the cardiovascular system should not be considered normal. True surgical correction may be the exception rather than the rule in CHD, and repair of a congenital cardiac lesion should not be equated to a cure for most children.

Despite these considerations, for children with good hemodynamic results, the risks associated with noncardiac surgery may not be significantly different from those of others without CHD. These children are considered to be doing well clinically, have a good functional status, require few or no medications, have no exercise restrictions, and undergo routine surveillance. They require minimal or no adjustment in perioperative care compared with that provided to children without CHD. In others, however, residual abnormalities exist. In some who are less fortunate, a pathologic process may remain or develop after cardiac surgery that is related to the primary disease or therapy. This may lead to severe cardiovascular or pulmonary impairment. These residua and sequelae may necessitate further medical or surgical interventions and may increase perioperative morbidity during noncardiac surgery.<sup>18</sup> Management of these children is influenced by several factors but to a significant extent by the residual problems of the disease and treatment and associated hemodynamic perturbations.<sup>19,20</sup>

Many publications have examined the implications of anesthesia for children and adults with CHD undergoing noncardiac surgery.<sup>10,19-33</sup> However, only a limited number of studies have provided data on perioperative outcomes.<sup>34-38</sup> In contrast to the extensive literature regarding perioperative cardiac assessment and risk stratification during noncardiac surgery in adults with heart disease and the development of guidelines aimed at improving clinical outcomes, the lack of rigorous scientific data on this subject for the pediatric age group has made an equivalent effort challenging.<sup>39</sup>

In this chapter, general principles of anesthesia practice are reviewed as they pertain to the care of children with CHD undergoing noncardiac surgery. Unique perioperative considerations and issues applicable to high-risk patient groups are described. Anesthesia management for these children is significantly influenced by factors such as structural abnormalities, pathophysiologic consequences of the defects, functional status, potential residua, sequelae, and long-term outcome.

## Preoperative Assessment

A detailed preoperative evaluation is indispensable for identifying and anticipating factors that may place a child with CHD at increased risk during anesthesia (Table 21-1).<sup>40,41</sup> An important goal of this assessment is to gather information regarding the nature of the cardiovascular disease and prior therapeutic interventions. A determination of functional status is based on clinical data. The history and physical examination, in addition to the laboratory data and ancillary tests, provide complementary information about anatomic or hemodynamic status, enabling an overall risk assessment. Based on this clinical assessment and

**TABLE 21-1** Factors That Place Children with Congenital Heart Disease at Increased Risk during Anesthesia for Noncardiac Surgery

Anticoagulation therapy
Arrhythmias
Congestive heart failure
Emergent surgery
History of implanted device (pacemaker or defibrillator)
Hypoxemia
Long-standing cyanosis
Major noncardiac surgery
Older age at the time of cardiac intervention
Older type of cardiac surgical procedure
Pulmonary hypertension/pulmonary vascular disease
Significant outflow tract obstruction
Significant sequelae or residua
Single-ventricle physiology or complex defects
Syncope
Unrepaired pathology
Ventricular dysfunction
Young age (infancy)

consideration of the major pathophysiologic consequences of a particular condition, a systematic, detailed, organized plan should be formulated for anesthesia and perioperative management. In some cases, the preoperative evaluation may establish the need to delay or defer elective noncardiac surgery, other interventions, or diagnostic procedures.

## HISTORY AND PHYSICAL EXAMINATION

As for all children undergoing anesthesia, the history and physical examination results are essential components of a thorough preoperative evaluation. In addition to the specifics regarding the present illness and planned procedure, the history should focus on the status of the cardiovascular system. Relevant information includes the type of cardiovascular disease and comorbid conditions, medications, allergies, prior hospitalizations, surgical procedures, anesthesia experiences, and complications. Symptoms, including tachypnea, dyspnea, tachycardia, rhythm problems, and fatigue, should be sought. Feeding difficulties and diaphoresis may represent significant symptoms in infants, whereas decreased activity level or exercise intolerance may be a concern for older children. Palpitations, chest pain, and syncope should be characterized. The history should include an assessment of growth and development because these may be affected in children with CHD. Failure to thrive suggests ongoing cardiorespiratory compromise. Those with decompensated disease, complex pathologies, associated genetic defects, or other syndromes may be particularly vulnerable. Recent illnesses such as intercurrent respiratory infections or pulmonary disease may increase the potential for perioperative complications and require careful appraisal of the risk/benefit ratio in elective cases.<sup>42,43</sup>

The physical examination should include the child's weight and height. Vital signs, including heart rate, respiratory rate, and blood pressure, should be documented. If the child is known or suspected to have or has been treated for any form of aortic arch obstruction or has had any systemic-to-pulmonary shunt, upper and lower extremity and the right and left upper extremity blood pressure recordings and palpation of the quality of pulses should

be documented. This assessment provides information about the patency of arterial beds and helps in the selection of blood pressure monitoring sites. The examination should explore suitable sites for venous and arterial access and identify potential difficulties. Emphasis should be given to the airway and cardiovascular system, with particular attention to any changes from previous examination findings.

General assessment should include the child's level of activity, breathing pattern, level of distress (if any), and presence of cyanosis. Respiratory evaluation should include the quality of the breath sounds and indicate the presence or absence of labored breathing, intercostal retractions, wheezing, rales, or rhonchi. Abnormalities may suggest congestive symptoms or a pneumonic process. Cardiac auscultation should include assessment of heart sounds, pathologic murmurs, and gallop rhythms. The presence of a thrill, representing a palpable murmur, should be documented. The abdomen should be examined for the presence of hepatosplenomegaly. Assessment of the extremities should include examination of pulses, overall perfusion, capillary refill, cyanosis, clubbing, and edema. Noncardiac anomalies or pathology that may affect anesthesia care (e.g., specific syndrome complex, potentially difficult airway, gastroesophageal reflux) should be recorded.

An important objective of the preoperative evaluation is to identify children with functional cardiopulmonary limitations imposed by their cardiovascular disease. Symptoms and signs consistent with congestive heart failure, cyanosis, hypercyanotic episodes, and compromised functional status (i.e., significant exercise intolerance or syncope episodes) should raise concerns about potential perioperative problems. The pediatric cardiologist should obtain information about the nature and severity of the cardiovascular pathology, describe the child's overall clinical status, and assess prior complications. The cardiologist should assist in the identification of children at great risk and optimize their preoperative clinical condition. The perioperative care teams should be alerted to any particular concerns that may affect the care of the child. The anesthesiologist should have a detailed understanding of the child's cardiac defect, pathophysiologic consequences, nature of the medical and surgical therapies applied, functional status, and implications for perioperative management. Although the surgical team may not have an in-depth understanding of the child's cardiovascular disease, by sharing the details of the surgical plan and likely perioperative issues with the anesthesiologist, problems may be anticipated and proactively addressed.

#### ANCILLARY STUDIES AND LABORATORY DATA

The baseline systemic arterial saturation value should be determined by pulse oximetry ( $\text{SpO}_2$ ) when the child is calm and, in most cases, while breathing room air. Acceptable values depend on many factors, including the specific cardiovascular defects, whether the child has a two- or a one-ventricle circulation, the preoperative versus postoperative status with respect to the cardiac pathology, and the stage in the palliative pathway for those undergoing such a strategy. Children who have undergone definitive procedures should be expected to have normal to a near-normal  $\text{SpO}_2$  value (at least 95%). After palliative interventions,  $\text{SpO}_2$  values typically range between 75% and 85%.

The extent of preoperative laboratory testing largely depends on the status of the patient and the type, anticipated duration, and complexity of surgery. Studies most commonly obtained include hematocrit, hemoglobin, electrolytes, and coagulation

tests. In cyanotic children, a complete blood cell blood count allows determination of polycythemia, microcytic anemia, and thrombocytopenia. Prothrombin time, partial thromboplastin times, and international normalized ratio (INR) provide an indication of clotting ability. Cyanotic children usually have increased red blood cell mass and relatively small plasma volumes. The collection of specimens for coagulation tests requires sampling tubes that adjust the amount or concentration of citrate to prevent artifactual prolongation of the values. For those receiving diuretic therapy, digoxin, or angiotensin-converting enzyme inhibitors, the determination of a basic metabolic panel may be useful. Blood typing and crossmatching should be performed depending on the anticipated need for blood administration.

A recent electrocardiogram (ECG) should be reviewed for any changes from prior studies (particularly regarding criteria consistent with chamber dilation or ventricular hypertrophy), the presence of rhythm abnormalities, and findings suggesting myocardial ischemia. If an arrhythmia is identified, further evaluation is warranted because it may reflect an underlying hemodynamic abnormality that may affect the perioperative course. A continuous ECG recording (i.e., Holter monitor) and further evaluation may be indicated in the child with a history of rhythm disturbance, palpitations, or syncope or with an ECG suggesting significant ectopy or arrhythmia. An exercise tolerance test or treadmill study may be warranted if there is concern about myocardial ischemia, as may be the case for the child with aortic stenosis, coronary artery anomalies, or exercise-induced arrhythmias.

Review of a recent chest radiograph, including a lateral view, provides information regarding cardiac size, chamber enlargement, and pulmonary vascularity. Prior studies such as echocardiograms, cardiac catheterizations, electrophysiologic procedures, and magnetic resonance imaging should be reviewed. In some cases, it may be necessary to obtain further diagnostic information before proceeding with the planned procedure if there are symptoms that merit additional investigations or issues of concern. These evaluations should be coordinated with the child's cardiologist. It is also important to consider whether the child may benefit from cardiac catheterization for diagnostic or interventional purposes to address significant structural, functional, or hemodynamic abnormalities before the anticipated procedure. In addition to providing potentially helpful information, the clinical status of the child can be substantially improved in many cases by catheter-based interventions. This may be of significant benefit when the anticipated procedure is considered to be major.

One of the goals of the preoperative evaluation is to obtain the most diagnostic information with the fewest tests and the least risk, discomfort, and expense for the child. The anesthesiologist is particularly suited to determine which tests are appropriate for optimal perioperative planning and whether additional data are needed.

#### INFORMED CONSENT

The physicians involved in the care of the child should meet with the patient and family to discuss the anesthetic plan and answer any questions. The preoperative consultation provides the opportunity to alleviate patient and parental anxiety. At the same time, the benefits and risks involved should be discussed. Although surgery in children with CHD, particularly in those with uncorrected defects, may carry an increased risk, it may not be possible to define the specific contribution of each factor to the overall risk.

## FASTING GUIDELINES

Although the optimal period of fasting for children before surgery has been the subject of some debate, most centers follow established guidelines to reduce the risk of aspiration.<sup>44-47</sup> The same guidelines are applicable to children with CHD with a few additional considerations. Intake of clear fluids or the intravenous administration of maintenance fluids may be required in some children to ensure adequate hydration if the fasting period is prolonged. This is particularly important in small infants and in patients with obstructive lesions, cyanotic disease, or single-ventricle physiology. Maintenance of adequate hydration and ventricular preload may limit potential detrimental hemodynamic changes associated with anesthesia and surgery.

## MEDICATIONS

Children with CHD may be receiving medications such as digoxin, diuretics, vasodilators, anticoagulants, antiarrhythmics, or immunosuppressant agents. Although there may be an occasional exception, such as diuretic or anticoagulation therapy, there is usually no need to discontinue chronic medications before surgery. It is often important to continue these drugs until the time of surgery, and in most centers, children are allowed to take scheduled oral medications with small sips of water preoperatively.

## Intraoperative Management

Anesthesia and surgery impose additional stresses on the cardiovascular system and provoke compensatory mechanisms to maintain homeostasis. It is important to assess the child's physiology and cardiovascular reserve to anticipate his or her ability to increase cardiac output to meet metabolic demands. This information, along with the nature and complexity of the surgery, can help to decide the extent of monitoring required. This information can be used to choose anesthetic agents and techniques that least affect the child's cardiovascular system. Prompt intervention is imperative if decompensation occurs. Good communication among the surgeon, cardiologist, anesthesiologist, and nursing teams during the entire perioperative period is essential in treating children with complex disease.

## GENERAL CONSIDERATIONS

### Anesthesia Care Provider

Anesthesia care should be provided by an experienced individual who is familiar with children with CHD, the planned operative procedure, and the surgeon's usual approach. The most important factor that an anesthesiologist can offer a child with CHD is a comprehensive understanding of the anatomic abnormalities, pathophysiology of the cardiac malformation, and how this may be affected by the anesthetic and surgical procedure. Familiarity with the most likely residua and sequelae is essential.<sup>18</sup> Adequate communication among all physicians involved enhances the likelihood of the best possible outcome.

### Premedication

The use of premedication to provide sedation and anxiolysis is routine before most surgical procedures because some degree of fear or anxiety is expected. This facilitates parental separation, entry into the operating room, placement of monitors, and induction of anesthesia. The cardiorespiratory effects of premedication in children may be influenced by the underlying systemic disease.<sup>48-52</sup>

Commonly used premedications include oral or intravenous benzodiazepines, opioids, and small amounts of hypnotic agents. Drugs such as barbiturates and ketamine are occasionally used. Alternative routes for premedication include intramuscular, intranasal, and rectal methods. Children with hemodynamic decompensation may require little or no premedication. Caution should also be exercised for those with a history of cardiovascular pathology associated with significant increases in pulmonary artery pressure or pulmonary arteriolar resistance because hypoventilation and hypoxemia may be detrimental. Conversely, children susceptible to hypercyanotic episodes or those with catecholamine-induced arrhythmias may benefit from heavy premedication. In selected children (e.g., infants and children with cyanotic heart disease), oxygen saturation monitoring after premedication and the administration of supplemental oxygen is recommended.<sup>50</sup>

### Intravenous Access

Secure intravenous access is mandatory for administration of fluids and medications during anesthesia care. In most children with CHD, intravenous access is established after an inhalational induction. In those considered at great risk, such as children with severe outflow tract obstruction, moderate to severe cardiac dysfunction, pulmonary hypertension, or potential for hemodynamic compromise, consideration should be given for placement of intravenous access before induction of anesthesia or very early in the induction. The size of the intravenous catheter should be determined by the anticipated fluid requirements. If peripheral access is poor, central venous access may be necessary, particularly if there is potential for large intravascular volume shifts and to allow monitoring of central venous pressure. Placement of a central venous catheter may be assisted by audio Doppler or two-dimensional ultrasound guidance (see Chapter 48). In the small infant with single-ventricle physiology, central venous cannulation with catheter placement in the superior vena cava may be undesirable in view of concerns about potential vascular complications that may affect pulmonary blood flow or subsequent surgical palliation. In these children, a small catheter or alternative approach (e.g., femoral venous access) should be considered. In children with an existent or potential right-to-left shunt, all air must be removed from intravenous infusion tubing. Air filters may be difficult to use in the operating room because they may restrict the rate at which intravenous fluids or blood may be administered in emergency situations. They may be more useful in the preoperative and postoperative periods.

### Emergency Drugs

In view of the potential for hemodynamic instability in some children with CHD that may occur under any circumstance and at any time, drugs for emergency situations should be prepared or immediately available to the anesthesiologist providing care.

## MONITORING

A basic principle of intraoperative monitoring is to use techniques or devices that provide useful information to help with clinical decision making and to avoid monitors that are distracting or redundant. Basic monitoring involves observation of the child, including skin color, capillary refill, respiration, pulse palpation, events on the surgical field, and color of shed blood. Standard noninvasive monitors used during most surgical interventions include oscillometric blood pressure assessment, electrocardiography, pulse oximetry, capnography, and temperature monitoring. A precordial stethoscope can be extremely helpful

for monitoring changes in heart tones that may suggest early hemodynamic compromise. In the child with CHD, relatively sophisticated and invasive monitoring may be needed.

### Arterial Blood Pressure Assessment

Basic blood pressure monitoring begins with pulse palpation. An automated blood pressure cuff is used in most children. The selection of monitoring site may be influenced by vascular anomalies (e.g., aortic arch pathology, aberrant origin and course of aortic arch vessels) or prior surgical interventions (e.g., Blalock-Taussig shunt, arterial cutdown). Direct systemic blood pressure monitoring by an indwelling arterial catheter may be necessary for beat-to-beat assessment and for blood gas analysis. In children, this is usually accomplished after induction of anesthesia. Arterial cannulation can be achieved percutaneously in most circumstances with a reduced risk of complications (see Chapter 48). Use of the radial arteries is preferable, particularly in the neonate, to minimize catheter-related vascular problems. Ultrasound guidance with Doppler or two-dimensional imaging may facilitate cannulation. The decision regarding the need for invasive monitoring is largely based on the child's clinical condition and nature of the surgical procedure.

### Electrocardiography

An ECG is used to monitor heart rate, cardiac rhythm, and ST-segment analysis. One or multiple leads typically are displayed. Most systems use two leads: standard lead II for arrhythmia monitoring plus inferior ischemia detection and precordial lead V<sub>5</sub> for lateral ischemia detection. Arrhythmias may occur as a result of hypoxia, electrolyte imbalances, acid-base abnormalities, intravascular or intracardiac catheters, and surgical manipulations near or around the thorax. Ischemia may be evident on direct examination of the ECG or ST-segment analysis.<sup>53</sup> Although in the adult population this is associated with worsened outcome, the implication for children is unknown.<sup>54,55</sup>

### Pulse Oximetry

Placement of an oximeter probe is well tolerated, even by uncooperative children, and it is typically one of the earliest monitors applied during induction of anesthesia. Monitoring arterial oxygen saturation is particularly useful in infants, cyanotic children, and those with complex anatomy or significant hemodynamic compromise. In addition to providing continuous assessment of oxygen-hemoglobin saturation and heart rate, the pulse oximeter waveform may indicate the adequacy of peripheral perfusion and cardiac output.<sup>56,57</sup> Other parameters that may be reflected by the SpO<sub>2</sub> include intracardiac or great artery-level shunting and pulmonary blood flow.

### Capnography

Capnography can confirm proper endotracheal tube placement, help to assess the adequacy of ventilation, and aid recognition of pathologic conditions such as bronchospasm, airway obstruction, and malignant hyperthermia. In spontaneously breathing, sedated children receiving supplemental oxygen through a nasal cannula, capnography monitors the end-tidal or exhaled carbon dioxide (PETCO<sub>2</sub>) concentration. A prospective, observational study in children undergoing cardiac catheterization with sedation administered by nonanesthesiologists found that monitored PETCO<sub>2</sub> values provided a reasonable estimate of arterial blood CO<sub>2</sub> values.<sup>58</sup> Although the absolute value for PETCO<sub>2</sub> may not be as reliable as in the presence

of an endotracheal tube, the capnograph waveform confirms the presence or absence of respirations and air exchange. End-tidal CO<sub>2</sub> monitoring also provides a gross index of pulmonary blood flow. In children with cyanotic heart disease, PETCO<sub>2</sub> values may underestimate arterial carbon dioxide tension (PaCO<sub>2</sub>) measurements due to altered pulmonary blood flow and ventilation/perfusion mismatch.<sup>59,60</sup>

### Temperature Monitoring

Temperature should be routinely monitored during most procedures. Although temperature swings are usually not profound, some children, particularly small neonates, may become significantly hypothermic because of the large body surface area to body weight ratio and decreased amount of subcutaneous tissue. This may influence oxygen delivery (i.e., increased oxygen consumption) and emergence from anesthesia, cause detrimental changes in hemodynamics, and affect hemostasis.

### Urinary Output Measurements

The production of urine is a useful index of the adequacy of renal perfusion and cardiac output. Urine output is usually monitored during cases involving major fluid shifts or blood loss or when the surgical procedure is expected to be prolonged. No specific value for urine output is necessarily predictive of good renal function in the postoperative period.

### Transesophageal Echocardiography

Numerous publications have documented the utility of transesophageal echocardiography as a monitoring device in high-risk adults undergoing noncardiac procedures.<sup>61-72</sup> Sporadic reports have demonstrated the utility of this imaging approach in children undergoing noncardiac surgery.<sup>73-78</sup> However, the contribution or application of this modality in the pediatric age group in this particular setting has not been well defined and requires further investigation.

## SELECTION OF TECHNIQUES AND AGENTS

Several anesthetic regimens have been used in children with CHD undergoing noncardiac surgery and studies or procedures that require deep sedation or immobility. Although no single formula or recipe is recommended, the anesthetic techniques and agents used for a particular situation should be selected in consideration of the procedure, the child's disease process and functional status, and the impact of the hemodynamic effects of the anesthetic and procedure on the pathophysiologic process. Factors such as age, physical characteristics, and preferences of the anesthesiologist must be taken into consideration. The primary goals of anesthesia management with respect to the cardiovascular system are to optimize systemic oxygen delivery, maintain myocardial performance within expected parameters for the patient, and ensure the adequacy of cardiac output. A potentially limited cardiovascular reserve, reduced tolerance for perioperative stress, and detrimental alterations of the balance between pulmonary and systemic blood flow during anesthesia and surgery should be considered. A carefully titrated anesthetic, regardless of the specific agent, is optimal.

### Anesthesia Technique

General anesthesia has the advantages of wide acceptance, ease of application, and relative certainty of effect. It is the appropriate choice for most children undergoing noncardiac surgery. Disadvantages include a greater potential for wide

fluctuations in the hemodynamics and a prolonged recovery period. The intravenous route allows for rapid induction of anesthesia. If intravenous access is not available, inhalational induction may be performed. Inhalational anesthetics dilate vascular beds and reduce sympathetic responsiveness. These are desirable goals for most children, even those with heart disease, because adequate myocardial function and a reactive sympathetic nervous system are usual. However, children with ventricular dysfunction may require an increased resting sympathetic tone to maintain systemic perfusion. Potent inhalational agents in this setting may further impair myocardial function, decrease sympathetic tone, and potentially cause cardiovascular decompensation. These children and others with a relatively fixed cardiac output may require a technique that combines several medications (i.e., balanced technique) to achieve anesthesia while minimizing the risk of hemodynamic compromise. A potent opioid, amnestic agent, and muscle relaxant technique minimizes myocardial depression and tends to leave sympathetic responsiveness intact while providing analgesia, amnesia, and immobility.

Regional anesthesia has been safe and effective in children with CHD (see Chapters 41 and 42).<sup>76-79</sup> Advantages of regional anesthesia, such as epidural and spinal techniques, include an effect largely limited to the surgical site, decreased number of systemic medications, a potentially brief recovery period, and usually a more pleasant experience for the child. Use of these techniques, however, may not always be effective. Regional anesthesia retains the potential for hemodynamic compromise, particularly in hypovolemic children or those with a fixed cardiac output. It is also contraindicated in those with coagulation defects. The administration of agents such as local anesthetics, opioids, or other adjuvants (e.g., clonidine) into the caudal space may attenuate the sympathetic outflow associated with surgical manipulation and noxious stimuli and facilitate postoperative pain management.

The choice of technique affects termination of the anesthesia and emergence. Anesthesia performed with fewer agents is inherently simpler and usually easier and more predictable to terminate. The availability of ultra-short-acting opioids (e.g., remifentanyl) and other agents (e.g., dexmedetomidine) has avoided the need for postoperative ventilation solely related to residual effects of depressant drugs. Ventricular function and the presence of intracardiac shunts can significantly affect uptake and distribution of inhalational anesthetics and the kinetics of intravenous medications (see Chapter 6).

### Inhalational Agents

The use of inhalational anesthetics has been at the forefront of pediatric anesthesia practice for many years.<sup>80,81</sup> Sevoflurane was introduced in the mid-1990s, replacing halothane for induction of anesthesia in many centers. A study on the safety and efficacy of inhaled agents in infants and children with CHD during cardiac surgery demonstrated twice as many episodes of hypotension, moderate bradycardia, and emergent drug use in those who received halothane compared with those who received sevoflurane.<sup>82</sup> These data and those from other studies that demonstrated the potential benefits of sevoflurane on hemodynamic stability and minimal impact on myocardial performance led to sevoflurane becoming the preferred anesthetic agent for children, particularly those with heart disease.<sup>83-88</sup> Nonetheless, in some jurisdictions and under some conditions, halothane may remain the primary anesthetic for children.

### Intravenous Agents

*Propofol* is one of the most frequently used medications for intravenous sedation and general anesthesia. It has been used in children with CHD in numerous settings.<sup>89-92</sup> The hemodynamic effects of propofol have been investigated in children with normal hearts and in those with cardiovascular disease. An echocardiographic study in infants with normal hearts undergoing elective surgery demonstrated that propofol did not alter heart rate, shortening fraction, rate-corrected velocity of circumferential fiber shortening, or cardiac index after intravenous induction.<sup>93</sup> However, this medication decreased arterial blood pressure to a greater extent than thiopental, an effect attributed to a reduction in afterload. A comparison of propofol and ketamine during cardiac catheterization found that propofol caused a transient decrease in mean arterial pressure and mild arterial oxygen desaturation in some children.<sup>94</sup> In view of the significantly faster recovery, it was concluded that propofol was a practical alternative to ketamine for elective cardiac catheterization in children.

Another investigation in 30 children with CHD undergoing cardiac catheterization demonstrated significant decreases in mean arterial blood pressure and systemic vascular resistance during propofol administration.<sup>89</sup> No changes in heart rate, mean pulmonary artery pressure, or pulmonary vascular resistance were observed. In children with intracardiac shunts, the net result of propofol was a significant increase in the right-to-left shunt, a decrease in the left-to-right shunt, and decreased pulmonary-to-systemic blood flow ratio, resulting in a statistically significant decrease in the PaO<sub>2</sub> and arterial oxygen saturation (SaO<sub>2</sub>), as well as reversal of the shunt direction from left-to-right to right-to-left in two patients. It was also shown that propofol could lead to further hemoglobin desaturation in children with cyanotic heart disease.

The effects of propofol have been examined in children undergoing electrophysiologic testing and radiofrequency catheter ablation for tachyarrhythmias. The drug has no significant effect on sinoatrial or atrioventricular node function or accessory pathway conduction in Wolff-Parkinson-White syndrome.<sup>95,96</sup> However, a study documented that ectopic atrial tachycardia may be suppressed during propofol administration in children.<sup>97</sup>

Collectively, these data suggest that the judicious use of propofol may be a reasonable option in children with adequate cardiovascular reserve who can tolerate mild decreases in myocardial contractility and heart rate and mild to moderate decreases in systemic vascular resistance. The effects of propofol on the direction and magnitude of intracardiac shunts may be an important consideration in children with cyanotic heart disease and may influence the hemodynamic assessment of those undergoing evaluation of pulmonary-to-systemic blood flow ratios in the cardiac catheterization laboratory.

*Thiopental*, a rapid-acting barbiturate, was used for many years for induction of anesthesia. Several investigations have documented the cardiovascular responses to this agent in the pediatric age group. In children with normal hearts, the cardiac index remains unchanged, although the shortening fraction decreases and alterations in load-independent parameters of contractility occur.<sup>93</sup> The myocardial depressant properties of barbiturates are well established, as are its effects on venodilation and blood pooling in the periphery. These data suggest that a subset of children who receive thiopental may be at risk for hemodynamic instability. It has been suggested that thiopental should be used with caution, particularly in those with limited reserve or

increased sympathetic tone. Thiopental is not available for use in the United States.

*Etomidate*, a carboxylated imidazole derivative, has anesthetic and amnestic properties but no analgesic effects. This agent demonstrates favorable qualities over other intravenous drugs due to its lack of effect on hemodynamics.<sup>98,99</sup> This, combined with laboratory and clinical data that support minimal effects on myocardial contractility, makes this drug a particularly desirable agent in critically ill children and in those with limited cardiovascular reserve.<sup>100</sup> Despite these benefits, several undesirable adverse effects are associated with etomidate, including pain on intravenous administration, myoclonic movements that may mimic seizure activity, and inhibition of adrenal steroid synthesis perioperatively.<sup>101,102</sup> Although used primarily as an induction agent, etomidate has been administered for sedation of children during cardiac catheterization and in other settings.<sup>103-105</sup> A concentrated form of this medication is available in Europe but not in the United States.

*Ketamine* is a dissociative anesthetic agent administered by the intravenous, intramuscular, and oral routes. In view of its sympathomimetic effects that result in an increased heart rate, blood pressure, and cardiac output, this drug has been widely used in children with heart disease, particularly in younger children. The effects of this agent on systemic vascular resistance make it a suitable choice in children with right-to-left shunts because pulmonary blood flow is enhanced. This contrasts with inhalational agents, which by causing systemic vasodilation may decrease pulmonary blood flow in the presence of an intracardiac communication and potentially worsen the degree of cyanosis. In clinical use, however, oxygen saturation typically increases with both agents. Additional favorable properties include intense analgesia at subanesthetic doses and a lack of respiratory depressant effects.

Several investigations have addressed the concern of potential detrimental changes in pulmonary vascular tone resulting from ketamine although no significant effects have been reported on pulmonary arterial pressures and pulmonary vascular resistance at the usual clinical doses.<sup>106-109</sup> Regarding its effect on myocardial performance, in-vitro investigations have shown a direct myocardial depressant effect in animal species and the failing adult human heart. This is considered to be the result of inhibition of L-type voltage-dependent calcium channels in the sarcolemmal membrane and may be a consideration in critically ill infants with severely impaired cardiac reserves. Additional undesirable effects of ketamine include emergence reactions, excessive salivation, vomiting, and increased intracranial pressure.

*Dexmedetomidine* is a selective  $\alpha_2$ -adrenergic agonist agent being increasingly used in the pediatric age group. Compared with clonidine, the drug exhibits greater specificity for the  $\alpha_2$ -adrenergic receptor over the  $\alpha_1$ -adrenergic receptor. Favorable effects of the drug include sedation, anxiolysis, and analgesia. This medication provides hemodynamic stability, although adverse effects have been reported, including bradycardia, hypertension, and hypotension. A study of the hemodynamic effects in children undergoing dexmedetomidine sedation for radiologic imaging demonstrated modest decreases in heart rate and blood pressure. These changes in response to moderate doses were independent of age, required no pharmacologic interventions, and did not result in any adverse events; however, high dose dexmedetomidine can be associated with significant bradycardia.<sup>110,110a</sup> In addition, treatment of dexmedetomidine-induced bradycardia with glycopyrrolate (5  $\mu\text{g/kg}$ ) has been associated with severe persistent hypertension.<sup>110b</sup>

Dexmedetomidine is used as a premedication agent, during diagnostic studies and procedural sedation, to reduce emergence delirium, in the treatment of symptoms associated with opioid withdrawal, and as an adjuvant agent in the operating room and postoperative settings.<sup>111</sup> In children with CHD, its benefits have been reported during monitored anesthesia care, diagnostic and interventional cardiac catheterization, intraoperative sedation, after cardiac and thoracic surgery, as a primary agent during invasive procedures, and in the treatment of perioperative atrial and junctional tachyarrhythmias.<sup>112-119</sup> This medication has also been used in children with pulmonary hypertension with good results.<sup>120,121</sup>

The effects of dexmedetomidine on cardiac electrophysiology have been examined in children; the drug significantly depresses sinus and atrioventricular nodal function.<sup>122</sup> Other findings included a reduction in the heart rate and increases in arterial blood pressure. Hammer and colleagues concluded that this medication should be considered undesirable for electrophysiologic studies and that it could be associated with adverse effects in patients at risk for bradycardia or atrioventricular block.<sup>122</sup> In contrast, another study concluded that dexmedetomidine was not associated with any significant or any atypical ECG interval abnormalities, except for a trend toward a decrease in heart rate in children with CHD.<sup>123</sup> Until additional data are available, it may be prudent to exercise caution when considering the use of dexmedetomidine in children with conduction abnormalities.

Although the experience suggests an overall safety profile in children with CHD, fragile patients may not tolerate the heart rate and blood pressure fluctuations associated with dexmedetomidine administration. Significant adverse effects have been described that include severe bradycardia progressing to asystole.<sup>124</sup>

*Opioids* and *benzodiazepines* are widely used medications in pediatric anesthesia practice. Opioids attenuate the neuroendocrine stress response associated with anesthesia and surgery.<sup>125,126</sup> After repair of CHD, these medications have been shown to blunt the stress response in the pulmonary circulation elicited by airway manipulations.<sup>127</sup> Morphine administration may be associated with histamine release and hypotension. The synthetic opioids are devoid of these effects and provide excellent hemodynamic stability with minimal changes in heart rate and blood pressure in children with CHD.<sup>128</sup> The primary concern about opioid administration is their central respiratory depressant effects because their primary cardiovascular manifestations are minimal. Benzodiazepines provide sedation and amnesia during the perioperative period. Midazolam administration may allow a reduction in the inspired concentration of inhalational anesthetic agents, which is a desirable feature in children with labile hemodynamics or in those considered at great risk for the myocardial depressant properties of inhalational anesthetics. Studies of the effects of benzodiazepines in children with CHD are limited.<sup>129</sup>

*Neuromuscular blocking drugs* facilitate endotracheal intubation and prevent reflex movement during surgery if the anesthetics alone are insufficient. All inhalational anesthetics potentiate the effects of nondepolarizing muscle relaxants. These medications have various onsets and durations of action and diverse hemodynamic effects. The cardiovascular and autonomic effects of muscle relaxants have been characterized mainly in adults with acquired cardiovascular disease<sup>130-133</sup> (see also Chapter 6). Drug selection is based on the need to facilitate endotracheal intubation and surgical relaxation, hemodynamic side effects, and the anticipated duration of surgery.

## INDUCTION OF ANESTHESIA

Induction of anesthesia in children with CHD most commonly can be accomplished using the inhaled or intravenous route. The intramuscular route (i.e., ketamine administration) may be preferable in some cases, particularly in an uncooperative, developmentally delayed, or combative child. Less common induction techniques include subcutaneous, intranasal, and rectal administration of agents. These various approaches may also be used in combination (see Chapter 4).

An intravenous induction may be preferable in some children in view of its potentially greater safety margin. In addition to the ability to titrate medications and rapidly correct hemodynamic alterations, other benefits include the speed of effect, although this may be slowed in children with large left-to-right shunts due to recirculation of the drug in the lungs. Left-to-right shunting results in a less concentrated amount of anesthetic agent reaching the brain and delayed onset of action. Right-to-left shunts speed intravenous induction because a significant portion of the medication bypasses the lungs (where it is degraded) and directly enters the systemic circulation, reaching the brain more rapidly than an intact circulation.

If intravenous access is not available, an inhalational induction is performed in most cases. A carefully titrated inhalational induction and early placement of an intravenous catheter usually is safe even in children with moderate hemodynamic disturbances, particularly after premedication has been given. This produces loss of consciousness, with acceptable conditions for establishing intravenous access. Inhalational induction may be delayed in cyanotic children and those with right-to-left shunts, particularly for anesthetics with reduced blood solubility, because the decreased pulmonary blood flow limits the rate of increase in the concentration of the anesthetic in the systemic arterial blood. The rapidity of an inhalational induction is increased in the presence of a reduced cardiac output because the anesthetic partial pressure in the alveoli increases more rapidly as less anesthetic is removed by the smaller pulmonary blood flow (see Chapter 6). Left-to-right intracardiac shunts have limited effects on the speed of induction of inhaled anesthetics.

## MAINTENANCE OF ANESTHESIA

After induction, anesthesia can be maintained using an inhalational, intravenous, or combined inhalational and intravenous technique. In children with CHD, anesthesia may result in hemodynamic changes regardless of the technique, agents, or experience of the anesthesiologist. Some children may not tolerate even minor alterations in hemodynamics. Factors that may lead to cardiovascular collapse in the marginally compensated child include hypovolemia, relative anesthetic overdose, increased vagal tone, positive-pressure ventilation, hypoxemia, airway obstruction, alterations in  $P_{aCO_2}$  or other factors that influence the balance between systemic and pulmonary blood flow, myocardial ischemia, arrhythmias, and anaphylaxis. The anesthesiologist should be prepared to manage these rare but occasionally unavoidable occurrences.

## EMERGENCE FROM ANESTHESIA

Most children undergoing noncardiac surgical interventions are expected to awaken immediately at the completion of the procedure or shortly thereafter. This usually involves reducing and then discontinuing intravenous or inhalational anesthetics, antagonizing neuromuscular blockade, and extubating the trachea. Ensuring the return of protective reflexes and monitoring

the adequacy of the airway and respirations are important considerations.

## Postoperative Care

The postoperative management of the child with CHD involves many of the same physiologic principles applicable to intraoperative care. The extent of the postoperative care, optimal place for recovery, and need for monitoring and hospitalization depend in large part on the child's clinical condition and type and extent of the procedure. Immediately after surgery, most children awaken from anesthesia and recover from muscle relaxants, which may impose various stresses and hemodynamic changes. Adequate oxygenation and ventilation along with airway protection must be ensured and may need to be provided if the child cannot manage these functions on his or her own. Significant hypoventilation must be avoided during this time because it may negatively affect pulmonary vascular tone and overall hemodynamics in vulnerable children with CHD. Adequate pain control and, sometimes, sedation are important postoperatively. This may be a challenging issue for the child who requires noncardiac surgery soon after a prolonged hospitalization in view of the increased likelihood for tolerance to analgesic and sedative drugs.

Observation and physical examination provide much information about the child's respiratory status, cardiac function, and systemic perfusion during the postoperative period. Adequacy of oxygenation and ventilation can also be assessed with noninvasive monitoring and blood gas analysis. Monitoring urine output may be helpful.

Hemoglobin or hematocrit values are monitored as a measure of oxygen-carrying capability in cases in which significant blood loss or the administration of fluids might have occurred. Serum electrolytes are screened if fluid shifts have taken place during the surgical and postoperative periods. Although digoxin is now used less frequently, particular attention should be given to the avoidance of hypokalemia in children receiving this drug. Serum glucose levels should be followed in neonates and small infants and dextrose-containing fluids administered as appropriate. Determination of ionized calcium ( $iCa^{2+}$ ) levels may be indicated for patients with a history of DiGeorge sequence because of a propensity for hypocalcemia. The required fluid replacement is dictated by the child's heart defect, type of surgery performed, and volume losses (see Chapters 8 and 10).

## Perioperative Problems and Special Considerations

Several potential perioperative problems related to multiple factors may be encountered while caring for children with CHD who require noncardiac interventions. Because it is not feasible to detail all possible problems and potential concerns, this section highlights the more common issues to serve as a framework.

### HYPOTENSION

Hypotension may be related to hypovolemia due to prolonged fasting, volume loss, arrhythmia, anesthetic agents, myocardial dysfunction, or mechanical influences associated with the operative procedure. A practical diagnostic approach to the hypotensive patient is to consider factors that may affect ventricular preload, contractility, afterload, and the assessment of cardiac

rhythm. Although the management of hypotension should be guided primarily by the causative factor, acutely increasing blood pressure by the administration of volume and an appropriate vasopressor, if indicated, often restores adequate perfusion while definitive therapy is instituted. Ensuring adequate intravascular volume with a fluid challenge often helps to restore perfusion and blood pressure, especially in hypovolemic patients. A pure  $\alpha$ -adrenergic agent such as phenylephrine increases systolic blood pressure without further increases in heart rate. Some children are unable to tolerate any degree of myocardial depression or reduction in sympathetic outflow and require continuous inotropic support or vasopressor infusions throughout and after the operative procedure.

## CYANOSIS

Cyanosis is a common finding in children with defects characterized by limited pulmonary blood flow or intracardiac mixing. As surgical management strategies evolve to target the youngest of infants, the effects of cyanosis may be limited in these children. However, in those requiring delayed surgery, palliation, or staged correction of their defects, the effects of cyanosis may be long lasting. Chronic hypoxemia affects all major organ systems. Compensatory mechanisms that attempt to provide adequate systemic oxygen delivery in the presence of chronic hypoxemia include polycythemia, increases in blood volume, alterations in oxygen uptake and delivery, and neovascularization. Despite the favorable effects of the adaptive responses, these alterations may be detrimental. Polycythemia, the most significant compensatory response, is associated with increases in blood viscosity and red cell sludging. The common occurrence of iron-deficiency anemia in cyanotic children further enhances hyperviscosity and the unfavorable consequences of this condition. Several hemostatic abnormalities (e.g., thrombocytopenia, altered platelet function, and clotting factor abnormalities) have been documented as a result of hypoxemia and erythrocytosis that may affect the coagulation system and increase perioperative risks.<sup>134-139</sup> This is compounded by increased tissue vascularity, with a large number of blood vessels per unit of tissue.

The increased blood viscosity in children with cyanosis is associated with stasis and a risk for thrombotic events.<sup>140</sup> If the hematocrit exceeds 65% preoperatively, some clinicians advocate phlebotomy to reduce the hematocrit to 60% to 65%. This limits sludging of red blood cells and increases oxygen delivery to tissues. If blood is removed by preoperative phlebotomy, it may be saved for autologous transfusion in the perioperative period.

During the perioperative period, adequate hydration should be maintained in children with cyanotic CHD, and care should be taken to avoid prolonged venous stasis. Cyanotic children are at risk for paradoxical embolic events, mandating meticulous attention to intravenous lines during fluid or drug administration. This is a reasonable routine approach for all children with CHD, regardless of the nature of the structural abnormalities. The addition of air filters to intravenous tubing should not replace vigilance.

## TETRALOGY SPELLS

Hypercyanotic episodes may result from further decreases in pulmonary blood flow in children with tetralogy (i.e., tet spells) and significant dynamic right ventricular outflow tract obstruction. Tet spells are rare during noncardiac surgery, probably because general anesthesia attenuates the triggers. Occasionally, however, increased cyanosis may occur without warning in response to obscure stimuli. Whatever the cause, worsening

cyanosis implies increases in dynamic obstruction and exacerbation of ventricular-level right-to-left shunting. Factors that decrease systemic blood pressure and systemic vascular resistance, such as hypovolemia and extreme vasodilation, should be avoided. Therapy consists of increasing blood volume and systemic vascular resistance, the latter using either phenylephrine 5  $\mu\text{g/kg}$  IV initially and then 1 to 5  $\mu\text{g/kg/min}$  by continuous infusion or norepinephrine 0.5  $\mu\text{g/kg}$  IV initially and then 0.1 to 0.5  $\mu\text{g/kg/min}$  by continuous infusion. Increasing the inspired oxygen concentration and reducing inspiratory ventilatory pressures may also produce clinical improvement. Additional therapies include increasing the level of sedation or anesthetic depth and  $\beta$ -adrenergic blockade (esmolol [50  $\mu\text{g/kg/min}$ ] has largely replaced propranolol in this setting) (see also Chapters 15 and 16). Pulmonary vascular resistance does not play a major role in the physiology of hypercyanotic episodes in tetralogy of Fallot.

## HEART FAILURE

In infants, congestive heart failure is most often due to ventricular volume overload resulting from communications at the ventricular level or between the great arteries. Heart failure may also result from severe valvar regurgitation or obstructive lesions. Structural defects may lead to heart failure as a result of poor myocardial contractility, compromising cardiac output and not meeting the systemic demands.

In children with significant pulmonary vascular congestion, positive-pressure mechanical ventilation may be necessary before and after surgery. In cases of elective surgery, it may be of significant benefit to optimize medical therapy or address the particular defects before the planned procedure.

In a retrospective review of 21 children with severe heart failure who underwent 28 general anesthetics, 10% had a cardiac arrest requiring unplanned postoperative admission to the intensive care unit, and 96% required perioperative inotropic support. The investigators concluded that general anesthesia for children with severe heart failure is associated with a significant complication rate.<sup>141</sup>

## VENTRICULAR DYSFUNCTION

Children with CHD may have ventricular dysfunction involving the right heart, left heart, both sides of the heart, regional cardiac tissue, or global cardiac tissue. It may be temporary or permanent. In systolic dysfunction, contractile function is primarily impaired. Diastolic dysfunction is associated with abnormal relaxation or ventricular compliance. Some children have systolic and diastolic dysfunction. Ventricular dysfunction may result from factors such as age at the time of the operation and chronicity of the cardiac workload (pressure or volume); may be caused by the primary disease, myocardial hypertrophy, ischemia, or cyanosis; or may occur as a direct effect of surgery (e.g., ventriculotomy, cardiopulmonary bypass, ischemic time, circulatory arrest). Diseases that affect cardiac muscle (e.g., myocarditis, dilated cardiomyopathy) may be associated with congestive symptoms, whereas others (e.g., restrictive cardiomyopathy) may lead to diastolic heart failure.

In children with cardiomyopathy that was accompanied by severe ventricular dysfunction, general anesthesia for noncardiac procedures was associated with an increased frequency of complications.<sup>142</sup> They often required hospital support before and after the procedure that in many cases included intensive care management. Hospital stay was prolonged for children with severe ventricular dysfunction compared with those with a lesser degree of impairment. Based on these findings, early

consideration of perioperative intensive care support was recommended for monitoring and optimization of cardiovascular therapy.<sup>142</sup>

### VENTRICULAR VOLUME OVERLOAD

Ventricular volume overload, which manifests as increased left atrial pressure, left ventricular end-diastolic pressure, and stroke volumes, is a common feature in many children with unoperated CHD. Long-standing volume overload results in atrial enlargement, ventricular dilation, and cardiomegaly. In the postoperative child, residual valvar regurgitation may be associated with altered loading conditions that, if significant, may result in congestive symptoms and ventricular dysfunction. The palliated single-ventricle patient may be particularly vulnerable to conditions associated with ventricular volume overload (e.g., systemic-to-pulmonary artery shunts).

### VENTRICULAR PRESSURE OVERLOAD

Pressure overload in the postoperative patient typically results from residual or recurrent muscular, valvar, or distal outflow obstruction or from increased pulmonary artery pressure or vascular resistance. In children with abnormal distal pulmonary arterial beds, for example, the hypoplastic vessels may not be amenable to surgical repair or other intervention, although associated defects may be satisfactorily addressed. This results in increased proximal pulmonary artery and right ventricular pressures and compensatory myocardial hypertrophy. Right ventricular pressure may exceed systemic values and compromise left ventricular function because septal shift may impair left ventricular filling or result in obstruction to systemic outflow. Abnormal pressure loads to the right ventricle may also result from progressive conduit stenosis after procedures that involve outflow tract reconstructions. Because of the anticipated need in children for successive conduit replacements, these surgical interventions are delayed as much as possible. This implies long-standing pressure loads on the myocardium with associated wall hypertrophy and potentially some element of ischemia until the criteria for surgical intervention have been fulfilled.

Whether the altered loading conditions affect the right or left ventricle primarily, the result is an increased demand due to the increased wall tension. This implies an increased susceptibility of the ventricular myocardium to the supply-and-demand relationship, a reduced tolerance for factors that may alter this fine balance, and an increased risk of ischemia.

### MYOCARDIAL ISCHEMIA

Several factors can cause myocardial ischemia in children with CHD. They include chronic hypoxemia, increased systolic and diastolic wall stress, and decreased coronary perfusion due to reduced diastolic pressures in the presence of large systemic-to-pulmonary shunts. The effects of cardiopulmonary bypass, aortic cross-clamping, and surgery itself cannot be ignored. Other conditions with a propensity for myocardial ischemia include congenital coronary artery lesions and the increased blood viscosity associated with cyanosis. The deprivation of myocardial perfusion may result in ventricular dysfunction and subsequent development of myocardial fibrosis.

### ALTERED RESPIRATORY MECHANICS

Chronically increased pulmonary blood flow and pulmonary artery pressures may result in progressive pulmonary vascular changes, increases in pulmonary vascular resistance, and alterations in lung mechanics. The primary effects on respiratory

mechanics are related to increased airway resistance and decreased lung compliance. These alterations may have detrimental respiratory consequences in children with inadequate palliation or residual shunts. In some children, left atrial dilation may lead to respiratory compromise (e.g., air trapping, atelectasis) due to bronchial compression.

### PULMONARY HYPERTENSION

Pulmonary hypertension is a relatively common feature of unoperated CHD. It usually is the consequence of an increased pulmonary blood flow. One of the benefits of early correction is a reduction in pulmonary artery pressures and the incidence of pulmonary vascular reactivity after cardiac surgery. However, in some cases, pulmonary hypertension may persist or develop after an intervention.

A less common entity is increased pulmonary vascular resistance, which may be reactive or fixed. The diagnosis is formally determined at cardiac catheterization and involves pulmonary vascular reactivity testing. Pulmonary hypertension and increased pulmonary vascular resistance represent risks for major perioperative complications in children, regardless of cause.<sup>143,144</sup>

Acute increases in pulmonary vascular tone, also known as pulmonary hypertensive crisis, may result in cardiac arrest. In the presence of an intracardiac communication that allows for shunting, acute increases in pulmonary artery pressure may manifest as arterial desaturation, bradycardia, and systemic hypotension. In the absence of an intracardiac communication, the acute increase in right ventricular afterload may lead to unfavorable leftward shifting of the interventricular septum, compromising left ventricular filling and decreasing cardiac output.

Several factors can increase pulmonary vascular tone (Table 21-2). Therapy should be aggressive in the acute setting, aimed at reducing pulmonary artery pressures with interventions such as additional sedation, hyperventilation, hyperoxygenation, and treatment of acidosis. The use of selective pulmonary vasodilators (e.g., inhaled nitric oxide, other agents) and inotropic support of the right ventricle may be indicated. Manipulation of pulmonary hemodynamics is challenged by the difficulty of directly measuring these parameters in children. Management of critical situations requires a thorough understanding of the pathophysiologic process and experienced clinical judgment. Because of the significant morbidity and potential periprocedural mortality for children with a history of severe pulmonary hypertension, an in-depth evaluation of the risk/benefit ratio of the planned procedure and its impact on the overall quality of life is essential.

### ENDOCARDITIS PROPHYLAXIS

The latest guidelines of the American Heart Association for the prevention of infective endocarditis indicate that routine antibiotic prophylaxis is no longer needed for most children

**TABLE 21-2** Factors Associated with Increased Pulmonary Vascular Tone

Acidemia
Atelectasis
Hypercarbia
Hypothermia
Hypoxemia
Stress response, stimulation, light anesthesia, pain
Transmitted positive airway pressure

with CHD (see Table 14-4).<sup>145</sup> In contrast to earlier guidelines, the administration of antibiotics solely to prevent endocarditis is not recommended for children undergoing genitourinary or gastrointestinal tract procedures, although neither of these subspecialty professional bodies have fully adopted the new guidelines. It is important to discuss the need for prophylaxis with the responsible physician.

The guidelines target individuals at increased risk for a poor outcome if they develop endocarditis (see Chapter 14). Preventive antibiotics for dental procedures are recommended for children with the following conditions:

- Prosthetic cardiac valve
- History of infective endocarditis
- Unrepaired cyanotic CHD, including palliative shunts and conduits
- Completely repaired congenital heart defect with prosthetic material or a prosthetic device, whether placed by surgery or by catheter intervention, during the first 6 months after the procedure
- Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibit endothelialization)
- Cardiac transplant recipients who develop cardiac valvulopathy

### SYSTEMIC AIR EMBOLIZATION

Intracardiac shunts in children with CHD allow for the possibility of right-to-left shunting and paradoxical systemic air embolization. This risk is further enhanced by the increased right-sided pressures associated with many cardiovascular malformations. Because this may lead to catastrophic consequences, it is imperative to ascertain the presence of or likelihood for intracardiac or vascular shunting or to assume that this may be the case in most children and consider appropriate precautions.

### ANTICOAGULATION

Anticoagulants, antiplatelet drugs, and thrombolytic agents are increasingly being used in children, particularly in those with CHD.<sup>146-150</sup> Decisions regarding management are primarily influenced by the nature of the procedure, urgency of the intervention, specific drug therapy, and expected effects or laboratory data. The major concern is the potential for bleeding. Recommendations for the management of children taking warfarin (Coumadin) vary widely.<sup>151-153</sup> The proposed strategies are quite heterogeneous, and the lack of consensus reflects the paucity of randomized trials addressing this issue. The problem is further complicated by the lack of guidelines specific to pediatric practice.<sup>154</sup>

If the indications for anticoagulation are for native valve disease or atrial arrhythmias, the risk of a major thromboembolic event is considered to be relatively small, and warfarin may be discontinued 1 to 2 weeks before the day of surgery. In those with mechanical prosthetic valves, the risk of thromboembolic events is greater. Many recommend discontinuing the oral anticoagulant a few days before surgery and allowing the prothrombin time to return to within 20% of normal.<sup>151</sup> Administration of parenteral vitamin K or clotting factors, including fresh frozen plasma (FFP), may be required to restore the prothrombin time within an acceptable range, especially in those with liver disease and in emergency cases. Some experts advise preoperative hospitalization, particularly in high-risk individuals such as those with mitral or combined valve prostheses, to discontinue warfarin therapy and to initiate a heparin infusion, which is continued up

until a few hours before surgery. Others suggest that low-molecular-weight heparin may be the better option instead of unfractionated heparin because the perioperative conversion from warfarin therapy to heparin can be accomplished without the need for hospitalization.<sup>152</sup>

Anticoagulation is usually reinitiated after 24 hours in children with valvular prostheses, and this may be achieved with a continuous heparin infusion or intermittent subcutaneous injections. The advantage of heparin is the ability to rapidly reverse the drug effect with protamine sulfate if bleeding complications occur. Oral anticoagulants are reinitiated 2 to 3 days after surgery if there are no bleeding concerns and the child is able to swallow oral medications. Although it has been suggested that there is no need to discontinue anticoagulation therapy for minor procedures, such as dental or ophthalmologic surgery in adults, guidelines for children are less clear.

The risk of bleeding from the surgical intervention versus the risk of a thromboembolism from a reduced anticoagulant dose determines to what extent and for what duration the anticoagulant therapy should be reduced. In some cases, the cardiologist and surgeon may decide to temporarily use aspirin therapy before and after surgery. There is disagreement regarding whether antiplatelet therapy is preferable to anticoagulation in children with prosthetic aortic valves or after certain surgical interventions.<sup>155-158</sup>

### CONDUCTION DISTURBANCES AND ARRHYTHMIAS

Acute rhythm disturbances may occur with the use of any anesthetic agent or technique and may be related to several factors. The administration of agents with vagolytic or sympathomimetic properties requires consideration in patients with prior history of or pathology associated with arrhythmias. Bradycardia may occur during induction of anesthesia, laryngoscopy, and endotracheal intubation, particularly in infants and in children with Down syndrome.<sup>159-161</sup> In most cases, bradycardia is self-limited and requires no therapy.

Certain lesions may be associated with rhythm abnormalities and the potential for acute hemodynamic deterioration, increasing perioperative risks. Conduction system disorders and rhythm disturbances may occur after cardiac surgery as a direct result of the procedure or may develop due to the inadequacy of the palliation or repair. Because cardiac arrhythmias are more prevalent among specific surgical subgroups, anticipation for their occurrence and planning for management are advocated.

### PACEMAKERS AND IMPLANTABLE CARDIOVERTER-DEFIBRILLATORS

An in-depth discussion of perioperative considerations related to implanted pacemakers or defibrillators can be found in Chapter 14. Consultation with a cardiologist or electrophysiologist is essential when caring for children with implanted devices. Unit interrogation and programming are required in most cases. The main goal is to avoid problems with hardware malfunction related to electromagnetic interference (i.e., electrocautery). Chronotropic agents and backup pacing modalities (e.g., transvenous, epicardial, transcutaneous) should be readily available and carefully considered in the event of pacemaker malfunction associated with an inadequate underlying heart rate. A magnet should be accessible to enable asynchronous pacing if required. Perioperative ECG monitoring is essential, as well as the use of modalities that can confirm pulse generation during pacing. Implanted devices should be interrogated and reprogrammed after the procedure.

## NERVE PALSIES

Surgery for CHD may be associated with transient or permanent injury to the recurrent laryngeal and phrenic nerves. Recurrent laryngeal nerve injuries may result in abnormal phonation or airway difficulties and lead to aspiration, particularly in small infants. Diaphragmatic palsies resulting from phrenic nerve injuries are associated with abnormal lung mechanics and limited pulmonary reserve, both of which may account for perioperative complications.

## EISENMENGER SYNDROME

Eisenmenger syndrome is characterized by irreversible pulmonary vascular disease and cyanosis related to reversal in the direction of an intracardiac or arterial level shunt.<sup>162,163</sup> This is unlikely to occur in the current surgical era, but it may occasionally occur in older children, adolescents, or adults with CHD. Morbidity is linked to problems associated with chronic cyanosis and erythrocytosis. Other problems include hemoptysis, gout, cholelithiasis, hypertrophic osteoarthropathy, and decreased renal function. Variables associated with poor outcome include syncope, increased right ventricular end-diastolic pressure, and significant hypoxemia (i.e., systemic arterial oxygen saturation less than 85%). Life expectancy is significantly reduced.<sup>164</sup> Most succumb suddenly, probably from ventricular tachyarrhythmias. Surgical modalities that have been advocated in selected patients include combined heart and lung transplantation<sup>165</sup> and lung transplantation alone.<sup>166</sup>

Despite the overall poor prognosis and the extremely high risk of a bad outcome, several reports have documented successes with a variety of anesthetic techniques and agents.<sup>167-171</sup> Nevertheless, it is vital that the family and patient, if of appropriate age, understand these risks before undertaking any procedure requiring anesthesia or deep sedation.

## CARDIAC TRANSPLANTATION

Cardiac transplantation may be considered the best option in end-stage cardiac pathology as a result of congenital or acquired disease.<sup>172,173</sup> A major consideration in the care of these children is the lack of external nerve supply of the transplanted heart. The physiology of the denervated heart implies that the usual autonomic regulatory mechanisms are not operational, increasing the vulnerability of transplanted children to hemodynamic alterations.<sup>174</sup> Compensatory responses may be delayed, further increasing the potential for compromise.

In the child with a transplanted heart, the resting heart rate is greater than normal due to the loss of parasympathetic inhibition. Critical determinants of cardiac output include the systemic venous return and maintenance of an adequate heart rate. During the early posttransplantation period, the heart rate is supported by exogenous chronotropes or pacing. Subsequently, the heart rate is driven by circulating catecholamines. Regardless of the time interval from transplantation, medications with chronotropic properties should be available, as should drugs with direct action on the myocardium and vasculature and access to emergent cardiac pacing modalities.

Chronic immunosuppression in children who have undergone cardiac transplantation presents several issues during noncardiac surgery. First, administration of multiple medications, particularly immunosuppressant agents, throughout the perioperative period is a concern. The potential need for stress-dose corticosteroids is a controversial subject. Second, immunosuppressive therapy is associated with adverse effects that may impact

various organ systems. Cyclosporine administration, for example, increases systemic arterial blood pressure, potentially influencing hemodynamics. The drug is also responsible for renal dysfunction. Anesthesia management must consider potential alterations in hepatic and renal function. Third, strict aseptic technique is needed in managing a child with a compromised immune system.

An additional concern is the potential for graft vasculopathy (i.e., small-vessel coronary artery disease). Because older children or adolescents with ongoing myocardial ischemia may not experience anginal symptoms, it is reasonable to assume that most of these children are at risk for ischemic events, particularly those who are several years after transplantation.

## PERIOPERATIVE STRESS RESPONSE

The typical physiologic response to painful stimuli in normal children consists of an increase in heart rate and blood pressure and a transient decrease in PaO<sub>2</sub>. These normal patterns, however, may be detrimental to children with CHD. Tachycardia may shorten diastolic filling time and diminish cardiac output, and hypertension increases ventricular afterload. The reduced ability of the postoperative child with CHD to increase cardiac output in response to stimulation and their limited maximal exercise capacity have been well documented for several cardiac malformations.

## Outcomes of Noncardiac Surgery

Limited data regarding the risks of noncardiac surgery and anesthesia in children with CHD raises concerns. A review of 110 children with CHD who underwent 135 anesthetics over a 1-year period found a 47% incidence of adverse events and more than one adverse event in a significant number of children.<sup>34</sup> Continuous monitoring of perioperative rhythm abnormalities in 70 children with CHD and a history of ventricular arrhythmias documented a 35% and 87% incidence of intraoperative and postoperative ventricular arrhythmias, respectively.<sup>175</sup> Other studies have reported cyanosis, treatment for congestive heart failure, poor health, and young age as risk factors.<sup>35</sup> A retrospective review of a large number of children documented that these risks involved major and minor interventions.<sup>37</sup>

Data from the Pediatric Perioperative Cardiac Arrest (POCA) registry shed further insight into this subject. Anesthesia-related cardiac arrests in children with congenital and acquired heart disease were examined. Causes of cardiac arrest were primarily cardiovascular in nature, occurring more frequently in those with heart disease than those without. Events occurred more frequently in the general operating room, usually during the maintenance period. Among children who suffered a cardiac arrest, the most common type of CHD was a single ventricle (i.e., Fontan physiology), particularly those managed early with palliation. The overall mortality rate for children with heart disease was greater than for those without heart disease, and children with aortic stenosis (i.e., Williams syndrome) and cardiomyopathy have the greatest mortality rate.<sup>176</sup>

## Specific Congenital Heart Defects

The anesthetic care of children with CHD undergoing noncardiac surgery is strongly influenced by the particular nature of the cardiovascular malformations, pathophysiology of the lesions, operative state (e.g., unoperated, prior palliative, definitive

procedure), complications associated with the primary pathology or treatment, and other comorbidities.<sup>12</sup>

This section addresses relevant anatomic features, hemodynamic consequences of selected cardiac defects, and treatment strategies. Potential residua, sequelae (Table 21-3), and long-term outcomes of the lesions are discussed, focusing on their implications for perioperative care.

## ATRIAL SEPTAL DEFECTS

### Anatomy and Pathophysiology

Defects in the interatrial septum, or atrial septal defects (ASDs) (see Fig. 15-1), are among the most common congenital cardiac anomalies (30% to 40% of CHD) in childhood. ASDs occur in 1 of 1500 live births. Based on their location, several types of defects have been identified:

1. *Ostium secundum or fossa ovalis defect*, the most common type (75%), results from a deficiency in the region of the fossa ovalis (see Fig. 15-1, B). These defects may be associated with mitral valve prolapse or mitral regurgitation.<sup>177-179</sup>
2. *Ostium primum defect*, a form of atrioventricular septal (canal or endocardial cushion) defect (see Fig. 15-1, A),<sup>180</sup> is characterized by a deficiency in the inferior portion of the interatrial septum. They account for 15% to 20% of ASDs. They frequently are associated with a commissure or cleft in the anterior leaflet of the mitral valve and various degrees of regurgitation.
3. *Sinus venosus defect*, which occurs in 5% to 10% of ASDs, typically is located at the superior aspect of the interatrial septum, below the region where the superior vena cava joins the right atrium (i.e., sinus venosus defect of the superior vena cava-type) (see Fig. 15-1, C).<sup>181</sup> It is frequently associated with anomalous pulmonary venous drainage.<sup>182</sup>
4. *Coronary sinus defect* is uncommon and consists of a communication between the left atrium and mouth of the coronary sinus. It is commonly associated with an unroofed coronary sinus and persistent left superior vena cava that drains directly into the left atrium, resulting in a right-to-left shunt.<sup>183</sup>
5. *Other entities* that may allow interatrial shunting include a patent foramen ovale (PFO) at one end of the spectrum and a common atrium at the other. A PFO has been identified in as many as 25% of individuals. This communication may have implications for perioperative care because it has the potential for right-to-left shunting and paradoxical emboli.<sup>184,185</sup> In a common atrium, there is complete or near-total absence of the interatrial septum. This may be found in complex CHD.

An atrial communication allows mixing of the pulmonary and systemic venous returns. A left-to-right shunt allows pulmonary venous blood to enter the right atrium. The magnitude of shunting correlates with the size of the defect, relative ventricular compliances, and pulmonary artery pressures. A clinically significant defect results in right-sided volume overload. A pulmonary-to-systemic blood flow ratio ( $\dot{Q}_{\text{pulm}}/\dot{Q}_{\text{sys}}$ ) that exceeds 2 to 1 and the potential detrimental effects of chronic right ventricular volume overload are indications for intervention.

### Treatment Options, Residua, Sequelae, and Long-Term Outcomes

Surgical closure of secundum ASDs in childhood provides excellent results, almost normal long-term survival, and negligible mortality.<sup>186-189</sup> Normal ventricular function should be anticipated after repair of these defects. Rarely, children may

demonstrate persistent right ventricular dilation and abnormal ventricular septal motion, but this may not be associated with a functional deficit.<sup>190</sup> Atrial arrhythmias and ventricular dysfunction may occur after late repairs as a result of chronic volume overload. Delayed defect closure may be a risk factor for the rare development of pulmonary hypertension or pulmonary vascular disease later in life due to the abnormally increased pulmonary blood flow.<sup>191</sup>

Transcatheter approaches are an alternative to surgery for closure of secundum ASDs in selected children, with excellent success rates for relatively small communications (see Chapter 20).<sup>192-194</sup> Complications are rare and may be associated with the intervention or occur at a later time.<sup>195</sup>

After surgical closure of ostium primum defects, morbidity manifests primarily as mitral valve dysfunction (e.g., mitral regurgitation) and left ventricular outflow tract obstruction.<sup>196-200</sup> In most children, outcomes are favorable after repair at an early age. After closure of sinus venosus defects, potential problems include pulmonary venous obstruction and loss of sinus node function.<sup>201-203</sup> Repair of coronary sinus defects consists of patch closure of the atrial communication at the mouth of the coronary sinus. This leaves a small right-to-left shunt as deoxygenated blood from the coronary sinus continues to drain directly into the left atrium.<sup>204</sup> If a connection between the left superior vena cava and left atrial connection persists, a variety of surgical approaches may allow redirection of the abnormal systemic venous return. For most children with atrial communications, significant postoperative sequelae are unlikely to occur, and outcomes are generally good. In most cases, no major repercussion from the repaired defect should be expected for future anesthesia care.

## VENTRICULAR SEPTAL DEFECTS

### Anatomy and Pathophysiology

Ventricular septal defects (VSDs) are the most common of all congenital cardiac anomalies, comprising 30% to 60% of CHD (excluding a bicuspid aortic valve) and occurring in 2 to 6 cases per 1000 live births (see Fig. 15-2, A).<sup>205</sup> VSDs can be found in isolation or in the context of other structural malformations. Large defects require early attention for symptoms related to congestive heart failure or pulmonary hypertension. VSDs have a greater rate of spontaneous closure in childhood—about 75% closure by 6 months to 1 year.<sup>206,207</sup>

Various classification schemes have been proposed for VSDs based on their anatomic location, size, restrictive or nonrestrictive nature, and hemodynamic significance.<sup>208,209</sup> The following scheme categorizes defects as four major morphologic types based on their anatomic location. In some cases, the boundaries of a defect may extend beyond the margin of a particular region of the ventricular septum into another.

1. *Perimembranous defects* (most common type) are located in the membranous region, under the septal leaflet of the tricuspid valve and just below the level of the aortic valve. They are frequently associated with redundant septal tricuspid valve tissue (e.g., aneurysm) that may limit shunting or eventually result in complete defect closure.
2. *Muscular defects* are located anywhere within the trabecular or muscle-bound component of the ventricular septum. Multiple defects give the appearance of a “Swiss cheese” septum, which complicates surgical closure.
3. *Doubly committed, subarterial or supracristal defects* are found within the region of the subpulmonary infundibulum. They

**TABLE 21-3** Potential Issues after Interventions for Selected Congenital Heart Defects

<b>Atrial Septal Defects</b> Residual intracardiac shunt Persistent right ventricular dilation and abnormal motion of interventricular septum Atrial arrhythmias, ventricular dysfunction if late repair Pulmonary venous obstruction (sinus venosus defect associated with anomalous pulmonary venous return) Mitral valve problems, left ventricular outflow tract obstruction (ostium primum defect with cleft mitral valve) Development of pulmonary vascular disease (rare)	Need for reoperation in those with bioprosthetic or mechanical valves or conduits After Ross procedure: autograft or right ventricular homograft failure, progressive aortic root dilation, or aortic regurgitation
<b>Atrioventricular Septal Defects</b> Mitral valve problems (regurgitation, stenosis) Left ventricular outflow tract obstruction Residual intracardiac shunts Atrioventricular block, conduction abnormalities Prior palliation with pulmonary artery banding might have resulted in inadequate protection of pulmonary vasculature or distortion of pulmonary artery anatomy. Pulmonary hypertension may persist.	<b>L-Transposition of the Great Arteries (Congenitally Corrected Transposition)</b> Residual defects (e.g., shunts, outflow tract obstruction) Systemic (right) ventricular dilation, dysfunction, failure Left-sided (tricuspid) valve regurgitation Atrioventricular block or arrhythmias
<b>Coarctation of the Aorta</b> Systemic hypertension Residual or recurrent obstruction Death from untreated pathology related to heart failure, aortic rupture or dissection, infective endarteritis or endocarditis, premature coronary artery disease, or cerebral hemorrhage Endocarditis risk with concomitant aortic valve disease	<b>Patent Ductus Arteriosus</b> Residual or recurrent shunting Increased pulmonary vascular resistance (now rare)
<b>Coronary Artery Anomalies</b> May go unsuspected for some time Myocardial ischemia Ventricular dysfunction May present as syncope or lead to sudden death	<b>Right Ventricular Outflow Tract Obstructions</b> Residual or recurrent obstruction resulting in ventricular pressure overload Pulmonary regurgitation may require intervention After right ventricle-to-pulmonary artery conduit: need for intervention or reoperation related to conduit failure
<b>d-Transposition of the Great Arteries</b> Residual pathology (e.g., intracardiac shunts, outflow tract obstruction) After atrial baffle procedure: baffle leak, obstruction of systemic or pulmonary venous pathways, progressive right ventricular dilation or failure, tricuspid regurgitation, sinus node dysfunction, or atrial arrhythmias After arterial switch operation: aortic root dilation, aortic regurgitation, supravalvar stenosis (pulmonary or aortic), or coronary insufficiency	<b>Single Ventricle</b> After aortopulmonary shunt: shunt stenosis with associated hypoxemia, ventricular volume overload, systemic ventricular dilation, distortion of pulmonary artery anatomy, or pulmonary hypertension After bidirectional Glenn connection or hemi-Fontan procedure: progressive cyanosis due to venous collaterals or other vascular communications, allowing venous pathways to bypass the pulmonary circuit or due to development of pulmonary arteriovenous malformations (more likely with classic Glenn anastomosis) After Fontan procedure: increased systemic venous pressures, right atrial hypertension (with atriopulmonary connection), sinus node dysfunction, atrial rhythm disturbances, atrioventricular valve regurgitation, hepatic dysfunction, thrombotic complications, coagulation defects, protein losing enteropathy, or progressive systemic ventricular dilation or dysfunction
<b>Ebstein Anomaly</b> Progressive tricuspid regurgitation and right-sided volume overload Right ventricular dysfunction Atrial tachyarrhythmias (including Wolf-Parkinson-White syndrome) Potential for paradoxical right-to-left shunting in the presence of an interatrial communication Valve repair or replacement may be necessary	<b>Tetralogy of Fallot</b> Residual or recurrent pathology (e.g., intracardiac shunts, right ventricular outflow tract obstruction, distal pulmonary artery bed abnormalities) Progressive pulmonary regurgitation with need for repeat intervention (e.g., right-sided heart dilation, dysfunction) Arrhythmias associated with poor hemodynamics Syncope or sudden death (arrhythmogenic cause) Restrictive right ventricular physiology
<b>Interrupted Aortic Arch</b> Residual intracardiac defects Subaortic obstruction Residual or recurrent aortic arch obstruction	<b>Truncus Arteriosus</b> Residual intracardiac shunting Revision of right ventricle-to-pulmonary artery reconstruction (for stenosis or regurgitation) Truncal (aortic) valve stenosis or regurgitation
<b>Left Ventricular Outflow Tract Obstructions</b> Residual or recurrent obstruction Aortic regurgitation, aortic root dilation Risk of endocarditis Ventricular dysfunction Potential subendocardial ischemia if ongoing ventricular pressure overload Coronary ostial stenosis, diffuse arteriopathy (supravalvar aortic stenosis)	<b>Ventricular Septal Defect</b> Potential residual defects Risk of endocarditis (diminishes with time after repair) Aortic regurgitation Rarely, increased pulmonary vascular resistance may not improve postoperatively

may be associated with aortic valve herniation or prolapse into the defect and aortic regurgitation.<sup>210</sup>

4. *Inlet defects* are located in the posterior aspect of the ventricular septum close to the atrioventricular valves. Associated anomalies of the atrioventricular valves frequently coexist.

The characterization of VSDs based on their size and likely hemodynamic significance is extremely useful when caring for children who have not undergone repair:

*Small defect:* The pulmonary-to-systemic systolic pressure ratio is less than 0.3, and the  $Q_{\text{pulm}}/Q_{\text{sys}}$  is less than 1.4. The defect causes negligible to minimal hemodynamic changes. Normal right ventricular systolic pressure, pulmonary vascular resistance, and left ventricular size are typically found.

*Moderate defect:* The systolic pressure ratio is greater than 0.3, and the  $Q_{\text{pulm}}/Q_{\text{sys}}$  is 1.4 to 2.2. The defect may be associated with volume overload and congestive symptoms. Some degree of left atrial and left ventricular dilation exists, as well as increased pulmonary artery pressures.

*Large defect:* The systolic pressure ratio is greater than 0.3, and the  $Q_{\text{pulm}}/Q_{\text{sys}}$  is greater than 2.2. The defect is associated with significant symptoms (e.g., failure to thrive, congestive heart failure). Cardiomegaly and increased pulmonary vascularity are frequent findings.

The physiologic effects of the communications that allow shunting at the ventricular level are determined by the size of the defect, amount of shunting, and relative pulmonary and systemic vascular resistances. Physiologically, isolated defects may be classified as pressure restrictive (i.e., right ventricular pressure less than left ventricular pressure) or nonrestrictive defects (i.e., equal or near-equal ventricular pressures). Restrictive defects often imply limited flow through the communication. This is frequently the case with small VSDs in which the pressure gradient determines the magnitude of shunting. If the defect is large and nonrestrictive, the amount of flow across the orifice depends on the ratio between the pulmonary and systemic vascular resistances. Reduced pulmonary vascular resistance in the context of a nonrestrictive VSD leads to a large left-to-right shunt, increased pulmonary blood flow, pulmonary hypertension, and increased myocardial work, as evidenced by a volume load to the left heart. Nonrestrictive left-to-right shunts result in pulmonary congestion and abnormal respiratory mechanics characterized by decreased lung compliance, increased airway resistance, and increased work of breathing. Increases in alveolar dead space and alveolar to arterial oxygen gradients are to be expected, as well as increases in minute ventilation and potential oxygen requirements.

An important perioperative consideration for children with defects associated with increased pulmonary blood flow is the pulmonary steal phenomenon, which may result from decreases in pulmonary vascular resistance as left-to-right shunting increases at the expense of systemic blood flow. This requires an appraisal of the factors that may influence pulmonary vascular tone to prevent compromises in systemic perfusion.

### Treatment Options, Residua, Sequelae, and Long-Term Outcomes

Surgical closure of VSDs early in childhood results in excellent outcomes, usually without sequelae.<sup>211-213</sup> Surgical intervention in older children may lead to reduced left ventricular function and increased left ventricular mass.<sup>214</sup> Small communications, although regarded as hemodynamically insignificant, may not be benign. This has led to ongoing controversy regarding the need

for definitive intervention. Several young children with moderate defects remain relatively asymptomatic until later life, when gradual decompensation may ensue related to increased end-diastolic volume and ventricular dilation. In these children, defect closure is indicated if the magnitude of the increase in pulmonary vascular resistance is not prohibitive, which is rarely the case. Severely increased pulmonary vascular resistance (more than 7 Wood units per  $\text{m}^2$ ) augments the risks associated with the surgical procedure, and it may not return to normal levels after the intervention.<sup>215</sup> If postoperative pulmonary hypertension persists, the prognosis is unfavorable, with the potential for eventual right ventricular failure.<sup>216</sup> Development of Eisenmenger syndrome (i.e., pulmonary vascular obstructive disease and reversal in the direction of the ventricular level shunt) has become rare due to early recognition and management of children with these defects.

Postoperative sequelae after VSD closure include residual or, less commonly, recurrent defects, arrhythmias or other conduction system disturbances, subaortic obstruction, and valvar regurgitation.<sup>217</sup> Although surgical closure is considered the gold standard, transcatheter closure by device placement is feasible for selected muscular and postoperative residual defects.<sup>218,219</sup> Early data demonstrate excellent closure rates with reduced rates of complications<sup>220</sup> (see also Chapter 20). Limited experience and follow-up are available with catheter-based interventions for closure of membranous communications.<sup>221-224</sup>

## ATRIOVENTRICULAR SEPTAL DEFECTS

### Anatomy and Pathophysiology

Atrioventricular septal defects (AVSDs), also known as atrioventricular canal defects or endocardial cushion defects, result in deficiency of the atrioventricular septum and altered formation of the atrioventricular valves (see Fig. 15-2, B).<sup>225</sup> These rare defects comprise only 4% of CHD cases, although they have a prevalence among patients with Down syndrome of 25%. AVSDs can be classified as follows:

1. The *complete form* (i.e., common atrioventricular canal defect) consists of an ostium primum defect, an interventricular communication at the superior aspect of the inlet or posterior muscular septum, and a common atrioventricular valve. They are frequently associated with various degrees of atrioventricular valve regurgitation.
2. The *partial form* (i.e., incomplete form) is characterized by an ostium primum ASD accompanied by a cleft or commissure in the left-sided atrioventricular valve. Two functionally distinct atrioventricular valvar orifices are usually identified (see "Atrial Septal Defects").
3. The *transitional or intermediate form* is a combination of a partial AVSD with a small, interventricular communication and two distinct atrioventricular valve components.

Complete defects are associated with nonrestrictive intracardiac shunting, excessive pulmonary blood flow, congestive heart failure, and systemic right ventricular and pulmonary artery systolic pressures. Without intervention, they may lead to early pulmonary vascular changes. The severity of atrioventricular valve regurgitation also influences the clinical presentation. Partial AVSDs are less likely to be associated with pulmonary overcirculation of sufficient severity to cause significant heart failure symptoms.

Perioperative concerns similar to those previously described in children with nonrestrictive ventricular communications are

applicable, but they also are magnified in those with unrepaired complete defects. In children with increased pulmonary vascular resistance and a reactive pulmonary bed, issues such as airway manipulation, light anesthesia, hypoxemia, or hypercarbia may lead to an increase in pulmonary artery pressures to suprasystemic levels.

### Treatment Options, Residua, Sequelae, and Long-Term Outcomes

The surgical approach for complete defects has evolved from a two-stage intervention (i.e., initial pulmonary artery banding to limit pulmonary blood flow and subsequent complete repair) to a single strategy of primary repair in infancy. For a complete defect, this consists of partition of the common atrioventricular valve, patch closure of the intracardiac communications, and closure of the left-sided valvar cleft. The long-term outlook after repair is generally good, with a small likelihood of residual dysfunction.<sup>226-228</sup>

Postoperative problems include left atrioventricular valve regurgitation or stenosis, residual intracardiac shunting, atrioventricular block, and subaortic obstruction.<sup>199,200</sup> Occasionally, pulmonary hypertension persists or develops postoperatively; it is more likely in children with Down syndrome. In the remote past, uncorrected defects resulted in Eisenmenger physiology, accounting for significant late morbidity and early death.<sup>229</sup> Considerations for noncardiac surgery in children after surgical repair include the residual effects of the prior ventricular volume load, the status of the atrioventricular valve, and patency of the left ventricular outflow tract.

## RIGHT VENTRICULAR OUTFLOW TRACT OBSTRUCTIONS

### Anatomy and Pathophysiology

Pulmonary valve stenosis is the most common pathology among children with right ventricular outflow tract obstruction.<sup>230</sup> Other lesions that result in obstruction to pulmonary blood flow include infundibular stenosis, muscle bundles within the body of the right ventricle, and anatomic alterations in the pulmonary arterial bed. These pathologies may be found in isolation or occur as part of more complex malformations. Such is the case in tetralogy of Fallot (discussed later), in which multiple anatomic levels of right ventricular outflow tract obstruction are typically encountered (see Fig. 15-5).

Although isolated valvar pulmonary stenosis is congenital in most cases, the disease can be progressive. In the uncomplicated or pure variant, an interatrial communication in the form of a PFO or secundum ASD may be identified, and the ventricular septum is intact.

The magnitude of right ventricular outflow tract obstruction is directly related to the degree of valvar narrowing. This imposes an afterload burden on the right ventricle, resulting in right ventricular hypertrophy, decreased ventricular diastolic compliance, and tricuspid regurgitation. In severe cases, the systolic pressure generated by the right ventricle may exceed that of the left ventricle. Cyanosis in children with pulmonary stenosis usually reflects right-to-left interatrial shunting and reduced pulmonary blood flow. It may be associated with severe right ventricular hypertrophy, fibrosis, or ventricular dysfunction.

Most children with mild to moderate valvar stenosis remain asymptomatic, and the pathology is relatively well tolerated chronically. Severe obstruction in older children is frequently associated with limited exercise tolerance. Subendocardial ischemia is a potential risk in children with a hypertensive,

hypertrophied right ventricle. Management is directed at maintaining coronary perfusion and an inotropic state of the myocardium.

### Treatment Options, Residua, Sequelae, and Long-Term Outcomes

Percutaneous balloon valvuloplasty is very effective and currently considered the treatment of choice for valvar pulmonary stenosis, replacing surgical valvotomy in most cases. Outcomes are excellent, and long-term issues are rare.<sup>231-233</sup> Dysplastic valves have a less favorable response to catheter-based interventions, and affected children are more likely to require surgery. Indications for repeat intervention include residual right ventricular outflow tract obstruction and progressive pulmonary regurgitation.<sup>234</sup>

In children with significant right ventricular hypertrophy undergoing noncardiac surgery, adequate ventricular preload and optimization of volume status are recommended. Further increases in right ventricular afterload should be avoided in those with residual or recurrent outflow tract obstruction.

## LEFT VENTRICULAR OUTFLOW TRACT OBSTRUCTIONS

### Anatomy and Pathophysiology

Left ventricular outflow tract obstruction may occur at the level of the aortic valve, supraaortic region, or subaortic region. It may take place in isolation or as part of complex cardiovascular disease. A *bicuspid aortic valve* is the most common of all congenital cardiac anomalies, occurring in approximately 2% of the general population.<sup>235</sup> Although it may not necessarily imply valvar stenosis, this abnormality can be associated with progressive obstruction or regurgitation. A bicuspid valve may be found in asymptomatic individuals or within the context of severe left heart obstruction. The prevalence of coexistent defects is relatively large and frequently includes patent ductus arteriosus, VSD, aortic coarctation, and other abnormalities of the aorta and its branches.

Infants with critical aortic stenosis and those with severe obstruction require early intervention in view of ductal dependency, heart failure symptoms, and the degree of ventricular dysfunction. Older children with moderate to severe obstruction may present with decreased exercise tolerance, syncopal episodes, or myocardial ischemia. Impedance to left ventricular ejection in aortic stenosis results in elevation of left ventricular systolic pressure and increased myocardial force. Ventricular hypertrophy is the compensatory response to the increased afterload. Contractile function is normal to increased, but diastolic impairment may occur.

In *supraaortic aortic stenosis*, the narrowing typically occurs at the sinotubular junction. The coronary arteries arise proximal to the area of obstruction and are subjected to increased systolic pressures equal to that of the left ventricle. The arteriopathy found in many of these children may involve the origin of the coronary arteries or other systemic and pulmonary vessels.<sup>236</sup> This malformation may occur as part of Williams syndrome, which is characterized by elfin facies, mental retardation, idiopathic hypercalcemia, and other features. Several reports have described unexpected complications in these children, including death during anesthesia care.<sup>237-240</sup> Affected children should be considered at increased risk for any procedure.

*Subaortic aortic stenosis* may take a variety of forms, including a discrete fibromuscular ridge or membrane, complex tunnel-like obstruction, or hypertrophy of the interventricular septum

(i.e., hypertrophic cardiomyopathy). The association of left ventricular obstructive lesions such as a bicuspid aortic valve, subaortic stenosis, aortic coarctation, and mitral valve inflow obstruction (e.g., parachute mitral valve, supravulvar mitral ring) is referred to as the *Shone complex*.

Hypoplastic left heart syndrome (HLHS) represents an extreme form of left ventricular outflow tract obstruction (see Fig. 15-10). It encompasses a constellation of malformations, affecting left-sided cardiac structures (e.g., mitral and aortic valves, aorta, arch) (see "Single Ventricle").

Common features of the anomalies that result in obstruction to left ventricular output include a pressure gradient across the involved region, increased left ventricular systolic pressure, increased myocardial force, and left ventricular wall stress. With chronic obstruction, the hypertrophied myocardium is at risk for subendocardial ischemia as a consequence of an imbalance in the ratio of myocardial oxygen supply and demand. Factors such as increases in left ventricular afterload, inadequate hypertrophic remodeling, and decreases in myocardial systolic or diastolic performance may compromise stroke volume and contribute to cardiac dysfunction and heart failure in this setting.<sup>241</sup> These issues are relevant for children with more than mild obstruction, and they influence anesthesia care during noncardiac surgery or other interventions.

#### **Treatment Options, Residua, Sequelae, and Long-Term Outcomes**

Individuals with a bicuspid aortic valve may remain asymptomatic for many years but are at risk for aortic stenosis or regurgitation and concomitant hemodynamic alterations. Some of those requiring surgical intervention during childhood undergo reoperation for recurrent stenosis or progressive regurgitation in the next 25 years.<sup>242</sup> Percutaneous balloon valvuloplasty may be a treatment option for critical or severe aortic valve disease.<sup>243</sup> Surgical alternatives include valvotomy, mechanical or bioprosthetic valve placement, and root replacement with homograft or autograft material. In the Ross operation, the native, diseased root is replaced by a pulmonary autograft, and an extracardiac conduit establishes continuity between the right ventricle and main pulmonary artery.<sup>244</sup> Repeat intervention for eventual failure of the right ventricular conduit is anticipated in these children.<sup>245</sup> In addition to surveillance of the right ventricular outflow tract, monitoring for aortic root dilation and concomitant regurgitation is an important component of follow-up.<sup>246,247</sup>

Management of discrete subaortic stenosis remains a challenge, and the timing of surgery is controversial.<sup>248</sup> Postoperative complications include residual or recurrent obstruction and progressive aortic regurgitation. For severe supravulvar obstruction, surgical intervention is recommended, and it results in adequate relief of the obstruction in most cases.<sup>249</sup>

Myocardial fibrosis and ventricular dysfunction may be a feature of severe aortic outflow obstruction in infancy. Although adequate relief of the obstruction results in significant clinical improvement, abolition of congestive heart failure, and myocardial remodeling in most children, ventricular hypertrophy or dilation persists along with various degrees of systolic or diastolic impairment in many. Other problems include myocardial ischemia, ventricular failure, and risk of sudden death.<sup>250,251</sup> Important concerns related to anesthesia and surgery are the potentially limited left ventricular functional reserve and alterations of the fine balance between myocardial oxygen supply and demand. Maintenance of coronary perfusion and ventricular contractile

function is key in the care of these children. Pharmacologic agents with vasoactive and inotropic properties should be readily available during anesthesia care.

### **PATENT DUCTUS ARTERIOSUS**

#### **Anatomy and Pathophysiology**

The ductus arteriosus is a vascular structure connecting the pulmonary trunk and thoracic aorta (see Fig. 15-4). It enables right ventricular output into the descending aorta during fetal life, within the context of typically increased pulmonary vascular resistance. Persistent patent ductus arteriosus (PDA) may be an isolated finding or associated with other forms of heart disease. Prematurity is an important risk factor.

The magnitude and direction of great artery shunting depends on the size of the communication and the pulmonary vascular resistance. In children with moderate or large left-to-right shunts, the physiologic effects are those of increased pulmonary blood flow and left ventricular volume overload.

#### **Treatment Options, Residua, Sequelae, and Long-Term Outcomes**

Children with a tiny or small PDA have a normal life expectancy.<sup>252</sup> Those with hemodynamically significant communications eventually develop symptoms related to left ventricular volume overload. In some cases, this predisposes them to moderate or severe pulmonary hypertension. Although unlikely in the current era, in the past, the long-standing, high-pressure, and high-flow states associated with a moderate or large communication resulted in Eisenmenger syndrome in some children.

Ductal closure can be performed by surgical ligation or division. This is the favored approach in preterm infants and those with large communications.<sup>253</sup> Percutaneous catheter occlusion can also be accomplished with a good success rate<sup>254</sup> (see also Chapter 20). Video-assisted thoracoscopic surgery has been used for ductal ligation.<sup>255,256</sup> Regardless of the approach, interruption of this vascular structure is rarely associated with long-term issues. Children can expect a normal cardiovascular reserve and should be managed accordingly during future anesthesia care.

### **COARCTATION OF THE AORTA**

#### **Anatomy and Pathophysiology**

Coarctation of the aorta is characterized by narrowing of the aortic lumen in the thoracic region. The constriction may be discrete or diffuse. In infants, a long, narrowed aortic segment often is associated with hypoplasia of the transverse arch and aortic isthmus, in which case other structural cardiac malformations may also exist.<sup>257</sup> Associated defects include a bicuspid aortic valve, VSD, mitral valve abnormalities, and other types of left-sided obstructive lesions.

Hemodynamic consequences result from obstruction to systemic blood flow and increased left ventricular afterload. During infancy, ventricular dilation and heart failure predominate. In older children, arterial hypertension is found proximal to the region of aortic obstruction, and they have some degree of left ventricular hypertrophy. Ventricular function is usually well preserved. Collateral circulation develops with a long-standing pathologic process.

#### **Treatment Options, Residua, Sequelae, and Long-Term Outcomes**

Symptoms associated with severe aortic arch obstruction or concomitant cardiovascular pathology lead to early intervention in

some children.<sup>258</sup> Alterations in ventricular systolic function associated with a neonatal presentation usually resolve after relief of the obstruction. Systemic hypertension and a residual gradient that exceeds 25 to 30 mm Hg are regarded as indications for repeat intervention. Various catheter-based and surgical approaches have been applied to the management of this lesion; each has advantages and disadvantages<sup>259</sup> (see also Chapter 20).

Repair at an early age is advocated in view of reduced surgical risks for the younger age group, and early repair minimizes late morbidity.<sup>260</sup> Long-term issues include systemic hypertension (independent of the hemodynamic result) and residual or recurrent aortic arch obstruction.<sup>261</sup> Left ventricular hypertrophy may persist in some children after repair, particularly in those undergoing interventions later in childhood. Abnormalities in diastolic ventricular function have been reported after successful repair.<sup>262</sup> Catheter techniques (i.e., balloon angioplasty with and without stent implantation) have been effective in relieving the obstruction and normalizing blood pressure.<sup>263</sup> This approach may be used as primary therapy or to address residual or recurrent disease.<sup>264</sup> Aortic aneurysms can occur around the area of coarctation or elsewhere in the aorta after surgical intervention or balloon angioplasty. Additional long-term problems result from coexistent defects, such as bicuspid aortic valve and premature development of coronary artery disease. Aortic coarctation has been associated with cerebral aneurysms.

## TETRALOGY OF FALLOT

### Anatomy and Pathophysiology

Tetralogy of Fallot (TOF) is the most common cyanotic cardiac lesion (see Fig. 15-5).<sup>265</sup> This malformation is characterized by right ventricular outflow tract obstruction, an interventricular communication, right ventricular hypertrophy, and aortic override. There is considerable variation in the severity of the disease, accounting for the spectrum of clinical manifestations. The subpulmonary obstruction arises from anterior deviation of the infundibular septum and may have dynamic and fixed components.<sup>266</sup> Pulmonary valve stenosis almost invariably exists, and the main pulmonary artery and distal branches often demonstrate various degrees of hypoplasia. The limitation of pulmonary blood flow and magnitude of ventricular level right-to-left shunting account for the degree of cyanosis.

Pressure overload accounts for hypertrophy of the right ventricular myocardium. The large, nonrestrictive VSD and the outflow obstruction result in a right ventricular pressure at systemic levels, and the pulmonary artery systolic pressure is reduced. Increases in the severity of the right ventricular outflow tract obstruction or decreases in systemic vascular resistance exacerbate right-to-left intracardiac shunting and systemic arterial desaturation, increasing the level of cyanosis. These features characterize hypercyanotic episodes or tet spells.

Several TOF variants are recognized, including the “pink” or mild forms at one end of the spectrum, and complex defects, such as pulmonary atresia with diminutive or discontinuous distal branches, at the other. Associated cardiovascular anomalies in children with TOF include an atrial communication, right aortic arch, multiple VSDs, persistent left superior vena cava to the coronary sinus, complete AVSD, and abnormal origin or course of the coronary arteries. Unoperated TOF is associated with the potential for hypercyanotic episodes and ventricular outflow tract obstruction.

### Treatment Options, Residua, Sequelae, and Long-Term Outcomes

The surgical management of TOF has evolved from a strategy of a staged approach with initial palliation using a systemic-to-pulmonary shunt to a single-stage, definitive repair in infants. Ongoing controversy exists about the favored approach in the neonate or very young infant in need of surgical therapy.<sup>267,268</sup> In selected cases, percutaneous balloon pulmonary valvuloplasty may be performed as a palliative, temporizing measure.<sup>269</sup> The definitive repair of TOF, although a successful operation enabling most children to be free of symptoms, may be associated with significant postoperative residua.<sup>270,271</sup> Volume loads may arise from pulmonary regurgitation, residual shunts, and the presence of aortopulmonary collaterals. Ventricular pressure loads, however, may result from residual or recurrent right ventricular outflow tract or obstruction to the pulmonary artery bed. This situation is associated with right ventricular hypertension, myocardial hypertrophy, and reduced ventricular compliance.

Conditions that may require repeat intervention include pulmonary regurgitation of significant severity, residual or recurrent pulmonary outflow tract obstruction, and residual, hemodynamically significant intracardiac shunts. Catheter-based procedures may be effective in the management of obstruction of the pulmonary vasculature, and they have been applied to rehabilitate the vascular tree in cases of significant underdevelopment. Children who have undergone right ventricle-to-pulmonary artery reconstruction by means of placement of an extracardiac conduit eventually develop conduit failure (i.e., stenosis or regurgitation) requiring reoperation.<sup>272</sup> Aortic root dilation can lead to increasing degrees of regurgitation and the need for surgical intervention.

In the past, most children underwent definitive repair at an older age, consisting of an extensive right ventriculotomy to facilitate resection of the infundibular obstruction and closure of the VSD. Many were also subjected to procedures that included placement of a large patch that encompassed the subpulmonic region, valve annulus, and supra-valvar region (i.e., transannular patch). Although effective in relieving the obstruction, this approach invariably resulted in pulmonary regurgitation, which was reasonably well-tolerated but progressed over time.

On late follow-up, pulmonary regurgitation has been identified as a major cause of morbidity, and it may result in progressive right ventricular dysfunction due to significant volume overload, ventricular arrhythmias with their associated disabilities, and even death. In recognition of the long-term morbidity linked to severe pulmonary regurgitation, the surgical strategy for this defect has undergone reappraisal and modification over the years.<sup>273</sup> A current method uses a transatrial approach for closure of the VSD, minimizing the size of an infundibular incision (if one is required) and avoiding or limiting the size of the transannular patch.<sup>274,275</sup>

Although surgical refinements have led to overall improvements in postoperative outcomes, the preoperative evaluation of these children should include inquiries regarding exercise tolerance as an indicator of functional status and an appraisal of right ventricular function, residual pathology, potential rhythm abnormalities, and conduction disturbances. Magnetic resonance imaging is extremely useful in the evaluation of right ventricular systolic function, quantitation of the severity of pulmonary regurgitation, and evaluation of the distal pulmonary vascular bed. Electrophysiologic testing and programmed ventricular

stimulation may be indicated to refine antiarrhythmic drug therapy, for ablation of arrhythmia foci, or for implantation of a cardioverter-defibrillator system.

Postoperatively, a subset of children develops a pattern that is characterized by right ventricular diastolic noncompliance, which is known as *restrictive right ventricular physiology*. It is associated with a reduced likelihood of progressive pulmonary regurgitation and right ventricular dilation. In these children, the right ventricle operates at a greater end-diastolic pressure, and the children demonstrate superior exercise performance in addition to a reduced likelihood of developing ventricular rhythm abnormalities.<sup>276</sup>

Perioperative goals for the child with pulmonary regurgitation and right ventricular dysfunction include optimizing right ventricular filling, maintaining or supporting right ventricular function, and minimizing factors that may further increase right ventricular work (e.g., increased pulmonary vascular resistance, increased peak inspiratory pressures). Any detrimental factor that may affect the right ventricle may also negatively affect the left ventricle due to ventricular interdependence. In children with restrictive right ventricular physiology, the myocardial supply-to-demand relationship is of particular importance because the stiff, poorly compliant right ventricular myocardium may not tolerate alterations in this balance and may be vulnerable to decreases in subendocardial oxygen delivery.

## D-TRANSPOSITION OF THE GREAT ARTERIES

### Anatomy and Pathophysiology

In D-transposition of the great arteries (D-TGA), the aorta arises from the anatomic right ventricle, and the pulmonary artery arises from the left ventricle (see Fig. 15-6). This anomaly accounts for the most common cause of cyanotic heart disease in the neonatal period. Associated defects include VSDs, left ventricular outflow tract obstruction, and coronary artery anomalies.

In D-TGA, the systemic and pulmonary circulations operate in parallel rather than in series, resulting in cyanosis. Mixing at the atrial, ventricular, or ductal level is essential for survival. Initial management in most infants includes prostaglandin E<sub>1</sub> therapy to maintain ductal patency and to enhance intercirculatory mixing. If restrictive, the interatrial communication may require enlargement by balloon atrial septostomy.

Because most neonates with D-TGA are otherwise healthy, the concerns before surgical correction primarily are those associated with diagnostic procedures or interventions in the cardiac catheterization laboratory. Considerations for anesthetic management primarily are related to cyanosis and heart failure, which are more likely to occur in infants with coexistent large VSDs. An inadequate communication for intercirculatory mixing may account for profound hypoxemia, potentially progressing to metabolic acidosis due to compromised tissue oxygenation. Less commonly, increased pulmonary vascular resistance may account for severe cyanosis despite prostaglandin E<sub>1</sub> therapy and an adequate anatomic communication.

### Treatment Options, Residua, Sequelae, and Long-Term Outcomes

Several decades ago, the approach to D-TGA consisted of an atrial baffle (i.e., atrial switch) or redirection procedure (i.e., Mustard or Senning operations). Physiologic correction was accomplished by allowing systemic venous blood to drain into the left ventricle

and pulmonary artery while pulmonary venous blood was rerouted through the tricuspid valve into the right ventricle and aorta. The right ventricle remained as the chamber ejecting against systemic afterload. These procedures provided relief of cyanosis and reasonably good survival.<sup>277</sup> In the long term, however, this approach led to complications such as sinus node dysfunction and atrial rhythm disturbances.<sup>278</sup> Progressive right ventricular dilation, tricuspid (i.e., systemic atrioventricular valve) annular dilation, associated regurgitation, and eventual right ventricular dysfunction or failure were causes of major morbidity.<sup>279-281</sup> In addition to the rhythm abnormalities and conduction defects, this problem was thought to account for sudden death in some individuals later in life. Other problems included progressive obstruction of venous pathways and intracardiac shunting through atrial baffle leaks. Abnormal right and left ventricular responses to exercise have also been documented in these patients.<sup>282</sup>

The arterial switch operation (i.e., Jatene procedure) is the standard surgical approach in neonates with D-TGA. The repair establishes a normal, concordant relationship between the ventricles and their respective great arteries, achieving anatomic correction. The procedure involves transection of the arterial trunks above the level of the semilunar valves, anastomotic connections to their appropriate outflows, translocation of the coronary arteries to the neo-aortic root, and closure of any intracardiac communications (see Fig. 15-7, A-E). Normal physiology is restored, enabling the left ventricle to function as the systemic pump. This procedure can be performed with good results, and long-term outcomes usually are very favorable.<sup>283-286</sup> Potential postoperative problems include supravalvar pulmonary or aortic obstruction. Neo-aortic root dilation and aortic regurgitation may be identified on follow-up. Ventricular function is normal in most cases.<sup>287</sup>

Anesthetic management of most children after the arterial switch operation should be the same as in those without structural or functional abnormalities. However, there is some concern about coronary complications in these children that may not be evident clinically or identified by routine surveillance methods. Investigations have demonstrated postoperative regional left ventricular wall motion abnormalities, evidence of myocardial perfusion defects, and pathologic changes in the coronary vasculature, suggesting a risk for coronary insufficiency.<sup>288-292</sup>

## CONGENITALLY CORRECTED TRANSPOSITION OF THE GREAT ARTERIES

### Anatomy and Pathophysiology

Congenitally corrected transposition of the great arteries, also known as L-transposition of the great arteries (L-TGA), is characterized by malposition of the great vessels and ventricular inversion (i.e., atrioventricular and ventriculoarterial discordance). In this anomaly, the right atrium empties into an anatomic left ventricle, which then contracts into the pulmonary trunk. The left atrium opens into an anatomic right ventricle, which ejects into the aorta. The aorta is typically oriented in a leftward and anterior position with respect to the pulmonary artery.

Cyanosis is absent because the circulations are physiologically corrected. The anatomic right ventricle functions as the systemic pump. Associated defects are frequently present and include pulmonary outflow tract obstruction, a ventricular communication, and tricuspid (left-sided) abnormalities. In some individuals,

this lesion may remain undetected until the onset of arrhythmias or syncope due to complete atrioventricular block or the effects of concomitant pathology.<sup>293</sup>

#### **Treatment Options, Residua, Sequelae, and Long-Term Outcomes**

Without associated defects, children with corrected transposition may do well for many years. Development of complete atrioventricular block is common with increasing age.<sup>294</sup> Selected children, particularly those at a young age or with coexistent defects that maintain left ventricular pressure at systemic levels, may be suitable candidates for a surgical intervention that restores the left ventricle as the systemic chamber.<sup>295</sup> This complex repair, known as the double-switch operation or a variation thereof, combines redirection of the systemic and pulmonary venous flows in an atrial baffle procedure with the arterial switch operation. This strategy, however, may not affect mortality compared with conservative management.<sup>296</sup>

Issues that require long-term surveillance in children with congenitally corrected transposition include right ventricular performance and tricuspid valve competency.<sup>297</sup> The overall long-term survival of individuals with this condition is substantially reduced compared with age-matched controls.<sup>298,299</sup>

### **TRUNCUS ARTERIOSUS**

#### **Anatomy and Pathophysiology**

Truncus arteriosus is characterized by a single arterial trunk that gives rise to the aorta, pulmonary root, and coronary arteries (see Fig. 15-8). A ventricular communication usually exists underneath the single arterial root or truncal valve. Various anatomic types are identified according to the origin of the pulmonary arteries from the arterial trunk.<sup>300,301</sup> Associated pathology includes a right aortic arch, aortic arch interruption, abnormalities of the truncal valve (e.g., abnormal number of cusps, stenosis, regurgitation), and coronary artery anomalies. Approximately one third of children with truncus arteriosus have DiGeorge syndrome (see Chapter 14).

Clinical features of the neonate with this defect largely depend on the status of the pulmonary vasculature. If the resistance is increased, the infant is well compensated. The normal decrease in pulmonary vascular resistance leads to symptoms related to pulmonary overcirculation and congestive heart failure, accounting for the need for surgical intervention early in life. Truncus arteriosus is one of the structural malformations associated with a significant risk for adverse events before correction, because balancing the pulmonary and vascular resistances may be quite challenging.<sup>302</sup> The physiology that characterizes a reduced pulmonary vascular resistance and a significant runoff setting is that of an increased arterial oxygen saturation, reduced diastolic arterial pressures (potentially leading to myocardial ischemia), systemic hypotension, impaired cardiac output, and hypoperfusion of distal beds.

#### **Treatment Options, Residua, Sequelae, and Long-Term Outcomes**

Surgery for truncus arteriosus consists of detaching the main pulmonary artery segment from the truncal root, repairing the ensuing aortic wall defect, closing the VSD to allow left ventricular output through the arterial root, and placing an extra-cardiac right ventricle-to-pulmonary artery conduit. Alternative approaches to establishing this continuity have been performed without the use of conduits.<sup>303</sup>

Neonates undergoing truncus arteriosus repair have excellent survival rates.<sup>304-307</sup> Late complications include conduit failure, residual or recurrent pulmonary artery obstruction, and truncal valve problems. Truncal valve dysfunction may require repair or replacement. The main issues of concern are the status of the right ventricle-to-pulmonary artery conduit and truncal root, consequences related to semilunar valve problems, and biventricular function.

### **EBSTEIN ANOMALY**

#### **Anatomy and Pathophysiology**

The classic findings in Ebstein anomaly for the tricuspid valve include a large sail-like anterior leaflet and apically displaced septal and posterior leaflets.<sup>308,309</sup> This configuration commonly results in an atrialized portion of the right ventricle and tricuspid regurgitation. Some degree of right ventricular dysplasia is common. An interatrial communication is a frequent finding, and it may produce right-to-left shunting and clinical cyanosis. The spectrum of disease ranges from minimal or no symptoms to intractable congestive heart failure.<sup>310</sup> A neonatal presentation implies a major clinical problem and usually portends a poor prognosis. Symptoms in older children include cyanosis, palpitations, dyspnea, and exercise intolerance. Initial symptoms may be related to supraventricular tachycardia.

#### **Treatment Options, Residua, Sequelae, and Long-Term Outcomes**

Children with Ebstein anomaly may require only conservative management and follow-up. In most cases, however, surgery is indicated for tricuspid regurgitation, closure of interatrial communications, or other associated problems. Procedures to ablate arrhythmias may be indicated. In contrast to adults, children are less likely to require valve replacement.<sup>311</sup> A cavopulmonary or Glenn connection may be performed in some cases as part of a so-called one and a half ventricle approach to limit the right-sided volume load associated with severe tricuspid valve regurgitation.<sup>312,313</sup> One report indicated good functional outcomes and long-term survival after surgery for Ebstein anomaly.<sup>314</sup> Atrial arrhythmias (including Wolf-Parkinson-White syndrome) are common before and after surgery.

### **INTERRUPTED AORTIC ARCH**

#### **Anatomy and Pathophysiology**

Interrupted aortic arch is an uncommon malformation characterized by discontinuity between the ascending and descending thoracic aorta (see Fig. 15-14). Ductal patency is essential for systemic perfusion beyond the area of interruption. This anomaly is classified in terms of the site of interruption. It is type A if it occurs distal to the left subclavian artery, type B if between the left carotid and left subclavian arteries, and type C if between the carotid arteries. Type B interruption is the most common variant, followed in frequency by types A and C.

Interrupted aortic arch is typically associated with a posteriorly malaligned VSD, resulting in subaortic obstruction. Other defects include a right aortic arch, aberrant origin of a subclavian artery, and truncus arteriosus. Many children with this anomaly have DiGeorge syndrome.

Neonatal presentation of interrupted aortic arch is related to ductal closure in the setting of aortic arch obstruction (e.g., congestive heart failure, poor perfusion, cardiovascular collapse, shock) and occasionally to differential cyanosis. Stabilization of the infant and initiation of prostaglandin E<sub>1</sub> therapy is critical.

The site of interruption and presence of coexistent anomalies can influence the selection of sites for blood pressure monitoring and pulse oximetry. An adequate response to prostaglandin E<sub>1</sub> therapy implies no significant gradient between the areas proximal and distal to the obstruction and an oxygen saturation differential (i.e., increased values in beds supplied proximal to the interruption, reduced values distally).

#### **Treatment Options, Residua, Sequelae, and Long-Term Outcomes**

Surgical intervention is necessary for interrupted aortic arch during the first few days of life. The goal is to establish aortic arch continuity and to address coexistent defects. The current approach favors a one-stage repair.<sup>315-317</sup> Survival in uncomplicated cases is excellent.<sup>318</sup> Problems after repair mainly involve the left ventricular outflow tract.<sup>319</sup> Reoperation may be required and in some cases may consist of left ventricular outflow tract enlargement (i.e., Konno procedure). Eventual aortic root or valve replacement or a Ross-Konno procedure may be necessary.

### **CONGENITAL ANOMALIES OF THE CORONARY ARTERIES**

#### **Anatomy and Pathophysiology**

Congenital anomalies of the coronary arteries include an abnormal origin of one of the main branches, aberrant vascular course, or pathologic communications that involve the coronary circulation.<sup>320,321</sup> The most common anomalies detected during childhood include anomalous origin of the left main coronary artery from the pulmonary artery (ALCAPA), coronary artery-to-pulmonary artery fistulas, and coronary cameral fistulas (i.e., connection between a coronary artery and cardiac chamber). Although rare, anomalous origin of a coronary artery from the incorrect (contralateral) sinus of Valsalva may occur in asymptomatic children and adolescents.<sup>322</sup> In some instances, a major coronary artery courses between the great arteries. This situation may be associated with compromised coronary blood flow and myocardial ischemia during exercise, presumably related to dilation of the arterial roots to accommodate the increased stroke volume.

The clinical presentation varies according to the nature of the anomaly. Infants and young children with ALCAPA may exhibit severe ventricular dysfunction and mitral valve regurgitation, which are largely ischemic in nature. Children with fistulous coronary artery connections may present with a heart murmur or evidence of ventricular volume overload. Significant symptoms may indicate congestive heart failure. Other coronary artery anomalies may manifest as myocardial ischemia, causing exertional syncope or chest pain, and in some cases, arrhythmias may lead to a near-death event.

#### **Treatment Options, Residua, Sequelae, and Long-Term Outcomes**

After surgical intervention for ALCAPA, most children demonstrate significant recovery of myocardial function. Others continue to exhibit alterations in myocardial performance and may develop dilated cardiomyopathy; if it is severe, they may require cardiac transplantation. A few children reach adulthood without symptoms or any intervention. Coronary artery fistulas resulting in congestive symptoms may be referred for catheter-based or surgical interventions. Anginal complaints, myocardial infarction, and sudden death are risks when an aberrant coronary artery courses between the arterial trunks. The risk is greater when the

left coronary artery originates from the right sinus of Valsalva and courses between the aorta and the right ventricular outflow tract. Sudden death is most likely to occur during or immediately after strenuous exercise. The implications of anesthesia for coronary artery anomalies primarily are related to the underlying potential for myocardial ischemia, effects of ventricular volume overload, and ventricular dysfunction.

### **SINGLE VENTRICLE**

#### **Anatomy and Pathophysiology**

The single-ventricle (i.e., univentricular heart) spectrum encompasses several congenital cardiac defects. They are characterized by abnormalities such as ventricular hypoplasia (i.e., HLHS), atrioventricular valve atresia (i.e., tricuspid atresia), or abnormal atrioventricular connections (i.e., double-inlet left ventricle). Pathologies with two distinct ventricles may also be considered in the functional single-ventricle category due to associated defects that preclude a biventricular circulation (i.e., unbalanced AVSD).

Single-ventricle physiology is characterized by complete mixing of the systemic and pulmonary venous circulations at the atrial or ventricular levels. Aortic or pulmonary outflow tract obstruction is a common feature in these pathologies. An important management strategy early in the palliation pathway involves optimizing the balance between the pulmonary and systemic circulations.

#### **Treatment Options, Residua, Sequelae, and Long-Term Outcomes**

Surgical interventions available for children with functional single-ventricle physiology include the following:

##### ***Aortopulmonary Shunt***

Infants with limited or ductal-dependent pulmonary blood flow require the creation of a connection between the systemic and pulmonary circulations. This most commonly takes the form of an aortopulmonary shunt, which is achieved by placement of a Gore-Tex graft between the right subclavian and right pulmonary arteries (i.e., modified right Blalock-Taussig shunt). This procedure augments or allows pulmonary blood flow. Potential problems include shunt malfunction associated with reductions in pulmonary blood flow and congestive heart failure related to excessive pulmonary blood flow. Several factors determine blood flow across an aortopulmonary shunt, with systemic arterial pressure playing a major role.

##### ***Pulmonary Artery Band***

Pulmonary artery banding results in limitation of pulmonary blood flow in children with minimal or no restriction. This procedure protects the pulmonary vascular bed from increased flow and excessive pressure, an essential requirement for subsequent strategies in the child with a functional single ventricle.

Distortion of the proximal branch pulmonary arteries may result from pulmonary artery band placement. The primary considerations for these children are the presence of an intracardiac communication, associated shunting, ventricular volume load, the consequences of ventricular hypertrophy developed as a response to the mechanical limitation of pulmonary blood flow, and issues associated with coexistent defects. In a few children, pulmonary artery banding may lead to ventricular dysfunction and the development of or an increase in the severity of atrioventricular valve regurgitation.

### Norwood Procedure

In infants with HLHS, its variants, and other lesions with similar hemodynamic consequences, systemic blood flow largely depends on patency of the ductus arteriosus. Cerebral and coronary blood flow is provided in retrograde fashion across a typically hypoplastic transverse aortic arch. A key strategy in the management of these infants before cardiac surgery is to optimize systemic perfusion and the balance between the pulmonary and systemic circulations. Alteration of this balance may manifest with signs of inadequate systemic output (e.g., hypotension, lactic acidosis, decreased urine output) within the context of high systemic arterial oxygen saturation, reflecting the relatively excessive pulmonary blood flow.

In this setting, maneuvers that increase pulmonary vascular resistance are indicated to improve hemodynamics. Measures employed include limiting inspired oxygen concentrations, the administration of subambient gas mixtures, and increasing the partial pressure of carbon dioxide ( $PCO_2$ ) by hypoventilation or the administration of inspired carbon dioxide. A comparison of hypoxia versus hypercarbia in infants with HLHS under conditions of anesthesia and paralysis demonstrated that although  $\dot{Q}_{pulm} / \dot{Q}_{sys}$  decreases in both conditions, inspired  $CO_2$  was more effective than hypoxic gas mixtures at increasing parameters associated with improved systemic output.<sup>323</sup> The administration of inspired  $CO_2$  may be favored over hypoventilation as a means of increasing pulmonary vascular resistance and improving the overall clinical condition.

The Norwood procedure is considered the first step among the three stages in the palliative pathway for infants with HLHS or similar cardiac malformations.<sup>324</sup> The intervention, also referred to as stage I single-ventricle palliation or reconstruction, is typically performed within the first few days of life. Surgery consists of aortic reconstruction or creation of a neo-aorta, establishing continuity between the native main pulmonary artery and aortic arch to provide for unobstructed systemic outflow from the right ventricle; the creation of an unrestricted atrial communication by means of an atrial septectomy; and establishing a source of pulmonary blood flow (see Fig. 15-11). For many years, pulmonary blood flow was established by fashioning a modified Blalock-Taussig shunt. Currently, a right ventricle-to-pulmonary artery conduit (i.e., Sano modification and similar variations) is used as an alternative to provide pulmonary blood flow. Although the potential benefits of one approach over the other have been elucidated, additional studies, some with long-term follow-up, are required to provide further information.<sup>325-331</sup>

Another approach, a hybrid stage I strategy, has been applied to selected neonates. In this procedure, a median sternotomy is performed, and both branched pulmonary arteries are banded. A stent is then delivered across the ductus arteriosus under fluoroscopic guidance,<sup>332,333</sup> and the interatrial communication is then enlarged.

Outcomes after the Norwood procedure vary; good results imply operative survival for 85% to 90% of infants.<sup>334</sup> Immediate postoperative problems include systemic hypoxemia, decreased myocardial performance, and excessive pulmonary blood flow. Monitoring of mixed venous oxygen saturation and cerebral near-infrared spectroscopy are helpful in balancing the pulmonary and systemic circulations in this setting. Occasionally, aortic arch obstruction occurs, and less commonly, the atrial septum becomes restrictive. Interstage mortality accounts for attrition among Norwood survivors.<sup>335</sup> Among infants who have undergone placement of a right ventricle-to-pulmonary artery conduit,

stenosis of the conduit associated with progressive cyanosis may account for significant interstage morbidity and often requires intervention or early second-stage palliation.<sup>336,337</sup>

The anticipated arterial oxygen saturation after stage I surgery is expected to be in the range of 75% to 85%. During perioperative care, blood pressure monitoring should consider the potential presence of a Blalock-Taussig shunt that may compromise ipsilateral subclavian artery flow. In these infants, the right ventricle ejects into the pulmonary and systemic circulations. Although this is a more stable arrangement compared with that before the Norwood procedure, it remains a relatively fragile parallel circulation. These infants display little tolerance to even the most common childhood conditions, and ailments such as dehydration, febrile illnesses, or other stresses that may have catastrophic consequences. Despite these challenges, successful outcomes have been reported during noncardiac surgery for a variety of procedures, including those that may be associated with significant hemodynamic perturbations, such as laparoscopic surgery.<sup>338</sup>

### Glenn Anastomosis or Hemi-Fontan Procedure

A cavopulmonary connection or Glenn procedure (i.e., stage II palliation) consists of the creation of a direct anastomosis between the superior vena cava and one of the pulmonary artery branches (see Fig. 15-12). This is considered an intermediary step in the sequential diversion of the systemic venous blood into the pulmonary vasculature in children with single-ventricle physiology. The original or classic operation consisted of an end-to-end anastomosis of the transected superior vena cava onto a disconnected right pulmonary artery, and it was complicated by increasing desaturation that was attributed in many cases to the development of pulmonary arteriovenous fistulae.<sup>339</sup> The current approach is to attach the superior vena cava to the right pulmonary artery in end-to-side fashion, preserving pulmonary artery continuity (i.e., bidirectional cavopulmonary anastomosis [BCPA] or bidirectional Glenn connection). Depending on the specific anatomic abnormalities, right, left, or bilateral BCPAs may be indicated.

An alternative approach in second-stage palliation is a hemi-Fontan procedure. It entails anastomosis of the superior vena cava to the pulmonary artery confluence and placement of a patch between the cavopulmonary anastomosis and common atrium. The patch allows systemic venous return from the superior vena cava to be diverted into the pulmonary circulation rather than enter the heart directly. Ligation of the systemic circulation-to-pulmonary artery connection (shunt or conduit) is performed as part of stage II palliation, whether a BCPA or hemi-Fontan procedure is undertaken.

The second-stage intervention requires a reduced pulmonary vascular resistance because of the passive nature of the pulmonary blood flow. This approach provides adequate palliation to a significant number of infants at an early age while conferring favorable hemodynamic benefits.<sup>340</sup> Diverting a portion of the systemic venous return directly into the pulmonary bed reduces the output requirements of the single ventricle while decreasing the ventricular volume load and myocardial work.

One study demonstrated a 12% rate of interstage attrition between BCPA and the Fontan procedure in children with HLHS palliation.<sup>341</sup> Risk factors included tricuspid valve regurgitation and low weight at the time of the BCPA. These factors may affect the anesthesia-related risks for noncardiac procedures required between these two stages of palliation.

Considerations include the passive nature of the pulmonary blood flow, the importance of maintaining adequate intravascular volume (i.e., minimal fasting) to enhance pulmonary blood flow, and limiting significant increases in pulmonary vascular tone. Pulmonary blood flow and systemic arterial oxygenation are significantly influenced by the interplay between pulmonary artery pressure (i.e., equal to the pressure in the superior vena cava), pulmonary venous pressure, and pulmonary vascular resistance. The expected systemic arterial oxygen saturation ranges between 75% and 85%. Although factors that increase pulmonary vascular resistance may negatively influence pulmonary blood flow, the observation has been made that early after BCPA, moderate hypercapnia with respiratory acidosis improves arterial oxygenation and reduces oxygen consumption, enhancing overall oxygen transport in these children.<sup>342</sup> Hyperventilation can decrease cerebral oxygenation and should be avoided.<sup>343</sup> Postoperative issues include hypoxemia related to the development of collateral vessels that bypass the pulmonary circulation, atrioventricular valve regurgitation, and impaired ventricular function.

### **Fontan Procedure**

The Fontan procedure is the final step (i.e., stage III reconstruction) in the separation of the pulmonary and systemic circulations in children with a functional single ventricle. This intervention allows passive blood flow from the inferior vena cava into the pulmonary vascular bed while bypassing the heart and achieves a circulation in series (see Fig. 15-13). A fenestration, or communication, between the systemic venous pathway and physiologic common atrium may be created in some cases. It allows right-to-left shunting, which provides cardiac output that is not solely dependent on pulmonary blood flow. It also alleviates potential problems associated with chronically increased systemic venous pressures. Common features of the numerous Fontan modifications are separation of the pulmonary and systemic circulations and relief of hypoxemia.<sup>344</sup> Pulmonary blood flow occurs without an intervening ventricular chamber. It depends critically on the transpulmonary pressure gradient (or driving pressure across the pulmonary bed) and is influenced by pulmonary vascular resistance. This blood flow determines cardiac output, emphasizing the importance of adequate hydration and maintenance of central venous pressure.

Several anatomic and hemodynamic variables influence Fontan physiology. Critical factors include unobstructed systemic venous return, status of the pulmonary vasculature, reduced intrathoracic pressures, systemic atrioventricular valve competency, systemic ventricular function, unobstructed systemic outflow, and atrial contribution to ventricular filling.<sup>345</sup> Long-term problems are related to sinus node dysfunction, loss of atrioventricular synchrony, atrial arrhythmias, atrioventricular valve regurgitation, ventricular dysfunction, venous pathway obstruction or thrombotic complications, and symptoms resulting from a chronic reduced cardiac output state.<sup>346</sup> Long-standing increases in systemic venous pressures in children after the Fontan procedure can produce hepatic dysfunction, coagulation defects, protein-losing enteropathy, and rhythm disturbances. The quality of life after the Fontan operation may be compromised by a late decline in functional status, reoperations, arrhythmias, and thromboembolic events.<sup>347-352</sup> Decreased exercise tolerance in most children represents limited cardiopulmonary reserve, which manifests as an inability to increase cardiac output to meet the metabolic demands associated with increased work.

In some cases, surgical revision to a more hemodynamically favorable Fontan modification is indicated.<sup>353,354</sup>

Several considerations are important in the perioperative care of children with Fontan circulation.<sup>355-357</sup> Even mild alterations in factors that influence cardiac output, such as ventricular preload, atrioventricular synchrony, contractile function, afterload, and stress response, may adversely impact hemodynamics. Ensuring the adequacy of hydration, preserving sinus rhythm, and limiting the stress response are key goals. Maintenance of adequate ventricular function may require the administration of inotropic or vasoactive agents perioperatively. Because systemic venous pressures are typically increased, the potential for bleeding and its effects on ventricular filling should be considered. The likelihood of blood loss with ensuing hemodynamic instability is exacerbated by the coagulation defects in these children.<sup>358</sup> The potential for end-organ dysfunction related to chronically decreased organ perfusion, particularly in the renal and hepatic systems, should be considered, and problems may require interventions to minimize perioperative morbidity. Drugs or devices appropriate for cardiac rhythm or arrhythmia management should be accessible.

Some principles apply to airway and ventilatory management after the Fontan operation. Although spontaneous ventilation favors phasic pulmonary flow patterns in these children, controlled ventilation is preferable in most cases. This approach minimizes the detrimental effects of factors such as hypoventilation, atelectasis, hypoxemia, hypercarbia, and respiratory acidosis on pulmonary vascular resistance during spontaneous ventilation, limiting passive drainage of systemic venous blood into the pulmonary circulation. The pH and PCO<sub>2</sub> should be maintained within the normal range, and arterial oxygen saturation should remain close to baseline. The saturation level may depend on the presence or absence of a fenestration and the degree of right-to-left shunting. Mechanical ventilation with large lung volumes may impair pulmonary blood flow as increases in mean intrathoracic pressures transmitted to the pulmonary vascular bed increase pulmonary artery pressures and decrease systemic venous return. Judicious use of mechanical ventilatory support is therefore warranted. Suggested parameters include smaller than usual tidal volumes and reduced positive end-expiratory pressures, allowing delivery of the smallest mean airway pressure possible and normal to relatively small inspiratory times (i.e., normal to slightly prolonged inspiratory-to-expiratory ratios). Although adequate minute ventilation may require increases in the respiratory rate, the potential detrimental effects of very fast rates should also be considered. The goals are to maintain adequate lung volumes, functional residual capacity, and optimal gas exchange.

## **Summary**

Noncardiac surgery in children with CHD can usually be accomplished in a safe and effective manner. A comprehensive understanding of the child's cardiovascular anatomy and physiology is essential to guide appropriate perioperative management and to achieve the best possible outcomes. Many children with CHD have undergone complete repair in infancy, with resultant normal or near-normal hemodynamics at the time of noncardiac surgery. Routine care is likely to be well tolerated by these children. Special attention must be paid to identify children at increased risk, particularly those with unrepaired defects or those who have undergone palliative interventions. Factors such as congestive heart failure, cyanosis, pulmonary hypertension, young age, or

significant residual or sequelae increase the potential for perioperative problems.

An important objective in caring for children with a history of CHD is to diminish cardiac-related morbidity and minimize the likelihood of an adverse outcome. An interdisciplinary approach is much preferred to accomplish this goal. Application of perioperative strategies that may limit the risks of anesthesia and surgery should be a combined effort by all health care providers involved. Anticipation of these risks can decrease the likelihood of complications and facilitate prompt and appropriate treatment when difficulties are encountered. Good communication among the perioperative team members is essential.

*The two strategies (modified Blalock-Taussig and right ventricle-pulmonary artery shunt) that allow for pulmonary blood flow in infants with hypoplastic heart syndrome or related anomalies were compared in infants undergoing the Norwood procedure. Infants (n = 555) at 15 North American centers were randomized to surgery that included one type of shunt or the other. For these children, transplantation-free survival at 12 months was better with the right ventricle-pulmonary artery shunt than with the modified Blalock-Taussig shunt. After 12 months, however, the data demonstrated no significant difference in transplantation-free survival between the two groups.*

Ramamoorthy C, Haberkern CM, Bhananker SM, et al. Anesthesia-related cardiac arrest in children with heart disease: data from the Pediatric Perioperative Cardiac Arrest (POCA) registry. *Anesth Analg* 2010;110:1376-82.

*This is a report from the Pediatric Perioperative Cardiac Arrest (POCA) registry on anesthesia-related cardiac arrests, with a focus on children with heart disease. The data was provided by a large number of North American institutions. Children with heart disease who suffered a cardiac arrest were sicker than those without heart disease and more likely to arrest from cardiovascular causes. Mortality rates were greater for those with heart disease. The events were more likely to occur in the general operating room compared with the cardiac setting. The subset of children with a single ventricle was the most common category of heart disease to suffer cardiac arrest. Children with aortic stenosis and cardiomyopathy had the greatest cardiac arrest-related mortality rates.*

Williams GD, Maan H, Ramamoorthy C, et al. Perioperative complications in children with pulmonary hypertension undergoing general anesthesia with ketamine. *Paediatr Anaesth* 2010;20:28-37.

*This is a retrospective study in children with pulmonary arterial hypertension to determine the nature and frequency of periprocedural complications and to assess whether ketamine administration was associated with complications. In this cohort (68 children), the incidence of cardiac arrest was 10% for major surgery, 0.78% for cardiac catheterization, and 1.6% for all procedures. There was no procedure-related mortality. Ketamine administration was not associated with an increased rate of complications.*

## Neuromuscular Disorders

Disorders of the Anterior Horn Cell  
Axonal Disorders  
Disorders of the Neuromuscular Junction  
Disorders of Muscle Fibers

## Epilepsy Summary

**DISORDERS OF THE NERVOUS SYSTEM** are common in childhood, and their diverse manifestations and complications may lead to diagnostic and surgical interventions that require anesthesia. Children with these disorders are subject to the same acute illnesses, such as acute appendicitis, as other children. Many neurologic disorders exert profound effects on other body systems that function under complex autonomic control. For example, dysfunction of bulbar musculature may predispose patients to aspiration in the perioperative period because protective reflexes may be incomplete. Medications taken for chronic conditions may interact with anesthetic agents, which may interact with an underlying disorder in specific ways. The mechanisms of these interactions are becoming better understood with advances in molecular genetics. Anesthesiologists must have an understanding of the patient's underlying neurologic or neuromuscular condition and its impact on anesthesia management to optimize the perioperative outcome.

## General Considerations

The term *neurologic disorder* encompasses a wide variety of conditions that may have extremely mild or very serious effects (Table 22-1).<sup>1-5</sup> These disorders are likely to be associated with a degree of physical, cognitive, or a combined disability. Many children with severe physical disabilities have normal intelligence and are competent to make decisions about treatment options. Those who are mildly cognitively impaired may wish to be consulted about treatment choices; adolescents in particular must be involved in decision making.<sup>6</sup> This approach is especially important in managing individuals with chronic disorders who are accustomed to

thinking about health issues and who often have strong and well-defined opinions about how they wish to be treated.<sup>7</sup>

When planning anesthesia for these individuals, physicians must become knowledgeable about them and their conditions. Assumptions should not be made about their level of comprehension or about how they and their parents view the choices available.<sup>8</sup> It was formerly acceptable practice for children with chronic neurologic disorders to be excluded from the full range of therapeutic options, but it is now essential that all options are included.<sup>9</sup>

Parents of children with chronic disorders of all types are usually accustomed to dealing with health care situations and often have thought carefully about the implications of various treatments. They know the child best and are usually most qualified to make decisions by proxy. Widespread use of the Internet has assisted many parents in becoming knowledgeable about their child's condition and about potential interventions.<sup>10</sup> Their aims are usually entirely appropriate, and this knowledge may assist physicians in their collaboration with children and parents in determining optimal management. Occasionally, the information has been obtained from an unreliable source and may be inaccurate or inappropriate for a particular child.<sup>11</sup> Misinformation can precipitate difficult situations for professionals, especially when there is a perceived disparity between the desires of the parents and those of the child or what the clinician considers to be in the child's best interest. The surgical team members usually are most involved in the process of obtaining informed consent, but the anesthesiologist must participate in the dialogue because anesthesia may be the part of treatment that carries the greatest risk.

Children with neurologic disorders usually have a regular physician overseeing their care, and this person should participate in the decision-making process. For elective procedures, the surgeon should establish contact with the child's regular pediatric specialist and anesthesiologist as soon as surgery is contemplated, inform them about the proposed operation, and seek their opinions to optimize perioperative management. Cognitive, communication, and behavioral problems; coexisting diseases; and drug therapy that may influence management of the anesthesia for these patients should be evaluated at an early stage.<sup>12</sup> Some children may be receiving long-term respiratory support, including cough assist devices and home ventilation, and all current therapies should be considered.

Oral communication may be difficult for some children with neurologic disorders. Use of age-appropriate assisted communication devices may help to ensure open communication between physician and patient.<sup>12</sup> Parents' opinions and attempts to protect their children should be respected and understood as a consequence of previous experiences, stress, frustration, anger, and probably guilt.<sup>13</sup> Each procedure has to be assessed in terms of morbidity, mortality, and probability of improving quality of life. All aspects must be clearly and objectively discussed with parents or guardians and informed consent forms signed.

**TABLE 22-1 Neurologic Disorders**

Condition	Prevalence	Reference
Cerebral palsy: all types	2.2 per 1000 live births	1
Epilepsy	5-10 per 1000 all ages	2
Central nervous system tumors	1-5 per 1000 all ages	3
Neuromuscular disorders (all ages)	1 per 2900 total population	4
Congenital myopathy	1 per 28,600	
Duchenne muscular dystrophy	1 per 3500	
Myotonic dystrophy	1 per 12,000	
Limb girdle dystrophy	1 per 90,000	
Spinal muscular atrophy	1 per 74,000	
Mitochondrial disorders	11.5 per 100,000 all ages	5

Clinicians who are responsible for providing emergency care to children must have the knowledge and skills required to manage children with neurologic disorders. A preoperative assessment may be required on an urgent basis, and a parent-held record of previous diagnoses and treatment is extremely helpful. Concurrent medications, previous reactions, and a history of complications such as respiratory insufficiency, electrolyte disturbance, or cardiac, renal, or hepatic dysfunction should be elicited before induction of anesthesia. A specific management plan for seizure medications is important for children who are likely to develop ileus postoperatively and thereby require a change from oral to intravenous medications.

## Static Neurologic Disorders

### CEREBRAL PALSY

*Cerebral palsy* is a disorder of movement, muscle tone, or posture that is caused by injury or abnormal development of the immature brain. It has a prevalence of 1 case per 500 live births.<sup>14</sup> Eighty percent of cases are acquired prenatally and have no obvious cause, although they are associated with prematurity low birth weight, intrauterine growth retardation, intracranial hemorrhage, and trauma. Birth complications, including asphyxia, are estimated to account for another 6% of cases. Postnatal causes of cerebral palsy (10%) usually arise from infectious causes (e.g., bacterial meningitis, viral encephalitis), trauma (e.g., motor vehicle collisions, falls, child abuse), or metabolic disturbance (e.g., hyperbilirubinemia).<sup>15</sup>

Classification depends on the severity, distribution, and the nature of the motor deficit. With the advent of modern imaging techniques, including magnetic resonance imaging (MRI), understanding the pathogenesis of cerebral palsy has advanced dramatically.<sup>16-18</sup> Clinical features are classified most commonly according to the type of motor deficit, its distribution, and the severity of the deficit (Table 22-2). Involvement of a single limb is referred to as *monoparesis*, of both limbs on one side of the body as *hemiparesis*, of both lower limbs as *diparesis*, of three limbs as *triparesis*, and of all four limbs as *tetraparesis* (i.e., *quadriparesis*). The motor deficit may manifest as hypotonia, spasticity, or extrapyramidal features such as choreoathetoid/dystonic movements or ataxia. A descriptive classification includes neurologic deficit and distribution (e.g., spastic diparesis, dystonic hemiparesis).

**TABLE 22-2 Cerebral Palsy**

Type and Cause	Motor Deficits	Distribution	Complications
Hypotonic Syndromic Dysgenesis Insult: hypoxia-ischemia	Low axial tone Variable limb tone Deep tendon reflexes usually increased	Diffuse	Learning disability Contractures Epilepsy Feeding dysfunction Hearing or vision impairment Respiratory infections
Spastic Insult: hypoxia-ischemia, vascular	Increased tone: pyramidal type Increased deep tendon reflexes	Monoparesis Diparesis Hemiparesis Triparesis Tetraparesis	
Choreoathetoid Insult: hypoxia-ischemia, neonatal hyperbilirubinemia, metabolic	Involuntary movement: often a mixture of choreoathetosis dystonia	May be diffuse (tetraparesis) or confined to one or more limbs Often coexists with spasticity	Hearing impairment Contractures Intellect often maintained
Ataxic Cerebral dysgenesis	Usually generalized truncal and limb ataxia May coexist with spasticity	May be diffuse but often associated with diparesis	Few, may be mild

Children with cerebral palsy require neuroimaging to confirm the diagnosis and underlying cause of the condition. Although some centers use oral sedation (i.e., midazolam or chloral hydrate) for neuroimaging, many children require general anesthesia. They may require multiple anesthetics throughout their lifetimes because of the associated comorbidities (i.e. respiratory, gastrointestinal, neuromuscular, and orthopedic), common surgical conditions, and problems unique to cerebral palsy that require treatment.<sup>19</sup>

Many of the comorbid conditions can affect anesthesia management. Understanding the pathophysiology and comorbidities of cerebral palsy allows anesthesiologists to anticipate and prevent perioperative complications.

### Multisystem Comorbidities

Most children with cerebral palsy have clinically significant oromotor dysfunction, and when associated with gastroesophageal reflux, it may lead to recurrent aspiration, decreased respiratory reserve, esophageal stenosis, and malnutrition.<sup>20</sup> Frequently employed procedures include fundoplication, gastrostomy, and esophageal dilation treatment.<sup>12</sup> Immobility, underhydration, and poor diet predispose patients to bowel stasis and constipation, which may become severe, with fecal impaction occurring occasionally. Malnutrition may depress immune responses, and electrolyte imbalance and anemia are common. Preoperative assessment of these parameters is essential.

Pulmonary complications are common causes of death in cerebral palsy. Aspiration associated with gastroesophageal reflux is the leading cause, and it may be exacerbated by excessive oral secretions, bulbar dysfunction, recurrent respiratory infection, and chronic lung disease.<sup>21,22</sup> Scoliosis may also restrict pulmonary function, with cardiopulmonary involvement depending on the curve pattern and the severity of the curve (see Chapter 30).<sup>12</sup>

Orthopedic operations are the most frequently performed procedures in children with cerebral palsy.<sup>12</sup> Procedures include tendon releases to ease contractures, femoral osteotomy, and hip adductor and iliopsoas releases.<sup>23</sup> The trend in orthopedic surgery is to perform multiple procedures involving tenotomies or osteotomies at different levels of all extremities during a single general anesthesia, rather than staging them during multiple operations.<sup>12,19</sup> Scoliosis often requires surgery to prevent further deterioration in lung function and to stabilize the spine to facilitate ambulation and sitting. Spinal fusion is considered in all children with progressive curves greater than 40 to 50 degrees.<sup>24</sup>

Botulinum toxin is commonly used to reduce muscle spasticity in afflicted children, and it may be injected with or without sedation or, more commonly, under general anesthesia. The need for repeated treatments (every 3 to 6 months) and the use of a nerve stimulator to confirm correct placement of the needle should be taken into consideration when assessing the child's need for sedation or anesthesia.

Approximately 30% of children with cerebral palsy have epilepsy. It is more common in spastic hemiplegia and less common in the ataxic and choreoathetotic forms. Generalized and focal seizures frequently occur. Anticonvulsants should be maintained until the surgery date (given the morning of surgery) and restarted as soon as possible in the postoperative period.<sup>12,25</sup>

### Anesthesia Considerations for Cerebral Palsy

The many multisystem comorbidities and therapies specific to children with cerebral palsy must be understood to minimize perioperative complications. Risk factors include an inability to

walk, severe neurologic deficit, major cognitive dysfunction, severe scoliosis, malnutrition, and the presence of a gastrostomy or tracheostomy.<sup>19</sup> Severely compromised children can be optimally managed postoperatively with admission to the pediatric intensive care unit to provide analgesia with comprehensive monitoring, maximum support, and aggressive respiratory care, and after they are stabilized, they can be transferred to a setting with less intense monitoring.

All medications that the child is receiving should be reviewed; they may include anticonvulsant, antireflux, and antispasticity agents. Baclofen should not be discontinued abruptly because it can produce acute withdrawal symptoms. Oral dantrolene has also been used to reduce spasticity. Because baclofen and dantrolene cause weakness, the dose of neuromuscular blocking drugs may need to be reduced because these antispasticity drugs can delay the return of adequate respiratory effort during emergence from anesthesia.

Most of these children have above-average intelligence. They have the same emotional and cognitive concerns as others about undergoing anesthesia, including preoperative anxiety that may require premedication. Children with contractures, especially in the upper extremities, may present a challenge for establishing intravenous access. If gastroesophageal reflux is not controlled, consideration should be given to rapid-sequence induction. Although these children have a neuromuscular disorder, intravenous succinylcholine yields only a normal release of potassium,<sup>26</sup> despite evidence of proliferation of extrajunctional acetylcholine receptors.<sup>27</sup> Maintenance of and emergence from anesthesia requires special considerations, including the possibility of a reduced minimal alveolar concentration (MAC),<sup>28</sup> resistance to neuromuscular blocking agents,<sup>29</sup> and reduced bispectral index (BIS) measurements.<sup>30</sup> If vomiting is likely to occur, the airway must be protected.

These children have normal responses to pain, which should be managed as if they were unaffected by cerebral palsy. Caudal or epidural analgesia may be a reasonable approach for perioperative pain management if the child does not have a ventricular-peritoneal shunt. Management and assessment of perioperative pain in children with neurocognitive impairment is addressed in Chapter 43.

### MALFORMATIONS OF THE NERVOUS SYSTEM

Malformations are common in pediatric neurologic practice and a frequent cause of early mortality. The appearance of the neural plate shows that the central nervous system (CNS) develops very rapidly in the 2-week embryo and continues until several years after birth. The cause of CNS malformations is largely uncertain, but timing appears to be more important than the nature of the insult in producing the specific type of malformation. Causative agents include maternal drugs such as sodium valproate, which is associated with neural tube defects (NTDs); infections such as cytomegalovirus, which can cause various cerebral lesions, depending on the time in gestation of the infection; toxins such as alcohol; vitamin deficiency (e.g., folic acid), and genetic disorders. Historically, because diagnostic investigation was limited, postmortem examination was required to demonstrate the neuropathologic changes causing the clinical disorder. MRI now can provide adequate images to enable a diagnosis in many instances (e.g., cortical dysplasia).<sup>31</sup>

### Neural Tube Defects: Cranial and Spinal Dysraphism

The prevalence of NTDs in the United States is about 6 in 10,000 live births. NTDs are a group of birth defects presumed to have

a common origin in failure of the neural tube to develop properly during the embryonic stage. NTDs include anencephaly, encephaloceles, and spina bifida.

The cause of NTDs is multifactorial, with genetic and environmental factors being the most important. Approximately 10% of NTDs are caused by chromosomal abnormalities such as trisomies (i.e., 18, 13, and 21), triploidy, and Turner syndrome. Preconceptual folic acid supplementation has reduced the prevalence of NTDs by 30% to 50%.<sup>32</sup> Along with antenatal ultrasound examination, screening is done for increased maternal serum levels of  $\alpha$ -fetoprotein, reduced human chorionic gonadotropin levels, and reduced unconjugated estriol levels; termination of pregnancy in cases that test positive has further reduced the prevalence of NTDs.<sup>33</sup>

*Anencephaly* is a lethal disorder that results from failure of the neural tube to form. This leads to disorganization of neural elements and the absence of skull formation.<sup>31</sup> Some deep cerebral structures may remain intact, and the brainstem may develop normally. With the latter, normal respiration and cardiovascular functions may develop, enabling the infant to survive for hours or days after birth. Other structures in the head and brain, including the eyes, face, and pituitary gland, may not develop normally.

*Encephalocele* is a herniation of neural tissue and meninges out of the skull through deficient skin and bone (see Fig. 24-11, *B*). They are frequently associated with other cerebral malformations, such as agenesis of the corpus callosum. Encephaloceles found anteriorly are associated with underlying brain, orbital structures, or pituitary gland anomaly. Posteriorly, encephaloceles are associated with cerebral or cerebellar tissue that herniates through a bony defect in the posterior cranium. Intranasal encephaloceles may be difficult to detect. These defects carry a poor prognosis for long-term survival. Most infants die, and in survivors, severe neurodevelopmental disability is common. Most of these children have hydrocephalus.<sup>34</sup>

*Spina bifida* refers to a group of conditions in which there is abnormal or incomplete formation of the midline structures over the back (see Fig. 24-11, *A*, in Chapter 24).<sup>31</sup> Skin, bony, and neural elements may be involved singly or in combination. Congenital malformations of the spinal cord may exist in isolation or in association with brain anomalies. These defects may present at birth, as in the case of the more severe and open lesions (i.e., spina bifida) or be identified later in childhood if the skin overlying the spinal defect is intact (e.g., spina bifida occulta). Those who develop a Chiari malformation may present with cervical cord or bulbar deficits, placing them at risk for respiratory embarrassment (see Figs. 24-12 and 24-13). Children with spinal cord

lesions are at increased risk for sensory deficits, making meticulous skin care and positioning essential to prevent pressure sores and damage to neuropathic joints.

*Spina bifida occulta* occurs in the absence of herniation of neural tissue or coverings so that the overlying skin appears to be intact and normal. In many cases, a hairy patch or a dermal sinus (i.e., sacral dimple) may communicate with the meninges or attach to the spinal cord or a lipoma that causes a fatty swelling overlying the bony defect. The spinal cord may be tethered by internal connection to such structures, making it vulnerable to trauma at surgery and during growth, especially at puberty. The spinal cord may be abnormally formed, with cartilaginous or bony spurs that damage or divide the cord during growth as the neural tissue grows at a slower rate than the surrounding bone (i.e., diastematomyelia). These infants may not be candidates for a caudal block because the spinal cord may end at an unusually low position.

*Spina bifida cystica*, which is the most common type of spinal dysraphism, manifests as an obvious lesion on the back. The defect may be diagnosed antenatally or at birth. The abnormally developed spinal cord may be covered by a layer of meninges (i.e., meningocele) or remain uncovered (i.e., myelomeningocele). Myelomeningoceles need to be repaired within a few days of birth to prevent infection and further damage to the neural tissues. A cerebrospinal fluid (CSF) leak or frank dural rupture may develop, leading to intravascular volume and electrolyte abnormalities that should be treated preoperatively.

When the defect is identified at birth, it is optimally managed in a specialist center by a multidisciplinary team (i.e., pediatrician, neurologist, neurosurgeon, orthopedic surgeon, and others) who can anticipate, prevent, and treat complications and assist in the child's long-term care. Children with dysraphism often develop postoperative hydrocephalus because of disrupted CSF flow and require a ventricular-peritoneal shunt. Long-term complications, including paraparesis, neurogenic bladder and bowel, renal insufficiency, trophic limb changes, pressure sores, joint contractures, and scoliosis, may require surgical repair and future intervention. These children are also at risk for latex allergy. From the outset, all children with NTDs should be considered latex sensitive and undergo management in a latex-safe environment. The anesthesia considerations for NTDs are presented in Chapter 24.

### Chiari Malformation

Chiari malformations of the nervous system may coexist with other anomalies and manifest in the neonatal period or later in the early decades of life (Table 22-3).

**TABLE 22-3 Chiari Malformations**

Type	Main Features	Associated Abnormalities	Neurologic Features
Chiari I	Downward displacement of cerebellar tonsils; elongation of fourth ventricle and lower brainstem	Platybasia, basilar impression, syringomyelia, hydrocephalus	Later onset (> age 12 years), cervical cord signs: tetraparesis, sensory deficits of upper limbs
Chiari II	Downward displacement of cerebellar vermis or tonsils alongside cervical cord, kinking of cord at C2-3 level	Myelomeningocele in most, brainstem anomalies, aqueduct stenosis	Present in neonate, macrocephaly, increased intracranial pressure, cranial nerve palsies, cord signs
Chiari III	Downward displacement of cerebellum into posterior encephalocele; elongation of fourth ventricle	Posterior defects: cervical spina bifida $\pm$ cranium bifidum	Present in neonate with signs of hydrocephalus $\pm$ brainstem and cervical cord signs
Chiari IV	Cerebellar hypoplasia	Usually none	$\pm$ Ataxia

$\pm$ , With or without.

### Syringomyelia

Syringomyelia results from a glial cell-lined cavitation within the spinal cord. Diagnosis has been greatly simplified by the use of MRI, which provides images of the spinal cord and the tubular fluid-filled space within.<sup>31</sup> The pathogenesis of syringomyelia remains unclear. It complicates several conditions, such as rare familial cases, congenital malformations, trauma, and meningeal infection. It has been reported as a coincidental finding in normal individuals.

Syringomyelia manifests with dissociated sensory loss, usually in the upper limbs, causing loss or impairment of pain and temperature sensation, which may cause trophic changes in the fingers and neuropathic joints. It may progress to paralysis and hyporeflexia later in life. The lower limbs may exhibit pyramidal signs; some lesion may extend upward (i.e., syringobulbia) and produce lower brainstem signs, such as stridor and laryngospasm (i.e., vocal cord palsy). Spinal deformity causes scoliosis at an early stage.

Treatment is controversial, especially if the lesion is asymptomatic. Management may focus on associated disorders because syringomyelia may progress slowly or not at all.

### Hydrocephalus

Hydrocephalus results from overproduction or impaired drainage of CSF from the brain.<sup>34</sup> In practice, overproduction is an uncommon source of hydrocephalus; these cases most often result from tumors of the choroid plexus. Obstructed CSF drainage is the far more common basis. Causes of hydrocephalus include intraventricular hemorrhage, Arnold-Chiari malformation, brain tumor, congenital obstruction, and myelomeningocele.

Children typically present with a headache and irritability, but signs and symptoms can progress to lethargy, seizures, vomiting, and ophthalmoplegia as pressure within the brain increases. If left untreated, it may lead to a reduced level of consciousness, oculomotor palsies, sluggish pupillary light reactions, bradycardia, and eventually respiratory arrest. Diagnosis of hydrocephalus is confirmed by neuroimaging, often with computed tomography (CT) in the acute situation, followed by MRI.

Surgical treatment for hydrocephalus involves insertion of a drainage system to shunt CSF from the brain to another site in the body (see Fig. 24-10). The anesthesia considerations for treating hydrocephalus are discussed in Chapter 24.

### DISORDERS OF VENTRAL INDUCTION

Holoprosencephaly is a cephalic disorder in which the forebrain of the embryo fails to develop into discrete hemispheres with normal connections.<sup>31</sup> There are three types:

1. **Lobar:** There is almost complete separation of the hemispheres, and the corpus callosum is almost absent.
2. **Semilobar:** The two hemispheres are divided posteriorly, with interhemispheric connections present anteriorly. The corpus callosum is absent anteriorly, and the thalami are fused in the midline.
3. **Alobar:** An undivided and small forebrain with a dorsal sac may contain some cortex. Severe facial defects may include cyclopia (i.e., single orbit with fused globes), cebocephaly (i.e., single nostril), and a midline cleft lip.

Associated malformations (e.g., congenital heart disease, scalp deficits, polydactyly) are common. Chromosomal anomalies may be identified, and a complex syndromic disorder may occur in some of these children. The diagnosis rests on a careful description of the external and internal morphology using MRI,

followed by genetic assessment. Complications include hydrocephalus, endocrine deficits, epilepsy, and severe complex disability, usually with a shortened life expectancy.

### DISORDERS OF CORTICAL DEVELOPMENT

Malformations of the cerebral cortex are many and varied. Although uncommon, development of lissencephaly or agyria (i.e., smooth cortex), pachygyria (i.e., thickened cortex), and polymicrogyria (i.e., multiple, small gyri) depends on the stage of embryogenesis affected.<sup>31</sup> MRI has advanced the identification of these features and their classification.

Environmental agents and genetic abnormalities have been identified for many of these malformations, and genetic derangements can produce a multisystem syndrome. Intrauterine insults in early pregnancy have been implicated in cases coming to autopsy. Clinical effects vary, and the severity depends on the site and extent of the lesion. Survivors may have no symptoms or have profound, complex neurodisability. Children may have learning disabilities, epilepsy, focal neurologic deficits, motor dysfunction, and other system involvement.

## Progressive Neurologic Disorders

### PRIMARY BRAIN TUMORS

The incidence of primary brain tumors is 2.6 per 100,000 children, and they account for more than 20% of all childhood malignancies. One third of these tumors occur before 5 years of age, and 75% occur before 10 years of age.<sup>35</sup> Two thirds are located infratentorially and one third supratentorially (Table 22-4).<sup>36</sup>

Pathologic classification, which is based on the cell of origin and degree of malignancy, extends from grade I (benign) to grade 4 (malignant).<sup>37</sup> The patient's presentation depends on the site of the tumor. Infants typically display irritability, failure to thrive, and macrocephaly, whereas older children develop headache, nausea, vomiting, seizures, gait disturbances, and visual deficits. If the lesion is rapidly expanding and is accompanied by significant cerebral edema or obstructs CSF drainage, the intracranial pressure (ICP) will increase. Occasionally, hemorrhage may occur into the tumor, causing a dramatic progression of signs and symptoms, mandating emergency treatment. Ultimately, brainstem decompensation and death ensue if the lesion is not treated.

Diagnosis of a primary brain tumor is usually confirmed with MRI and magnetic resonance spectroscopy (MRS). Tissue diagnosis by a biopsy is always desirable, although not always achievable. Microscopy of CSF may yield tumor cells and facilitate the diagnosis. Image-guided biopsy may be possible and is preferred for appropriately sited lesions.

Surgery is the mainstay of treatment and is usually combined with radiotherapy or chemotherapy, or both. Preoperatively, cerebral edema should be treated with corticosteroids to reduce ICP, alleviate symptoms and signs, and enable correction of fluid and electrolyte abnormalities. Seizures require anticonvulsant therapy. Nutrition may be poor and necessitate aggressive management with enteral and parenteral feedings. Operative intervention for raised ICP may require CSF diversion by shunting internally or externally. Depending on the tissue diagnosis and location, total resection of the tumor may be indicated, although the timing of the surgery may depend on whether the tumor should first be treated with radiation therapy or chemotherapy. Aggressive surgery with the intent of completely resecting the tumor

**TABLE 22-4** Common Central Nervous System Tumors in Childhood

Tumor Type	Percentage of All Childhood CNS Tumors	Clinical Features	Treatment	Prognosis or Survival
Medulloblastoma	14-20	Acute ataxia ↑ Intracranial pressure	Surgical excision + radiotherapy or chemotherapy in children <2 years old	75% at 5 years 50% at 10 years
Cerebellar astrocytoma (80% cystic)	15-20	Subacute-chronic ataxia Head tilt ± ↑ Intracranial pressure	Surgical excision	100% at 5 years, if totally excised
Posterior fossa ependymoma	6-10	Cranial nerve palsies Stiff neck ataxia ↑ Intracranial pressure	Surgical excision Radiotherapy	40% at 5 years but 14% if <5 years old
Brainstem glioma	6-16	Cranial nerve palsies Long tract signs ↑ Intracranial pressure late	(Stereotactic) biopsy if possible. Radiotherapy ± chemotherapy: depends on age and cell type	Survival variable and depends on cell type
Craniopharyngioma	6-10	Endocrine disorders ↑ Intracranial pressure Visual impairment	Surgery Hormonal therapy	Survival variable
Visual pathway glioma	3-5	Proptosis, ↓ vision Associated disorders (e.g., neurofibromatosis type I)	Controversial and individualized	Variable
Pineal region tumors	<2	↑ Intracranial pressure Loss of upward gaze	Surgery ± radiotherapy	Variable
Hemisphere glioma	25-30	α Location: ↑ intracranial pressure, seizures, focal neurologic deficit	Surgery ± radiotherapy ± chemotherapy	Depends on cell type
Meningioma	<2	↑ Intracranial pressure Seizures	Surgery	Variable
Ganglioma and dysembryoplastic neuroepithelial tumor (DNET)	1-5	Focal epilepsy	Surgery	Good May cure epilepsy
Primitive neuroepithelial tumor (PNET)	1-2	↑ Intracranial pressure, focal neurologic deficit	Surgery + radiotherapy	Poor
Intraventricular tumors, various cell types	5	↑ Intracranial pressure: hydrocephalus	Shunting and surgical excision	Variable
Basal ganglia tumors, various cell types	5	Hemiparesis, dystonia	Stereotactic biopsy Radiotherapy if malignant	Depends on cell type

CNS, Central nervous system; ±, with or without; ↓, decreased; ↑, increased.

improves the prognosis for many tumor types but carries with it significant risks of residual neurologic deficits.

The 5-year survival rate of greater than 60% for primary brain tumors largely reflects improved imaging, aggressive surgery, and evidence-based therapy.<sup>38</sup> Unfortunately, children who survive CNS tumors frequently have permanent neurologic deficits, including epilepsy, learning disabilities, visual or hearing impairment, and growth and endocrine disorders. Short-term and long-term follow-up evaluations by specialist teams are required, along with careful emotional and social support for children and their families. Some children have genetic predispositions for CNS tumors, such as neurofibromatosis (i.e., schwannomas of the spinal cord, peripheral nerve tumors, skeletal deformities, carcinoid syndrome, and multiple endocrine neoplasia, including pheochromocytoma) and tuberous sclerosis (i.e., brain tumors, cardiac rhabdomyomas, renal abnormalities, and hepatoma), and they require genetic analysis and long-term follow-up.

Tumors of the spinal cord are rare in childhood. They may be benign or malignant and sited within the cord (intramedullary) or outside (extramedullary). Symptoms and signs may initially be

nonspecific and vague, especially in young children. This may delay the diagnosis and increase the risk of spinal cord compression. Delayed relief of compression may cause vascular compromise, which may lead to total and irreversible paralysis of the limbs, bladder, and bowel and permanent, severe disability. Diagnosis is best made by MRI of the cord, which provides details of the lesion and adjacent structures without the risk of further decompensation, a problem raised by the use of myelography in the past.<sup>36</sup>

Treatment usually involves surgery to decompress the cord and excise or biopsy the lesion. For intramedullary tumors, excision may be impossible, and biopsy may risk further damage to the spinal cord. Cell type may be determined by CSF examination. Follow-up treatment with radiotherapy may be indicated. Children with established neurologic deficits require a program of rehabilitation.

#### METABOLIC DISEASE

Inborn errors of carbohydrate, protein, or fat metabolism usually are genetic in origin. The molecular defects of many of these metabolic disorders have been identified.

**TABLE 22-5 Neurometabolic Disorders**

Lysosomal diseases
Mucopolidoses, sialidoses, disorders of glycoprotein metabolism
Peroxisomal disorders
Amino acid disorders
Organic acid disorders
Neurotransmitter disorders
Urea cycle disorders
Disorders of vitamin metabolism
Lactic acidosis
Respiratory chain disorders
Mitochondrial fatty acid $\beta$ -oxidation defects
Disorders of cholesterol metabolism
Disorders of copper metabolism
Miscellaneous disorders

These diseases may cause a static encephalopathy but more often produce a progressive course with loss of physical and intellectual skills. Epilepsy, especially myoclonus, is common, as is loss of vision, neuropathy, deafness, or involvement of other organ systems (particularly cardiac). Some neurometabolic diseases are associated with intellectual deficits and some with physical deficits; systemic features may be prominent, and neurologic signs are common (Table 22-5).

There are three main groups of neurometabolic diseases<sup>39</sup>:

1. Those with a known enzymatic defect, including disorders of amino acid metabolism (e.g., phenylketonuria), peroxisomal disorders (e.g., adrenoleukodystrophy), and lysosomal storage disorders (e.g., Tay-Sachs disease)
2. Those with abnormal storage accumulation in CNS cells, including lysosomal storage disorders and mucopolysaccharidoses
3. Those with no identified biochemical defect (e.g., Cockayne syndrome), a heterogeneous group that is shrinking as research identifies the biochemical defects

There is considerable overlap among the three groups. All of these disorders are rare, and although some are treatable, most are relentlessly progressive and associated with early death. Many patients show a steady decline, with a gradual increase in symptoms and loss of function or a stepwise deterioration with bouts of acute illness leading to a sudden loss of function.

Treatment is available for only a few of the diseases and consists primarily of dietary strategies, although some pharmacologic treatments are used. Started early, especially in the presymptomatic phase, treatment may prevent neurologic complications. An example is phenylketonuria, a disorder of amino acid metabolism. The prevalence varies by population, with an incidence of 1 case per 100,000 people in the United States. Screening occurs in the neonatal period, and affected children are begun on a special diet. Those who have good dietary management throughout life may develop relatively few problems, although close monitoring by a specialist team of physicians and dieticians is essential to ensure metabolic stability. Unfortunately, treatments may be of questionable benefit for many children.

Disorders that cause lactic acidosis are the most common of these diseases, although many individuals who harbor the genetic substrate for one of these disorders may not express it or may come to diagnosis very late in life.<sup>40</sup> The features of these diseases are extremely varied, and although the

neuropathologic, biochemical, and imaging abnormalities are well recognized, a precise diagnosis may remain elusive.

### Anesthesia Considerations for Progressive Neurologic Disorders

The risks associated with general anesthesia for children with progressive neurologic disorders include problems posed by fasting and by the need to keep the patient's metabolism stable during a period of stress. Meticulous planning with the child's metabolic specialist is essential before elective procedures. In the case of emergency surgery, the children and parents should be aware of or have written instructions regarding the preferred management of nutrition and metabolic indices, or they should have a resource person to call for specific advice.

## Neuromuscular Disorders

Neuromuscular disorders are caused by an abnormality of any component of the lower motor neuron system: anterior horn cell in the spinal cord, axon, neuromuscular junction, or muscle fiber (Fig. 22-1).<sup>41</sup> The cardinal features are weakness of skeletal muscles that is proximal, distal, or generalized in distribution, hypotonia, and reduced deep tendon reflexes. True fatigability suggests a defect of the neuromuscular junction. Neuropathy is characterized by distal weakness and sensory deficit. Joint contractures, scoliosis, and respiratory and cardiac involvement are common complications, and some conditions are associated with cognitive deficits.

### DISORDERS OF THE ANTERIOR HORN CELL

#### Spinal Muscular Atrophies

The spinal muscular atrophies (SMAs) are a group of disorders in which there is progressive degeneration of the anterior horns of the spinal cord and death of motor neurons. They are inherited as an autosomal recessive trait. The type of SMA (I, II, or III) is determined by the age of onset and the severity of symptoms.<sup>41</sup> The diagnosis is a clinical one, but confirmation by molecular testing for the survival of motor neuron gene (*SMN*) in a blood sample is now possible, and electrophysiology and muscle biopsy are no longer necessary.<sup>42</sup> Curative treatment is not available, but much can be done to improve duration and quality of life, especially for mildly affected children.

Type I SMA (i.e., Werdnig-Hoffmann disease) manifests at or soon after birth in most cases. The infant may appear neurologically normal at first, but the typical picture soon emerges. Parents may first notice an abnormal breathing pattern as the intercostal muscles are affected, and the respiratory pattern becomes diaphragmatic, with a bell-shaped chest observed clinically and radiographically. The infant is usually very alert and interactive but severely weak and floppy. There is good facial expression and normal eye movements, but the tongue fasciculates, and the tendon reflexes are absent. There is no cardiac involvement. Weakness, hypotonia, and bulbar involvement lead to progressive respiratory insufficiency and swallowing dysfunction, which are frequently complicated by episodes of aspiration. Most children die within the first 2 years of life, mainly due to respiratory complications. Management is essentially palliative, with gentle physiotherapy to keep the limbs flexible and special care with feeding. Noninvasive nocturnal ventilation is increasingly used, but invasive ventilation through a tracheostomy is not considered appropriate in most medical centers. This issue has provoked considerable debate in the literature.<sup>43</sup>

**FIGURE 22-1** Diagram of a lower motor neuron. (Modified from Dubowitz V. Muscle disorders in childhood. Philadelphia: WB Saunders; 1978. Courtesy A. Moosa, MD.)

Type II SMA is an intermediate form, and it is the most prevalent. Because the weakness is milder, many children survive for years with meticulous multidisciplinary therapy, orthopedic and respiratory management, and care with nutrition. Onset occurs at 6 to 18 months of age. The clinical signs are similar to those of type I SMA, and the children are bright, intelligent, and particularly verbal. Type II patients usually achieve independent sitting at some stage, but these children never bear weight or walk. Respiratory infections are a particular problem, and noninvasive nocturnal respiratory support (i.e., biphasic or continuous positive airway pressure) with a facemask and portable ventilator is well tolerated by children and parents. This improves well-being and enables remarkably full activity despite weakness.<sup>44,45</sup>

Joint contractures are almost inevitable, as is progressive scoliosis, which usually appears early, and management is difficult in the very young child. Operative correction and stabilization

with instrumentation is delayed as long as possible to prevent the complications of pubertal growth with a fixed spine; children usually tolerate the procedure well if they are carefully prepared and managed.

Some children with type II SMA develop feeding difficulties because of weakness of bulbar musculature or as a complication of chronic nocturnal hypoventilation. Good nutrition is essential for health, and supplementation and gastrostomy feeding may be required.<sup>46</sup>

Type III SMA (i.e., Kugelberg-Welander disease) is a mild variant with similar signs of flaccid and areflexic weakness of lower more so than upper limbs and with proximal predominance. These children attain independent walking, although it may be later than normal and tenuous. There is often deterioration around the time of puberty, when the growth spurt causes the previously precariously balanced muscle groups to become dysfunctional. Obesity and joint contracture also may affect the situation. Aggressive measures to keep the child walking are often effective and delay or prevent scoliosis and lower limb contracture.<sup>47</sup> Respiratory support may be necessary for nocturnal hypoventilation. Prognosis for long-term survival is good.

Other SMA variants exist in childhood. A rare type (SMA with respiratory disease) has severe diaphragmatic involvement and respiratory failure in infancy.<sup>48</sup> Some variants have associated features such as cerebellar atrophy, distal involvement, or additional myopathic features.

#### *Anesthesia Considerations for Spinal Muscular Atrophies*

Children with SMA present for a variety of surgical procedures, including gastrostomy placement, tracheostomy, and spinal surgery, and they may also require anesthesia for diagnostic evaluation.<sup>49</sup> Rigorous preanesthesia evaluation is essential; perioperative care needs to be tailored to each child's needs, and postoperative respiratory support may be required. A variety of anesthesia techniques have been used successfully with and without muscle relaxants. Various degrees of sensitivity to non-depolarizing relaxants have been described, and it seems prudent to avoid or reduce the dose of these agents. If they are used, neuromuscular function should be assessed continuously and the effect of the relaxant antagonized at the conclusion of surgery. Spinal and epidural anesthesia and postoperative epidural analgesia have been used without adverse effects; however, the potential for respiratory depression may be increased with the addition of neuraxial opioids.

#### **Poliomyelitis**

Poliomyelitis is a highly contagious, infectious disease caused by poliovirus, a human enterovirus. Most poliovirus infections are asymptomatic. If symptomatic, it occurs in two phases: an acute, nonspecific, febrile illness followed by aseptic meningitis and acute, flaccid, lower motor neuron paralysis. It typically manifests asymmetrically and may affect any muscle group. In children with respiratory involvement, lifelong ventilation may be needed. Fortunately, this situation is almost unheard of in the Western world because polio has been almost eradicated by immunization.<sup>50</sup>

#### **AXONAL DISORDERS**

##### **Hereditary Neuropathies**

Hereditary neuropathies are a group of inherited disorders that affect the peripheral nervous system. There are four main subcategories: hereditary motor and sensory neuropathy (most common

is Charcot-Marie-Tooth disease),<sup>51</sup> hereditary sensory neuropathy, hereditary motor neuropathy, and hereditary and autonomic sensory neuropathy.

Clinical presentation depends on the subtype and can occur at any age. Children usually present with disorders of gait or foot deformity, or they may come to the attention of a neurologist or geneticist through an affected parent. Clinical signs are usually confined to the lower limbs in the early years and may lead to orthopedic intervention before diagnosis. Some neuropathies are associated with multisystem involvement, including cardiac, autonomic, and respiratory systems, and a complete preoperative assessment of these children is essential.<sup>52</sup>

Peripheral neuropathy is a component of various neurometabolic disorders in which there is involvement of other parts of the nervous system or of other organs. For example, in the leukodystrophies, demyelination affects central and peripheral axons, giving a clinical picture of combined upper and lower neuron features. There are many neurometabolic disorders (e.g., mucopolysaccharidoses, sphingolipidoses, urea cycle disorders, organic disorders, amino acid disorders) with many variants, and presentation can occur at all ages from birth to adulthood. In children with mitochondrial diseases, peripheral neuropathy is often found, along with myriad other features.<sup>53</sup>

Multisystem degenerations are often genetically determined disorders of the nervous system that rarely begin in childhood.<sup>52</sup> Features may include dementia, epilepsy, extrapyramidal signs, brainstem dysfunction, vision and hearing impairment, anterior horn cell involvement, and peripheral neuropathy. They tend to have a progressive course.

### Acquired Disorders of the Peripheral Nerves

Acquired disorders of the peripheral nerves are rare in childhood. In clinical practice in the developed world, neuropathies complicating metabolic or nutritional disorders and treatment for cancer are the most common forms. In underdeveloped parts of the world, nutritional deficiencies, especially of vitamins E, B<sub>1</sub>, B<sub>6</sub>, B<sub>12</sub>, niacin, and thiamine, are important. The neuropathic features may be overshadowed by the other characteristics of the disease.

### Guillain-Barré Syndrome

Guillain-Barré syndrome is an acute demyelinating disorder that causes progressive weakness usually 2 to 4 weeks after an illness with features of a viral infection or after immunization.<sup>33</sup> The inflammatory lesions in the peripheral nerves typically are associated with loss of myelin. In severe cases, the axons are damaged, a feature that is also seen in some acute cases without significant demyelination. The precise pathologic process has not been delineated, but various antibodies, immune complexes, and complement components have been found, suggesting causal heterogeneity.

The disorder is rare in children younger than 3 years of age, and the onset is usually sudden, although subacute presentations have been reported. The first sign is weakness in the lower limbs, which characteristically ascends the body, next affecting the trunk, the upper limbs, and occasionally the cranial nerves. It causes a flaccid paralysis, usually sparing sensory function but causing pain and areflexia at all levels. Autonomic neuropathy may develop, causing instability of blood pressure and cardiac arrhythmias. Involvement of respiratory muscles may produce acute respiratory failure or apnea that necessitates tracheal intubation.

Guillain-Barré syndrome is diagnosed clinically, and the diagnosis is reinforced by finding an increased protein concentration in the CSF (despite a normal cell count) and abnormalities on nerve conduction studies. The studies may confirm demyelination by showing lowered nerve conduction velocity with distal delay, axonal involvement by low-amplitude action potentials, and in early cases, abnormality or absence of the H reflex, indicating absence of the spinal reflex arc. MRI of the spine may show thickening and contrast enhancement of the nerve roots and cauda equina.<sup>54</sup>

Patients with very mild symptoms that do not interfere with activities of daily living can be observed for deterioration without treatment. Corticosteroids are ineffective and may delay recovery. Intravenous immunoglobulin and plasmapheresis are the current treatment options.<sup>53</sup>

Supportive care in the intensive care unit may be needed for children with severe bulbar or respiratory weakness.<sup>55</sup> Children with axonal neuropathies are usually slower to recover motor function than those with demyelination, and our impression is that early treatment with intravenous immunoglobulin may alter the course.

### Chronic Inflammatory Demyelinating Polyneuropathy

Chronic inflammatory demyelinating polyneuropathy is extremely rare in childhood, and it is usually confined to older age groups. It manifests in a subacute or relapsing and remitting pattern with prominent sensory involvement. diagnostic investigations are similar to those for acute Guillain-Barré syndrome. Corticosteroids, intravenous immunoglobulin, and plasma exchange have been effective.<sup>55</sup> Although these treatments may be effective in the short term, recurrences may take place, and the usual pattern is that of a chronic, disabling, and relapsing and remitting condition that does not threaten longevity but interferes significantly with the quality of life.<sup>56</sup>

### Nerve Palsies

Like neuropathies, nerve palsies are uncommon in childhood.<sup>51</sup> The most common palsy encountered in children is neonatal or congenital facial nerve palsy. Cranial nerve palsies, especially those that involve the eye muscles, are usually related to intracranial disease such as increased ICP in children, but they may also be isolated findings that result from viral infections. In the latter instances, recovery is the norm.

Peripheral nerve palsies such as carpal tunnel syndrome have been reported in childhood.<sup>57</sup> They may complicate severe juvenile arthritis<sup>58</sup> or storage disorders such as mucopolysaccharidoses. Because symptoms may be difficult to elicit from children at the best of times, identifying palsies may be problematic in severely learning disabled children. Specialist care may require routine assessment of nerve conduction and possible surgical decompression. Concern has been expressed regarding the emergence of carpal tunnel syndrome as a type of repetitive strain injury in children due to excessive use of video games.<sup>59</sup> Case reviews refer to other types of repetitive strain injury, such as basketball training and skiing, as etiologic factors.<sup>60</sup>

## DISORDERS OF THE NEUROMUSCULAR JUNCTION

### Myasthenia Gravis

Myasthenia gravis is a disorder of the neuromuscular junction. The autoimmune disorder is characterized by one of several lesions of acetylcholine-mediated transmission.<sup>61</sup> Weakness results from antibodies that block acetylcholine receptors,

inhibiting the excitatory effects of acetylcholine at the neuromuscular junction. This reduction in the number of acetylcholine receptors results in a characteristic pattern of progressively reduced muscle strength with repeated use and recovery of muscle strength after a period of rest.

### *Neonatal Transient Myasthenia Gravis*

Neonatal myasthenia gravis is caused by placental transfer of antibodies to acetylcholine receptors from an affected or previously affected mother. The infant may present with feeding difficulties or respiratory dysfunction.<sup>62</sup> Treatment, which involves anticholinesterase medications, must be tailored to the nature and severity of the weakness, and intensive support occasionally is required. This form of myasthenia gravis is a transient disorder for which treatment is temporary and the risk of recurrence small. It should be anticipated in the offspring of any woman who has active myasthenia gravis or a history of the disorder, because cases have been described in infants of mothers in remission from myasthenia gravis.

### *Congenital Myasthenic Syndromes*

Congenital myasthenia gravis represents several genetically determined defects of the neuromuscular junction that have in common an exercise-induced weakness of skeletal muscle.<sup>63</sup> Fourteen genetic mutations have been identified, but many cases of congenital myasthenia gravis do not have an identified mutation. Inheritance of mutations usually follows an autosomal recessive pattern.

Although rare, congenital myasthenia gravis should be considered in the differential diagnosis of any neonate or infant who presents with motor problems (e.g., weakness, hypotonia, fatigability), eye signs (e.g., ptosis, ophthalmoplegia, pupillary abnormalities), and respiratory insufficiency (e.g., recurrent apneas, ventilator dependence). Late-onset muscle weakness has been reported in adolescence or early adulthood. Diagnosis may be difficult because the classic features of myasthenia gravis, including responses to anticholinesterase medications, may be absent.<sup>64</sup> A Tensilon test, electromyography with repetitive nerve stimulation, a muscle biopsy, and molecular analysis in a specialist center should be sought to confirm the diagnosis.

### *Juvenile Myasthenia Gravis*

Juvenile myasthenia gravis, like the adult version of the disease, is an immunologic disorder that may be associated with enlargement of the thymus gland and the presence of circulating antiacetylcholine receptor antibodies. Occurring at any age, fatigable weakness suggests the diagnosis, which may be confirmed by electromyography and by antiacetylcholine receptor antibody analysis.

Treatment of myasthenia gravis varies with the type and biochemical characteristics. Careful titration of pyridostigmine is needed. Corticosteroids and surgical thymectomy are indicated for patients with immunologic abnormalities.<sup>65</sup>

### *Anesthesia Considerations for Myasthenia Gravis*

The anesthesiologist may become involved in the management of children with myasthenia gravis for several reasons<sup>66</sup>:

- Children may suffer a crisis requiring mechanical ventilation or when large-bore central access is attempted to facilitate plasma exchange transfusion.
- They may require thymectomy.
- They may undergo elective or emergency surgery unrelated to their myasthenia.

The severity of the muscle weakness and the muscle groups affected by the disease should be documented preoperatively,

focusing on respiratory and bulbar function. Myasthenic patients' responses to muscle relaxants depend on the type of relaxant. Decreased density of acetylcholine receptors at the motor end plate means that children with myasthenia may require up to four times the calculated dose of succinylcholine to establish a depolarizing muscle block. Because succinylcholine is metabolized by acetylcholinesterase, its metabolism is reduced and duration of action prolonged in the setting of chronic acetylcholinesterase inhibition. For this reason, succinylcholine is best avoided in these children.

The activity of nondepolarizing muscle relaxants is increased as their duration of action is increased. Unfortunately, the degree to which the sensitivity is increased is somewhat unpredictable and depends on an interaction between the severity of the disease (e.g., level of acetylcholine receptor antibodies) and the efficacy of treatment. Inhalational anesthetic agents inhibit neuromuscular transmission, and these effects may be exaggerated in myasthenia gravis patients. However, no clinically significant postoperative neuromuscular depression has been demonstrated with isoflurane, sevoflurane, or desflurane. These potential neuromuscular effects are not shared by propofol, making total intravenous anesthesia (TIVA), in theory at least, the technique of choice for these children. For all but the most minor surgery in the patient with stable myasthenia gravis without significant respiratory or bulbar compromise, a tracheal tube and intermittent positive-pressure ventilation are likely to be required. If possible, intubation of the trachea should be performed without the use of muscle relaxants. Tracheal intubation with inhalational anesthetics alone or propofol with a short-acting opioid has been described in these children.<sup>67</sup>

### *Myasthenia-like Syndrome*

The toxin of *Clostridium botulinum* produces a myasthenia-like syndrome that may occur through two mechanisms: ingestion of food contaminated by *C. botulinum* toxin, including contaminated honey, and wound infection by *C. botulinum*. Features include blurring of vision with ptosis, dilated and unresponsive pupils, cranial nerve palsies, limb paralysis with areflexia, feeding difficulty, and respiratory insufficiency. Diagnosis depends on clinical suspicion, identification of the toxin in residual food, and electromyography.

Treatment is supportive, and recovery may take weeks to months.<sup>68</sup> Succinylcholine is contraindicated in children with infections that affect the neuromuscular junction, including botulism and tetanus.<sup>69</sup>

## **DISORDERS OF MUSCLE FIBERS**

### **Myopathies**

#### *Congenital Myopathies*

Congenital myopathies are rare disorders that have extreme variations in the type and severity of features (Table 22-6).<sup>70</sup> The myopathies may manifest at any age, but in many cases, they become apparent only in adulthood, challenging the *congenital* designation.<sup>71</sup> In infancy, the usual features are weakness and hypotonia (i.e., the floppy baby).<sup>72</sup> Although these are inherited disorders, there is often no family history, and because many cases are autosomal dominant or X-linked recessive, the carrier parent may have subclinical signs of a myopathy.

Children usually present with ptosis, facial weakness, limb weakness (proximal more than distal), and there may be evidence of respiratory muscle weakness and cardiomyopathy. In some cases, the extraocular muscles may be affected with external

ophthalmoplegia. Joint contractures and scoliosis can also develop. Infants often have characteristic facies, with a long and narrow face, prominent ears, and a narrow, high-arched palate. Deep tendon reflexes are reduced or absent. The diagnosis usually is confirmed by characteristic findings on muscle biopsy. Molecular analysis is available for many of these myopathies in specialist laboratories.<sup>73</sup>

Paralleling the clinical features, the course of congenital myopathies varies greatly. Many individuals are mildly affected and may come to diagnosis only if a more severely affected child is diagnosed. All parents, even those without symptoms, must be carefully examined by a neurologist with expertise in neuromuscular disease to detect very mild weakness of particular muscles. For a parent who demonstrates weakness, it may help to perform a muscle biopsy and molecular testing to confirm the diagnosis. For many children with congenital myopathy, there is little or no deterioration in muscle strength as the child ages, and many children experience gradual improvement in muscle strength and a reduction in symptoms. However, weakness is severe in some cases, and clinical complications, including deglutition difficulties and respiratory failure, limit survival, although these features are not specific to congenital myopathies.<sup>74,75</sup>

Support of respiration and nutrition may be necessary. Minimally invasive methods such as noninvasive nocturnal ventilation by facemask are indicated to assist with management at home. Regular passive movements and careful management of posture and positioning to prevent contractures, especially scoliosis, is essential. Meticulous care of skin, joints, bowels, and teeth help to avoid the need for more invasive management. A complete evaluation of cardiovascular and respiratory status is required before anesthesia and surgery.<sup>76</sup>

Malignant hyperthermia (MH) is a disorder of skeletal muscle that manifests in response to anesthetic triggering agents. Central core disease is a myopathy closely associated with MH (see Chapter 40), with extreme variation in the severity of its features. MH and central core disease are primarily disorders of calcium regulation in skeletal muscle. Genetic testing identifies mutations in the ryanodine receptor gene (*RYR1*) in most affected individuals, accounting for their susceptibility to MH.<sup>77</sup> The *RYR1* gene encodes the channel that controls calcium release from the sarcoplasmic reticulum in skeletal muscle and to a lesser extent in other organ systems. *RYR1* abnormalities alter the channel kinetics for calcium inactivation, and calcium buildup causes excessive skeletal muscle contraction due to disinhibition of the normal actin-myosin interaction. The level of adenosine triphosphate (ATP) decreases, leading to anaerobic and aerobic metabolism and to acidosis. Other effects of MH include heat production, sympathetic nervous system activation, hyperkalemia, tachycardia,

**TABLE 22-7 Metabolic Myopathies**

muscle rigidity, tachypnea, disseminated intravascular coagulation, fever, myoglobinuria, and multiorgan dysfunction and failure.

The in vitro contracture test (IVCT) was developed to confirm susceptibility to MH by studying the contracture of muscle fibers in response to triggers such as caffeine and halothane.<sup>78</sup> This is an invasive and expensive investigation because an open muscle biopsy is required, and very few specialized centers perform this procedure. Most individuals with central core myopathy may be susceptible to MH, as demonstrated by IVCT, which has been the only means to confirm MH susceptibility until the emergence of molecular testing.<sup>79</sup> DNA analysis can provide a fairly reliable test for susceptibility to MH for 60% of affected individuals who have had an IVCT but for only 20% of those who have not had an IVCT (see Chapter 40).<sup>80</sup> However, the complexity of the situation is such that assessment and advice by a specialist is recommended rather than immediately embarking on DNA analysis so that the child and family may benefit from appropriate investigation and interpretation. Any individual with central core disease and his or her family should be informed about the clinical situation, diagnosis, and possible risks and complications, including MH, and should be offered a specialized investigation. An individual who may be susceptible to MH should carry information to inform medical staff in an emergency.<sup>81</sup> Any elective operative procedure must be meticulously planned in advance with the full involvement of the anesthesiologist.

### Metabolic Myopathies

Metabolic myopathies (Table 22-7) are uncommon and complex. Most affected children have multisystem involvement of sufficient severity to mask the myopathic features. The most important concerns for the anesthesiologist are the risk of metabolic instability during surgery and the need for close liaison with the child's pediatrician to plan fluid and electrolyte balance and nutritional management.<sup>81,82</sup>

### Mitochondrial Disorders Underlying Myopathies

Mitochondrial disorders are a common cause of inherited neurologic disease in children, occurring in 1 of 5000 live births. They are caused by mutations in mitochondrial or nuclear DNA. The respiratory chain is under bigenomic control: nuclear DNA codes for 85% of the proteins, and mitochondrial DNA codes for 15%. Nuclear DNA is inherited along mendelian inheritance patterns, whereas mitochondrial DNA follows maternal inheritance patterns in a ratio of 9 to 1. Most mitochondrial disorders in children are determined by nuclear DNA, whereas those in adults are determined by mitochondrial DNA. The organs involved by mitochondrial disease are determined by the presence of defective nuclear or mitochondrial DNA in the embryo. The relative amount of defective DNA in affected tissues determines the severity of the disease. Disruption of the most fundamental cellular energy process, the mitochondrial respiratory

**TABLE 22-8** Clinical Mitochondrial Syndromes in Childhood

Syndrome	Features
Alper-Huttenlocher, neuronal degeneration	Catastrophic onset of epilepsy, paralysis, ataxia, dementia, visual impairment, liver disease; death usually in months
Leigh encephalomyeloneuropathy	Brainstem signs predominant; relapsing/remitting or steadily progressive to death
Infantile myopathy and lactic acidosis	Hypotonia in infancy, feeding difficulties, respiratory problems, cardiomyopathy; fatal and nonfatal forms
Leber hereditary optic neuropathy (LHON)	Progressive visual loss in childhood, cardiac arrhythmias, dystonia
Kearns-Sayre (KSS)	Progressive external ophthalmoplegia, pigmentary retinopathy, deafness, heart block, choreoathetosis and ataxia, myopathy, endocrine disorders
NARP	Neuropathy, ataxia, retinitis pigmentosa
MELAS	Mitochondrial encephalomyopathy, lactic acidosis, stroke-like episodes, dementia
MERFF	Myoclonic epilepsy, myopathy with ragged red fibers (muscle Gomori trichrome stain), ataxia
MNGIE	Myoneurogenic gastrointestinal encephalopathy

chain, results in a diverse and variable group of multisystem disorders known collectively as mitochondrial disease. Involvement of the brain, nerves, and muscles can occur in isolation or in combination.

Diagnosis relies on characteristic clinical features, an understanding of mitochondrial genetics, and a logical, informed approach to investigations. Abnormalities of the mitochondrial genome are extremely common, and they can cause devastating phenotypes or be completely subclinical. Assessment and diagnosis are challenging.<sup>5</sup>

Neurologic symptoms and signs are common. However, they tend to be varied and include myopathy, neuropathy, stroke-like episodes, ataxia, dementia, epilepsy, migraine, sensorineural deafness, and pigmentary retinopathy. The more common clinical scenarios in childhood are outlined in Table 22-8. Involvement of other organ systems, such as diabetes mellitus, gastrointestinal disease, and cardiomyopathy, may coexist or dominate the clinical picture. Evidence of mitochondrial dysfunction, such as lactic acidosis, increased CSF protein, and ragged red fibers on muscle biopsy, may or may not exist. Assessment of the child with atypical and otherwise unexplained features should include a search for evidence of mitochondrial abnormalities. The clinical details determine the investigative plan, which should include cerebral imaging with MRI and MRS (to detect lactate peaks), blood biochemistry (i.e., creatine kinase, lactate, and glucose levels), tests of urinary amino and organic acids, cardiologic assessment (i.e., chest radiography, electrocardiogram, and echocardiogram), electroencephalography, and exercise testing and neurophysiology, leading to mitochondrial studies of blood and muscle tissue. Muscle biopsy investigations include histopathology, electron microscopy, respiratory chain enzymology, and molecular analysis of mitochondrial DNA. Further investigation with respiratory chain enzymes and molecular genetic analysis is indicated in some cases.<sup>83</sup>

Treatment of mitochondrial disorders includes management of specific features such as antiepileptic therapy and efforts to maintain stability of metabolic pathways. Vitamins and other supplements such as coenzyme Q<sub>10</sub> (i.e., ubiquinone), riboflavin, thiamine, and carnitine are referred to as the *mitochondrial cocktail* and are used in most of the mitochondrial disorders. Use of the cocktail is largely based on the assumption that higher doses of these agents may improve mitochondrial energy generation.<sup>84</sup> Arginine has been used in the treatment of patients with mitochondrial encephalopathy with lactic acidosis and stroke-like episodes (MELAS).<sup>85</sup>

### *Anesthesia Considerations for Myopathies*

The challenge for the anesthesiologist is to maintain metabolic stability and prevent complications. In children prone to lactic acidosis, intravenous fluids that contain lactate should be avoided, whereas administration of glucose-containing solutions is essential in any but the shortest of procedures to avoid hypoglycemia.<sup>82</sup> In all children with mitochondrial disorders, the preoperative fasting period should be kept to a minimum to avoid hypovolemia and depletion of glucose stores. Stresses that may provoke increased energy requirements, such as perioperative pain, hypothermia, or hyperthermia, must be minimized. Children with Kearns-Sayre syndrome must have adequate assessment and perioperative monitoring because they may have cardiac conduction abnormalities as well as myopathy, diabetes, proximal renal tubular acidosis, and other multisystemic abnormalities.<sup>84</sup>

Inhalational and intravenous forms of anesthesia have been used successfully in children with mitochondrial disorders. Few serious complications have occurred, and none related to anesthesia were reported in two retrospective reviews of perioperative complications after general anesthesia in children with mitochondrial myopathies.<sup>82,86</sup> Inhalational anesthetics have been used without consequences in these children, and there is no evidence that this population has a greater susceptibility to MH than normal children.<sup>87</sup> However, mitochondrial disorders result from a variety of molecular changes and have varied responses to anesthetics.<sup>88</sup>

All inhalational anesthetics and propofol depress mitochondrial function at several levels. It has been suggested that children who develop metabolic acidosis and myocardial failure after propofol infusions for extended periods (more than 5 mg/kg/hr for more than 48 hours) have a subclinical form of a mitochondrial disorder. Although propofol infusion syndrome (PRIS) impairs mitochondrial oxidation and transport of free fatty acids in a manner not unlike that in mitochondrial myopathies, there is no evidence that the two disorders are linked. In a review of 61 patients with PRIS, seven (four children and three adults) developed PRIS during anesthesia.<sup>89</sup> Impaired tissue perfusion (as seen in sepsis) may be a common underlying mechanism. Propofol interferes with fatty acid metabolism and the respiratory chain, in much the same manner as other anesthetics and medications, suggesting that its use during general anesthesia for children with mitochondrial myopathies is reasonable, and it has been used widely.<sup>90,91</sup> Evidence suggests that any anesthesia technique may be used in children with mitochondrial myopathies.

Sensitivity and resistance to nondepolarizing neuromuscular blocking agents have been reported in children with these myopathies. To ensure appropriate dosing, the drugs should be titrated judiciously while neuromuscular blockade is monitored.

### Muscular Dystrophies

Muscular dystrophies represent a group of more than 30 inherited disorders of muscle that may occur in infancy, childhood, or adulthood (Table 22-9). The word *dystrophy* implies a destructive progressive process, and although this is the characteristic clinical course for many of those afflicted with muscular dystrophies, the course is extremely slow or has no muscle strength deterioration for others.<sup>92</sup>

This area of neurology has advanced greatly due to developments in molecular genetics and to a lesser extent in muscle pathology. Duchenne muscular dystrophy was the first inherited disorder for which the causative gene and defective protein were identified.<sup>92</sup> Characterization of defective proteins leads to advances in immunohistochemistry that can assist diagnosis using a muscle biopsy. Detection of genetic mutations enables the diagnosis to be determined using a blood specimen in most instances, removing the need for muscle biopsy in many children. The mutated gene and molecular site of the defect have been identified for most of the common disorders, enabling much more focused management and informed counseling of families.<sup>93</sup>

The characteristic clinical features of muscular dystrophy include muscle weakness, the distribution of which varies from

type to type; contractures, sluggish deep tendon reflexes, and involvement of respiratory and heart musculature. Other features, including learning disabilities, deafness, and ophthalmologic disorders, often exist. The creatine kinase level may be normal or increased to a minor or major degree; it provides an important marker for some disorders, such as the dystrophinopathies, in which it is raised on the order of 100 times normal. Diagnosis rests on careful clinical assessment, creatine kinase determination, molecular analysis, and muscle biopsy. Although there is no specific curative treatment for any of these disorders, advances in understanding the molecular genetic defect and proteins responsible for a disease have focused the search for an effective pharmacologic treatment to reverse the clinical signs and symptoms.<sup>94,95</sup>

For an infant who presents with severe weakness and hypotonia, signs of facial weakness, reduced alertness, and reduced respiratory effort raise the possibility of a congenital myotonic dystrophy (DM1), which is usually inherited from the mother in an autosomal dominant fashion. Clinical suspicion of DM1 may be confirmed by molecular testing for the affected gene (*DMPK*), which codes for myotonic dystrophy protein kinase. This protein is expressed predominantly in skeletal muscle, and the gene is located on the long arm of chromosome 19. This information negates the need for a muscle biopsy. A similar infant with good facial muscle movement, alertness, areflexia, and a diaphragmatic respiratory pattern indicating intercostal weakness is most likely to have SMA. The molecular test for the survival motor neuron is indicated to avoid the need for a muscle biopsy. Similar principles may be applied to children who present later in childhood. For example, a boy with gait abnormalities and a creatine kinase level 10 to 100 times normal is most likely to have a dystrophinopathy, and targeted molecular genetic testing can avoid the need for a biopsy.<sup>96</sup>

### Myotonic Dystrophy

Myotonic dystrophy is the most common inherited neuromuscular disorder in the general population, and many cases remain subclinical or undiagnosed.<sup>4</sup> All degrees of severity are possible, from the almost immobile infant with the congenital variant to the elderly adult with minimal motor weakness. Severity of the muscle weakness correlates with the molecular defect.

These children are susceptible to prolonged recovery from anesthesia, and care should be taken with the use of sedative medications and neuromuscular blocking agents.<sup>97</sup> Sensitivity to succinylcholine is increased, and maximal use of regional nerve blocks or local infiltration with local anesthetic agents should be employed whenever possible to minimize the need for opioids.

Most children with congenital or later-onset myotonic dystrophy have some degree of learning difficulties, which may be severe. One or the other parent is affected to a greater or lesser extent. In congenital cases (DM1), the mother is always the affected parent and, in most instances, is not aware of the disorder, the diagnosis is made by the pediatrician or pediatric neurologist who sees the child.<sup>98</sup> The infant does not demonstrate signs of myotonia, and a muscle biopsy is not helpful for the diagnosis at this age. The finding of facial weakness and clinical myotonia in the mother strongly suggests this disorder in a weak and floppy neonate.<sup>99</sup> The neonatal literature suggests that shaking the maternal hand (i.e., mother is unable to easily release her grip) may be sufficient to allow the pediatrician to make this

diagnosis.<sup>100</sup> However, because it is possible to confirm the diagnosis by molecular testing of blood from the infant and mother, it is no longer necessary to rely on clinical expertise in muscle strength testing. Genetic counseling is essential and should be offered to the wider family circle. It is not unusual to uncover a large kindred with previously unsuspected disease in this situation.

These infants may require intensive care in the neonatal period, including respiratory support, but they tend to improve with age. However, significant learning disability is the rule, and the input of the multidisciplinary child development team followed by special schooling is the norm. Specific conditions requiring surgery include scoliosis and joint contractures, and perioperative care must be carefully planned.<sup>98</sup>

### Dystrophinopathies

The next most commonly encountered dystrophies are the dystrophinopathies. Duchenne muscular dystrophy (DMD) is the more severe phenotype, and Becker muscular dystrophy (BMD) is the milder phenotype. Both dystrophies are inherited in an X-linked recessive pattern and affect boys almost exclusively.<sup>101</sup> These disorders are caused by a deficiency of dystrophin (i.e., less than 3% of the normal content in DMD), a muscle membrane protein essential to the skeletal and cardiac muscle cytoskeleton and to neural tissue. Dystrophin reinforces the inner strength of the myocyte during lateral stretching and is involved in signal transduction (Fig. 22-2). DMD occurs as a result of mutations, mainly deletions in the dystrophin gene (*DMD*, locus Xp21.2).<sup>96</sup>

In affected children, muscle strength deteriorates between the ages of 2 and 8 years, and use of a wheelchair is usually required

before adolescence. Respiratory, orthopedic and cardiac complications emerge with increasing age. By 8 to 10 years of age, serial echocardiograms should be performed to document cardiomyopathy. Because the lack of dystrophin affects the integrity of neural tissue, progressive cognitive dysfunction may occur. The absence of dystrophin predisposes the muscle to tearing from normal use or from use of drugs such as succinylcholine. Additional damage to skeletal muscle cells appears to stem from increased intracellular calcium concentrations, which may result from a defect in the sarcoplasmic reticulum. Upregulation of acetylcholine receptors has also been reported in these children. Without intervention, children with DMD usually die by a mean age of 19 years.

Coordination of clinical care is a crucial component of DMD management. Care is best provided in a multidisciplinary setting in which the individual and family can collaborate with specialists about the required multisystem management of DMD. Depending on local services, coordinated clinical care can be provided by a wide range of health care professionals including neurologists or pediatric neurologists, rehabilitation specialists, neurogeneticists, pediatricians, and primary care physicians. The person responsible for coordination of clinical care must be aware of the available assessments, tools, and interventions to proactively manage all potential issues for the child with DMD.

For children with DMD, glucocorticoids are the only available medication that slows the decline in muscle strength and function, which reduces the risk of scoliosis and stabilizes pulmonary function.<sup>102</sup> Cardiac function may also improve; the limited data indicate a slower decline in echocardiographic measures of cardiac dysfunction.<sup>103,104</sup> Prednisone is commonly used,

**FIGURE 22-2** Schematic diagram of the proteins associated with dystrophin in skeletal muscle cells. The three key elements of the membrane skeleton and signal transduction path are laminin 2, which is the extracellular component; dystrophin-associated protein complex (DAPC) with its  $\alpha$  and  $\beta$  dystroglycan, sarcoglycan, and cytoplasmic subunits, which is the transmembrane component; and dystrophin, which is the intracellular component. The cytoplasmic subunit of the DAPC comprises syntrophin (SY) and dystrobrevin (DYB). Sarcospan (SP) has four transmembrane-spanning helices, and its expression is lost in patients with Duchenne muscular dystrophy. Dystrophin is the pivotal element that reinforces the muscle cell cytoskeleton, and it mediates signal transduction across cell membranes through its interactions with syntrophin, dystrobrevin, and neuronal nitric oxide synthase. Notice that the noncontractile F-actin binds to the N terminus of dystrophin. (From Goodwin FC, Muntoni F. Cardiac involvement in muscular dystrophies: molecular mechanisms. *Muscle Nerve* 2005;32:577-88.)

although deflazacort is an alternative used in some countries and is probably just as effective. The most effective prednisolone regimen appears to be 0.75 mg/kg/day. International guidelines for initiation of steroids and other pharmacologic agents and the implementation of multidisciplinary care are clearly outlined in a Consensus Statement on Standard of Care for Congenital Muscular Dystrophies.<sup>105</sup>

If lower limb contractures exist despite range-of-motion exercises and splinting, surgery can be considered in some scenarios.<sup>106</sup> The approach must be strictly individualized.<sup>105</sup> Surgical intervention is frequently used to treat lower limb contractures and enable rehabilitation in long leg orthoses so that the ambulatory phase may be prolonged.<sup>107</sup> This is usually indicated for children between 8 and 12 years of age, and it is well tolerated and successful if supported by a specialist team, but it may increase the burden of care for parents and families.<sup>108</sup>

Patients not treated with glucocorticoids have a 90% chance of developing significant progressive scoliosis<sup>109</sup> and a small chance of developing vertebral compression fractures due to osteoporosis. Although glucocorticoids can reduce the risk of scoliosis,<sup>110,111</sup> the risk of vertebral fracture is increased.<sup>112,113</sup> Spinal care should involve an experienced spinal surgeon and comprises scoliosis monitoring, support of spinal and pelvic symmetry, and spinal extension by the wheelchair seating system. Children receiving glucocorticoids should be monitored for painful vertebral body fractures. Corrective spinal surgery improves posture and seating options, eliminates pain due to vertebral fracture from osteoporosis, and slows the rate of respiratory decline.<sup>109,114</sup> The procedure is fraught with difficulty due to postoperative respiratory weakness and possible cardiac dysfunction.<sup>114</sup> Careful preparation and liaison among the pediatrician or neurologist, surgeon, and anesthesiologist is essential; a plan for postoperative management, including the provision of intensive care, should be made.<sup>81</sup>

Facioscapular muscular dystrophy is less often encountered in childhood, and specific surgical and anesthesia issues are limited. There are several phenotypes in childhood, including a severe neonatal form and a variably progressive childhood type that may be associated with sensorineural deafness. Irregular alignment between phenotype and genotype implies inconsistent expression of the molecular defect.<sup>115,116</sup> These children may benefit from surgery to fix the scapulae, which improves functionality of the upper limbs.<sup>117,118</sup>

Limb girdle syndromes (no longer a single entity; see Table 22-9) occur infrequently. Some have cardiac and respiratory implications and require preoperative assessment. In Emery-Dreifuss muscular dystrophy (EDMD), a syndrome in which cardiac conduction defects and dysrhythmias are common, syncope is usually the presenting complaint. These children are followed by a specialist team that includes a cardiologist.<sup>81</sup>

### *Anesthesia Considerations for Muscular Dystrophies*

The anesthesia implications for muscular dystrophies are dictated by the age of the child and severity of the disease. In early childhood, those affected by DMD undergo destruction of skeletal muscle, and when exposed to triggers that include succinylcholine and inhalational anesthetics, they have presented with severe rhabdomyolysis and hyperkalemia that resulted in cardiac arrest. Some children who were not known to have muscular dystrophy had a cardiac arrest during inhalational anesthesia as the first sign of the disorder. In contrast, during adolescence and adulthood, progressive cardiac and respiratory failure are the major concerns.

The severity of DMD usually is greater than that of BMD and EDMD.

Despite extensive documentation that inhalational anesthetics or succinylcholine, or both, can trigger life-threatening rhabdomyolysis in children with muscular dystrophy, this problem persists.<sup>119-121</sup> Case reports have described rhabdomyolysis, hyperkalemia, and cardiac arrest with or without the use of succinylcholine in children with DMD. No single inhalational anesthetic appears to be without blame.

The defect in dystrophinopathies results from the lack of the membrane-stabilizing protein dystrophin. It has been suggested that the addition of another destabilizing agent, such as an inhalational anesthetic, predisposes these children to mild or severe rhabdomyolysis, hyperkalemia, and death. Those most at risk for these complications are younger children, some of whom are undiagnosed until the perioperative rhabdomyolysis develops and establishes the diagnosis. Adolescents in whom muscle breakdown has waned and muscle mass has been lost and replaced by fatty infiltration have had uneventful perioperative courses when exposed to inhalational anesthetic agents and succinylcholine. Although succinylcholine is infrequently used today, the mortality rate associated with a succinylcholine-induced cardiac arrest is 30%.<sup>122</sup>

Although there is insufficient evidence to contraindicate inhalational anesthetics in children with muscular dystrophy, total intravenous anesthesia (TIVA) has emerged as an alternative to inhalational anesthetics in them.<sup>108</sup> In the absence of a compelling reason, it seems prudent to avoid inhalational anesthetics in children with DMD.<sup>121,123</sup> At the same time, without knowledge of the minimum concentration of inhalational anesthetic that triggers muscle breakdown, there is little justification for cleaning anesthetic workstations as in cases of MH. However, in certain clinical situations, such as a child with DMD and a difficult airway for whom an intravenous technique may be contraindicated or who refuses establishing IV access awake, brief exposure to an inhalational anesthetic to secure the airway seems reasonable. The anesthesia technique could then be converted to TIVA. The child should be carefully monitored for the signs of rhabdomyolysis (i.e., serum K<sup>+</sup> level) and the urine for myoglobin to detect a subclinical reaction, even if the risk is low, to avoid sequelae.<sup>123</sup>

Rhabdomyolysis caused by anesthetic agents may mimic MH.<sup>124</sup> The risk of MH in DMD children is the same as in the general population.<sup>125</sup> Hyperkalemic arrhythmias are most effectively reversed by rapid intravenous administration of calcium (10 mg/kg of calcium chloride), which may be repeated until the arrhythmias abate. Other therapies, including hyperventilation, administration of bicarbonate, albuterol, and insulin and glucose, are also recommended. The hyperkalemia associated with acute rhabdomyolysis may be refractory to the usual treatments and may require a prolonged resuscitation (see Chapter 8).

Boys with undiagnosed DMD have been anesthetized with inhalational agents and developed rhabdomyolysis. To minimize the risk of this complication, clinicians should question family members about any history of dystrophinopathies during the preoperative evaluation, mild signs of hypotonia, and motor weakness and delayed motor milestones. However, at least 30% of children represent a new mutation and therefore lack a positive family history. A brief developmental and neuromuscular history should be obtained, and if there is any question or suspicion, it is reasonable to measure a random blood creatine phosphokinase concentration preoperatively.

### Undiagnosed Myopathy

The child with a possible myopathy (e.g., floppy, hypotonic, motor developmental delay) but without a definitive diagnosis can pose a problem to the anesthesiologist.<sup>126</sup> A careful history and physical examination should be carried out. Blood creatine kinase and lactate concentrations should be evaluated, and the child's pediatrician or pediatric neurologist contacted for advice. If a progressive muscular dystrophy cannot be excluded (in the presence of an increased creatine kinase level), it may be prudent to avoid inhalational anesthetics, although their careful use for induction may be considered. An increased creatine kinase level in an asymptomatic infant or child may suggest a progressive muscular dystrophy, and inhalational anesthetics should be used with caution unless DMD or BMD are excluded.

## Epilepsy

Epilepsy is a common disorder in childhood, with a prevalence of 0.5% to 1% in the school-aged population. It is defined as the tendency to have recurrent spontaneous seizures. A seizure is a sudden, excessive, uncontrolled electrical discharge of cortical neurons.<sup>127</sup>

Any part or all of the cerebral cortex may be involved, and the manifestations of seizures are numerous. The first and most important step in managing epilepsy is to establish a correct diagnosis by determining whether the episodes are epileptic, classifying the episodes, and identifying the epilepsy syndrome that matches the clinical features (Table 22-10).

Diagnosis of seizures is largely a clinical process, with investigations providing information to determine cause (imaging) or seizure syndrome (electroencephalography). The cause may be a cerebral lesion of any type, in which case neurologic deficits may coexist, such as in cerebral palsy, or it may be a genetic disorder with no other neurologic features.

**TABLE 22-10 Epilepsy**

#### Classification of Seizure Types

Self-limited seizures

Generalized

Focal

Continuous seizures

Status epilepticus

#### Epilepsy Syndromes in Childhood

Neonatal seizures

Early infantile epileptic encephalopathy (Ohtahara)

Early myoclonic encephalopathy

Benign familial convulsions

Infantile spasms (West)

Febrile seizures

Benign myoclonic epilepsy of infancy

Primary generalized epilepsy

Absence seizure syndromes

Generalized tonic clonic seizure syndromes

Juvenile myoclonic epilepsy (Janz)

Benign focal epilepsy syndromes (centrotemporal or occipital)

Lesional focal epilepsy

Data from the International League against Epilepsy. Available at <http://www.ilae.org> (accessed June 2012).

After a diagnosis of seizures has been made, the next step is to determine the epilepsy syndrome. This is achieved by reviewing the following:

- Seizure type
- Age
- Associated features
- Electroencephalographic features
- Interval since the last seizure
- Current medication, timing of the last dose, and blood levels

The details of the epilepsy syndrome can guide further investigations, help to plan treatment, and educate the family regarding the prognosis.<sup>128</sup>

Management is directed at treating the cause if possible and in preventing seizures using antiepileptic drugs. Medication is chosen according to the seizure type and epilepsy syndrome, taking into account the age of the child, associated disorders, and other maintenance medications.<sup>129</sup> Most of the current antiepileptic drugs are licensed for use in childhood, although there are limitations for some drugs, especially in younger children. The aim of the treatment is to eliminate all seizures with the least number of antiepileptic drugs at the minimum doses. The American Epilepsy Society guidelines and practice parameters are available at [www.aesnet.org](http://www.aesnet.org), and the U.K. Epilepsy guidelines are available at [www.nice.org.uk/CG020](http://www.nice.org.uk/CG020).

For children with epilepsy who are undergoing surgical procedures under anesthesia, the main problems are provocation or increased frequency of seizures, which have several causes:

- Anti-seizure medication missed due to perioperative fasting
- Epileptogenic anesthetics (e.g., enflurane)
- Hypoxia
- Electrolyte disturbance (e.g., hyponatremia)
- A direct effect of neurosurgery on the brain
- Cerebrovascular instability
- Coincidental exacerbation of severe epilepsy
- Postoperative ileus resulting in poor drug absorption

Certain disorders that cause epilepsy may be associated with other medical conditions, such as cardiorespiratory deficits, nutritional difficulties, and learning disabilities.<sup>130</sup>

Preparation for surgery should include a thorough review of the child's clinical status, including consultation with the physician who manages the child's epilepsy. For most minor elective procedures, there is no need to miss or omit any medication in the perioperative period, and parents should be advised to give regular medications as usual on the morning of surgery and anesthesia. Careful scheduling of the time of surgery may facilitate this because many children receive antiepileptic drugs on twice-daily regimens, with doses given at 8 AM and 8 PM. If surgery is scheduled for late morning or early afternoon, no medication need be missed. For children with complex epilepsy, such as those undergoing neurosurgery for the epilepsy itself, careful preoperative assessment is imperative.<sup>131</sup> In managing surgery and anesthesia in children with epilepsy, the aim is to prevent seizures and enable smooth and effective treatment (Table 22-11).

## Summary

Neurologic disease is common in childhood. Many severely disabled children are living longer but with increasingly complex medical and social needs. The challenges for surgeons and anesthesiologists in treating them include consent, complications of anesthesia, and issues related to long-term outcomes. The key to

**TABLE 22-11** Perioperative Medication Management for Children with Epilepsy**Preoperative Management**

- Liaise with child's pediatrician or neurologist.
- Clarify usual seizure types, frequency, and trigger factors.
- Review and document regular medication regimen (ideally twice daily).
- Check antiepileptic drug level (phenobarbitone, phenytoin, or carbamazepine only).
- Review rescue medication regimen.
- Check drug allergies and adverse reactions.

**Management for Minor or Day Surgery**

- Schedule for early afternoon.
- Allow usual morning medication.
- Avoid prolonged fasting.
- Aim for evening medication as usual.

**Management for Major Surgery**

- Ensure regular medications up to fasting.
- Use intravenous preparations of regular drugs (phenytoin, phenobarbitone, valproate, benzodiazepine), if possible; use same doses two or three times daily.
- If regular drugs not possible, administer the following:
  - Phenytoin: Give intravenous load of 20 mg/kg (maximum, 1 g) and then give twice-daily maintenance dose of 2.5-5.0 mg/kg.
  - Benzodiazepine: Give intravenously as rescue.
- If enteral administration is possible, reestablish regular maintenance and wean intravenous phenytoin dose.

effective management is good basic neurologic and pediatric care with careful preparation, including close liaison with parents and the child's usual clinicians.

**MILLIONS OF CHILDREN UNDERGO SURGERY** with anesthesia every year.<sup>1</sup> During the perioperative period they are exposed to a multitude of stressors capable of interfering with normal brain development. Pain, stress, inflammation, hypoxia, and ischemia have all previously been shown to adversely affect the immature central nervous system. However, recent findings from animal studies have indicated that sedatives and anesthetics—the very drugs used to reduce pain and stress—may themselves undesirably influence brain development by triggering structural and functional abnormalities. There is now an extensive body of work, mostly based on laboratory research, that has defined this phenomenon and explored mechanisms and protective strategies. However, translating these laboratory findings to humans in clinical settings is laden with uncertainties and questions.

Human epidemiologic studies have found mixed evidence for an association between surgery (and anesthesia) in childhood, and subsequent neurodevelopmental delay. Some studies identified more learning disabilities in children after surgery with general anesthesia early in life, whereas others have not. Although surgery or comorbidities may play a central role in these abnormalities, emerging laboratory data regarding the deleterious effects of anesthesia without surgery has forced clinicians to consider the possibility that anesthetics may play a role in this

phenomenon. However, similar to the uncertainties surrounding animal studies, the interpretation of the human data is fraught with substantial limitations.

Any discussion of the long-term effects of anesthetics on the developing brain is further complicated by the fact that anesthetic drugs may be neuroprotective under certain conditions, and may indeed mitigate brain damage that is due to inflammatory responses, hypoxia-ischemia, or other insults that might occur during the perioperative period.

It is currently impossible to provide any definitive statements about the effects of anesthesia on neurodevelopment. This chapter provides an overview of the current laboratory and clinical data concerning the affect of sedatives, anesthetics, and analgesics on the immature brain.

## Background

About 160 years ago, William T. G. Morton conducted the first public demonstration of a drug-induced, reversible coma, later termed anesthesia, at the Massachusetts General Hospital and instantaneously revolutionized the field of surgery. After witnessing Morton's demonstration, Oliver Wendell Holmes coined the name for what he saw from the greek words "an" (without)

and “esthesia” (sensitivity). The inscription on Morton’s tombstone, “Inventor and Revealer of Inhalation Anesthesia: Before Whom, in All Time, Surgery was Agony; By Whom, Pain in Surgery was Averted and Annulled; Since Whom, Science has Control of Pain,” represents a powerful testament to the tremendously positive impact that anesthesiology has made on the field of medicine. This positive impact is now tempered by the possibility that anesthetics may impede normal brain development in the young. During the first century of their use, general anesthetics quickly became ubiquitous during surgery, although they were also regarded with serious concern because they were combustible and they depressed the hemodynamic and respiratory systems. Accordingly, up until 25 years ago, general anesthesia was rarely used in critically ill neonates because of the fear of myocardial depression and hemodynamic instability. Perioperative drug regimens were limited by some to neuromuscular blocking drugs and nitrous oxide. However, with the realization that unopposed pain exerted deleterious effects on the developing brain, that dramatic stress responses to painful stimulation can be detected even in preterm infants, and that modern anesthetics and analgesics can abolish these responses without substantial hemodynamic compromise, pediatric anesthesia, for the past two decades, has afforded critically ill neonates the benefits of amnesia, analgesia, and immobility during increasingly invasive surgery. These surgical interventions have helped to save lives and preserve the quality of life in one of the most vulnerable of patient populations. All the while, the powerful effects of general anesthetics on the brain were thought to be limited to the duration of immediate exposure, and no serious long-term adverse effects were expected following emergence from anesthesia. This notion of safety is now being seriously questioned, because apoptosis (defined as programmed cell death, see later) has been detected in neonatal animals during and immediately after anesthesia, and long-term learning defects have been reported in animals and children that were exposed to anesthesia at a young age.

## Normal Brain Development

The human brain undergoes a complex and extended process of enormous growth in cell number, synapses, and connections. Combined with this expansion of cells and connections, massive regressive processes also occur during normal brain development. These expanding and regressive processes allow the brain to fully develop and eventually execute complex tasks, such as talking, walking, reading, writing, calculating, acquiring social skills, perfecting fine motor dexterity, and planning and executing long-term objectives, while at the same time maintaining all life-sustaining functions. In order to accomplish these tasks, several specialized cells populate the brain. These cells are commonly divided into two large groups: neurons and glial cells, the latter subdivided into astrocytes and oligodendrocytes. Neural development starts with proliferation from a neural stem cell, followed by migration of that cell to its final place, differentiation into a specialized neuron, outgrowth of synapses during synaptogenesis to integrate into neural networks, and, finally, myelination of axons. In humans, many of these specialized processes occur in utero, but will also continue for an extended period of time postnatally. Indeed, some brain regions exhibit lifelong neurogenesis.

In utero and during the early postnatal period, the human brain initially undergoes a rapid growth in size and cell number,

and is then pared back to achieve the efficient network of about 100 billion neurons of the adult brain. At birth, the size of the immature brain is one-third that of the adult brain, doubling in size within the first year of life, and reaching 90% of its eventual size by 6 years of age.<sup>2</sup> This dramatic growth spurt coincides with a remarkable overabundance of neurons and neuronal connections. In fact, less than half the neurons generated during development survive into adulthood.<sup>3,4</sup> Superfluous neurons that lose in the competition for a limited amount of trophic factors are removed by programmed cell death. Also called apoptosis, this cellular suicide program is built into every mammalian cell. Apoptotic cells enter a well-orchestrated, stepwise, and energy-consuming destruction process that involves a cascade of enzymes called caspases and ultimately leads to the breakdown of cellular proteins and DNA.<sup>5</sup> This process is heavily used during development, such as during embryonic deletion of the interdigital mesenchymal tissue to separate fingers and toes. Similar to the clotting cascade, the apoptotic cascade remains active throughout life and is held in check by antiapoptotic factors, whereas proapoptotic factors promote its execution. Neurons are protected from apoptosis by neurotrophic factors. Conversely, noxious stimuli, such as pain, hypoxia, and ischemia, can increase the level of proapoptotic factors and activate the apoptotic suicide program, leading to neuronal cell death.

In addition to an overabundance in the total number of neurons generated during early development, the mammalian brain also forms an excess of neuronal connections, or synapses, during this period. Depending on brain region, synaptic density reaches its maximum in infants and young toddlers between 3 and 15 months of age, and will undergo a progressive reduction by about half into adulthood.<sup>6</sup> Connections that are active with continued electrical and chemical signals are sustained, whereas those with little or no activity are lost.

In summary, brain architecture changes rapidly and dramatically throughout life. Neuronal density is greatest during fetal life, and excess neurons are eliminated via apoptosis, predominantly in utero, during the neonatal period and throughout infancy.<sup>7</sup> Rapid growth of dendrites and synaptic connections occurs during infancy and early childhood, and unneeded dendrites and synapses are trimmed back, predominantly during later childhood and adolescence.<sup>6,7</sup>

Accordingly, the first several years after birth represent a critical period of development for many brain regions. Recent findings in animals suggest that exposure to anesthetics or sedatives may interfere with proper neuronal development, brain architecture, and subsequent function. Although the exact molecular mechanisms by which anesthetics afford their therapeutic properties of amnesia, analgesia, and immobility are only incompletely understood, their interaction with a wide variety of ion channels, such as sodium, calcium, and potassium channels, as well as several cell membrane proteins, including the receptors for  $\gamma$ -aminobutyric acid (GABA), glycine, glutamate (and *N*-methyl-D-aspartate [NMDA]), acetylcholine, and serotonin, make it conceivable that anesthetics could interfere with normal electrical and chemical activity in the developing brain. In fact, both GABA and NMDA play critical roles as trophic factors and in regulating neuronal maturation and programmed cell death. During brain development, GABA directs cell proliferation, neuroblast migration, and dendritic maturation.<sup>8</sup> Developmental NMDA receptor stimulation fosters survival and maturation of some neurons.<sup>9,10</sup> It is therefore not implausible that anesthetics might interfere with these developmental processes.

## Effects of Anesthetic Exposure on the Developing Brain

Concerns regarding neurologic abnormalities following general anesthesia in young children were first raised more than half a century ago, when postoperative personality changes were observed following the administration of vinyl ether, cyclopropane, or ethyl chloride for otolaryngologic surgery.<sup>11</sup> However, these abnormalities were felt to be psychological in nature because they were alleviated by the timely administration of preoperative sedative drugs.<sup>11,12</sup> Approximately two decades later the focus of research shifted to examine the effects of anesthetics in animal models that represented occupational exposure in pregnant healthcare workers.<sup>13-16</sup> Delayed synaptogenesis and behavioral abnormalities were observed in neonatal rats born to dams that were chronically exposed to subanesthetic doses of halothane during their entire pregnancy. However, interest in the effects of anesthetics on children did not elicit widespread interest until publications began to appear 10 years ago. In a seminal study in neonatal rat pups, widespread neuronal degeneration was observed after repeated injections of ketamine.<sup>17</sup> This led to numerous editorials and review articles, and more than 200 publications in which structural brain abnormalities and/or

functional impairment were demonstrated after a wide variety of immature animal species (including chicks, mice, rats, guinea pigs, swine, sheep, and rhesus monkeys) were exposed to almost every sedative and anesthetic in clinical use.<sup>18-65</sup> However, no discussion about the effects of drug exposure on the developing brain would be complete without examining the effects of opioid analgesics in the developing brain.<sup>54,55</sup> Accordingly, this chapter will examine the various specific effects of sedatives, anesthetics, and analgesics in the immature brain.

### APOPTOTIC CELL DEATH

The most widely studied deleterious consequence of exposure to sedatives or anesthetics in immature animals is apoptosis, or programmed cell death. Although neuronal apoptosis eliminates approximately 50% to 70% of neurons throughout the brain during development, at any particular time, this natural process affects only a small fraction of cells. Exposure to anesthetics or sedatives briefly, but dramatically, increases the number of apoptotic neurons (Fig. 23-1). Some studies demonstrated up to a 68-fold increase in the density of degenerating neurons after a combination of anesthetics in neonatal rats, compared with control animals, although it remains unclear what fraction of the entire neuronal population these degenerating neurons represent. Unpublished data from one of the authors' laboratory suggest

**FIGURE 23-1** Prolonged exposure to anesthetics causes widespread apoptotic cell death in the developing animal brain. Representative photomicrographs of brain sections from 7- to 8-day-old mice exposed to 6 hours of equipotent doses of 7.4% desflurane, 1.5% isoflurane, 2.9% sevoflurane in 30% oxygen, respectively, or fasted, unanesthetized litter mates in room air (*no anesthesia*). These doses were previously determined to represent 0.6 minimum alveolar concentration for the respective anesthetics. Arrows mark clusters of cells in layer II/III of neocortex that are dying from programmed cell death and are therefore labeled for the apoptotic marker, activated caspase 3 (bright green). Scale bar = 500  $\mu$ m. (*curved arrow*) (From Istaphanous GK, Howard J, Nan X, et al. Comparison of the neuroapoptotic properties of equipotent anesthetic concentrations of desflurane, isoflurane, or sevoflurane in neonatal mice. *Anesthesiology* 2011;114:578-87.)

that a 6-hour exposure to a clinically relevant dose of isoflurane triggers apoptotic cell death in 2% of neurons in the superficial cortex of neonatal mice, whereas less than 0.1% of neurons undergo physiologic apoptosis in this region in unanesthetized litter mates (Loepke, personal communication). Interestingly, dying neurons are immediately adjacent to seemingly unaffected neighboring cells (Fig. 23-2), and the exact mechanism and selectivity of the cell death process remains unknown. Increased neuroapoptosis has also been observed following either in vitro or in vivo, exposure to a wide variety of sedatives and anesthetics, including chloral hydrate, clonazepam, diazepam, midazolam, nitrous oxide, desflurane, enflurane, halothane, isoflurane, sevoflurane, ketamine, pentobarbital, phenobarbital, propofol, and xenon, as well as opioid receptor agonists, in a wide variety of species, including chicks, mice, rats, guinea pigs, piglets, and rhesus monkeys (E-Table 23-1). Cell death-selective stains, such as cupric silver and Fluoro-Jade (EMD Millipore, Billerica, Mass.), have confirmed the cellular demise in neurons that positively stain for activated caspase 3, the central executioner enzyme of the apoptotic cascade.

Apoptosis represents an inherent, energy-consuming process using a cascade of enzymes called caspases. Apoptosis is highly conserved among species and culminates in self-destruction and elimination of cells, even under physiologic conditions, when these cells are functionally redundant or potentially detrimental to the organism.<sup>208</sup> Apoptosis involves an orderly breakdown of the cell that includes chromatin aggregation, nuclear and cytoplasmic condensation, and partitioning of cytoplasmic and nuclear material into apoptotic bodies for subsequent phagocytosis, without an extensive inflammatory response. That contrasts with the features observed during necrosis, which include energy failure, cellular swelling, membrane rupture, and release of cytoplasmic content into the extracellular compartment, followed by an inflammatory response.<sup>208</sup> Accordingly, apoptosis has also been termed cellular suicide and is extensively used during tissue homeostasis, endocrine-dependent tissue atrophy, and normal embryogenesis (e.g., ablation of tail tissue as part of tadpole metamorphosis in amphibians). Similarly, brain cells are also produced in excess during normal brain development, and up to 50% to 70% of immature neurons are eliminated during normal brain maturation in rodents, nonhuman primates, and humans.<sup>3,4</sup> Accordingly, physiologic apoptotic cell death is critical to establish proper brain structure and function, and any disruption of this process can lead to massive brain malformations and intrauterine demise.<sup>209</sup> However, in addition to this intrinsic pathway of physiologic, developmental apoptosis, cell death can also be triggered by pathologic, extrinsic factors, such as hypoxia and ischemia.<sup>210</sup> It currently remains unknown whether anesthesia-induced neuroapoptosis accelerates physiologic programmed cell death or whether it eliminates cells not destined to die, as in pathologic apoptosis.

Animal studies have identified a narrow window of maximum susceptibility to neuronal cell death induced by several anesthetic drugs, such as the NMDA antagonist ketamine, the GABA agonist isoflurane, or ethanol (a combined NMDA antagonist and GABA agonist). Ketamine-induced neuronal demise occurs in neonatal rodents between 5 and 7 days of age, or before 6 days of age in monkeys, but not in older animals.<sup>17,69,139</sup> Similarly, neurotoxicity was not detected after isoflurane anesthesia in 1-day-old animals or in those more than 10 days of age, whereas neuroapoptosis reached a maximum effect at 7 days of age.<sup>87</sup> However, preliminary data from the laboratory of one of the

**FIGURE 23-2** Neurons affected by apoptotic cell death following anesthetic exposure are surrounded by seemingly unaffected cells. Representative photomicrograph from a 7-day-old mouse following a 6 hour exposure to 1.5% isoflurane, showing neocortical cells stained for the apoptotic cell death marker activated caspase 3 (blue, top), the neuronal marker NeuN (red, middle), and a merged image of the two stains (bottom). The majority of dying cells are identified as postmitotic neurons, as indicated by the purple cells coexpressing activated caspase 3 and NeuN in the bottom (arrows), whereas some cells expressing caspase 3 are NeuN-negative (arrowheads). Importantly, cells affected by anesthetic-induced neuroapoptosis are surrounded by numerous, seemingly unaffected neurons. Scale bar = 10  $\mu$ m. (Image courtesy the Loepke Laboratory.)

authors challenges the notion that anesthetic-induced neuroapoptosis is limited to this age range (Loepke and associates, unpublished data). Conversely, intrauterine exposure to clinical doses of isoflurane in prenatal rats may actually decrease physiologic apoptosis and improve subsequent memory retention,<sup>96</sup> whereas only supraclinical doses of isoflurane induced neuroapoptosis in this setting.<sup>112</sup>

**E-TABLE 23-1** Preclinical Studies Examining Structural and Neurocognitive Effects of Anesthetic Exposure Early in Life

Anesthetic Agent	Dose and Duration	Species, Age	Pathology	Study
Buprenorphine	1.5 mg/kg/day to dam	Rat, E7-E21 or P10	Decrease in striatal nerve growth factor	Wu et al. <sup>66</sup>
Chloral hydrate	50-300 mg/kg × 1	Mouse, P5	Increased neuroapoptosis, ameliorated by lithium	Cattano et al. <sup>67</sup>
Clonazepam	0.5-4 mg/kg × 1	Rat, P7	Increased neurodegeneration	Bittigau et al. <sup>68</sup>
Clonazepam	0.5-4 mg/kg × 1	Rat, P7	Increased neurodegeneration	Ikonomidou et al. <sup>69</sup>
Desflurane	7% for 30-120 minutes	Rat, P16	No increase in neurodegeneration or gross changes in dendritic arborization, increase in number of dendritic spines	Briner et al. <sup>70</sup>
Desflurane	7.4% for 6 hours	Mouse, P7-P8	Increased neuroapoptosis compared with no anesthesia, but similar to equi-anesthetic doses of isoflurane or sevoflurane	Istaphanous et al. <sup>71</sup>
Desflurane	8% for 6 hours	Mouse, P6	Increased neuroapoptosis, compared with sevoflurane and isoflurane, and long-term impairment in memory function	Kodama et al. <sup>72</sup>
Dexmedetomidine	1-75 µg/kg × 3	Rat, P7	No increase in neuroapoptosis	Sanders et al. <sup>73</sup>
Diazepam	10-30 mg/kg × 1	Rat, P7	Increased neurodegeneration	Ikonomidou et al. <sup>69</sup>
Diazepam	5-30 mg/kg × 1	Rat, P7	Increased neurodegeneration above 10 mg/kg, prevented by flumazenil	Bittigau et al. <sup>68</sup>
Diazepam	5 mg/kg × 1	Mouse, P10	No increased neurodegeneration in cortex, but increased in thalamus, no subsequent behavioral or learning deficits	Fredriksson et al. <sup>74</sup>
Diazepam	20 mg/kg on P6 and on P8	Rat, P6 and P8	Inhibition of neurogenesis	Stefovska et al. <sup>75</sup>
Enflurane	2-4% for 0.5 hour	Mouse, prenatal E6-E17	Learning impairment in adulthood	Chalon et al. <sup>76</sup>
Fentanyl	50 µg/kg/hr for 72 hours	Rat, P14	Diminished morphine antinociceptive sensitivity in juvenile and adult animals	Thornton et al. <sup>77</sup>
Fentanyl	0.1, 1, or 10 µg/kg × 3	Mouse, P4 and P5	Significant exacerbation of ibotenate-induced white-matter brain lesions at highest dose	Laudenbach et al. <sup>78</sup>
Fentanyl	30 µg/kg + 15 µg/kg/hr for 4 hours	Swine, P5	Slightly increased neuronal apoptosis, not statistically significantly different from control	Rizzi et al. <sup>79</sup>
Halothane	10 ppm for 40 hours/week	Rat, conception to P60	Learning deficits and decrease in synaptic density	Quimby et al. <sup>13</sup>
Halothane	10 ppm for 40 hours/week	Rat, conception to P60	Defects in visual and spatial learning tasks	Quimby et al. <sup>14</sup>
Halothane	50-200 ppm continuously	Rat, conception to P28	Dose-dependent decrease in cerebral synapse density	Uemura et al. <sup>15</sup>
Halothane	25-100 ppm continuously	Rat, conception to P60	Decrease in apical and basal dendritic length and numbers	Uemura et al. <sup>80</sup>
Halothane	25-100 ppm continuously	Rat, conception to P60	Decrease in synaptic density, no learning impairment	Uemura et al. <sup>16</sup>
Halothane	1-2% for 0.5 hour	Mouse, prenatal E6-E17	Learning impairment in adulthood	Chalon et al. <sup>76</sup>
Heroin	10 mg/kg/day to dam	Mouse, E8-E18	Hyperactivity and spatial learning deficits in adulthood	Yanai et al. <sup>81</sup>
Heroin	10 mg/kg/day to dam	Mouse, E9-E18	Increased neuronal apoptosis and impaired spatial learning and memory in juvenile animals	Wang et al. <sup>82</sup>
Heroin	500 µg/mL	Rat, E16-E17 cortical neuronal cultures	Decrease in neuronal viability, increase in apoptosis and DNA fragmentation	Cunha-Oliveira et al. <sup>83</sup>
Isoflurane	0.2-0.3 mmol/L	Mouse, P14 and P60 hippocampal slices	Block of synaptic transmission more pronounced in P14 slices compared with older animals	Simon et al. <sup>84</sup>

**E-TABLE 23-1** Preclinical Studies Examining Structural and Neurocognitive Effects of Anesthetic Exposure Early in Life—cont'd

Anesthetic Agent	Dose and Duration	Species, Age	Pathology	Study
Isoflurane + nitrous oxide + midazolam	0.75% + 75% + 9 mg/kg for 6 hours	Rat, P7	Increased neuroapoptosis and neurodegeneration, adult learning impairment	Jevtovic-Todorovic et al. <sup>85</sup>
Isoflurane	0.75-1.5% for 6 hours	Rat, P7	Increased neurodegeneration	Jevtovic-Todorovic et al. <sup>85</sup>
Isoflurane + midazolam + thiopental	1.5% for 4 hours + 1 mg/kg + 7 mg/kg to ewe	Sheep, prenatal E120	No increase in neuroapoptosis, as assessed 6 days postanesthesia	McClaine et al. <sup>86</sup>
Isoflurane + nitrous oxide + midazolam	0.75% + 75% + 9 mg/kg for 2-6 hours	Rat, P1-P14	Increased neuroapoptosis following exposure on P7, not P1-P3 or P10-P14	Yon et al. <sup>87</sup>
Isoflurane + nitrous oxide + midazolam	0.55% + 75% + 1 mg/kg for 4 hours	Swine, P5	Increased neurodegeneration in neocortex	Rizzi et al. <sup>88</sup>
Isoflurane	1.5% for 1-5 hours	Rat, organotypic slice culture	Increased neurodegeneration only after 5 hours of exposure	Wise-Faberowski et al. <sup>89</sup>
Isoflurane	2.4% for 24 hours	Rat, primary cortical neuron culture	Increased apoptosis	Wei et al. <sup>90</sup>
Isoflurane + nitrous oxide + midazolam	0.75% + 75% + 9 mg/kg for 2-6 hours	Rat, P7	Increased neuroapoptosis, ameliorated by estradiol	Lu et al. <sup>91</sup>
Isoflurane + nitrous oxide + midazolam	0.75% + 75% + 9 mg/kg for 6 hours	Rat, P7	Increased neuroapoptosis, ameliorated by melatonin	Yon et al. <sup>92</sup>
Isoflurane	0.75% for 4 hours	Mouse, P5	Increased neuroapoptosis, ameliorated by pilocarpine	Olney et al. <sup>93</sup>
Isoflurane	0.75% for 6 hours	Rat, P7, and mouse organotypic hippocampal slices	Increased neuroapoptosis, exacerbated by nitrous oxide and ameliorated by xenon	Ma et al. <sup>94</sup>
Isoflurane	2.4% for 24 hours	Rat, primary cortical neuron culture	Increased cellular degeneration, blocked by isoflurane or halothane preconditioning	Wei et al. <sup>95</sup>
Isoflurane	1.3% for 6 hours	Rat, prenatal E21	Decrease in neuroapoptosis, no impaired learning, improved memory retention in juvenile animals	Li et al. <sup>96</sup>
Isoflurane + nitrous oxide + midazolam	0.75% + 75% + 9 mg/kg for 6 hours	Rat, P7	Decreased neuronal density in multiple brain areas in adulthood	Nikizad et al. <sup>97</sup>
Isoflurane + nitrous oxide + midazolam	0.55% + 75% + 1 mg/kg for 4 hours	Guinea pig, prenatal E20-E50	Increased neuroapoptosis between E35-E40 and decreased adult neuronal density, not after E50 or in fentanyl control group	Rizzi et al. <sup>98</sup>
Isoflurane	0.75% for 4 hours, 1.5% for 2 hours, or 2% for 1 hour	Mouse, P5-P7	Increased neuroapoptosis	Johnson et al. <sup>99</sup>
Isoflurane + nitrous oxide	0.75% + 75% for 6 hours	Rat, P7	Increased neuroapoptosis in spinal cord	Sanders et al. <sup>100</sup>
Isoflurane		Mouse, P4	Increased neuroapoptosis, ameliorated by hypothermia	Olney et al. <sup>101</sup>
Isoflurane + nitrous oxide	0.55% + 75% or individually for 2-8 hours	Rat, P7	Increased neuroapoptosis and neurodegeneration after exposure of 6 hours or longer, ameliorated by L-carnitine, no increase by either agent administered individually	Zou et al. <sup>102</sup>
Isoflurane	1-2% for 10 minutes	Mouse, P0	Neonatal and adolescent impairment in tests of body coordination and adult learning; decreased hippocampal cellularity and volume, more pronounced in males	Rothstein et al. <sup>103</sup>
Isoflurane	1.2% for 12 hours	Rat, primary cortical neuron culture	Increased cytotoxicity, ameliorated by xestospongine C	Wang et al. <sup>104</sup>
Isoflurane	0.75% for 6 hours	Rat, P7	Increased neuroapoptosis, no effect on short-term, but impairment of long-term memory, ameliorated by dexmedetomidine	Sanders et al. <sup>73</sup>

**E-TABLE 23-1** Preclinical Studies Examining Structural and Neurocognitive Effects of Anesthetic Exposure Early in Life—cont'd

Anesthetic Agent	Dose and Duration	Species, Age	Pathology	Study
Isoflurane	0.75% for 6 hours	Mouse, P8 organotypic hippocampal slices	Increased neuroapoptosis, ameliorated by dexmedetomidine, not reversed by gabazine	Sanders et al. <sup>73</sup>
Isoflurane	1.5% for 6 hours	Mouse, P7	Increased neurodegeneration early after exposure, no adult learning impairment, no decreased adult neuronal density	Loepke et al. <sup>105</sup>
Isoflurane	1 MAC for 1-4 hours	Rat, P7	Widespread brain cell death following exposure for >2 hours, not 1 hour; adult neurocognitive deficits only after 4-hour exposure	Stratmann et al. <sup>106</sup>
Isoflurane	1 MAC for 4 hours	Rat, P7	Decreased progenitor proliferation, deficits in fear conditioning and memory impairment in adulthood	Stratmann et al. <sup>107</sup>
Isoflurane	3.4% for 4 hours	Rat, neuronal progenitor culture, harvest P2, 2-12 weeks in culture	No neurodegeneration or activation of caspases 3 or 7, decrease in caspase 9, inhibition of proliferation, preferential differentiation to neurons	Sall et al. <sup>108</sup>
Isoflurane	1.4%	Rat, cortical and hippocampal neuron culture, harvest P1, DIC 5	Increased neuroapoptosis, reduction in dendritic spines and number of synapses, ameliorated by administration of tPA or inhibition of p75 <sup>NTR</sup>	Head et al. <sup>109</sup>
Isoflurane + nitrous oxide + midazolam	0.75% + 75% + 9 mg/kg for 6 hours	Rat, P7	Decreased synaptic density in subiculum 2 weeks after treatment	Lunardi et al. <sup>110</sup>
Isoflurane	1.6% for 5 hours	Rhesus monkey, P5	Increase in apoptotic cell death of neurons in neocortex and immature oligodendrocytes in white matter	Olney et al. <sup>111</sup>
Isoflurane	1.3% or 3% for 1 hour to dam	Rat, E21	No increase in neuroapoptosis or S100 $\beta$ blood levels following lower dose, but both increased following higher dose	Wang et al. <sup>112</sup>
Isoflurane	1.7% for 35 minutes $\times$ 4 days	Rat, P14, and mouse, P14	No increased immediate hippocampal neuronal cell death, no difference in adult learning of easy task, impairment in adult learning of difficult learning and recognition tasks	Zhu et al. <sup>113</sup>
Isoflurane	1.6% for 5 hours	Rhesus monkey, P5	Increase in neocortical apoptotic cell death	Brambrink et al. <sup>114</sup>
Isoflurane	1.5% for 30-120 minutes	Rat, P16	No increase in neurodegeneration or gross changes in dendritic arborization, increase in number of dendritic spines	Briner et al. <sup>70</sup>
Isoflurane	0.75% for 6 hours	Mouse, P7	Increased neuroapoptosis and serum levels of S100 $\beta$ immediately following exposure, no long-term impairment in learning and memory tests	Liang et al. <sup>115</sup>
Isoflurane	2% for 2 hours and/or caffeine 80 mg/kg IP	Mouse, P4	Increased neuroapoptosis following caffeine, worse than following isoflurane exposure, demonstrating potentiation following combination exposure	Yuede et al. <sup>116</sup>
Isoflurane	1.5% for 6 hours	Mouse, P7-P8	Increased neuroapoptosis compared with no anesthesia, but similar to equianesthetic doses of desflurane or sevoflurane	Istaphanous et al. <sup>71</sup>
Isoflurane	2% for 90 minutes for each time point	Mouse, P10, P20, P30, P60, and P90	No behavioral or cognitive abnormalities in adulthood	Kulak et al. <sup>117</sup>
Isoflurane + nitrous oxide	0.75% isoflurane + 70% nitrous oxide for 6 hours	Rat, P7	Increased neuroapoptosis and subsequent altered cognitive function, which were ameliorated by xenon pretreatment	Shu et al. <sup>118</sup>
Isoflurane + nitrous oxide	0.75% isoflurane + 70% nitrous oxide for 6 hours	Rat, organotypic hippocampal slice culture	Increased neuroapoptosis, which was ameliorated by xenon pretreatment	Shu et al. <sup>118</sup>
Isoflurane + nitrous oxide + midazolam	0.55% + 75% + 1 mg/kg for 4 hours	Swine, P5	Increased neuroapoptosis in cerebral cortex, compared with control or a fentanyl-treated comparison group	Rizzi et al. <sup>79</sup>

**E-TABLE 23-1** Preclinical Studies Examining Structural and Neurocognitive Effects of Anesthetic Exposure Early in Life—cont'd

Anesthetic Agent	Dose and Duration	Species, Age	Pathology	Study
Isoflurane	3% for 24 hours	Rat, astroglial culture	Impairment in growth of immature glia, delay in glial maturation, without effects on total actin or GFAP levels	Lunardi et al. <sup>119</sup>
Isoflurane	1.5% for induction + 1% for 4 hours	Mouse, 1 month	Transient decrease in dendritic filopodia elimination in somatosensory cortex, without effects on dendritic spine density	Yang et al. <sup>120</sup>
Isoflurane	0.7%, 1.4%, or 2.8% for 6 hours	Rat, embryonic neuronal stem cells	No effect on neural stem cell viability. Two higher concentrations inhibited cell proliferation	Culley et al. <sup>121</sup>
Isoflurane	1.5% or 5% for 6-12 hours	Mouse, cortical neuronal culture	No cytotoxicity observed, even when adding clinical doses of nitrous oxide or ketamine	Campbell et al. <sup>122</sup>
Isoflurane	1.4% from 15 minutes to 4 hours	Mouse, primary neuronal culture and hippocampal slice culture	Increased apoptosis and cytoskeletal destabilization	Lemkuil et al. <sup>123</sup>
Isoflurane + intrathecal bupivacaine	1% for 1 or 6 hours	Rat, P7, P14, P21	Neuroapoptosis in brain and spinal cord after 6 hours exposure, but not 1 hour; intact spontaneous motor performance in adulthood	Yahalom et al. <sup>124</sup>
Isoflurane and/or nitrous oxide	1% and/or 70% for 8 hours	Rhesus monkey, P5-P6	No neuroapoptosis observed following either agent alone, neuroapoptosis increased following anesthetic combination	Zou et al. <sup>125</sup>
Isoflurane + nitrous oxide + midazolam	0.75% + 75% + 9 mg/kg for 6 hours	Rat, P7	Enlargement and impairment of structural integrity of mitochondria and decreased density in subiculum, as well as increased autophagic activity	Sanchez et al. <sup>126</sup>
Isoflurane + nitrous oxide	0.75% isoflurane + 70% nitrous oxide for 6 hours	Rat, P7	Increased neuroapoptosis and subsequent altered cognitive function, which were ameliorated by xenon pretreatment	Shu et al. <sup>127</sup>
Isoflurane	2% for 6 hours	Mouse, P6	Increased neuroapoptosis, but no long-term impairment in memory function	Kodama et al. <sup>72</sup>
Ketamine	20 mg/kg × 7	Rat, P7	Increased neurodegeneration	Ikonomidou et al. <sup>17</sup>
Ketamine	25-75 mg/kg × 1-7	Rat, P7	Increased neurodegeneration only after 7 repeated doses of 25 mg/kg	Hayashi et al. <sup>128</sup>
Ketamine	50 mg/kg × 1	Mouse, P10	Cortical neurodegeneration; hypo- and hyperactivity, abnormal habituation in adulthood	Fredriksson et al. <sup>129</sup>
Ketamine	50 mg/kg × 1	Mouse, P10	Neurodegeneration, worsened by coadministration of diazepam	Fredriksson et al. <sup>74</sup>
Ketamine	50 mg/kg × 1	Mouse, P10	Neurodegeneration and impairment in memory tasks in adulthood	Fredriksson et al. <sup>130</sup>
Ketamine	10-25 mg/kg × 1-7	Rat, P7	Neurodegeneration observed after highest dose, plasma levels 7 times higher than during human anesthesia	Scallet et al. <sup>131</sup>
Ketamine	1.25-40 mg/kg × 1	Mouse, P7	Neurodegeneration after doses of 5 mg/kg or higher, no gross neurobehavioral abnormalities 7 days after treatment	Rudin et al. <sup>132</sup>
Ketamine	0.1-10 μmol/L for 6-48 hours	Rat, forebrain neuron culture	Increased DNA fragmentation after higher doses for longer periods of time	Wang et al. <sup>133</sup>
Ketamine	10-40 mg/kg × 1	Mouse, P7	Increased neurodegeneration following doses of 20 mg/kg or higher, worsened by midazolam coadministration	Young et al. <sup>134</sup>
Ketamine	1-20 μmol/L for 2-24 hours	Rhesus monkey, forebrain neuron culture	Increased DNA fragmentation and decreased mitochondrial function after higher doses for longer periods of time	Wang et al. <sup>135</sup>
Ketamine	0.01-40 μg/mL for 1-48 hours	Rat, GABAergic neuron culture	Neuronal cell loss and decrease in dendritic length and branching with higher concentrations for longer exposure times	Vutskits et al. <sup>136</sup>

**E-TABLE 23-1** Preclinical Studies Examining Structural and Neurocognitive Effects of Anesthetic Exposure Early in Life—cont'd

Anesthetic Agent	Dose and Duration	Species, Age	Pathology	Study
Ketamine	100 $\mu$ mol/L for 48 hours	Rat, cortical neuron culture	Increased apoptosis, ameliorated by NMDA, IGF-1, alsterpaullone, or iodoindirubin	Takadera et al. <sup>137</sup>
Ketamine	0.1-30 $\mu$ mol/L for 24 hours	Rat, cortical neuron culture	Decreased cell viability and increased DNA fragmentation, ameliorated by erythropoietin	Shang et al. <sup>138</sup>
Ketamine	20-50 mg/kg/hr $\times$ 24 hours	Rhesus monkey, E122, P5, or P35	Increased neurodegeneration in two younger age groups, ketamine plasma levels higher than in humans	Slikker et al. <sup>139</sup>
Ketamine	10-10 $\mu$ g/mL for 1-24 hours	Rat, GABAergic neuron culture	Neuronal cell loss with higher concentrations or longer exposure times	Vutskits et al. <sup>140</sup>
Ketamine	2.5 mg/kg $\times$ 2 for 4 days	Rat, P1-P4	Minimal neurodegeneration, but ketamine ameliorated pain-induced neurodegeneration and subsequent learning abnormalities	Anand et al. <sup>141</sup>
Ketamine	25 mg/kg $\times$ 1	Mouse, P10	No increase in neurodegeneration, but subsequent learning impairment, worsened by coadministration of thiopental or propofol	Fredriksson et al. <sup>142</sup>
Ketamine	1-20 $\mu$ mol/L for 24 hours	Rat, forebrain neuron culture	Increased DNA fragmentation after higher doses, blocked by nitroindazole	Wang et al. <sup>143</sup>
Ketamine	5-25 mg/kg $\times$ 1	Mouse, P10	Dose-dependent alterations in levels of developmentally expressed proteins and adult behavioral abnormalities	Viberg et al. <sup>144</sup>
Ketamine	2.5 mg/kg $\times$ 2 for 4 days	Rat, P1-P4	No increase in neuronal cell death, no change in adult learning and exploratory behavior and ameliorated pain-induced neurodegeneration and behavioral abnormalities	Rovnaghi et al. <sup>145</sup>
Ketamine	20 mg/kg $\times$ 6	Rat, P7	Decreased body weight 1-3 days after exposure, no abnormal spontaneous behavior observed during first 4 days	Boctor et al. <sup>146</sup>
Ketamine	30 mg/kg + 15 mg/kg every 90 minutes $\times$ 2	Mouse, P15-P90	No increase in neurodegeneration, impairment in dendritic spine development following exposure on P20 or younger	Vutskits et al. <sup>147</sup>
Ketamine	40 mg/kg	Mouse, P5	Increased neuroapoptosis, ameliorated by lithium coadministration	Straiko et al. <sup>148</sup>
Ketamine	5-20 mg/kg $\times$ 1-6	Rat, P7	Increased apoptosis and neurodegeneration only observed following 6 repeated doses of 20 mg/kg	Zou et al. <sup>149</sup>
Ketamine	20 mg/kg $\times$ 7	Rat, P7	Increased apoptosis and neurodegeneration, decreased weight gain, increase in BDNF and TrkB cDNA	Ibla et al. <sup>150</sup>
Ketamine	20-50 mg/kg/hr for 3-25 hours	Rhesus monkey, P5-P6	Neuronal degeneration only in neocortex following 9 hour exposure or longer, no degeneration in deeper brain areas	Zou et al. <sup>151</sup>
Ketamine	30 mg/kg + 15 mg/kg every 90 minutes $\times$ 2	Mouse, P15	Increase in dendritic spine density and decrease in spine head diameter in the somatosensory cortex and hippocampus	De Roo et al. <sup>152</sup>
Ketamine	100 mg/kg/day $\times$ 5 days	Mouse, P8-P12	Impaired dendritic spine maturation immediately following exposure, which subsided within 2 weeks	Tan et al. <sup>153</sup>
Ketamine or (S)-ketamine	1-8 mmol/L or 0.6-4 mmol/L for 24 hours	Human, neuroblastoma cells	Increased apoptosis, but up to 80% less cell death following (S)-ketamine	Braun et al. <sup>154</sup>
Ketamine	5-20 mg/kg $\times$ 5	Rat, P7	Increased neuroapoptosis in neocortex and thalamus, increase in cell cycle proteins	Soriano et al. <sup>155</sup>
Ketamine	0.1-1000 $\mu$ mol/L $\times$ 6-48 hours	Rat, cortical neuron culture	Increase in expression of caspase 3 and cell cycle proteins	Soriano et al. <sup>155</sup>

**E-TABLE 23-1** Preclinical Studies Examining Structural and Neurocognitive Effects of Anesthetic Exposure Early in Life—cont'd

Anesthetic Agent	Dose and Duration	Species, Age	Pathology	Study
Ketamine	20 mg/kg every 2 hours × 6	Rat, P7	Increased neurodegeneration in frontal cortex	Shi et al. <sup>156</sup>
Ketamine	3-15 mg/kg intrathecal L4-6	Rat, P3, P7, or P21	Increased neuronal cell death and subsequent altered spinal cord function after injection at P3, but not at P7 or P21	Walker et al. <sup>157</sup>
Ketamine	20 mg/kg bolus +20-50 mg/kg/hr for 24 hours	Rhesus monkey, P5-P6	Decreased performance of the National Center for Toxicological Research Operant Testing Battery and motivation	Paule et al. <sup>158</sup>
Ketamine	20 mg/kg every 2 hours × 6	Rat, P7	Greater accumulation of a radioactive tracer and more cell death in frontal cortex in adulthood	Zhang et al. <sup>159</sup>
Ketamine + xylazine	42.5 + 4.3 mg/kg every 90 minutes × 3	Mouse, 1 month	Transient increase in dendritic filopodia formation in somatosensory cortex, without effects on dendritic spine density	Yang et al. <sup>120</sup>
Ketamine	100 μmol/L, 1 mmol/L, or 3 mmol/L	Mouse, cortical neuronal culture	Cytotoxicity only observed in doses of 1 mmol/L or higher	Campbell et al. <sup>122</sup>
Ketamine	18.4-86.5 mg/kg/hr for 5 hours to dam	Rhesus monkey, E120	Increased neuroapoptosis, especially in cerebellum, caudate-putamen, and nucleus accumbens	Brambrink et al. <sup>160</sup>
Ketamine	18.4-56.0 mg/kg/hr for 5 hours	Rhesus monkey, P6	Increased neuroapoptosis, especially in basal ganglia and thalamus	Brambrink et al. <sup>160</sup>
Methadone	10 mg/kg/day to dam	Rat, E5-E21	Decreased brain monoamines in juveniles and hyperresponsiveness in adulthood	Rech et al. <sup>161</sup>
Methadone	10-15 mg/kg/day to dam	Rat, E8-E21	Increased excitability tested in juvenile animals using the acoustic startle reflex	Hutchings et al. <sup>162</sup>
Methadone	9 mg/kg/day to dam	Rat, E7-E21	Increased noradrenergic activity in hippocampus of male juveniles	Robinson et al. <sup>163</sup>
Methadone	9 mg/kg/day	Rat, P1-P10	Reduced activity of dopaminergic neurons in frontal cortex of juvenile males	Robinson et al. <sup>163</sup>
Methadone	9 mg/kg/day to dam	Rat, E7-E21	Reduction in nerve growth factor, disruption of cholinergic neuronal activity	Robinson et al. <sup>164</sup>
Methadone	9 mg/kg/day to dam	Rat, E7-E21 or P10	Reduction in nerve growth factor in striatum	Wu et al. <sup>66</sup>
Midazolam	9 mg/kg × 1	Rat, P7	No increase in neurodegeneration	Jevtovic-Todorovic et al. <sup>85</sup>
Midazolam	9 mg/kg × 1	Mouse, P7	Increased neuroapoptosis	Young et al. <sup>134</sup>
Midazolam	9 mg/kg × 1	Mouse, P5	Increased neuroapoptosis	Olney et al. <sup>93</sup>
Midazolam	3-9 mg/kg × 1	Rat, P1-P14	No increase in neuroapoptosis	Yon et al. <sup>87</sup>
Midazolam	0.25-25 μg/mL	Rat, GABAergic neuron culture	No effect on neuronal survival	Vutskits et al. <sup>165</sup>
Midazolam	25 mg/kg + 15 mg/kg every 90 minutes × 2	Mouse, P15-P90	No increase in neurodegeneration, impairment in dendritic spine development following exposure on P20 or younger	Vutskits et al. <sup>147</sup>
Midazolam	25 mg/kg + 15 mg/kg every 90 minutes × 2	Mouse, P15	Increase in dendritic spine density and decrease in spine head diameter in the somatosensory cortex and hippocampus	De Roo et al. <sup>152</sup>
Midazolam	50 mg/kg	Mouse, P10	No impairment of learning and memory in adulthood	Xu et al. <sup>166</sup>
Midazolam	50 mg/kg/day × 5 days	Mouse, P8-P12	Impaired dendritic spine maturation immediately following exposure, which subsided within 2 weeks	Tan et al. <sup>153</sup>
Morphine	10 mg/kg/day	Rat, E12-P5	Gender- and region-specific changes in μ-opioid receptor density, decrease in neuronal density, and reduction in dendritic growth, partially reversed by naltrexone	Hammer et al. <sup>167</sup>
Morphine	5 mg/kg/day	Rat, P1-P4	Decreased μ-opioid receptor density in striatum following exposure	Tempel et al. <sup>168</sup>

**E-TABLE 23-1** Preclinical Studies Examining Structural and Neurocognitive Effects of Anesthetic Exposure Early in Life—cont'd

Anesthetic Agent	Dose and Duration	Species, Age	Pathology	Study
Morphine	20 mg/kg/day to dam, except for E11—10 mg/kg/day	Rat, E11-E18	Decreased $\mu$ -opioid receptor density in adulthood	Rimanoczy et al. <sup>169</sup>
Morphine	1 $\mu$ mol/L for 1-2 days	Mouse, P5-P6 cerebellar neuronal precursor culture	Marked decrease in DNA synthesis, without effect on cell survival	Hauser et al. <sup>170</sup>
Morphine	5 mg/kg $\times$ 3 doses, then 10 mg/kg twice a day to dam	Rat, E11-E18	Impairment in spatial learning in adulthood	Slamberova et al. <sup>171</sup>
Morphine	20 mg/kg	Mouse, P4-P5	Suppression of DNA synthesis in astrocytes	Stiene-Martin et al. <sup>172</sup>
Morphine	1-100 $\mu$ mol/L for 5 days	Human, GW16-22 fetal microglial, astrocyte, and neuronal cultures	Progressive increase in apoptosis in neurons after 2-day exposure, or microglia after 3 days, but not in astrocytes. Apoptosis blocked by naloxone	Hu et al. <sup>173</sup>
Morphine	2 mg/kg/day to dam, progressively increased by 2 mg/kg/day	Rat, E0-P21	Impairment in spatial learning in young adulthood	Yang et al. <sup>174</sup>
Morphine	20 mg/kg/day	Chick, E12-E16	Impairment in long-term memory formation	Che et al. <sup>175</sup>
Morphine	2 mg/kg/day	Rat, P3-P7	Impairment in adult cognitive function	McPherson et al. <sup>176</sup>
Morphine	0.5, 1, or 3 mg/kg	Rat, P7	Increased pain behavior to a pain challenge several days after morphine injection	Zissen et al. <sup>177</sup>
Morphine	15 $\mu$ mol/L for 7 days	Mouse, E16 hippocampal neuronal culture	Increased apoptosis, decreased neuronal density	Svensson et al. <sup>178</sup>
Morphine	4 mg/kg/day	Mouse, P5-P9	Impairment in reward-mediated learning in adulthood	Boasen et al. <sup>179</sup>
Morphine	5 mg/kg $\times$ 3 doses, then 10 mg/kg twice a day to dam	Rat, E11-E18	Decreased synaptic plasticity and impaired learning in juveniles	Niu et al. <sup>180</sup>
Morphine	2 mg/kg/day to dam, progressively increased by 2 mg/kg/day, maximum 14 mg/kg/day	Rat, E0-P21	Decreased performance in learning tasks in adulthood	Lin et al. <sup>181</sup>
Morphine	5 $\mu$ g/kg/day $\times$ 8 days	Rat, P8-P14	Increased nociceptive response throughout adulthood, which could be blocked by ketamine	Rozinsky et al. <sup>182</sup>
Nitrous oxide (hyperbaric)	50%-150% for 2-6 hours	Rat, P7	No increase in neurodegeneration	Jevtovic-Todorovic et al. <sup>85</sup>
Nitrous oxide (hyperbaric)	50%-150% for 2-6 hours	Rat, P1-P14	No increase in neuroapoptosis	Yon et al. <sup>87</sup>
Nitrous oxide	75% for 6 hours	Rat, P7, and mouse organotypic hippocampal slices	No increase in neuroapoptosis in rats, increased neuroapoptosis in mice	Ma et al. <sup>94</sup>
Pentobarbital	5-10 mg/kg $\times$ 1	Rat, P7	Increased neurodegeneration	Bittigau et al. <sup>68</sup>
Pentobarbital	0.5, 5, or 50 $\mu$ g/mL	Rat, PC12 pheochromocytoma cell culture	Dose-dependent inhibition of apoptotic cell death triggered by oxygen-glucose deprivation	Morimoto et al. <sup>183</sup>
Pentobarbital	10-20 mg/kg	Rat, P7	Impairment in spatial learning; however hypercarbia and hypoxia observed during exposure	Tachibana et al. <sup>184</sup>
Phenobarbital	40-100 mg/kg	Rat, P7	Increased neuroapoptosis, ameliorated by $\beta$ -estradiol	Bittigau et al. <sup>68</sup>
Phenobarbital	50 mg/kg	Rat, P7	Increased neuroapoptosis, ameliorated by $\beta$ -estradiol	Asimiadou et al. <sup>185</sup>
Phenobarbital	30 mg/kg $\times$ 2	Mouse, P6	Long-term alterations in brain protein expression	Kim et al. <sup>186</sup>

**E-TABLE 23-1** Preclinical Studies Examining Structural and Neurocognitive Effects of Anesthetic Exposure Early in Life—cont'd

Anesthetic Agent	Dose and Duration	Species, Age	Pathology	Study
Phenobarbital	75 mg/kg	Rat, P7-P8	Increased neuroapoptosis, enhanced by lamotrigine administration	Katz et al. <sup>187</sup>
Phenobarbital	25 mg/kg	Mouse, P0	Neonatal and adolescent impairment in tests of body coordination and adult learning; decreased hippocampal cellularity and volume, more pronounced in males	Rothstein et al. <sup>103</sup>
Phenobarbital	50 mg/kg (P6), 40 mg/kg (P8)	Rat, P6 and P8	Inhibition of neurogenesis	Stefovska et al. <sup>75</sup>
Propofol	0.5-10 µg/mL for 8 hours	Rat, GABAergic neuron culture	Dose-dependent decrease in GABAergic enzyme GAD after higher doses	Honegger et al. <sup>188</sup>
Propofol	10-100 µg/mL for 2 hours to 10 days	Rat, dissociated neuronal culture P1 or P7	Increased cell death in P1 neurons following higher doses, no evidence for neurotoxic effects in organotypic hippocampal culture on P7	Spahr-Schopfer et al. <sup>189</sup>
Propofol	1-50 µg/mL	Rat GABAergic neuron culture	Increased neuronal cell death following highest dose, altered dendritic development following lowest dose	Vutskits et al. <sup>165</sup>
Propofol	5-500 µmol/L for 2-24 hours	Chick, neuron explant culture	Dose-dependent neurite growth cone collapse	Al-Jahdari et al. <sup>190</sup>
Propofol	10-60 mg/kg × 1	Mouse, P10	Increased neurodegeneration following highest dose	Fredriksson et al. <sup>142</sup>
Propofol	25-300 mg/kg × 1	Mouse, P5-P7	Increased neuroapoptosis following doses higher than 50 mg/kg	Cattano et al. <sup>191</sup>
Propofol + fentanyl	6 mg/kg/hr + 10 µg/ kg/hr for 24 hours	Swine, P0	No increased neurodegeneration	Gressens et al. <sup>192</sup>
Propofol	5 µmol/L for 5 hours	Rat, hippocampal neuron culture	Increased neuroapoptosis	Kahraman et al. <sup>193</sup>
Propofol	50 mg/kg + 25 mg/kg every 90 minutes × 2	Mouse, P15-P90	No increase in neurodegeneration, impairment in dendritic spine development following exposure on P20 or younger	Vutskits et al. <sup>147</sup>
Propofol	25 mg/kg	Rat, P7	Increased neuroapoptosis, decrease in nerve growth factor	Pesic et al. <sup>194</sup>
Propofol	50-100 mg/kg	Mouse, P5	Increased neuroapoptosis, ameliorated by lithium coadministration	Straiko et al. <sup>148</sup>
Propofol	0.01-1 mg/mL for 3-48 hours	Rat, primary cortical neuron culture, harvested E18	Highest concentration improved cell viability after up to 6 hours of exposure, but reduced cell viability after more than 12 hours	Berns et al. <sup>195</sup>
Propofol	30 mg/kg every 90 minutes × 3	Rat, P6	Increase in neurodegeneration in some brain areas, especially in parts of thalamus and subiculum, subtle neurologic impairment in adult animals	Bercker et al. <sup>196</sup>
Propofol	50 mg/kg + 25 mg/kg every 90 minutes × 2	Mouse, P15	Increase in dendritic spine density and decrease in spine head diameter in the somatosensory cortex and hippocampus	De Roo et al. <sup>152</sup>
Propofol	40 mg/kg + 20 mg/ kg/hr for 6 hours	Rat, P5, P10, P15, P20, or P30	Decrease in dendritic spine density following exposure between P5-P10, but increased density at P15-P30	Briner et al. <sup>197</sup>
Propofol	10 or 60 mg/kg	Mouse, P10	Reduction in brain-derived neurotrophic factor, no changes in adult spontaneous behavior, but reduced sedative effect of diazepam in adulthood	Pontén et al. <sup>198</sup>
Propofol	50 mg/kg × 7 days	Rat, P7-P14	No increase in neuroapoptosis, only in hypoxic condition	Tu et al. <sup>199</sup>
Propofol	100 mg/kg × 1	Mouse, P5	Increased neuroapoptosis in hippocampus	Pearn et al. <sup>200</sup>
Propofol	3 µmol/L for 6 hours	Mouse, neuron culture, harvested P1-P3, DIC 5-7	Increased neuroapoptosis, mediated by P75 neurotrophin receptor activation	Pearn et al. <sup>200</sup>
Sevoflurane	4% for 24 hours	Rat, primary cortical neuron culture	No increase in apoptosis	Wei et al. <sup>90</sup>

**E-TABLE 23-1** Preclinical Studies Examining Structural and Neurocognitive Effects of Anesthetic Exposure Early in Life—cont'd

Anesthetic Agent	Dose and Duration	Species, Age	Pathology	Study
Sevoflurane	2% for 12 hours	Rat, primary cortical neuron culture	No increase in cytotoxicity	Wang et al. <sup>104</sup>
Sevoflurane	1.7% for 2 hours	Mouse, P7	Increased neuroapoptosis	Zhang et al. <sup>201</sup>
Sevoflurane	3% for 6 hours	Mouse, P6	Increased neuroapoptosis, impairments in fear conditioning and social interaction in adulthood	Satomoto et al. <sup>202</sup>
Sevoflurane	4% or 8% for 12 or 6 hours, respectively	Rat, primary cortical neuron culture, E18	No difference in cell viability compared with untreated controls	Berns et al. <sup>203</sup>
Sevoflurane	3%-5% for 6 hours	Rat, P6	No increase in neurodegeneration immediately after exposure, no long-term neurologic impairment	Bercker et al. <sup>196</sup>
Sevoflurane	2.1% for 0.5-6 hours	Rat, P4-P8	Seizure activity during exposure and neuroapoptosis partially blocked by administration of bumetanide	Edwards et al. <sup>204</sup>
Sevoflurane	2.5% for 30-120 minutes	Rat, P16	No increase in neurodegeneration or gross changes in dendritic arborization, increase in number of dendritic spines	Briner et al. <sup>70</sup>
Sevoflurane	1.1% for 6 hours	Mouse, P7	Increased neuroapoptosis immediately following exposure, no long-term impairment in learning and memory tests	Liang et al. <sup>115</sup>
Sevoflurane	2.1% or 3% for 2 hours or 6 hours	Mouse, P6	Increased neuroapoptosis following the longer, but not the shorter exposure time. Transgenic Alzheimer disease mice more susceptible	Lu et al. <sup>205</sup>
Sevoflurane	2.9% for 6 hours	Mouse, P7-P8	Increased neuroapoptosis compared with no anesthesia, but similar to equianesthetic doses of desflurane or isoflurane	Istaphanous et al. <sup>71</sup>
Sevoflurane	3.8% for 6 hours	Mouse, P6	Increased neuroapoptosis, less than with desflurane and isoflurane, and long-term impairment in memory function	Kodama et al. <sup>72</sup>
Sevoflurane	1 MAC × 4 hours	Rat, P7	Memory impairment, alleviated by environmental enrichment	Shih et al. <sup>206</sup>
Sufentanil	2 µg/kg x3	Mouse, P4 and P5	No exacerbation of ibotenate-induced white-matter brain lesions	Laudenbach et al. <sup>78</sup>
Thiopental	5-25 mg/kg × 1	Mouse, P10	No increase in neurodegeneration by itself, but exacerbation and learning abnormalities in conjunction with ketamine	Fredriksson et al. <sup>142</sup>
Xenon	75% for 6 hours	Rat, P7 and mouse organotypic hippocampal slices	No increase in neuroapoptosis	Ma et al. <sup>94</sup>
Xenon	70% for 4 hours	Mouse, P7	Increased neuroapoptosis, but decreased isoflurane-induced neuroapoptosis	Cattano et al. <sup>207</sup>

BDNF, Brain-derived neurotrophic factor; DIC, days in culture; GAD, glutamic acid decarboxylase; GFAP, glial fibrillary acidic protein; IP, intraperitoneal; MAC, minimal alveolar concentration; TrkB, tyrosine-related kinase B.

### LONG-TERM BRAIN CELLULAR VIABILITY, NEUROLOGIC FUNCTION, AND BEHAVIOR

In order to answer the important question whether anesthetics simply hasten physiologic apoptosis or whether they induce pathologic apoptosis, long-term neuronal density and neurologic function have to be assessed in adult animals exposed to anesthesia as neonates. If exposure to anesthetics or analgesics only temporarily accelerated physiologic apoptosis, one would expect normal cell counts and function in adult animals. Conversely, a permanent neuronal cell loss and long-term neurocognitive impairment after anesthetic exposure early in life would suggest that anesthesia-induced neuronal apoptosis may be pathologic in nature. However, this would only be true if the organism was unable to compensate for the neonatal cell loss by increasing neuronal plasticity and repair. To answer these questions, several studies measured neurologic function, assessed behavior, and/or determined neuronal density in adult animals after they were exposed to anesthesia in the neonatal period. Unfortunately, results from these studies are conflicting. Several studies reported long-term neurocognitive or behavioral abnormalities after exposure of neonates to enflurane, halothane, isoflurane, sevoflurane, propofol, or ketamine, or to a combination of isoflurane, nitrous oxide, and midazolam.\* Importantly, however, many of these studies only observed abnormalities in very specific tests or subsets of neurocognitive batteries, whereas many other neurobehavioral domains remained intact. For example, a 6-hour exposure to midazolam, isoflurane, and nitrous oxide in neonatal rats led to transient impairment in a water maze learning task in young adulthood and in older animals, whereas, in the same animals, several other tests of behavior and learning, including acoustic startle response, sensorimotor tests, spontaneous behavior in an open field, and learning and memory in the radial arms maze, remained unimpaired.<sup>85</sup> Similarly, after a 4-hour exposure to the minimal alveolar concentration (1 MAC) of isoflurane in 7-day-old rats, long-term memory retention was abnormal at two time points, whereas performance at several other time points, as well as in other tests of learning and memory, remained intact.<sup>107</sup> Accordingly, the relevance of these limited learning deficits remains uncertain. Similar to humans, performance of rodents and primates in learning tasks depends to a great extent on maternal behavior and rearing conditions, making them strong confounders during neurocognitive testing.<sup>105,211-213</sup> Moreover, another obvious and important factor in neurocognitive testing is the verification of similar degrees of motivation when comparing separate groups of animals. For example, a 24-hour exposure to ketamine sedation early in life impaired subsequent performance of rhesus monkeys in learning and memory tests, in addition to decreasing their motivation to perform these tasks.<sup>158</sup>

Studies of prolonged opioid administration in immature animals have also found evidence for long-term impairment in learning tasks,<sup>174-176,179-181</sup> as well as altered pain responses in adult animals after exposure to morphine, fentanyl, heroin, or methadone early in life.<sup>†</sup>

Conversely, several other investigations have observed no neurologic abnormalities after administration of midazolam, isoflurane, sevoflurane, or ketamine, even when using complex

neurologic tests in neonatal animals.\* It remains to be determined whether these differential findings are attributable to the anesthetic doses, exposure times, species, or related to the type or timing of the neurologic tests performed. Interestingly, escalating exposure times of isoflurane in neonatal rats caused neuronal apoptosis beginning at 2 hours of anesthesia, but no evidence of long-term neurologic abnormalities until 4 hours of anesthesia.<sup>106</sup> In another study, a 6-hour exposure to isoflurane caused significant apoptosis immediately after exposure in neonatal mice, but resulted in no measurable long-term deficit in performance of complex neurologic tests as adult animals.<sup>105</sup> Moreover, in brain regions significantly affected by the neonatal neuroapoptosis, adult neuronal density was not diminished compared with unanesthetized litter mates.<sup>105</sup> These findings could either suggest that isoflurane may only accelerate physiologic apoptosis or that the developing brain's plasticity and capacity for repair could compensate for a pathologic insult early in life. Conversely, a study in similarly aged rats observed a permanent elimination of neurons, as well as neurologic abnormalities in adult animals, after exposure to isoflurane, nitrous oxide, and midazolam as neonates, suggesting that either the specific combination of anesthetic drugs (isoflurane alone vs. the combination exposure) or species differences (rats vs. mice) could affect any relationships between neonatal neuroapoptosis and long-term function and neuronal density.<sup>97</sup> Alternatively, these conflicting results may be explained by the dissimilar testing environment, because neurocognitive tests are easily transferable among laboratories.<sup>214</sup> On the other hand, neonatal apoptosis may not be causally linked to adult neurocognitive performance at all, as evidenced by substantial apoptosis immediately after carbon dioxide-induced hypercarbia in neonatal rats without long-term neurologic sequelae.<sup>107</sup>

### EFFECTS ON NEUROGENESIS AND GLIOGENESIS

The generation of new neurons, or neurogenesis, as well as new astrocytes, or gliogenesis, is most active in the immature brain in utero or soon after birth. Accordingly, anesthetic exposure during this critical period may interfere with neuronal proliferation, or even eliminate neuronal precursor cells, thereby portending permanent reductions in neuronal density and long-term neurologic impairment. To test this relationship, several studies have investigated the effects of anesthetic exposure, primarily isoflurane, on progenitor viability and rates of neurogenesis. Although isoflurane did not cause neural progenitor cell death *in vitro*, 3.4% isoflurane for 4 hours did decrease the rate of neuronal proliferation and increased neuronal fate selection.<sup>108</sup> These findings were recently confirmed *in vitro*, where 2.8% isoflurane for 6 hours resulted in no effects on neural stem cell viability and larger doses inhibited cell proliferation.<sup>121</sup> Similarly, morphine has been found to decrease DNA synthesis in cerebellar neuronal precursors without affecting cell survival.<sup>170</sup>

Isoflurane also impairs the growth of immature astrocytes and delays their maturation after 24 hours of 3% isoflurane, although this enormous exposure had no effect on cell viability.<sup>119</sup> Morphine, although increasing apoptosis in neurons and microglia, did not affect astrocytes in a study involving human fetal cell cultures.<sup>173</sup>

### ALTERATIONS IN DENDRITIC ARCHITECTURE

The immature brain accumulates an overabundance of neuronal connections in infancy, and the number of dendrites and

\*References 13, 14, 74, 76, 85, 103, 106, 107, 113, 118, 129, 130, 142, 144, 158, 196, 198, 202

†References 77, 81, 82, 161, 162, 177

\*References 72, 96, 105, 106, 115, 117, 132, 141, 145, 166, 196

synapses dramatically decreases after the first year of life. Several studies have examined the effects of propofol, isoflurane, sevoflurane, desflurane, midazolam, and ketamine on dendritic arborization and synaptic architecture.\* A common theme in these studies is that anesthetics can affect dendritic arborization and synaptic density, and that the direction of this change, whether it is an increase or a decrease in the number of dendritic spines, depends on the age at which the animals were exposed to anesthetics, and therefore the developmental state of the brain. During the first 2 weeks of life, the evidence indicates that anesthetic exposure leads to a decrease in synaptic and dendritic spine density in small rodents, while causing an increase in the number of dendrites beyond that age.<sup>110,197</sup> However, the permanence of these changes remains controversial, with some studies only observing a transient effect after ketamine, midazolam, or isoflurane anesthesia early in life.<sup>120,153</sup>

### DECREASE IN TROPHIC FACTORS

Isoflurane- or propofol-based anesthesia in the neonatal animal has been associated with a decrease in brain-derived neurotrophic factor (BDNF),<sup>91,109,198</sup> a protein integral to neuronal survival, growth, and differentiation. The cellular mechanism involves a reduction in tissue plasminogen activator and plasmin, which converts proBDNF to BDNF. Accordingly, isoflurane triggered proBDNF/p75<sup>NTR</sup> (p75 neurotrophin receptor) complex-mediated apoptosis in neonatal mice.<sup>109</sup> Moreover, prolonged exposure to opioid receptor agonists early in life has also been found to alter nerve growth factors in the immature brain.<sup>66,164</sup>

### DEGENERATION OF MITOCHONDRIA

Ultrastructural morphologic abnormalities have been reported in mitochondria of pyramidal neurons in the subiculum of 7-day-old rats after 6 hours of isoflurane, nitrous oxide, and midazolam.<sup>126</sup> A morphometric analysis demonstrated mitochondrial enlargement, impaired structural integrity, and decreased mitochondrial density, indicative of a protracted injury to the mitochondria after anesthetic exposure. Moreover, ultrastructural examination of pyramidal neurons of anesthetized animals by electron microscopy revealed evidence for increased autophagy, a form of cell death.

### ABNORMAL REENTRY INTO CELL CYCLE

Ketamine induces reentry of postmitotic neurons into cell cycle in immature rats.<sup>155</sup> Neuronal progenitor cells enter cell cycle during proliferation, but mature neurons lose this ability, and if they are forced to reenter cell cycle they will follow a path to apoptotic cell death.

### DESTABILIZATION OF THE CYTOSKELETON

The integrity of the cellular cytoskeleton is critical for proper neuronal morphology and function. Actin is one of the major components of the cytoskeleton of all eukaryotic cells, and participates in important cellular processes, including cell signaling, motility, and cell division. It is also essential in the formation of dendritic spines. Isoflurane can lead to depolymerization of actin in neurons and astrocytes, initiating cytoskeletal destabilization, impairment of astrocyte morphologic differentiation and maturation, as well as neuronal apoptosis.<sup>119,123</sup>

### EFFECTS ON THE DEVELOPING SPINAL CORD

Most animal studies have focused on the effect of general anesthetics and sedatives on the developing brain. However, it is important to also consider the developmental impact of anesthetics on the spinal cord. After 6 hours of 0.75% isoflurane with 75% nitrous oxide in 7-day-old rats, neuroapoptosis increased in the lumbar region of the spinal cord.<sup>100</sup> Similar results were reported after 6 hours of isoflurane in a similar model, although 1 hour of isoflurane or spinal bupivacaine resulted in no neuroapoptosis.<sup>124</sup> Intrathecal ketamine causes neuroapoptosis in the developing spinal cord of 3-day-old rats, but not at 7 days of age.<sup>157</sup> Preservative-free ketamine was associated with long-term alterations in spinal cord function and gait disturbances,<sup>157</sup> whereas, in a separate study, even high-dose intrathecal morphine produced no signs of spinal cord toxicity.<sup>215</sup>

### Putative Mechanisms for Neurotoxicity

The exact mechanisms that trigger the above responses to anesthetics and sedatives in the immature brain remain unresolved. Elucidating these mechanisms is critical in order to establish the relevance of these findings for pediatric anesthesia and neonatal critical care medicine, as well as to develop mitigating interventions, if necessary. The current, overarching hypothesis is that anesthetics and sedatives interfere with normal GABA<sub>A</sub> and NMDA receptor-mediated activity, which are the putative targets for unconsciousness, amnesia, and immobility,<sup>216</sup> but are also essential for mammalian central nervous system development.<sup>9,217</sup> Some have suggested that administering GABA<sub>A</sub>-receptor agonists and/or NMDA-receptor antagonists may cause abnormal neuronal inhibition during a vulnerable period in brain development, triggering apoptosis in susceptible neurons, which in turn leads to neurocognitive impairment and decreased neuronal density in adults.<sup>22,60,85,97</sup> Other lines of evidence suggest that the NMDA receptor-blocking properties of ketamine may upregulate NMDA receptors, rendering the neurons more susceptible to excitotoxic injury caused by endogenous glutamate immediately after ketamine withdrawal.<sup>135,139</sup> However, several observations violate both hypotheses; neuronal cell death has been reported during exposure to anesthetics and not only after their discontinuation. Moreover, several anesthetics with minimal NMDA-receptor interaction, such as propofol and barbiturates, have demonstrated robust neurotoxic properties, whereas the neurotoxic potency of the NMDA-antagonist xenon is limited, therefore casting doubt on receptor upregulation being the sole mechanism for anesthetic neurotoxicity. In terms of abnormal neuronal inhibition being the main trigger for apoptosis in developing neurons, GABA<sub>A</sub>-receptor stimulation indeed decreases neuronal activity in the mature brain; however, it also causes excitation in developing neurons,<sup>218</sup> thereby contradicting the inhibition hypothesis. In immature neurons, intracellular chloride (Cl<sup>-</sup>) concentration is high, thus GABA-induced opening of Cl<sup>-</sup> channels allows this anion to exit the cell, leading to membrane depolarization. On the other hand, the intracellular Cl<sup>-</sup> concentration is low in mature neurons. When anesthetics open Cl<sup>-</sup> channels in mature neurons, ions enter the cell, thereby hyperpolarizing the membrane. This reversal of the cellular Cl<sup>-</sup> gradient occurs as a result of a switch from the immature Na<sup>+</sup>-K<sup>+</sup>-2Cl<sup>-</sup> cotransporter 1 (NKCC1) to the mature brain form, K<sup>+</sup>-Cl<sup>-</sup> cotransporter 2 (KCC2).<sup>219</sup> Along these lines, studies in neonatal rats demonstrated excitatory properties in the brain and episodes of epileptic seizures during sevoflurane anesthesia in

\*References 70, 109, 110, 120, 136, 140, 152, 153, 165, 197

neonatal rats.<sup>204</sup> Isoflurane has also been shown to cause an excessive release of  $\text{Ca}^{2+}$  from the endoplasmic reticulum via over-activation of inositol 1,4,5-trisphosphate receptors (InsP3Rs) in neonatal rats in vivo and in vitro.<sup>220</sup> A similar mechanism may be linked to the production of Alzheimer-associated increases in  $\beta$ -amyloid protein levels after anesthesia.<sup>221</sup> Moreover, whereas xenon and hypothermia cause neuronal inhibition, they do not appear to exacerbate isoflurane-induced neuronal cell death, as expected by cumulative neuronal inhibition, but rather significantly reduce it.<sup>94,101,207</sup>

Importantly, evidence indicates that equianesthetic concentrations of the three contemporary inhalational anesthetics cause similar degrees of neuroapoptosis, suggesting that it is the anesthetic depth and not the doses of the anesthetics that determines the cytotoxic potency.<sup>71</sup> However, other studies have failed to link the anesthetic and the apoptotic mechanisms. Specifically, although racemic ketamine and (S)-ketamine both elicit their anesthetic effects via NMDA-receptor blockade, (S)-ketamine induces up to 80% less cell death in vitro when compared with equipotent doses of racemic ketamine.<sup>154</sup> Moreover, concomitant administration of the GABA<sub>A</sub>-receptor antagonist gabazine did not attenuate neuroapoptosis induced by the GABA agonist isoflurane, whereas the  $\alpha_2$ -agonist dexmedetomidine did.<sup>73</sup> Decreases in anesthetic-induced neuronal activity may therefore be less important than the disruption of the neuronal balance of excitation and inhibition, as demonstrated by a series of studies that examined anesthesia-induced dendritic morphologic changes in mice.<sup>70,152</sup> Whereas simultaneous blockade of excitatory and inhibitory activity with tetrodotoxin did not lead to structural changes during synaptogenesis as would have been expected from a causative relationship between neuronal inhibition and structural damage, the administration of either GABA<sub>A</sub>-agonistic or NMDA-antagonistic compounds alone altered synaptogenesis.<sup>152</sup>

It is not entirely clear at this time whether cytotoxicity is a direct effect of the anesthetic itself, or of anesthetic byproducts, or by the metabolic acidosis and respiratory derangements that have been observed during anesthesia in small rodents.<sup>105,107,222</sup> Hypercarbia can trigger widespread neuroapoptosis, even in unanesthetized neonatal rats exposed to increased partial pressures of carbon dioxide. Whereas apoptotic cell death was quantitatively indistinguishable from neurodegeneration in isoflurane-treated litter mates, which were also hypercarbic, adult neurocognitive impairment was only observed in the isoflurane-treated animals.<sup>107</sup>

Lastly, experimental models of neurodegeneration have implicated reentry of postmitotic neurons into the cell cycle, leading to cell death. Ketamine exposure has been found to induce aberrant cell cycle reentry, leading to apoptotic cell death in the developing rat brain.<sup>155</sup>

## Specific Anesthetic and Sedative Agents

In order to provide a succinct overview of the available laboratory data, we briefly review the effects of each class of anesthetics separately. Although the effects of some anesthetics, such as ketamine and isoflurane, have been extensively studied on the developing brain, the effects of others, such as xenon and desflurane, have not. However, the current data suggest that all anesthetics exert deleterious effects to some degree, on the developing animal brain (see E-Table 23-1). It is important to appreciate that although the MAC values for inhalational anesthetics are fairly constant across species, equipotent dosing of intravenous (IV)

medications is not. That is, the dose of most IV medications to effect sedation or anesthesia in animals is approximately 6- to 10-fold greater than that in humans. The dosing is further complicated by the different routes by which drugs are administered in neonatal animals, which include the subcutaneous and intraperitoneal (IP) routes, as opposed to the oral or IV routes in humans. The possible importance of the interspecies differences in the pharmacology of IV medications on neuroapoptosis and cognitive dysfunction has not been addressed.

### KETAMINE

Possibly the most frequently studied anesthetic is ketamine, an antagonist of the NMDA and glutamate receptor that also interacts with other cell membrane proteins, such as muscarinic and opioid receptors, as well as voltage-gated calcium channels. Ketamine's properties, which include potent analgesia, dissociative anesthesia, and relative hemodynamic stability, have made it a popular choice for procedural sedation in children, as well as for induction of anesthesia in children with critical congenital heart disease or pulmonary hypertension.<sup>223-225</sup> However, about 10 years ago, a seminal study that examined the effects of repeated IP injections of ketamine on the brain of neonatal rats observed widespread apoptosis.<sup>17</sup> Seven injections of 20 mg/kg of ketamine, administered over a 9 hour period in evenly divided intervals, to 7-day-old rat pups caused a 3- to 31-fold increase in degenerating neurons, depending on brain region. This led to speculation that these changes might contribute to neuropsychiatric disorders.<sup>17</sup> These initial findings for ketamine have been confirmed in more than fifty studies in small rodents, as well as nonhuman primates, both in vitro and in vivo (see E-Table 23-1). Several of these studies have identified relationships between neurodegeneration and dose, duration of treatment, as well as animal species and age during exposure. Single doses of up to 75 mg/kg or multiple IP injections up to 17 mg/kg/hr for 6 hours were not neurotoxic to neonatal rat brains,<sup>128</sup> whereas single doses between 20 and 50 mg/kg were neurotoxic to neonatal mice brains.<sup>74,134</sup> Six or seven repeated injections of 20 to 25 mg/kg consistently cause apoptosis in neonatal rat brains.<sup>17,128,131,149,150</sup> Although the doses of ketamine in these small-animal models appeared to be excessive and plasma concentrations in the rodents were up to 7 times greater than those in humans,<sup>131</sup> these increased doses are consistent with the requirements for IV anesthesia in small animals (refer to later section on interspecies comparison). Coadministration of midazolam, diazepam, propofol, or thiopental compounded the neuronal injury caused by ketamine.<sup>74,134,142</sup> Studies in rats, mice, and nonhuman primates suggest that the susceptibility to ketamine-induced neurotoxicity is limited to a brief period after birth, with a maximum impact between 3 and 7 days of age in small rodents and less than 35 days of age in monkeys.<sup>17,139</sup> Beyond these ages, ketamine-induced neuroapoptosis subsides. In addition to apoptosis, both small rodents and nonhuman primates that were anesthetized with ketamine have exhibited impaired learning tasks later in life.<sup>129,130,158</sup>

In summary, ketamine is the most frequently studied anesthetic, in terms to its neurotoxic effects, and has repeatedly been shown to cause widespread apoptosis (an effect that is exacerbated by the coadministration of other anesthetics), as well as neurologic impairment in adult animals exposed early in life. Importantly, long-lasting learning impairment has been demonstrated in nonhuman primates, the closest animal model to humans.<sup>158</sup> However, these animals were anesthetized with

ketamine for 24 hours to produce this effect, a duration that exceeds the usual clinical scenario. Furthermore, it is unclear whether the observed learning abnormalities could not be explained by a reduction in motivation to perform the learning tasks.<sup>158</sup>

### INHALATIONAL ANESTHETICS

The second most commonly studied class of drugs is the inhalational anesthetics (see E-Table 23-1). The anesthetics desflurane, sevoflurane, isoflurane, enflurane, and halothane exert their anesthetic properties predominantly by their agonistic effects on the GABA<sub>A</sub> receptor, but also by differing degrees on glycine, NMDA, acetylcholine, serotonin (5-HT<sub>3</sub>),  $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA), and kainate receptors. Whereas GABA represents the main inhibitory neurotransmitter in the adult central nervous system, it has excitatory properties in the developing brain,<sup>218</sup> which may have implications for neurotoxicity, as discussed previously. Most studies of inhalational anesthetics examined either isoflurane alone or a combination of midazolam, isoflurane, and nitrous oxide. This combination of GABA agonists and NMDA antagonists has been repeatedly found to cause widespread increases in brain cell degeneration in neonatal animals.<sup>85,87,91,92</sup> In addition to the immediate deleterious effects on brain structure, long-term abnormalities in spatial learning tasks and decreased neuronal cell density in adult rats have been observed after exposure to this anesthetic combination early in life.<sup>85,97</sup> One MAC of isoflurane administered as the sole anesthetic for 4 hours to neonatal rats led to neurocognitive deficits in rats when they matured to adults,<sup>106,107</sup> whereas up to 0.6 MAC for 6 hours in neonatal mice, while causing widespread neuronal degeneration immediately after exposure, failed to cause neurocognitive deficits or decreases in neuronal density in adulthood.<sup>105,115</sup> These inconsistent findings raise the question of whether neonatal neuronal apoptotic cell death is linked directly to behavioral and learning abnormalities in adulthood. Neuronal cell death has also been observed in neonatal rhesus monkeys after 5 hours of 0.75% to 1.5% isoflurane,<sup>114</sup> although long-term neurologic studies in this species have not yet been published.

Similar to isoflurane, sevoflurane has also been shown to induce neuroapoptosis in neonatal mice,<sup>71,115,202</sup> although the long-term effects on learning and behavior are conflicting.<sup>72,115,202</sup> To date, few studies have examined desflurane in this context. Desflurane causes age- and species-dependent neuronal cell death in 7-day-old mice, but not 16-day-old rats.<sup>70,71</sup>

Few studies have compared the neurotoxicity of contemporary anesthetics. At equianesthetic concentrations of desflurane, isoflurane, and sevoflurane in neonatal mice, the degree of neuronal degeneration in the superficial neocortex, a brain region significantly affected in this model, is similar.<sup>71</sup> These results contrast with those from a study of lower concentrations of sevoflurane and isoflurane, in which cell death was less after the former than the latter, but without differences in neurocognitive performance in adult rats.<sup>115</sup> In another comparative mouse study, desflurane caused a greater degree of neurodegeneration than isoflurane and sevoflurane, and long-term neurologic impairment only occurred after desflurane.<sup>72</sup> The significance of these differential findings remains unknown, but could be related to methodologic differences.

Although largely phased out from clinical pediatric anesthesia practice, halothane and enflurane have been shown to induce brain abnormalities. These anesthetics were studied in models of

intermittent or chronic occupational exposure during pregnancy, and caused subsequent delayed synaptogenesis and behavioral and learning abnormalities in rats after fetal exposure.<sup>13-16,76</sup>

In summary, inhalational anesthetics represent one of the most frequently used classes of anesthetics in pediatric anesthesia, and their neurotoxic properties have been extensively studied. Consistent findings include widespread apoptosis immediately after exposure in a wide variety of animal models, including nonhuman primates. However, neurologic impairment in adult animals exposed early in life to anesthesia has not been a consistent finding, and in fact some studies have found no neurologic impairment at all. Therefore long-lasting learning impairment has not been convincingly linked to neonatal neuroapoptosis. Primate studies on long-term neurocognitive outcomes after inhalational anesthesia early in life have not yet been published.

### NITROUS OXIDE

Nitrous oxide, an NMDA antagonist, is the oldest anesthetic in clinical use, although its low potency (MAC of 115% in adult humans) necessitates the coadministration of other anesthetics to provide surgical anesthesia. Anesthetic combinations with nitrous oxide often include the GABA agonist midazolam, and the mixed GABA-agonist/NMDA-antagonist isoflurane.\* In rats, nitrous oxide alone did not induce neuronal apoptosis,<sup>85,87,94</sup> whereas in an *in vitro* study, it did cause neuronal cell death in mouse hippocampal slices.<sup>94</sup> When administered in combination, however, nitrous oxide has been shown to exacerbate neuronal cell death induced by isoflurane, and also to contribute to long-term neurologic abnormalities in rats when combined with isoflurane and midazolam.<sup>85</sup>

### XENON

Due to the cost differential between other inhalational anesthetics and this rare, colorless, and odorless noble gas, xenon has not reached widespread clinical anesthesia practice, despite its NMDA-antagonistic, anesthetic properties.<sup>226</sup> Xenon has a relatively low anesthetic potency, with a MAC measuring between 65% and 70% in adults<sup>227,228</sup>; its low blood-gas solubility speeds emergence from anesthesia.<sup>229</sup> Xenon's effects on neuronal apoptosis have been examined by two groups, with slightly differing results. Although 75% xenon for 6 hours did not cause neuronal apoptosis in 7-day-old rat pups,<sup>94</sup> 70% xenon for 4 hours did increase neuroapoptosis in 7-day-old mice.<sup>207</sup> Interestingly, both studies demonstrated that xenon decreased the neurodegeneration induced by isoflurane anesthesia,<sup>94,207</sup> which may have relevance to the phenomenon's putative mechanism, as discussed.

### BENZODIAZEPINES

Benzodiazepines, such as clonazepam, diazepam, and midazolam, have been investigated regarding their effects on the immature brain, either alone or in combination with other drugs. These GABA agonists are frequently used in toddlers and older children for preoperative anxiolysis, but infrequently in neonates and infants. Studies have shown that they increase neuronal degeneration in small-animal models, depending on the dose, region of the brain, species, and age of the animal. Although single doses of 5 mg/kg of diazepam or 9 mg/kg of midazolam IP did not increase neuronal cell death in neonatal rats,<sup>68,85</sup> 5 mg/kg

\*References 79, 85, 87, 91, 92, 97, 98

subcutaneous diazepam did cause neuronal cell death in some brain regions in mice, though this was not associated with learning deficits in adults.<sup>74</sup> In these studies, the neuroapoptosis associated with diazepam was significantly augmented by the coadministration of other sedatives, such as ketamine.<sup>74</sup> Studies have consistently reported increased neuroapoptosis in neonatal rats after diazepam in doses of 10 mg/kg or greater,<sup>68,69</sup> an effect that was prevented by the coadministration of the benzodiazepine-antagonist flumazenil in one study.<sup>68</sup> Two studies reported no neurocognitive learning disabilities in adult mice after they were sedated with diazepam or midazolam as neonates.<sup>74,166</sup>

### CHLORAL HYDRATE

The sedative chloral hydrate, a chlorination product of ethanol that is a GABA agonist as well as NMDA antagonist, has been largely supplanted by barbiturates and benzodiazepines in pediatric clinical practice. However, it is still being used in doses of up to 120 mg/kg for sedation for radiology studies,<sup>230</sup> and its neurotoxic properties have been investigated. Preliminary results indicate that it causes neuroapoptosis in the cerebral cortex and the caudate-putamen complex in immature mouse pups in doses of 100 mg/kg or greater.<sup>67</sup> The neurofunctional outcome in adult mice, however, has not as yet been investigated.

### BARBITURATES

Barbiturates act largely via the GABA<sub>A</sub> receptor, but also exert effects via nicotinic acetylcholine, AMPA, and kainate receptors. Thiopental alone, in doses of 25 mg/kg subcutaneously in neonatal mice, did not induce apoptosis, although when doses of 5 mg/kg were administered in conjunction with 25 mg/kg of ketamine subcutaneously, neuronal degeneration occurred and was associated with long-term impairment of learning and memory.<sup>142</sup> Pentobarbital and phenobarbital have been shown to induce neurodegeneration in mouse and rat pups. Furthermore, after receiving these sedatives as neonates, long-term alterations in brain protein expression and learning and memory have been observed,<sup>103,184,186</sup> although in one study these long-term alterations may be attributed in part to hypoxia and hypercarbia during the neonatal sedation.<sup>184</sup> Interestingly, estradiol has been shown to attenuate phenobarbital-induced neuroapoptosis.<sup>68,185</sup>

### PROPOFOL

In recent years, propofol has supplanted the barbiturates as the IV induction agent of choice in children. Propofol predominantly acts via GABA and glycine receptor-agonistic properties, but also weakly on nicotinic, AMPA, and NMDA receptors, and has been repeatedly studied regarding its neurotoxic profile, both in vitro and in vivo. The overall consensus of this body of literature is that propofol, in a dose- and exposure time-dependent fashion, has dramatic effects on the developing brain in animals. Propofol has consistently caused neuroapoptosis after doses exceeding 50 mg/kg (subcutaneous or IP) or repeated doses exceeding 20 mg/kg/hr for 4 to 5 hours in neonatal small rodents.<sup>142,148,191,196</sup> Interestingly, lithium protected from propofol-induced neuroapoptosis in neonatal mice.<sup>148</sup> However, after 24 hours of IV anesthesia with propofol (6 mg/kg/hr) and fentanyl (10 µg/kg/hr), there was no evidence of apoptosis.<sup>192</sup> Apart from overt neuronal cell death, propofol decreases the GABAergic enzyme glutamic acid decarboxylase,<sup>188</sup> decreases nerve growth factors,<sup>194,198</sup> and causes neurite growth cone collapse in tissue culture.<sup>190</sup> In addition, propofol alters dendritic spine architecture in developing rats, depending on the age at

the time of anesthetic exposure.<sup>197</sup> For example, dendritic spine density decreased if the rat was anesthetized during week 1 of life, but it increased spine development if exposure took place during week 3 of life; the mechanism of these differing responses remains elusive.<sup>197</sup>

### DEXMEDETOMIDINE

Unlike other anesthetics and sedatives, dexmedetomidine is a sedative and analgesic that does not interact with GABA, NMDA, or opioid receptors, but rather acts by stimulating presynaptic  $\alpha_2$ -adrenergic receptors. Given this different mechanism of action, it is interesting that dexmedetomidine, administered in three IP injections of 1 to 25 µg/kg at 0, 2, and 4 hours to 7-day-old rat pups, did not cause neuronal apoptosis, but attenuated isoflurane-induced neuroapoptosis. Even a dose of 75 µg/kg dexmedetomidine (75-fold greater than the median effective dose needed for sedation), did not cause apoptosis in this model. Furthermore, dexmedetomidine prevented the long-term cognitive impairment from isoflurane.<sup>73</sup>

### OPIOID ANALGESICS

To date, only one study investigated neurotoxic properties of opioids in relation to an inhalational anesthetic regimen. Mechanically ventilated, neonatal pigs, sedated with an IV bolus of 30 µg/kg fentanyl followed by 15 µg/kg/hr for 4 hours, exhibited significantly less neuroapoptosis in several regions of the brain, compared with an intramuscular injection of 1 mg/kg of midazolam, followed by 4 hours of 0.55% isoflurane and 75% nitrous oxide.<sup>79</sup> These initial findings are interesting, although future neurotoxicity studies that include opioid infusions need to also include adjuvants that produce amnesia, as is customary in pediatric anesthesia practice. Moreover, when comparing different anesthetic regimens regarding their neurotoxic potential, equianesthetic potency should be established during the study.

Importantly, however, the long-term consequences of opioid administration to the immature brain needs to be further elucidated before recommending such a regimen as an alternative strategy. Similar to GABA and NMDA receptors, opioid receptors are also intimately involved in early brain development and synaptogenesis,<sup>231,232</sup> which would make it plausible that opioids could similarly affect brain development during the critical period of synaptogenesis. Increased neuronal cell death and decreased neuronal density after perinatal exposure to opioid receptor agonists, such as morphine and heroin, have been observed in developing animals.<sup>82,83,233</sup> Chronic buprenorphine and methadone treatment early in life have been found to diminish concentrations of nerve growth factors in the immature brain.<sup>66,164</sup> Moreover, immediate and permanent reductions in  $\mu$ -opioid receptor density have been observed after perinatal exposure to morphine,<sup>168,169</sup> and may be associated with long-term impairment of memory and cognitive function in small animals,<sup>171,174-176,179-181</sup> as well as exaggerated nociceptive responses to a pain challenge later in life.<sup>177,182</sup> Stimulation of the  $\kappa$ -opioid receptor may amplify neuronal cell death induced by proapoptotic agents.<sup>234</sup> High-dose fentanyl has been shown to significantly exacerbate white-matter brain lesions induced by glutamatergic overstimulation in mice.<sup>78</sup> All these animal data suggest that prolonged perinatal exposure to opioids may have immediate and long-term effects on the developing brain and may amplify proapoptotic stimuli, although the effects of a brief or single dose exposure to opioids is not well understood.

These data suggest that further studies into the interactions of opioid analgesics and anesthetics in the developing brain are warranted.

## Exposure Time, Dose, and Anesthetic Combinations

Neuronal injury depends on the anesthetic dose and/or duration of anesthesia for inhalational anesthetics, and the dose, route of administration, and the number of doses for injectable anesthetics. Moreover, combinations of several anesthetics and sedatives have, in general, caused more neuroapoptosis and long-term cognitive changes than have single drugs. For example, combinations of midazolam, nitrous oxide, and isoflurane cause a much greater degree of neuroapoptosis in neonatal rats than isoflurane alone, even when the latter is administered at a greater inspired concentration.<sup>85</sup> In the case of ketamine, its neurodegenerative potency is amplified when coadministered with thiopental or propofol.<sup>142</sup> Anesthetic combinations of mixed GABA agonists and NMDA antagonists demonstrate exaggerated effects. This evidence supports the notion that a deeper level of anesthesia increases the neuroapoptotic injury. However, two anesthetics, xenon and dexmedetomidine, which actually attenuate the neurotoxic effects of isoflurane anesthesia,<sup>73,94,207</sup> do not lend support to this notion.

## Deleterious Effects of Untreated Pain and Stress

Given the evidence for deleterious effects of anesthetics and analgesics on the developing brain and the paucity of complete anesthetics devoid of cytotoxicity, would children fare better by withholding potentially toxic drugs and allowing them to experience the pain and stress of surgery? Of course such a practice would be unethical, and there is a plethora of evidence of the deleterious effects caused by the stressful conditions of exposing the immature nervous system to recurrent painful stimulation. Noxious stimulation in the neonate has been associated with subsequent hyperalgesia or hypoalgesia, depending on the type and severity of injury.<sup>235</sup> Repetitive painful skin lacerations for procedures as minor as blood draws in neonates have been found to lead to long-term, local sensory hyperinnervation.<sup>236</sup> In addition to these local responses, repetitive, inflammatory pain early in life has been found to result in hyperalgesia and lasting changes in nociceptive circuitry of the adult dorsal horn.<sup>237</sup> Repeated painful injections into the paws of rat pups resulted in a generalized thermal hypoalgesia.<sup>235</sup> In addition to altered pain processing and sensory perception, repetitive or persistent pain in the neonate alters behavior and cognitive function in adulthood, decreases pain thresholds, and increases vulnerability to stress and anxiety disorders or chronic pain syndromes later in life.<sup>141,238-241</sup>

In addition to painful stimulation, early adverse emotional experiences can also induce long-lasting abnormalities, such as imbalances of the inhibitory nervous system,<sup>242</sup> impairment of normal development of the nociceptive system, long-term behavioral changes,<sup>243</sup> and persistent learning impairment.<sup>179</sup> Therefore fetuses, neonates, and infants subjected to pain and stresses associated with invasive procedures without adequate anesthesia and analgesia may be at risk for long-term adverse outcomes.

Accordingly, preemptive administration of analgesics and sedatives, such as morphine or ketamine, has been found to ameliorate the deleterious effects of neonatal pain in some of the animal studies.<sup>141,179,241</sup> However, either the presence of painful stimulation or 5 days of morphine administered to neonatal mice independently impaired adult rewarded behavior, although the combination did not.<sup>179</sup>

Clinical reports have also demonstrated that human neonates and infants can mount a metabolic and endocrine response to perioperative stress and painful stimulation, which include surges in catecholamine, cortisol,  $\beta$ -endorphin, insulin, glucagon, and growth hormone levels.<sup>244-246</sup> Some of these markers, such as cortisol, remain increased for more than a year after the insult, possibly as a result of cumulative stress related to multiple painful procedures early in life.<sup>247</sup> Inhalational anesthetics, opioid analgesics, as well as regional anesthesia, inhibit intraoperative stress and improve postoperative outcomes.<sup>245,248,249</sup> Moreover, adequate perioperative anesthesia reduced the incidence of other complications, such as the incidence of sepsis and disseminated intravascular coagulation, that led to a decrease in overall mortality.<sup>250</sup> Even less invasive procedures, such as circumcisions performed without analgesia in young boys, can exaggerate responses to painful challenges (e.g., immunizations) later in life.<sup>251</sup> Conversely, topical or regional anesthesia for circumcision blunts not only the immediate humoral stress response during the procedure,<sup>252</sup> but also pain-induced, long-term hyperalgesia.<sup>251</sup> In preterm neonates, painful stimulations early in life have also been associated with subsequent diminished cognition and motor function.<sup>253</sup> In a retrospective study of children greater than 1 year of age who were born at less than 32 weeks gestational age without significant neonatal brain injury or major sensorineural impairment, the more skin-breaking procedures from birth to term (including heel sticks, intramuscular injections, chest tube placements, and central line insertions) predicted poorer subsequent cognitive and motor development (as assessed using the Bayley Scales of Infant Development II) when compared with term controls. Importantly, after controlling for severity of illness, duration of morphine administration, and exposure to postnatal dexamethasone, gestational age at birth was not significantly associated with cognitive or motor outcome. These findings suggest that repetitive pain-related stressful experiences and not prematurity per se was responsible for the poor neurodevelopmental outcome.<sup>253</sup> Although this study did not examine the effects of anesthetic or analgesic administration during painful stimulation on subsequent outcome, a small, retrospective study suggested an improvement in outcome after administering anesthesia during painful stimulation.<sup>254</sup> Painful stimulation during reduction of herniated bowel without anesthesia in infants suffering from gastroschisis tended to more frequently lead to serious adverse events, such as bowel ischemia, need for total parenteral nutrition, and unplanned reoperation, than in infants undergoing the same procedure with general anesthesia.<sup>254</sup> However, despite persistently large numbers of painful and stressful procedures performed in vulnerable neonates, data indicate that the majority of these procedures are still not accompanied by adequate analgesia or anesthesia.<sup>255</sup>

Together, the data from animals and humans suggest that pain-related stress experienced early in life is deleterious to the developing nervous system, that pain in children remains undertreated, and that analgesics and/or anesthetics may alleviate many of the degenerative effects of unopposed pain and improve outcome. If anesthetics protect from the deleterious effects of

painful stimulation, but confer their own cytotoxic adverse effects, the major question remains whether other compounds can alleviate these adverse effects.

## Potential Alleviating Strategies

Whereas the translational relevance of anesthetic-induced neurotoxicity in neonatal animals to humans remains unresolved, several laboratory studies have tested strategies to alleviate some of the deleterious effects of anesthetics and sedatives in animals. These have been directed at both the immediate effects after anesthesia, such as neuronal cell death, as well as long-term abnormalities, such as neurocognitive impairment. Importantly, many studies administered adjuvants immediately before or during anesthesia, thereby maintaining an adequate level of anesthesia and analgesia to avoid the deleterious effects of unopposed pain.

The sedative dexmedetomidine and the anesthetic xenon possess very limited neurotoxic potencies themselves, but dramatically reduce isoflurane-induced neuroapoptosis.<sup>73,94,207</sup> In addition, the coadministration of dexmedetomidine prevents long-term memory impairment after 6-hour isoflurane exposure in rats.<sup>73</sup> Interestingly, neuroprotective preconditioning has been demonstrated in pheochromocytoma PC12 cells in which pretreatment with a small concentration of isoflurane prevented the neurotoxic response to a subsequent greater dose.<sup>95</sup> In vitro studies, the inositol triphosphate-receptor antagonist xestospongin C, tissue plasminogen activator, plasmin, inhibition of the neurotrophic receptor p75<sup>NTR</sup> and the RhoA receptor, or prevention of cytoskeletal depolymerization with either jasplakinolide or TAT-Pep5 significantly attenuated isoflurane-mediated neuroapoptosis.<sup>104,109,123</sup> In addition, L-carnitine attenuated neuronal apoptosis after 6 hours of isoflurane and nitrous oxide in 7-day-old rat pups.<sup>102</sup> Supplementation with the naturally occurring hormones  $\beta$ -estradiol or melatonin prevented the deleterious effects on neuronal survival of a prolonged exposure to midazolam, isoflurane, and nitrous oxide.<sup>87,91</sup> Similarly, coadministration of  $\beta$ -estradiol significantly reduced phenobarbital-induced neuroapoptosis.<sup>68,185</sup> The only potentially protective agent that has been unsuccessfully tested in published studies is the GABA antagonist gabazine.<sup>73</sup> On the other hand, pilocarpine reduces neuroapoptosis induced by the GABA agonists isoflurane and midazolam, while augmenting the damage after administration of the NMDA antagonist phencyclidine, based on preliminary results from neonatal mice.<sup>93</sup> Preliminary data from the same laboratory also suggest that whole-body hypothermia with a targeted brain temperature of less than 30° C may protect from the neuroapoptotic ramifications of a 4-hour exposure to 0.75% isoflurane or to 40 mg/kg of IP ketamine in neonatal mice.<sup>41,101</sup> Another therapy that has been successfully tested in mouse pups that received 40 mg/kg of ketamine or 100 mg/kg of propofol was lithium, 3 to 6 mEq/kg subcutaneously, which abolished the anesthetic-induced neuroapoptosis in cortex and the caudate-putamen complex.<sup>148</sup>

Because the applicability and extent of anesthetic neurotoxicity has not been established in humans, it is obviously premature to recommend any of these protective strategies for children. Moreover, the safety of many of these drugs and interventions has not been established in human neonates and infants. Tissue plasminogen activator and plasmin promote fibrinolysis and may not be first-line treatments during invasive surgical procedures. The sex hormone  $\beta$ -estradiol may not be a feasible adjuvant in prepubescent boys. The safety of pilocarpine in young children

may be hampered by its proconvulsant activity observed in animal studies.<sup>256,257</sup> Lithium has been labeled harmful to the human fetus and may cause neurocognitive impairment in young children.<sup>258-260</sup> Whole body hypothermia below 30° C may not be a clinically feasible modality because even mild perioperative hypothermia, at least in adults, has been causally linked to numerous complications, including increased blood loss and transfusion requirements, morbid myocardial outcomes, prolonged postanesthetic recovery and hospitalization, thermal discomfort, as well as an increased risk of surgical wound infections.<sup>261</sup> Therefore hypothermia to treat anesthesia-induced neurotoxicity is unlikely to play a substantive role during routine pediatric anesthesia, but may have a role in infants undergoing hypothermic cardiopulmonary bypass for heart surgery to treat congenital defects. Unfortunately, the latter population often presents with neurocognitive abnormalities before anesthesia.<sup>262</sup> Although xenon's scarcity renders it a very expensive anesthetic, dexmedetomidine's wider availability and increased usage in pediatric anesthesia makes it a more attractive option for further research into protective strategies.<sup>263,264</sup>

## Anesthetic Neuroprotection

Even relatively brief periods of inadequate oxygen or blood flow to the brain may lead to neuronal injury and long-term neurologic impairment, because of the limited tolerance of the brain to ischemia. Importantly, animal studies have repeatedly confirmed the protective properties of anesthetics when administered during episodes of brain hypoxia-ischemia. However, most of these studies have been conducted in adult animals.<sup>265</sup> In immature animal models, anesthetics have also been found to reduce neurologic injury and improve functional outcome after brain ischemia. Desflurane alleviates neuronal cell death and early neurologic dysfunction in a model of the neonatal pig during hypothermic cardiopulmonary bypass and deep hypothermic circulatory arrest.<sup>266,267</sup> Isoflurane treatment before hypoxia-ischemia protects the brain and improves survival in neonatal rats and mice.<sup>268-270</sup> Both xenon and sevoflurane protect the immature brain during simulated hypoxia-ischemia in an in vitro model.<sup>271</sup> Furthermore, sevoflurane may be protective in a neonatal mouse in vivo model.<sup>272</sup> These findings in immature animals suggest that critically ill human neonates could potentially benefit from these protective properties during clinical scenarios of neurologic injury, such as cardiopulmonary bypass, neurologic surgery, or perioperative cardiocirculatory arrest; these potential benefits need to be weighed against the potential neurotoxic properties of the current anesthetics.

## Critical Evaluation of Animal Studies and Interspecies Comparisons

To determine whether the findings from animal studies should guide clinical practice, it is important to rationally evaluate how well animal studies represent the human clinical scenario.\*

To date, no animal model has been developed that covers all aspects of human physiology and pathophysiology during surgical procedures. The task of modeling potential vulnerabilities of the developing human brain in animals is complicated by the

\*References 2, 22, 85, 105-107, 158, 273-278

fact that human CNS development is much more protracted than that of any of the model species. However, human neurocognitive performance is also much more complicated compared with lower animals, and therefore a potential injury might have a greater impact in such a complex system.

### DURATION OF EXPOSURE

In order to elicit toxic effects, the designs of many animal studies include durations of anesthesia from 1 to 24 hours. Accordingly, some of these times may extend well beyond the average time of routine pediatric anesthesia. However, expressing the duration of anesthesia as a fraction of a subject's life span, thereby equating a 6-hour anesthetic in mice to a 2-week or greater anesthetic in humans, is probably an oversimplification. The duration of neurodevelopment may not be immediately relevant when considering the likelihood of injury at a cellular level. Nonetheless, the extent of the injury and its functional implications may potentially be related to the duration of the entire brain developmental period, even though the mechanism of anesthetic-induced neurodegeneration is unknown. Because human brain development occurs at a much slower pace than in any of the other species, similar exposure times could have different effects on potential susceptibility and the ability for postexposure repair among species. For example, the brain reaches adult size at 20 days of age in rats, 3 years of age in rhesus monkeys, 7 years of age in chimpanzees, and not until 15 years of age in humans.<sup>2,279,280</sup>

Exposure to anesthesia during a larger proportion of the period of development could be expected to have a greater impact on total development and maturation. Similarly, given the plasticity of the developing brain, it seems conceivable that brains with slower growth rates possess more time for repair.<sup>281,282</sup> Conversely, in complex organisms, such as humans, relatively minor degrees of injury in crucial areas and at crucial times during development could have relatively profound long-term effects.

### ANESTHETIC DOSES

In all animal studies, doses needed for injectable anesthetics to cause neuronal degeneration were greater, sometimes by orders of magnitude, when compared with weight-based doses commonly used in human clinical practice. However, to produce immobility, small animals also required significantly greater doses of IV anesthetics than larger animals. Due to their smaller size, greater metabolic rate, and shorter physiologic time, drug doses in animals significantly differ from those used in humans.<sup>283</sup> Using a process called allometric scaling, which takes these species differences into account, animal drug doses comparable to human doses have been estimated to be approximately three-, six-, or twelvefold greater, respectively, for monkeys, rats, or mice (see also Chapter 6).<sup>283,284</sup> Whereas drug doses used in anesthetic neurotoxicity studies frequently still exceed these doses calculated using allometric scaling, they do not include a significant safety margin (Fig. 23-3). Moreover, using allometrically scaled

**FIGURE 23-3** Neurodegenerative effects of injectable anesthetics in developing animals are dose-dependent. Blue bars represent doses of the respective anesthetics not causing neurodegeneration in rats and mice; pink bars represent doses causing neurodegeneration in animals. Figure includes only studies using single injections of anesthetics and doses used in animals were scaled to doses for children by using an allometric scaling technique, based on calculations outlined in reference 284. Neurotoxic data are based on experiments described in references 17, 68, 69, 74, 85, 128, 131, 134, 139, 142, 151, 194.

doses, plasma concentrations for ketamine, for example, were approximately 3 to 10 times greater in small rodents and monkeys than those observed during clinical human practice.<sup>131,139</sup> This suggests that the neurotoxic properties observed with large doses of injectable anesthetics, such as ketamine, would only have direct applicability to humans if the anesthetic and the neurotoxic effects were based on the same molecular mechanism, which has yet to be verified. Otherwise, animal studies would expose subjects to much greater plasma concentrations of a neurotoxicant than those used during anesthesia in humans, thereby leading to an overestimation of the neurotoxic effects of IV anesthetics in laboratory studies.

Doses for inhaled anesthetics generating immobility in animals, on the other hand, are much closer to clinically used doses. Moreover, similar to human anesthesia, potency of inhaled anesthetics increases with subject age, necessitating larger doses in younger animals,<sup>71,222,285</sup> which could suggest closer applicability of laboratory data to humans.

### EXPERIMENTAL VERSUS CLINICAL CONDITIONS

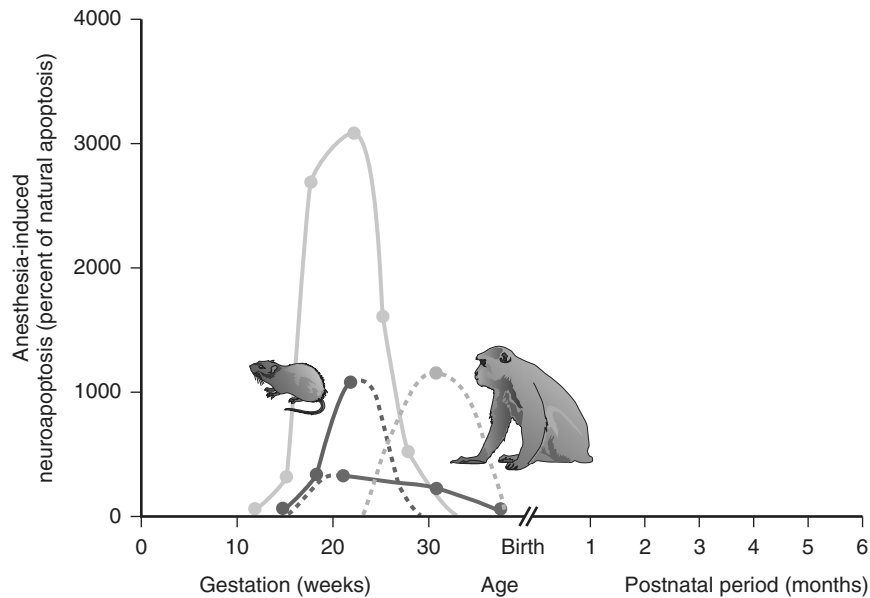

Another important distinction between laboratory studies in animals and clinical studies in humans is the presence of significant comorbidities, such as the presence of stress and pain associated with the underlying disease that require the administration of anesthetics and analgesics. Very few of the laboratory studies to date have included the presence of surgical stress that may increase or decrease the degree of anesthesia-induced neurotoxicity. Tail clamping or injection of caustic substances are used as a model for surgical stress. Results from these studies varied: one study reported no influence of the painful stimulus on anesthesia-induced apoptosis,<sup>206</sup> whereas a second reported that painful stimulation increased anesthetic-induced neuroapoptosis.<sup>127</sup> In contrast, therapeutic effects have been demonstrated with concomitant administration of small doses of analgesics or sedatives, compared with no analgesia or sedative when pain was induced.<sup>141,179</sup>

When studies measured metabolic and respiratory effects of anesthetic exposure in small rodent species, several demonstrated significant differences from pediatric anesthesia practice, such as extensive hypercarbia, metabolic acidosis, and hypoglycemia observed in the small rodents.<sup>105,107,222</sup> Tracheal intubation and mechanical ventilation do not seem to completely obviate these abnormalities.<sup>222</sup> In stark contrast to anesthesia in children, administering clinical doses of anesthetics for as little as 2 to 4 hours can be lethal for more than 20% of small rodents,<sup>105</sup> even when intermittent painful stimuli were applied.<sup>107</sup> Moreover, rearing conditions after anesthesia have a profound impact on the brain's repair mechanisms after injury. Environmental enrichment and exercise dramatically increase neurogenesis in rodents and therefore may facilitate plasticity and repair after anesthesia, compared with regular cage housing conditions.<sup>286,287</sup> Children face daily cognitive challenges in their "enriched" environment, different from laboratory animal housing,<sup>79,114,139,158</sup> that could attenuate the postulated neurocognitive effects of anesthesia. This is highlighted in a recent study in which environmental enrichment reversed the deleterious effects of anesthesia on subsequent neurologic performance in rats, resulting in performance similar to environmentally enriched, unanesthetized animals and superior to unenriched control and anesthesia-exposed animals.<sup>206</sup> This study suggests that neurobehavioral outcome depends on multiple factors and that anesthesia may be only one minor insult compared with the many other more significant events in childhood.

### COMPARATIVE BRAIN DEVELOPMENT

A major obstacle in translating animal data to humans centers on the difficulties of matching up brain maturational stages in model animals with the equivalent stages of the immature human brain. The ongoing discussion regarding these comparisons is somewhat reminiscent of the cliché of 1 "dog year" being equivalent to 7 "human years." Because animal studies have suggested that anesthesia-induced neuroapoptosis may be limited to very defined, early stages of development, such as from 3 to 10 days of age in small rodents,<sup>17,87</sup> it becomes imperative to identify the equivalent period during human brain development, in order to assess human applicability of the animal data and to adequately plan clinical studies.

Brain architecture and development, however, are not easily compared among mammalian species. Small rodents, such as mice and rats, have a smooth (or lissencephalic) brain surface, whereas humans and monkeys exhibit the typical fissured, gyrencephalic brain surface of gyri and sulci. Overall brain size and number of neurons are vastly different between humans and animal species. Moreover, brain development varies dramatically in terms of timing and duration. Whereas considerable brain development takes place postnatally in rodents, most critical steps in humans occur in utero.<sup>273</sup> It has generally been accepted that mice and rats are born at relatively earlier stages of brain maturity compared with humans, but that neurodevelopment in small rodents rapidly catches up with humans, mostly during the first 2 to 3 weeks of the rodent's life. Older data based on simple estimations of brain cell numbers and degree of myelination have been interpreted to mean that the first week of life in small rodents, when the peak of vulnerability to anesthetic neurotoxicity occurs, equates to an extended time span in humans, from the third gestational trimester all the way to the third year of life.<sup>2,22,274</sup> However, more contemporary approaches, including computational models, have approximated the 7-day-old rat to be closer in brain maturity to human fetuses at 20 to 22 weeks gestation, and the immature rhesus monkey to approximate the immature human brain closer to term (Fig. 23-4).<sup>275-277,288</sup> According to these models, stages of brain maturity equivalent to term human neonates are not reached until after postnatal day 14 in rats or mice (online calculator available at <http://www.translatingtime.net>, accessed January 23, 2012). Therefore it remains questionable whether rodent models hold relevance to routine pediatric anesthesia in term neonates and infants, or whether they more closely correspond to brain maturational states during fetal surgery in midgestation. Nonhuman primates, on the other hand, exhibit brain maturation more comparable to human brain maturation at birth and could be more applicable to neonatal anesthesia. Interestingly, a recent study in rhesus macaques corroborates the greater fetal susceptibility by demonstrating a higher degree of neuroapoptosis after ketamine anesthesia in utero compared with postnatally.<sup>160</sup> However, major differences in brain development still exist between humans and nonhuman primates. In general, brain development progresses at a much slower pace in humans and developmental stages are up to 50% longer. Even on a cellular level, remarkable differences exist between humans and animals; cell cycle duration during cortical neurogenesis is approximately 17 hours in mice, 28 hours in macaque monkeys, and 36 hours in humans.<sup>282</sup> All these differences indicate that it is not sensible to directly apply observations of anesthetic effects in the developing animal brain of any species to human clinical anesthesia practice.

**FIGURE 23-4** The degree of neuronal apoptotic cell death following anesthetic exposure is highly dependent on the age of the animal during exposure. Graphs demonstrate the percent increase of apoptotic cell death compared with natural apoptosis following an exposure to an isoflurane/nitrous oxide–based anesthetic in immature rats (dark gray) or very young macaque monkeys (dark brown) or prolonged exposure to ketamine in immature rats (light gray) or macaque monkeys (tan). Solid lines connect the available data points; interrupted lines represent extrapolations of the available data. Neurotoxicity data were derived from references, 17, 91, 114, 139. To infer the potential age of anesthetic vulnerability in humans, respective brain maturity in the animal species during exposure were equated to the corresponding state of the developing human brain, and relative human ages for each data point were plotted accordingly, using the mathematical model outlined in references, 276, 277, 288 and available in the online calculator at <http://www.translatingtime.net>.

#### ASSESSING NEUROBEHAVIORAL OR COGNITIVE OUTCOMES

Translating neurodevelopmental outcomes from animals to humans is difficult. Human cognitive performance includes the vast capacity for learning, the ability for abstract thinking, the aptitude for solving complex mathematical equations, and even the capability of inventing and operating complex machinery. Cognition is a complex process that includes such diverse processes as perception, attention, working memory, long-term memory, executive function, language, and social cognition. These brain functions are all difficult to model in animals.<sup>278</sup> It is therefore imperative to critically evaluate any animal models attempting to replicate human cognitive performance. Moreover, it is important to assess the validity of these models in the context of the critical period for human brain development that they are trying to represent. Current assessment of neurocognitive performance after developmental exposure largely relies on hippocampal-dependent tests administered to adult animals following anesthetic exposure early in life.<sup>85,105-107,158</sup> However, it remains unclear whether these are the same domains that may potentially be targeted in children during anesthesia. Brain regions maximally affected by anesthesia may change with the age of the animal and developmental state of the brain.<sup>79,160</sup> Accordingly, subsequent neurobehavioral abnormalities may vary depending on the age at which anesthesia was administered.

This discussion, however, does not entirely discredit the results from small animal studies, but rather seriously limits the generalizability of their findings to clinical pediatric anesthesia practice. More closely resembling clinical pediatric anesthesia practice, several large-animal models have used tracheal intubation and mechanical ventilation.<sup>79,114,160</sup> However, none of these large-animal studies included surgical stimulation during the anesthesia.<sup>79,114,139,158</sup>

#### Long-Term Outcome in Children Exposed to Anesthesia and Surgery

The difficulties in translating animal data to clinical anesthesia in human infants increases the importance of identifying potential clinical evidence for or against neurologic abnormalities in children after otherwise uneventful anesthesia early in life. Unfortunately, this question is not easily answered.

There is evidence for an association between surgery with anesthesia in early childhood and subsequent altered neurodevelopmental outcome.<sup>37</sup> Some human cohort studies have demonstrated an association between major surgery in the neonatal period and poor neurodevelopmental outcome.<sup>289</sup> Children born with esophageal atresia had a lower IQ and more frequently suffered from depression, emotional, and behavioral problems compared with the general population.<sup>290</sup> Children with congenital diaphragmatic hernia repair also have a high rate of neurologic sequelae.<sup>291</sup> Extremely premature, low-birth-weight neonates who underwent laparotomy had poorer neurodevelopmental outcomes compared with matched controls.<sup>292</sup> A cohort of infants who underwent major surgery did not perform as well in school as a matched control group of healthy infants or with infants who had major nonsurgical medical conditions.<sup>293</sup> In a randomized trial of indomethacin treatment in 426 infants less than 1000 g at birth, neurologic impairment was present in significantly more of the 110 children who had undergone surgery (53%) compared with that in the 316 children who had received medical therapy (34%).<sup>294</sup> In a study of extremely preterm infants, the IQ of those who had undergone surgery was lower at 5 years of age and exhibited more sensorineural disability than those who had not undergone surgery.<sup>295</sup>

These studies all included infants with major confounding factors, such as congenital malformations or very preterm birth,

which might increase the risk of poor neurodevelopmental outcome independent of surgery and anesthesia. Moreover, surgery itself can lead to poor outcome as a result of the perioperative neurohumoral and inflammatory response, or the hemodynamic instability associated with major surgery. Severity of illness may have also been greater in surgical patients compared with their respective control groups. Thus, whereas these studies suggest that some infants undergoing major surgery are at increased risk of poor neurodevelopmental outcome, none of the studies provide conclusive evidence that surgery or even anesthesia is the cause of the increased risk of poor neurodevelopmental outcome.

Several recent cohort studies have focused primarily on the effects of anesthesia. In an established population-based, retrospective birth cohort, Wilder and colleagues studied the association between anesthetic exposure before 4 years of age and the subsequent development of learning disabilities.<sup>296</sup> Regression was used to calculate hazard ratios for anesthetic exposure as a predictor of learning disability, with adjustment for gestational age at birth, sex, and birth weight. Of 5357 children in the cohort, 593 had been exposed to general anesthesia before 4 years of age. Compared with those not exposed to anesthesia, a single exposure was not associated with an increased risk of learning disability (hazard ratio = 1.0; 95% confidence interval [CI] of 0.79 to 1.27). However, children who underwent two separate episodes of anesthesia had an increased risk of a learning disability (hazard ratio = 1.59; 95% CI of 1.06 to 2.37) and those who underwent 3 or more separate episodes of anesthesia had an even greater risk (hazard ratio = 2.60; 95% CI of 1.60 to 4.24). The association between learning disability and multiple episodes of anesthesia remained after adjusting for American Society of Anesthesiologist physical status. The risk for a learning disability also increased according to the cumulative duration of anesthesia. However, this study suffered from several deficiencies. Because the study reported anesthetics administered between 1976 and 1982, the most common anesthetic treatment was halothane and nitrous oxide, and none of the children were monitored with pulse oximetry or capnography. It is not possible to determine in how many of these children excessive hyperventilation or unrecognized desaturation had occurred. Furthermore, the maternal birth histories were not described (e.g., magnesium may cause neuroapoptosis or be neuroprotective). Three different learning disabilities were considered with equipoise in the final analysis, and these disabilities were not tested in all children, but only when a teacher or parent requested testing. These questions limit the external validity of these data.

To reduce the impact of confounding factors, using the same population-based, retrospective birth cohort, the same group conducted further studies with a matched cohort design.<sup>297</sup> The researchers matched 350 children exposed to anesthesia before the age of 2 to 700 children not exposed to anesthesia. The matching was based on several known risk factors for learning disabilities: gender, mother's education, birth weight, and gestational age at birth. Outcomes of interest were: learning disability, need for individualized education program for an emotional or behavioral disorder, and group-administered achievement tests. In the analysis, an adjustment was also performed for burden of illness. The primary finding was that children exposed to two or more occurrences of anesthesia (but not a single occurrence) were at increased risk for having a learning disability (hazard ratio = 2.12 with 95% CI of 1.26 to 3.54), and an amplified need for individualized education programs for speech and language impairment. However, there was not an increased need for a

program for emotional or behavioral disorders. The authors also detected an association between multiple exposures to anesthesia and lower mathematical scores. The same criticisms apply to this study as to the earlier study from this institution.<sup>296</sup>

To investigate a potential association between perinatal exposure to general anesthesia during cesarean delivery and subsequent diagnosis of learning disability,<sup>298</sup> the risk of a learning disability was compared in the 193 children delivered via cesarean section under general anesthesia, the 304 delivered via cesarean section under regional anesthesia, and 4823 delivered vaginally without any anesthesia. The association between mode of delivery and learning disability was adjusted for sex, birth weight, gestational age at birth, exposure to anesthesia before 4 years of age, and maternal education. The risk of disability was similar between children delivered by vagina with no anesthesia, and cesarean delivery under general anesthesia, but risk of disability was less in children delivered via cesarean under regional anesthesia than by vagina with no anesthesia (hazard ratio = 0.64, 95% CI of 0.44 to 0.92;  $P = 0.017$ ). The results implied that brief exposure to general anesthesia during delivery was not associated with subsequent learning disability, but the reason why the risk was less with regional anesthesia compared with no anesthesia is unclear, although this may suggest the possibility of substantial confounding influences. To explore the possibility that the regional blockade was protective, the authors subsequently compared those born without general anesthesia by vaginal delivery, with and without regional analgesia, and found no difference in risk of learning disability.<sup>299</sup>

Using the same epidemiologic cohort, the same research group detected an increased prevalence of attention deficit hyperactivity disorder (ADHD) in children who had undergone repeated surgical procedures with anesthesia, compared with none or only one exposure.<sup>299a</sup> Kalkman and associates performed a small pilot study to test the feasibility of using a cohort of children who had urologic surgery, in order to test the association between age at surgery and neurobehavioral outcome (measured with the Child Behavior Check List).<sup>300</sup> In their sample of 314 children, they found no evidence for an association between timing of surgery and neurobehavioral outcome.

DiMaggio and colleagues performed a retrospective cohort analysis using the New York State Medicaid records.<sup>301</sup> The researchers matched 383 children who underwent hernia repair before 3 years of age to 5050 children who did not undergo inguinal hernia repair. After adjustment for sex, age, and complicating birth conditions (such as low birth weight), children who had hernia repair were more than twice as likely to have a subsequent diagnosis of a developmental or behavioral disorder (hazard ratio = 2.3, 95% CI of 1.3 to 4.1).

To reduce environmental confounding effects, the authors then proceeded to use the data from the New York State Medicaid program to construct a retrospective sibling birth cohort.<sup>302</sup> Once again, they assessed the association between exposure to anesthesia in children less than 3 years of age and the subsequent risk of diagnosis of developmental or behavioral disorders. A total of 10,450 siblings were identified; 304 of whom underwent surgery before 3 years of age, without any history of behavioral or developmental disorders before the surgery, and 10,146 children who did not undergo surgery. The association of exposure to anesthesia with subsequent developmental or behavioral disorders was assessed with both proportional hazards modeling, and pair-matched analysis. As with their previous study, they found evidence for an association between surgery and poor neurodevelopmental outcome. The incidence of developmental

or behavioral disorders was 128.2 diagnoses per 1000 person-years for those that had surgery and 56.3 diagnoses per 1000 person-years for those that did not. This association persisted when adjusted for sex, history of birth-related medical complications, and clustering by sibling status; the estimated hazard ratio of developmental or behavioral disorders associated with any exposure to anesthesia was 1.6 (95% CI of 1.4 to 1.8). The risk increased from 1.1 (95% CI of 0.8 to 1.4) for one operation to 2.9 (94% CI of 2.5 to 3.1) for two operations and 4.0 (95% CI of 3.5 to 4.5) for three or more operations. The number of siblings available for a matched analysis was relatively small. There were only 138 sibling pairs. In the pair-matched analysis there was no evidence for an association between surgery and poor outcome, with a relative risk of 0.9 (95% CI of 0.6 to 1.4); however, the small numbers may limit the power of this analysis.

Even better than sibling studies, investigations involving identical twins may further reduce confounding environmental and genetic influences. Performing such a study, Bartels and associates examined the possible association between anesthesia exposure before 3 years of age and school performance in 1143 monozygotic twin pairs.<sup>303</sup> In the identical twins who were discordant for exposure to anesthesia (one twin was exposed to anesthesia and the other was not), their school performance was identical. This would suggest that surgery with anesthesia may not be the cause of poor school performance. Interestingly, the school performance in both the discordant pairs and the pairs where both twins underwent surgery was poorer than that for concordant twin pairs where neither twin was exposed to anesthesia. This finding could imply that there may exist an unknown genetic factor that increases the risk of both the need for surgery and poor school performance.

The Western Canadian Complex Pediatric Therapies Follow-up Group recently published a prospective follow-up study of 95 infants at 2 years of age who underwent surgical correction for congenital heart disease at the Alberta Children's Hospital from April 2003 to December 2006.<sup>304</sup> A multiple logistic regression analysis of variables associated with developmental delay found that only more days of ventilatory support postoperatively and older age at surgery were associated with significant developmental delay. There was also no evidence for an association between the sedation variables and significant motor delays. However, the use of two neurocognitive assessment tools during the study period precluded an analysis of the cognitive and motor scores as continuous variables, which may have been a more sensitive way to detect subtle impairment.

Hansen and colleagues used a very large Danish birth cohort to compare academic performance in 2689 children that had inguinal hernia repair in infancy with 14,575 children who were randomly selected as an age-matched sample from the general population.<sup>305</sup> Those who had hernia repair performed worse at school, but there was no evidence for any association between surgery and school performance after adjustment for likely confounding variables. In contrast to the studies of DiMaggio and Wilder, this study detected no evidence for an association between surgery and poor neurobehavioral outcome.

Lastly, in a recent study using the Western Australian Pregnancy Cohort (Raine), Ing and colleagues found an association between language and abstract reasoning deficits in 10-year-old children who were exposed to one or more anesthetics prior to age 3, compared with previously unexposed children. After adjustment for confounders, any anesthetic before age 3 increased the risk ratio of disability in receptive, expressive, or total language as measured by the Clinical Evaluation of Language

Fundamentals (CELF) test, as well as abstract reasoning (Raven's Colored Progressive Matrices) to between 1.7 and 2.1 of unexposed controls, whereas other tests of vocabulary, behavior, and motor function were unaffected by exposure.<sup>305a</sup>

## Outcome after Exposure to Anesthesia Outside of the Operating Room

The operating room is not the only area where anesthetic neurotoxicity may be relevant. Ketamine and benzodiazepines are frequently administered in the emergency room, and in neonatal and pediatric intensive care units. These drugs may be administered for a protracted period of time, increasing their theoretical risk of neurotoxicity.<sup>53,55</sup>

Unfortunately, determining the clinical relevance of any neurotoxicity in intensive care patients is even more difficult than for the operating room. The total number of children that can be examined is smaller, they tend to be a very heterogeneous population, and most importantly, these children often have multiple significant confounding comorbidities, including exposure to anesthesia, which could significantly affect neurologic outcome. To date, there is mixed evidence that exposure to anesthetic or sedative drugs is associated with poorer neurobehavioral outcome. A Cochrane review found some evidence for worsened short-term outcome in neonates who had prolonged exposures to midazolam infusions.<sup>306</sup> In contrast, after correction for severity of illness, another study (using the EPIPAGE cohort) found no evidence for an association between prolonged sedation exposure and adverse neurologic outcome.<sup>307</sup> In that study, however, many children received opioids for sedation rather than benzodiazepines.

## Limitations of the Available Clinical Studies

There are numerous reasons why the clinical data on neurobehavioral outcomes after anesthesia are difficult to interpret, and it is perhaps not surprising that clinical studies return conflicting results. None of the currently available clinical studies are prospective randomized trials. Due to their retrospective nature, several of these studies require mathematical adjustments, such as multiple logistic regression analyses for confounding variables. However, this limits the findings to known or suspected confounders, and does not address as yet unknown variables that may be more important to the outcome.

Epidemiologic studies are generally unable to separate the effects of surgery, or the need for surgery, from the potential anesthetic effects. As previously discussed, surgery may result in significant neurohumoral stress and/or inflammatory responses that may influence neurocognitive outcome, in addition to metabolic, hemodynamic, and respiratory events that occur perioperatively. Data collection for several of the epidemiologic studies occurred before continuous pulse-oximetry and capnography monitoring were standard, and at a time when inhalational anesthetics with profound adverse cardiovascular effects, such as halothane, were used.<sup>296-297</sup> Prospective studies of capnography and pulse oximetry have demonstrated that the very population considered to be at risk (those under 2 years of age) had the greatest incidence of desaturation events, hypercarbia, and hypocarbia.<sup>308-310</sup>

Children undergoing surgery or diagnostic procedures early in life may suffer more frequently from concomitant chromosomal and genetic abnormalities or comorbidities, such as prematurity, which have been linked to abnormal neurobehavioral outcomes. For example, children with cyanotic congenital heart disease often have abnormal neurocognitive development before any surgical or anesthesia intervention.<sup>262</sup> The indication for surgery or for a diagnostic procedure requiring anesthesia, such as injury or infection, may artificially increase the incidence of neurodevelopmental abnormalities in the anesthetized cohort.<sup>262</sup> On the other hand, it has been argued that subjects suffering from underlying abnormalities adversely affecting neurodevelopment that do not receive the required surgery may be introduced into the pool of unanesthetized children, and therefore mask potentially toxic effects of anesthesia.<sup>57</sup>

Further complicating the interpretation of retrospective data is the substantial gap in time between exposure and neurologic assessment. The advantage of performing neurologic assessments in school-age children includes the increased precision and greater predictive value of such assessments compared with neurobehavioral testing performed for children under 2 years of age, for both prospective and retrospective studies.<sup>311</sup> However, especially in retrospective studies that cannot adequately control for confounders, the protracted time interval between surgery and the neurocognitive assessment may introduce even more "noise" into the study by increasing the time for negative influence of other environmental confounders of brain development or, conversely, the positive effects of repair mechanisms and plasticity to affect neurologic outcome.

Current animal studies do not provide sufficient guidance on the specific dose or duration of the anesthetic exposure that may lead to long-term impairment, the individual neurocognitive domains that may be affected, or the particular age at which the human brain may potentially be most susceptible to the neurotoxic effects of anesthetic exposure.

No consensus exists, even in the animal literature, concerning what duration of anesthesia exposure is required to induce long-lasting injury. Although the anesthetic exposure may represent a much larger fraction of an animal's life than a humans, at the cellular level apoptosis is likely to be triggered by a more similar duration of exposure. However, cell cycle duration and also the developmental period of the brain are considerably greater in humans than in rodents. It is therefore plausible, if an anesthesia-induced increase in apoptosis does occur in humans during a few hours of exposure, that it may be functionally less important than the same increase in apoptosis over the same period of time in a rodent. Similarly, the plasticity and capacity for recovery may differ between species. On the one hand, it can be argued that the period of development in humans is greater than it is in animals, and hence there may be more time for recovery, but on the other hand, human development is far more complex and humans may therefore be more vulnerable. Moreover, injuries during critical periods of development may have an exaggerated effect compared with the same injury outside of these periods.<sup>273,312</sup> Accordingly, studies that find no evidence of association with shorter exposures may not be generalizable to all applications of anesthesia, and studies that find evidence for an association with greater exposure times may not be applicable to short exposures.

As children grow they develop additional skills and abilities, and wider arrays of psychometric tests can be applied to evaluate these more extensive neurobehavioral domains. However, we

currently lack adequate information on which specific domains to examine in humans following anesthetic exposure, complicating the interpretation of human cohort studies. Many of these studies use summary scores, such as IQ or average school grades. These outcome measures may miss subtle effects confined to specific neurobehavioral domains. Similarly, a diagnosis of developmental delay or behavioral problems may also miss more subtle changes in particular areas. In contrast, broad batteries of detailed tests are increasingly likely to find at least one association purely by chance.

The vulnerable period in humans, if it exists, has not been clearly identified. Animal data seem to suggest that anesthetic exposure may be most relevant during pregnancy or in early infancy, but it could be possible that the period of vulnerability may extend beyond infancy and young age. These critical uncertainties not only complicate the interpretation of published studies, but make the design of future, prospective studies very difficult.

Lastly the possible neuroprotective effects of anesthesia complicate this conundrum even further. Infants undergoing surgery who experience major intraoperative adverse events, such as cardiopulmonary arrest, are generally expected to suffer from abnormal neurologic outcomes, irrespective of their anesthetic exposure. Neurologic abnormalities observed after an otherwise uneventful procedure are considered neurotoxic effects of anesthesia. However, because anesthetics may also, at least partially, protect from the harmful metabolic, immunologic, and humoral responses to surgery and pain,<sup>245</sup> an alternative explanation may be that inadequate levels of anesthesia, insufficient postoperative pain relief, or unabated inflammation may be the culprit for the observed neurodevelopmental abnormalities. It is also possible that anesthetics may protect in major adverse settings, but may be deleterious in the absence of toxic stimuli, causing injury during minor procedures, but ameliorating injury during major surgery, such as complex heart surgery involving cardiopulmonary bypass.

In summary, there is mixed evidence for an association between anesthesia exposure in early childhood and poor neurobehavioral outcome in human studies. Collection of more definitive data supporting a deleterious role for anesthetics during brain development are complicated by uncertainties regarding the toxic threshold dose for anesthetics, the lack of information about the age of maximum susceptibility, and ambiguity related to the most appropriate neurobehavioral domains to examine. On the other hand, any positive association between anesthetic exposure and learning abnormalities may be spurious because of sampling bias in selecting children in need of early-life surgery and the inability to separate anesthetic effects from those of surgery and related comorbidities. Currently, clinical studies have not established causation between exposure to anesthesia in young children and adverse neurobehavioral outcomes, but at the same time, they do not rule out that possibility.

## Future Research

Further animal data will continue to provide information on the mechanisms of and susceptibility to anesthetic neurotoxicity. Understanding the mechanisms will be critical in translating the animal findings to clinical settings. Moreover, future animal work may also assist in determining which domains of neurobehavioral outcome are most likely to be affected, and this would assist in the design of human clinical trials. If neurotoxicity is found to

be clinically relevant, animal data will also guide in devising prevention strategies.

Further human clinical studies must also be performed. Cohort studies will better identify children most at risk and characterize the neurobehavioral changes that occur. Because of the multiple confounding factors, cohort studies will always have great difficulty determining if the outcomes are a result of the surgery, the comorbidities, or the anesthetic exposure. Finding evidence for a lack of neurologic abnormalities in certain populations would provide some reassurance that laboratory studies in animal models lack immediate clinical relevance, however, it is important to note that such findings may not be automatically generalizable to all clinical settings.

Future clinical studies will need to take into account unique human functions, such as language skills. Moreover, ongoing and future research will have to better delineate the effects of early life exposure to surgery with anesthesia on specific neurologic domains. Preliminary results presented at the British Journal of Anaesthesia Special Workshop on Anesthesia, Neurotoxicity, and Neuroplasticity (Salzburg, Austria, June 2012) indicate that infant anesthesia may subsequently affect certain forms of recognition memory more than others and may also have differential effects dependent on gender. (Greg Stratmann, MD, PhD, personal communication).

To definitively answer this important health concern, clinical trials provide the strongest evidence. However, such trials are difficult to perform, as randomization to anesthesia or no anesthesia is impossible. It is, however, feasible to randomize to different types of anesthetic agents or approaches, such as regional versus general anesthesia. Even when using this approach, the appropriate outcome measure still has to be better defined. To perform a meaningful neurobehavioral assessment requires that the child is at least 2 years of age, if executive function is to be assessed, and 5 years of age or older would be preferable.

Even if anesthesia-induced neuroapoptosis is found to be clinically irrelevant, it is still important to recognize that there is a strong association between major surgery in neonates and abnormal neurobehavioral outcome. Thus the questions become which other factors may be causing the poor outcome and which perioperative interventions could be performed by anesthesiologists to improve outcomes in these children.

## Recommendations for Clinical Practice

The currently available laboratory data are not sufficient to make recommendations for clinical pediatric anesthesia practice. As outlined above, numerous laboratory studies have unequivocally documented deleterious effects of anesthetic exposure on the developing animal brain. Although these results should not be easily dismissed, the problems in translation from animal to human are substantial. Epidemiologic studies in children are also contradictory and can neither rule out nor confirm anesthetic-related neurotoxicity. Accordingly, the U.S. Food and Drug Administration (FDA) and the International Anesthesia Research Society (IARS) state that “dangers to infants and children from anesthesia remain unproven at this point” (<http://www.smarttots.org/familyResourceCenter.html>).

Pediatric surgery is never entirely elective, and in neonates may be required in order to preserve life, such as for critical congenital heart disease, necrotizing enterocolitis, or congenital diaphragmatic hernia. Accordingly, calls to postpone infant

surgery are not easy to accommodate. Delaying surgery is also problematic, as no vulnerable or safe period has been identified in animal studies to guide this practice. Accordingly, the FDA and IARS have stated, “Currently, there is no scientific basis for delaying essential surgery” (<http://www.smarttots.org/familyResourceCenter.html>). It might be reasonable to delay purely elective surgeries; however, these only represent a very small fraction of surgeries performed in children.

It is well documented that neonates are at an increased risk for respiratory and cardiovascular complications during anesthesia, which influences the choice of anesthetic technique and drugs used in this population. It would be very unwise to change practice based on concerns over anesthetic neurotoxicity, while potentially increasing the risks of cardiovascular or respiratory complications. Similarly, it must be stressed that insufficient anesthesia and analgesia are definitely associated with poor neurologic outcomes.

Lastly, when discussing the risks and benefits of anesthesia with parents, pediatricians, and surgeons, anesthesiologists need to be cautious not to cause undue alarm, while taking the matter of potential toxicity seriously and not hastily dismissing any parental concern.

# Pediatric Neurosurgical Anesthesia

CRAIG D. McCLAIN, SULPICIO G. SORIANO, AND MARK A. ROCKOFF

24

## Pathophysiology

Intracranial Compartments  
Intracranial Pressure  
Cerebral Blood Volume and Cerebral Blood Flow  
Cerebral Perfusion Pressure  
Cerebrovascular Autoregulation

## Management of Anesthesia

Preoperative Evaluation  
Premedication  
Monitoring  
Induction  
Airway Management and Intubation  
Neuromuscular Blocking Drugs  
Positioning

## Local Anesthesia

Maintenance of General Anesthesia  
Apoptotic Neurodegeneration  
Blood and Fluid Management  
Temperature Control  
Venous Air Emboli

## Emergence

## Special Situations

Trauma  
Craniotomy  
Hydrocephalus  
Congenital Anomalies  
Neuroradiologic Procedures

**CHILDREN REQUIRING NEUROSURGICAL PROCEDURES** present unique challenges to pediatric anesthesiologists. In addition to addressing problems common to general pediatric anesthesia practice, anesthesiologists must consider the effects of anesthesia on the developing central nervous system (CNS) of children with neurologic disease. This chapter reviews the age-dependent physiology of the CNS of children undergoing neurosurgical procedures requiring anesthesia.

## Pathophysiology

### INTRACRANIAL COMPARTMENTS

The skull can be compared to a rigid container with almost incompressible contents. Under normal conditions, the intracranial space is occupied by the brain and its interstitial fluid (80%), cerebrospinal fluid (CSF, 10%), and blood (10%). In pathologic states, space-occupying lesions such as edema, tumors, hematomas, or abscesses alter these proportions. The Monro-Kellie hypothesis, elaborated in the 19th century, states that the sum of all intracranial volumes is constant. An increase in volume of one compartment must be accompanied by an approximately equal decrease in volume of the other compartments, except when the cranium can expand to accommodate a larger volume. Gradual increases in intracranial volumes, such as a slow-growing tumor or hydrocephalus, can be compensated by the compliant nature of open fontanelles and sutures in young children; increasing head circumference can result.<sup>1</sup> However, herniation can occur in children with open fontanelles if large increases in intracranial pressure (ICP) develop acutely. In the nonacute situation, the brain can compensate for pathologic increases in intracranial volume by intracellular dehydration and reduction of interstitial fluid.<sup>2-4</sup>

Under normal conditions, CSF exists in dynamic equilibrium, with absorption balancing production. The rate of CSF production in adults is approximately 0.35 mL/min or 500 mL/day.<sup>5</sup> The average adult has 100 to 150 mL of CSF distributed throughout the brain and subarachnoid space. Children have correspondingly smaller volumes of CSF, but the rate of CSF production is similar to that of adults.<sup>5,6</sup>

Production of CSF is only slightly affected by alterations of ICP and is usually unchanged in children with hydrocephalus.<sup>6</sup> Some drugs, including acetazolamide, furosemide, and corticosteroids, are mildly effective in transiently decreasing CSF production.<sup>1,7,8</sup> There is an inverse relationship between the rate of CSF production and serum osmolality; an increase in serum osmolality causes a decrease in CSF production. Choroid plexus papillomas causing overproduction of CSF are rare but are more likely to occur during childhood.

Absorption of CSF is not well understood, but the arachnoid villi appear to be important sites for reabsorption of CSF into the venous system. One-way valves between the subarachnoid space and the sagittal sinus appear to open at a gradient of about 5 mm Hg. Some resorption may occur from the spinal subarachnoid space and from the ependymal lining of the ventricles. Resorption increases with an increase in ICP. However, CSF absorption is decreased by pathologic processes that obstruct arachnoid villi or interfere with CSF flow, such as intracranial hemorrhage, infection, tumor, and congenital malformations.<sup>9</sup>

### INTRACRANIAL PRESSURE

Increased ICP causes secondary brain injury by producing cerebral ischemia and ultimately causing herniation. Ischemia occurs when ICP increases and cerebral perfusion pressure (CPP) decreases. As cerebral blood flow (CBF) and the supply of

**FIGURE 24-1** Cerebral blood flow (CBF), cerebral perfusion pressure (CPP), and brain ischemia. Changes in CBF and CPP affect neuronal synaptic function and cellular integrity. When CBF decreases to 15 to 20 mL/100 g/min, there is distinct neuronal dysfunction on the electroencephalogram (EEG). At 15 mL/100 g/min, the EEG is essentially flat, and electrical activity ceases to function. At 6 to 15 mL/100 g/min, a penumbral state occurs in which there is energy for cellular integrity but insufficient energy for synaptic function. Neuronal survival is unlikely if this low CBF is allowed to persist for more than an ill-defined but critical period. At less than 6 mL/100 g/min, there is no energy for cellular membrane integrity. Infarction occurs at this stage unless reperfusion is accomplished immediately.

nutrients are curtailed, cell damage and death occur, leading to increased intracellular and extracellular water and further increases in ICP. When ICP increases, CPP can decrease, the brain can become ischemic, and cell death can ensue (Fig. 24-1).<sup>10</sup>

### Herniation Syndromes

Several herniation syndromes exist. The most common is *trans-tentorial* herniation, in which the uncus of the temporal lobe is displaced from the supratentorial to the infratentorial space. Compression of the third cranial nerve and brainstem results in pathognomonic signs of pupillary dilatation, hemiparesis, and loss of consciousness. If this compression is not promptly relieved, apnea, bradycardia, and death occur.

In *cerebellar* herniation, the cerebellar tonsils herniate through the foramen magnum from the posterior fossa to the cervical spinal space. This can lead to obstruction of CSF circulation and ultimately to hydrocephalus. Compression of the brainstem results in cardiorespiratory failure and death.

### Signs of Increased Intracranial Pressure

The clinical signs of increased ICP vary in children. Papilledema, pupillary dilation, hypertension, and bradycardia may be absent despite intracranial hypertension, or these signs may occur with normal ICP.<sup>9,11</sup> When associated with increased ICP, they are usually late and dangerous signs.<sup>12</sup> Chronic increases in ICP are

often manifested by complaints of headache, irritability, and vomiting, particularly in the morning. Papilledema may not be present even in children dying as a result of intracranial hypertension.<sup>13</sup> A diminished level of consciousness and abnormal motor responses to painful stimuli are frequently associated with an increased ICP.<sup>9</sup> Computed tomography (CT) or magnetic resonance imaging (MRI) can reveal small or obliterated ventricles or basilar cisterns, hydrocephalus, intracranial masses, and midline shifts. Diffuse cerebral edema is a common finding when increased ICP is associated with closed-head injury, encephalopathy, or encephalitis.

### Monitoring Intracranial Pressure

Techniques to monitor ICP in adults have been successfully used in children.<sup>14-16</sup> Ventricular catheters are generally accepted as the most accurate and reliable means of measurement, permitting removal of CSF for diagnostic or therapeutic indications. The major risks of intraventricular catheters are infection and hemorrhage; although rare, they can lead to devastating complications. These catheters may be difficult to insert precisely when they are needed most, as in a patient with severe cerebral edema with small ventricles. Compared with intraventricular catheters, subarachnoid bolts can be placed even when the ventricles are obliterated. This procedure minimizes trauma to brain tissue and poses less risk of serious infection and hemorrhage. The major disadvantages are that subarachnoid bolts may underestimate ICP, particularly in areas distant from their insertion site, and they are difficult to stabilize in infants with thin calvaria.

Epidural monitors that do not require a fluid interface can be implanted outside the dura, avoiding the risks of CSF contamination and the limitations of fluid-dependent systems.<sup>17,18</sup> Most epidural systems correlate well with intraventricular measurements, but they cannot be recalibrated after insertion. Epidural monitors have also been secured noninvasively to the open anterior fontanelle of infants and appear to reflect changes in ICP. Fiberoptic catheters with self-contained transducers can also be used to measure ICP from intraventricular, subarachnoid, or intraparenchymal sites. These monitors avoid some of the problems of external fluid-filled transducers, but like epidural transducers, they cannot be recalibrated after insertion.

The normal ICP in children is less than 15 mm Hg. In term neonates, normal ICP is 2 to 6 mm Hg; it is probably even less in preterm infants. Children with intracranial pathology but normal ICP values occasionally exhibit pressure waves, which are considered abnormal.<sup>9</sup> In children with open fontanelles, the ICP may remain normal despite a significant intracranial pathologic process; increasing head circumference may be the first clinical sign. Bulging fontanelles may not develop, especially when the process evolves slowly.

### Intracranial Compliance

The absolute value of ICP does not indicate how much compensation is possible. If the ICP increases significantly, compensatory mechanisms have failed. However, pathologic states may be present despite an ICP within the normal range. Intracranial compliance (i.e., the change in pressure relative to a change in volume) is a valuable concept. Figure 24-2 is a schematic diagram of the relationship between the addition of volume to intracranial compartments and ICP. The shape of the curve depends on the time over which the volume increases and the relative size of the compartments. At normal intracranial volumes (point 1), ICP is low, but compliance is high and remains so despite small

**FIGURE 24-2** Idealized intracranial compliance curve for intracranial pressure (ICP) plotted against intracranial volume.

increases in volume. If volume increases rapidly, compensatory abilities are surpassed, and further increases in volume are reflected as increases in pressure. This can occur when the ICP is still within normal limits but the compliance is low (point 2). If the ICP is already increased further volume expansion causes a rapid increase in ICP (point 3). In clinical practice, compliance can be evaluated with a ventriculostomy catheter or by observing the response of ICP to external stimulation (e.g., tracheal suction, coughing, agitation).

Several physiologic and mechanical factors such as a greater percentage of brain water content, less CSF volume, and greater percentage of brain content to intracranial capacity contribute to a relatively decreased intracranial compliance in children compared with adults.<sup>2</sup> Children may be at increased risk for herniation compared with adults when similar relative increases in ICP have occurred. However, infants faced with a slowly increasing ICP may have a greater compliance due to their open fontanelles and sutures.

### CEREBRAL BLOOD VOLUME AND CEREBRAL BLOOD FLOW

In addition to CSF, cerebral blood volume (CBV) represents another compartment in which compensatory mechanisms influence ICP. Although the CBV occupies only 10% of the intracranial space, changes related to dynamic blood volume occur, often initiated by anesthesia or intensive care procedures. As with other vascular beds, most intracranial blood is contained in the low-pressure, high-capacitance venous system. Increases in intracranial volume are initially met by decreases in CBV. This response is apparent in hydrocephalic infants, in whom venous blood shifts from intracranial to extracranial vessels, producing distended scalp veins.<sup>19</sup>

In the normal adult, CBF is approximately 55 mL/100 g of brain tissue per minute.<sup>20-22</sup> This represents almost 15% of the cardiac output for an organ that accounts for only 2% of body weight. Estimates of CBF are less uniform for children. Normal CBF in healthy awake children is approximately 100 mL per 100 g of brain tissue per minute, which represents up to 25% of cardiac output.<sup>23,24</sup> CBF in neonates and preterm infants (approximately 40 mL/100 g/min) is less than in children and adults.<sup>25,26</sup> In infants, CBF is subject to modification by sleep states and feeding.<sup>27</sup>

CBF is regulated to meet the metabolic demands of the brain. In adults, the cerebral metabolic rate for oxygen consumption (CMRO<sub>2</sub>) is 3.5 to 4.5 mL O<sub>2</sub>/100 g/min; in children, it is greater.<sup>23</sup> General anesthesia reduces CMRO<sub>2</sub> by as much as

**FIGURE 24-3** The effects of increasing mean blood pressure (BP), arterial partial pressure of oxygen (PaO<sub>2</sub>), and arterial partial pressure of carbon dioxide (Paco<sub>2</sub>) on cerebral blood flow (CBF) in the normal brain. (From Shapiro HM. Intracranial hypertension: therapeutic and anesthetic considerations. *Anesthesiology* 1975;43:447.)

50%.<sup>28</sup> Coupling of CBF and CMRO<sub>2</sub> is probably mediated by the effect of local hydrogen ion concentration on cerebral vessels. Conditions that cause acidosis (e.g., hypoxemia, hypercarbia, ischemia) dilate the cerebral vasculature, which augments CBF and CBV. A reduction in brain metabolism (i.e., CMRO<sub>2</sub>) similarly reduces CBF and CBV. When autoregulation is impaired, CBF is determined by factors other than metabolic demand. If the CBF exceeds metabolic requirements, luxury perfusion or hyperemia exists. Many pharmacologic agents act directly on the cerebral vasculature to alter CBF and CBV.

### CEREBRAL PERFUSION PRESSURE

CPP is a useful and practical estimate of the adequacy of the cerebral circulation, because CBF is neither easily nor widely measured. Defined as the pressure gradient across the brain, CPP is the difference between the systemic mean arterial pressure (MAP) at the entrance to the brain and the mean exit pressure (i.e., central venous pressure [CVP]). When ICP is increased, it replaces CVP in the calculation of CPP. In supine children, the mean CPP is the difference between the MAP and the mean ICP (CPP = MAP – ICP). If the brain and heart are positioned at different heights, all pressures should be referenced at the level of the head (e.g., external auditory meatus).

### CEREBROVASCULAR AUTOREGULATION

#### Effects of Blood Pressure

In adults, CBF remains relatively constant within a MAP range of 50 to 150 mm Hg (Fig. 24-3). Autoregulation enables brain perfusion to remain stable despite moderate changes in MAP or ICP. Autoregulation is partially mediated by myogenic control of arteriolar resistance. When CPP decreases, cerebral vessels dilate to maintain CBF, thereby increasing CBV. When CPP increases, cerebral vasoconstriction occurs, maintaining the CBF with a reduced CBV. When ICP and CVP are low, MAP normally approximates CPP. Beyond the range of autoregulation, CBF becomes pressure dependent. In children with chronic hypertension, the upper and lower limits of autoregulation are increased. Cerebral autoregulation can be abolished by acidosis, medications, tumor, cerebral edema, and vascular malformations, even at sites far removed from a discrete lesion.<sup>20</sup>

The limits of autoregulation are not known for normal infants and children, but autoregulation probably occurs at lower absolute values than in adults.<sup>29</sup> Although the lower limit of autoregulation in adults is approximately 50 mm Hg, this blood pressure may be beyond that of the neonate. Intact autoregulatory mechanisms have been demonstrated within lower blood pressure ranges in newborn animals compared with mature animals.<sup>30</sup> Cerebral autoregulation may also be abolished in critically ill humans.<sup>31</sup>

### Effects of Oxygen

CBF is constant over a wide range of oxygen tensions. When the partial pressure of arterial O<sub>2</sub> (PaO<sub>2</sub>) decreases to less than 50 mm Hg, CBF increases exponentially in adults; for example, at a PaO<sub>2</sub> of 15 mm Hg, CBF is doubled compared with normal (see Fig. 24-3).<sup>32</sup> The resulting increase in CBV increases ICP when intracranial compliance is low; the lower limit for PaO<sub>2</sub> is probably less in neonates. Oxygen delivery is more important than the actual PaO<sub>2</sub>. Evidence suggests that hyperoxia decreases CBF. Kety and Schmidt demonstrated a 10% decrease in CBF in adults breathing 100% O<sub>2</sub>, although decreases of 33% have been reported in neonates.<sup>33,34</sup>

### Effects of Carbon Dioxide

The relationship between the arterial partial pressure of carbon dioxide (PaCO<sub>2</sub>) and CBF typically is linear (see Fig. 24-3). In adults, a 1-mm Hg increase in PaCO<sub>2</sub> increases CBF by approximately 2 mL/100 g/min.<sup>33</sup> The direct effect of changes in PaCO<sub>2</sub> on CBF and the consequent effect on CBV are the basis for the fact that hyperventilation reduces ICP. Likewise, increases in PaCO<sub>2</sub> increase the CBF, although the limits at which this occurs in neonates differ from those in adults. In lambs and monkeys, CBF does not seem to change in response to decreased PaCO<sub>2</sub>.<sup>35</sup> There are no data to suggest what the limits of PaCO<sub>2</sub> are in human infants and children. Similarly, there is little information about the extent and duration of cerebrovascular responsiveness to hyperventilation in brain-injured and critically ill children. Moderate hyperventilation has been used to reduce ICP immediately, but several reports have demonstrated worsening cerebral ischemia in children with compromised cerebral perfusion.<sup>36-38</sup>

Autoregulation of CBF is impaired in areas of damaged brain.<sup>39</sup> Blood vessels in an ischemic zone are subject to hypoxemia, hypercarbia, and acidosis, which are potent stimuli for vasodilation. These vessels develop maximally reduced cerebrovascular tone or vasomotor paralysis. Small, localized lesions may impair autoregulation in areas far removed from the site of injury.<sup>20</sup> The extent of autoregulatory impairment varies in brain-damaged children.

## Management of Anesthesia

### PREOPERATIVE EVALUATION

#### History

Preoperative evaluation of infants and children is discussed in Chapter 4. Children who are scheduled for neurosurgery might have been healthy until the onset of their symptoms, might have been developmentally delayed from birth, or may have impaired neuromuscular function. The anesthetic plan, including postoperative care, needs to consider the particular issues of each child and the disease state.

A history of food or drug allergies, eczema, or asthma may provide warning of an adverse reaction to the contrast agents frequently used in neuroradiologic procedures. Special attention

should be given to symptoms of allergy to latex products, such as lip swelling after blowing up a toy balloon or tongue swelling after insertion of a rubber dam is into the mouth by a dentist, because latex anaphylaxis has been reported in some children who have undergone multiple operations, especially those with a meningomyelocele.<sup>40</sup> Latex allergic children may also report allergies to fruits (e.g., kiwi, banana, avocado, strawberry, and others).

Concurrent pediatric diseases and symptoms of neurologic lesions may influence the conduct of anesthesia. Protracted vomiting, enuresis, and anorexia due to intracranial lesions should prompt evaluation of hydration and electrolytes. Diabetes insipidus or inappropriate secretion of antidiuretic hormone is common. A history of the use of aspirin or aspirin-containing remedies for headaches or respiratory tract infections is information that is not usually forthcoming but may have important implications for operative and postoperative bleeding. Corticosteroids are often initiated at the time of diagnosis of intracranial tumors, and they should be continued and a pulse dose administered during the perioperative period. Therapeutic concentrations of anticonvulsants should be verified preoperatively and maintained perioperatively. Children receiving long-term anticonvulsants may develop toxicity, especially if seizures are difficult to control; this is frequently manifested as abnormalities in hematologic or hepatic function, or both. Children receiving chronic anticonvulsant therapy may also require increased amounts of sedatives, nondepolarizing muscle relaxants, and opioids because of enhanced metabolism of these drugs (see also Chapters 6 and 22).<sup>41-43</sup>

### Physical Examination

The physical examination should encompass a brief neurologic evaluation, including level of consciousness, motor and sensory function, normal and pathologic reflexes, integrity of the cranial nerves, and signs and symptoms of intracranial hypertension. Examination of pupillary size and responsiveness can detect benign anisocoria. Preoperative respiratory assessment should include the effects of motor weakness, impaired gag and swallowing mechanisms, and evidence of active pulmonary disease, such as aspiration pneumonia. Muscle atrophy and weakness should be documented, because upregulation of acetylcholine receptors may precipitate sudden hyperkalemia after administration of succinylcholine and induce resistance to nondepolarizing muscle relaxants in the affected limbs.<sup>44</sup>

### Laboratory and Radiologic Evaluation

In all but the most minor procedures, laboratory data should include a hematocrit determination. Blood typing and cross-matching should be performed for any major procedure. The need for additional studies, such as evaluation of coagulation parameters, serum electrolyte levels and osmolality, blood urea nitrogen and creatinine values, arterial blood gas analysis, chest radiography, or electrocardiography (ECG), is determined on an individual basis. Liver function tests and a hematologic profile should be obtained if not recently reviewed in children on long-term therapy with anticonvulsants. Specific neuroradiologic studies are usually obtained by the neurosurgeon and should be reviewed by the anesthesiologist. For example, the anesthesiologist should know which children with a ventriculoperitoneal shunt have "slit ventricles," because these children have special risks in the perioperative period<sup>45</sup> (see "Hydrocephalus"). Information on the amount of sedation needed to perform radiologic studies may also be helpful in planning the induction of

anesthesia. Preoperative neurophysiologic studies, including electroencephalography (EEG) and evoked potentials, may provide a baseline for comparison of intraoperative and postoperative evaluations.

### PREMEDICATION

Sedation is usually withheld from pediatric neurosurgical patients until they arrive in the preoperative area to allow titration of drug to desired effect while under direct supervision. Opioids are usually withheld preoperatively because they may cause nausea or respiratory depression, especially in children with increased ICP, and sedatives alone usually are adequate to relieve anxiety.

Sedatives are administered in the parents' presence to facilitate a smooth separation and induction. Midazolam (0.5 to 1.0 mg/kg) may be given orally; it usually requires 10 to 20 minutes to take effect. Incremental doses of intravenous midazolam (0.05 mg/kg) may also be useful in children who tolerate intravenous placement.

### MONITORING

Minimal monitoring for pediatric neuroanesthesia requires a stethoscope (precordial or esophageal), electrocardiograph, pulse oximeter, sphygmomanometer, capnograph, and thermometer. Neuromuscular blockade monitoring is also important, but nerve stimulators may give misleading information about the extent of relaxation if applied to a denervated extremity. If the child has paresis, nerve stimulation should be at a site of normal neurologic function. Precordial Doppler ultrasound is recommended in children undergoing craniotomy, especially in the head-up position, because the relatively large head size of children places them at increased risk for air emboli. Monitoring devices for ICP are used for the same indications as in adults. Intraoperative EEG and electrophysiologic monitoring require advanced coordination among the neurosurgeon, anesthesiologist, and neurophysiologist. Urinary output should be measured during prolonged procedures, in cases with anticipated large blood loss, and when diuretics or osmotic agents are administered.

An arterial catheter is placed for craniotomies in which there is a potential for sudden and severe hemodynamic changes. Small child size should not preclude the use of invasive monitoring and may actually be an indication for a more aggressive approach. An increase in the paradoxical arterial pressure waveform with positive-pressure ventilation is often an excellent indication of intravascular volume deficiency and the need for fluid replacement (see Fig. 10-10). Intraarterial catheters can be placed percutaneously in the radial, dorsalis pedis, or posterior tibial arteries even in small infants, and it is rarely necessary to resort to surgical cutdown. The arterial transducer should be zeroed at the level of the head if the head and heart positions are different so that CPP can be accurately assessed. The lateral corner of the eye or the external auditory meatus approximate the level of the foramen of Monro, and either is a convenient landmark. In the first days of life, the umbilical artery and the umbilical vein can be cannulated. These catheters should be discontinued as soon as alternative access is established because of the potential for serious complications.

Percutaneous central venous cannulation (i.e., external or internal jugular, femoral, or subclavian veins) using the Seldinger technique is possible even in the smallest infants (see Chapter 48). However, in children undergoing neurosurgical resections, consideration should be given to sites other than neck veins, such as the femoral vein, thereby avoiding the Trendelenburg position

during catheter insertion and the risk of accidental carotid artery puncture and hematoma formation, which may compromise CBF and intracranial venous drainage. If there is no issue with ICP, the subclavian vein is a reasonable alternative. Cannulation of antecubital veins may provide central venous access, but threading the catheter into the inlet of the right atrium may be technically difficult in small children. When rapid blood loss is a consideration in a small child in whom adequate peripheral venous access is difficult to obtain, a single-lumen, large-bore catheter is most commonly inserted in a femoral vein. Catheters inserted into the femoral veins usually are accessible to the anesthesiologist during most neurosurgical procedures. Multiple-lumen central venous catheters are inadequate for rapid blood transfusion. All central catheters should be removed as soon as possible after the procedure to minimize the risk of venous thrombosis.

### INDUCTION

For children with intracranial hypertension, the primary goals during induction are to minimize severe increases in ICP and decreases in blood pressure. Most intravenous drugs decrease CMRO<sub>2</sub> and CBF, which consequently decreases ICP.<sup>46</sup> Historically, sodium thiopental (4 to 8 mg/kg) was the default induction agent for neurosurgical cases. However, sodium thiopental is no longer available in the United States, although it remains available in other countries. In the United States, propofol has become the intravenous induction agent of choice for most children. Propofol (2 to 4 mg/kg) appears to have similar cerebral properties and an antiemetic effect; however, its antiemetic effect is usually not relevant for lengthy procedures. Etomidate, a possible neuroprotective agent, can be used if hemodynamic stability is a concern.<sup>47-49</sup> Ketamine should be avoided because of its known ability to increase cerebral metabolism, CBF, and ICP. Sudden increases in ICP have been reported after ketamine administration, especially in infants and children with hydrocephalus.<sup>50,51</sup>

Other measures to reduce ICP during induction include controlled hyperventilation and administration of fentanyl and supplemental hypnotics before laryngoscopy and intubation. Lidocaine (1.5 mg/kg) limits the increase in ICP when administered intravenously just before laryngoscopy.<sup>52</sup>

Sevoflurane has replaced halothane for inhaled inductions because of its more rapid onset, acceptability for pediatric patients, and hemodynamic stability. Similar to isoflurane in its cerebral physiologic effects, sevoflurane with hyperventilation appears to blunt the increase in ICP due to cerebral vasodilation from inhalational anesthetic agents alone.<sup>53-55</sup> Sevoflurane offers an additional advantage because it causes less myocardial depression compared with halothane.<sup>56</sup> However, sevoflurane when combined with hyperventilation produces epileptiform activity as measured by EEG. This may occur even in children with no history of clinical seizure activity (see Chapter 6).<sup>57</sup>

A common presentation is an uncooperative toddler who has an intracranial tumor and moderately decreased intracranial compliance and is agitated and resistant to separation from parents. Some clinicians would argue that a crying, agitated child has demonstrated a tolerance to increased ICP and that an intravenous induction is safer. Fortunately (for the anesthesiologist, although not for the child), children who have severe intracranial hypertension typically have a decreased level of consciousness, and it becomes easier to insert an intravenous catheter in those situations when it is most necessary.

## AIRWAY MANAGEMENT AND INTUBATION

Airway management must be effective and smooth to avoid the ICP-increasing effects of hypoxemia, hypercarbia, and coughing. Opioid administration and supplemental hypnotics before intubation improve cerebral compliance and minimize increases in ICP caused by laryngoscopy and intubation.

Either oral or nasal intubation may be appropriate. Nasotracheal intubation offers the advantage of increased stability and increased comfort for children when postoperative intubation is necessary. Nasotracheal tubes are often used for children who will be in the prone position (e.g., for a posterior fossa craniotomy), children whose airway will be inaccessible during the surgical procedure, and for smaller children.

Contraindications to nasal intubation include choanal stenosis, possible basilar skull fracture, transsphenoidal procedures, and sinusitis. If nasotracheal intubation is planned, it is advantageous to prepare the nares with topical vasoconstrictors, recognizing that systemic hypertension can occur in response to nasally administered vasoconstrictors. Placing a few drops of 0.25% phenylephrine (Neo-Synephrine) or oxymetazoline on cotton-tipped applicators and positioning them in the nares against the nasal mucosa can prevent overdose and help to gauge the patency of the nasal passage when anesthesia has been induced. It may also be useful to use a red rubber catheter or a nonlatex nasal trumpet to gently dilate the nares and minimize the risk of bleeding.<sup>58</sup> Whichever route is chosen for intubation, it is important to secure the tracheal tube with care because loss of airway intraoperatively in a prone child in pins or a child with limited airway access can result in disaster.

In prolonged, combined neurosurgical and craniofacial reconstructions, the tracheal tube may be sutured to the nasal septum or wired to the teeth. A nasogastric or orogastric tube is inserted after intubation to decompress the stomach and evacuate gastric contents; leaving it open to gravity drainage during the case can prevent positive pressure from building up in the stomach if air leaks around an uncuffed tracheal tube. The child's eyes should be closed and covered with a large, clear, waterproof dressing.

## NEUROMUSCULAR BLOCKING DRUGS

Because of its rapid onset and brief duration of action, succinylcholine is frequently used to facilitate intubation in children with a full stomach. The intubating dose is 1 to 2 mg/kg given intravenously or 4 to 5 mg/kg given intramuscularly.<sup>59</sup> In children, it may be safest to precede this with atropine (0.01 to 0.02 mg/kg) to prevent bradycardia. Succinylcholine does not significantly increase ICP in humans,<sup>60</sup> and any effect may be minimized by pretreatment with a nondepolarizing muscle relaxant.<sup>61</sup> However, this may make succinylcholine less effective, even when the dose of succinylcholine is increased. Succinylcholine is contraindicated when it may induce life-threatening hyperkalemia in the presence of denervation injuries due to various causes, including severe head trauma, crush injury, burns, spinal cord dysfunction, encephalitis, multiple sclerosis, muscular dystrophies, stroke, or tetanus.<sup>62</sup>

Alternatively, nondepolarizing muscle relaxants such as rocuronium, pancuronium, cisatracurium, or vecuronium may be used, but all have a slower onset of action than succinylcholine. However, when rocuronium is administered in sufficiently large doses (1.2 mg/kg), the onset of action is comparable with that of succinylcholine, with equivalent intubating conditions achieved in less than 1 minute.<sup>63</sup>

## POSITIONING

Positioning is an especially important consideration in pediatric neuroanesthesia. Children with increased ICP should be transported to the preoperative holding area and operating room with the head elevated in the midline position to maximize cerebral venous drainage.

After the child is in the operating room, the neurosurgeons and anesthesiologists must have adequate access to the child. In infants and small children, slight displacement of the tracheal tube can result in extubation or endobronchial intubation. During prolonged procedures, it is important for the anesthesiologist to be able to visually inspect the tracheal tube and circuit connections and to suction the tracheal tube when necessary. Using proper draping and a flashlight, the operator can usually create a "tunnel" to ensure access to the airway. All but very small children are placed in pins in a Mayfield head holder. The direction of the tube exiting the nares should be adjusted to remove pressure and avoid the risk of ischemia, particularly for cases that will continue for several hours. Neonates and small infants have thin calvaria, so head-pinning systems are often avoided. Instead, there are a variety of non-pin-based headrests available for these children. Adequate padding should be used in such situations (Figs. 24-4 and 24-5). Extreme head flexion can cause brainstem compression in children with posterior fossa pathology, such as

**FIGURE 24-4** **A**, The child is positioned prone before surgery. Extreme head extension was needed for correction of craniosynostosis, but the equipment for securing the head was the same as that used for a prone craniotomy. **B**, This particular frame uses gel pads to support the chin, ears, and forehead.

**FIGURE 24-5** Resuscitation from the modified standard sitting position. The normal operative position (**A** and **B**) is compared with the resuscitation position (**C**). The position can be expeditiously changed by one control of the operating table.

a mass lesion or Arnold-Chiari malformation. Extreme flexion can also cause high cervical spinal cord ischemia and tracheal tube kinking and obstruction.<sup>64</sup>

Extremities should be well padded and secured in a neutral position (i.e., palm supinated or neutral to avoid ulnar nerve compression). It is important to avoid stretching peripheral nerves and to prevent skin and soft tissue pressure injury because of direct contact with surgical accessories such as instrument stands and grounding wires (see Fig. 24-5). It is also important to ensure that extremities that are not directly visible to the anesthesiologist (e.g., those on the opposite side of the operating room table) cannot fall off the table during surgery, even if the table is rotated. In older children and adolescents undergoing prolonged procedures, deep vein thrombosis prophylaxis should be considered using compression or pneumatic stockings.<sup>65,66</sup>

### Prone Position

The prone position is commonly used for posterior fossa and spinal cord surgery. The torso should be supported to ensure free abdominal wall motion because increased intraabdominal pressure may impair ventilation, cause vena cava compression, and increase epidural venous pressure and bleeding. This is achieved most easily by placing silicone rolls or rolled blankets laterally on each side of the child's chest running from the shoulders toward the pelvis. A separate silicone roll or rolled blanket under the pelvis may occasionally be necessary in larger children. These rolls must not press into the flexed hips or compress the femoral nerve or genitalia. Placing the rolls in this position should also allow a precordial Doppler monitor to be easily placed on the anterior chest without undue pressure.

The head position depends on the surgical procedure. If surgery is limited to the lower spine, the head may be rotated and supported by padding, with care taken to avoid direct pressure on the eyes and nose and to keep the ears flat. For posterior fossa surgery, the head usually is suspended in pins to maintain central alignment of the head and maximal flexion. For infants and toddlers, a cerebellar head frame is another alternative when the cranium is too thin for pins. In this situation, the child's forehead and cheeks rest on a well-padded head frame, and the eyes are free in the center of a horseshoe-shaped support. Ensure that the tracheal tube is properly positioned (after taping) and does not migrate to a main-stem position while positioning the child prone. This can be confirmed while the child is still supine by flexing the child's head onto the chest and auscultating air entry bilaterally. Tape used to fix other tubes (e.g., gastric, esophageal) should not adhere to the tracheal tube tape so that accidental dislodgement of these tubes does not cause an extubation. An emergency plan should be formulated to turn the child supine if it suddenly becomes necessary.<sup>67</sup>

Significant airway edema may develop in a child who is in the prone position for an extended period. Oral airways are best avoided because they can cause edema of the tongue. Alternatively, a folded piece of gauze can be inserted between the teeth to prevent the tongue from extruding. Rarely, prophylactic postoperative intubation may be necessary if a great deal of facial swelling has developed during a prolonged surgery. Postoperative vision loss has been linked with prolonged spine surgery in the prone position and significant blood loss.<sup>68</sup> Avoidance of direct pressure on the globe of the eyes, staged procedures to decrease surgical time, and maintenance of stable hemodynamics with

avoidance of excessive intraoperative fluid administration should be ensured in prone children.<sup>69</sup>

### Modified Lateral Position

Insertion or revision of ventriculoperitoneal shunts may require that the child be rotated from the supine to the semilateral position. This is achieved by placing a roll under the child's dependent axilla (to prevent a brachial plexus injury). The knees should be supported in a slightly flexed position and the heels padded. This position is also used for some temporal and parietal craniotomies.

### Sitting Position

The sitting position is now used less commonly in pediatric neurosurgical procedures and is rarely used in children younger than 3 years of age. However, this position may be used for morbidly obese children who cannot tolerate the prone position due to excessive intrathoracic and abdominal pressures. When it is used, precautions to prevent hypotension and air embolism must be followed. The lower extremities should be wrapped in elastic bandages. The head must be carefully flexed to avoid kinking the endotracheal tube, advancing it into a bronchial position, or avoid compressing the chin on the chest, which can block venous and lymphatic drainage of the tongue. Extreme flexion can also result in brainstem or cervical spinal cord ischemia, or both. As in the prone position, nasotracheal tubes are often used because they are more secure. The child's upper extremities are supported in the child's lap. Control levers to lower the head position should be easily accessible to the anesthesiologist and unencumbered by wires and drapes (see Fig. 24-5).

### LOCAL ANESTHESIA

Local anesthetic should be injected subcutaneously before a skin incision to provide analgesia, and epinephrine is included in the local anesthetic to reduce cutaneous blood loss. If 0.25%

bupivacaine with 1 : 200,000 epinephrine is used, the dose should be limited to 0.5 mL/kg. When greater volumes are required, the solution can be diluted with normal saline. This dilute solution is still effective for vasoconstriction and provides a prolonged sensory block postoperatively. Specific blocks of supraorbital and supratrochlear nerves can provide analgesia from the frontal area to the midcoronal portion of the occiput.<sup>70</sup> Blockade of the great occipital nerve provides analgesia from the posterior of the occiput to the midcoronal area of the occiput, whereas block of the supraorbital nerve provides analgesia to the front of the occiput (see Figs. 41-9 and 41-10).<sup>71,72</sup>

### MAINTENANCE OF GENERAL ANESTHESIA

General anesthesia is required for most therapeutic and many diagnostic procedures in pediatric neurosurgery. Ventilation is controlled if intracranial hypertension is a concern. Although spontaneous ventilation provides another indication of brainstem function, its disadvantages (eg., hypoventilation, increased potential for air embolism) are usually outweighed by the safety of controlled ventilation.

Maintenance of general anesthesia can be accomplished using inhalational anesthetics, intravenous infusions, or a combination of these drugs. Anesthetics that decrease ICP and CMRO<sub>2</sub> and maintain CPP are most desirable (Table 24-1). The commonly used inhalational agents uncouple CBF and CMRO<sub>2</sub> such that CBF increases while CMRO<sub>2</sub> decreases. All potent inhalational agents are cerebral vasodilators, which increase the CBF and ICP. Low concentrations of isoflurane, sevoflurane, or desflurane, combined with ventilation to maintain normocarbida, minimally affect CBF and ICP.<sup>53,54,73</sup> Isoflurane is often the inhalational agent of choice for maintenance of neuroanesthesia. At two times the minimal alveolar concentration (MAC), this dose of isoflurane induces a level of anesthesia that is associated with an isoelectric EEG while, unlike several other inhalational agents, maintaining hemodynamic stability. Enflurane is no longer used

**TABLE 24-1** Neurophysiologic Effects of Common Anesthetic Agents

CBF, Cerebral blood flow; CMRO<sub>2</sub>, cerebral metabolic rate for oxygen; CPP, cerebral perfusion pressure; CSF, cerebrospinal fluid; ICP, intracranial pressure; MAP, mean arterial pressure; N/A, not applicable; SSEP, somatosensory evoked potential; ↑, increased; ↓, decreased; 0, no change.

NOTE: The relative number of arrows refers to the degree of effect on the noted parameter. For example, CMRO<sub>2</sub> is decreased much more with isoflurane than opioids. In cells with up and down arrows, there are conflicting reports on the effect of the drug.

and may be epileptogenic, especially when combined with hyperventilation.<sup>74</sup> Other studies have demonstrated a similar effect with sevoflurane and hyperventilation, but the clinical implications of this are yet to be defined.<sup>75</sup>

Practitioners debate the routine use of nitrous oxide for intracranial neurosurgical procedures. Opponents cite the increased risk of postoperative nausea and vomiting (PONV) with nitrous oxide in a surgical population already at greater risk for PONV.<sup>76</sup> Proponents cite studies that failed to demonstrate an increased risk of PONV.<sup>77</sup> Nitrous oxide can increase CBF in humans in a dose-dependent fashion through cerebral vasodilatation.<sup>78,79</sup> This increase in CBF can lead to an increase in ICP, which can be deleterious if the child already has reduced intracranial compliance.<sup>80</sup> Nitrous oxide can also affect somatosensory and motor evoked potentials, especially when concentrations in excess of 50% are used.<sup>81-83</sup> Animal data have shown that nitrous oxide can counteract the protective effects of thiopental in a model of cerebral ischemia.<sup>84</sup>

Proponents of the use of nitrous oxide for intracranial procedures cite the long track record of safety. There are no outcome studies in humans showing a difference between using nitrous oxide or not. It is often of great clinical interest to obtain a neurologic assessment immediately after the conclusion of an intracranial procedure, and some practitioners prefer the use of nitrous oxide to aid in achieving this goal. Studies have demonstrated the safety of using nitrous oxide in a variety of combinations with other agents during intracranial procedures.<sup>85</sup> Nitrous oxide is relatively contraindicated, however, if the child has undergone a craniotomy within the past few weeks because air can remain in the head for prolonged periods after previous neurosurgery.<sup>86</sup>

Fentanyl is often administered as part of an opioid-based technique because it is easily titratable with minimal adverse effects. A common loading dose is 5 to 10 µg/kg, with a dose of 2 to 5 µg/kg/hr usually adequate for maintenance. Adverse effects, including hypotension, can be avoided by giving the loading dose incrementally. Practitioners commonly use other opioids such as remifentanyl and sufentanyl. Dexmedetomidine, an  $\alpha_2$ -agonist sedative, has also been used in children for neurophysiologic monitoring, for awake craniotomies, to facilitate smooth wake-ups after neurosurgical procedures, and for neuroprotection.<sup>87-90</sup>

### APOPTOTIC NEURODEGENERATION

Several investigators have demonstrated that commonly used anesthesia drugs accelerate programmed cell death (i.e., apoptosis) in the CNS of immature rodents and rhesus monkeys.<sup>91-93</sup> This laboratory observation has provoked a heated debate about its relevance to anesthetizing neonates,<sup>94-97</sup> which has been extended to the lay press.<sup>98</sup> Although these experimental paradigms have yielded some surprising findings, extrapolating these data to the practice of anesthetizing human neonates is questionable (see Chapter 23).

The animal and in vitro studies have significant limitations with respect to the experimental model, agent dosage or concentration, duration of exposure (absolute and compared with human exposures), lack of surgical stimulation, and developmental age and stage. No detectable clinical marker or syndrome is associated with early anesthesia exposure in former neonates who have undergone surgery and anesthesia at birth or in the first several years of life during rapid brain growth (i.e., synaptogenesis). In the only primate study, the degree of apoptosis after 3 hours of a ketamine infusion was similar to that of the control

but significantly less than after a 24-hour infusion.<sup>93</sup> This occurred in the presence of blood concentrations of ketamine that were 10-fold to several hundred-fold greater than those reported after a single dose of ketamine in infants. These findings suggest that in this model, ketamine-associated neurodegeneration is a time-dependent, dose-dependent phenomenon whose limits have not been established.

Despite the confounding effects of prematurity and coexisting congenital anomalies, clearly characterized syndromes have been associated with maternal consumption of alcohol and anticonvulsant drugs. Discrepancies in neurocognitive outcomes exist.<sup>92,99</sup> Most neonatal and infant surgery is urgent, and anesthesia care is essential to proceed safely. Several retrospective database studies suggest that multiple anesthesia episodes are associated with learning disabilities and cognitive dysfunction, but most of these children were anesthetized before pulse oximetry and capnography were a standard of care. Unrecognized episodes of hypoxemia or excessive ventilation with reduced CBF might have contributed. It is also unclear whether children who required more than one surgical procedure when younger than 4 years of age might have had neurocognitive developmental issues that were associated with the pathology requiring surgery and were totally separate from exposure to anesthetic agents.<sup>100-102</sup> One retrospective study demonstrated that identical twins who were discordant for general anesthesia and surgery showed no evidence of cognitive dysfunction in follow-up assessments.<sup>103</sup>

In summary, a growing body of evidence supports the idea that some anesthetic agents are harmful to the developing brain in various species of neonatal animals. There is neither adequate evidence nor a consensus among practitioners that this phenomenon occurs in very young humans, but this remains an area of great interest and research.

### BLOOD AND FLUID MANAGEMENT

Blood loss is difficult to estimate accurately during neurosurgery because most of the losses are absorbed by the operative drapes and the surgical field is difficult for the anesthesiologist to visualize. Accuracy can be improved if all suctioned blood is collected in calibrated containers visible to the anesthesiologist and an overhead camera provides a view of the operative field at all times. Blood loss is usually greatest at the beginning of surgery, when the scalp is incised, and when a large bone flap is removed.

Fluid and blood product management is discussed in Chapters 8 and 10. Disruption of the blood-brain barrier by underlying pathologic processes, trauma, or surgery predisposes neurosurgical patients to cerebral edema, which may be exacerbated by excessive administration of intravenous fluids. Intravenous fluid management during neurosurgical anesthesia involves cerebral perfusion, cerebral edema, water and sodium homeostasis, and serum glucose concentration.

In most cases, blood transfusions are not planned and attempts are made to avoid administration of blood products with their associated risks. Crystalloid solutions are commonly administered. Lactated Ringer solution is not considered a truly isotonic solution because its osmolality is 273 mOsm/L (normal: 285 to 290 mOsm/L). Normal saline, which is slightly hypertonic (308 mOsm/L), is the fluid of choice because reduction of serum osmolality is not desirable. However, rapid infusion of large volumes of normal saline has been associated with a hyperchloremic non-anion gap metabolic acidosis.<sup>104</sup> The clinical significance of this acidosis is not clear. If there are large fluid requirements during surgery, alternating bags of lactated Ringer

solution with normal saline can minimize the risk of hypernatremia and acidosis and avoid hyposmolality.

Inducing dehydration with osmotic and loop diuretics is a useful strategy to minimize cerebral edema and provide an optimal surgical field. However, hypotension and rebound effects may be associated with their use. Rapid administration of hypertonic solutions can cause profound but transient hypotension due to peripheral vasodilation.<sup>105</sup> Glucose-containing solutions usually are unnecessary during neurosurgical procedures because blood glucose concentrations are well-maintained even in small children in the absence of intravenous glucose administration during typical (balanced) neurosurgical anesthetics. However, glucose may be indicated when hypoglycemia is a concern, such as in diabetic children, children receiving hyperalimentation, preterm and full-term neonates, and malnourished or debilitated children. In these situations, glucose solutions should be administered at or slightly below maintenance rates (by constant infusion pump) and serum glucose concentrations should be monitored periodically throughout surgery. The potential association of larger cerebral infarct size with hyperglycemia (i.e., blood glucose values in excess of 250 mg/dL) during ischemia is of particular concern.<sup>106</sup>

Meticulous management of fluids and blood products to minimize cerebral edema is a cornerstone of pediatric neuroanesthesia. Although cerebral hemorrhage is fortunately a rare event, when it does occur, it can be sudden and catastrophic. All children should have secure, large-bore intravenous access, and blood products should be available along with the means for warming the blood.

### TEMPERATURE CONTROL

Because the head accounts for a large proportion of an infant's body surface area, infants are particularly susceptible to heat loss during neurosurgical procedures. Attention should be focused on maintaining normal temperature from the time the child is brought into the operating room, although moderate hypothermia during neurosurgery may be useful to decrease the CMRO<sub>2</sub>. Ambient room temperature should be increased during positioning, preparation, and draping. Infrared warming lights may be helpful for infants, and warming blankets may be useful for infants weighing less than 10 kg. Forced-air warming remains the most effective means of maintaining body temperature.<sup>107</sup>

### VENOUS AIR EMBOLI

Venous air embolism (VAE) is a potential danger during intracranial procedures. The larger the pressure gradient between the operative site and the heart, the greater the potential for clinically significant entrainment of air into the central circulation.<sup>108</sup> For example, when the operative site is far above the heart (e.g., in a seated craniotomy) or when the CVP is low (e.g., acute blood loss during craniofacial procedures), it creates an environment for a VAE. Intracranial procedures are a particular concern because intracranial venous sinuses have dural attachments that impede their ability to collapse. Other potential air entry sites during neurosurgical procedures include bone, bridging veins, and spinal epidural veins. The sequence of events that should be followed when a VAE occurs is to identify the problem, stop further air entrainment, and support the circulation. Understanding the cause, prevention, and treatment of VAE is crucial because the consequences can be life-threatening.

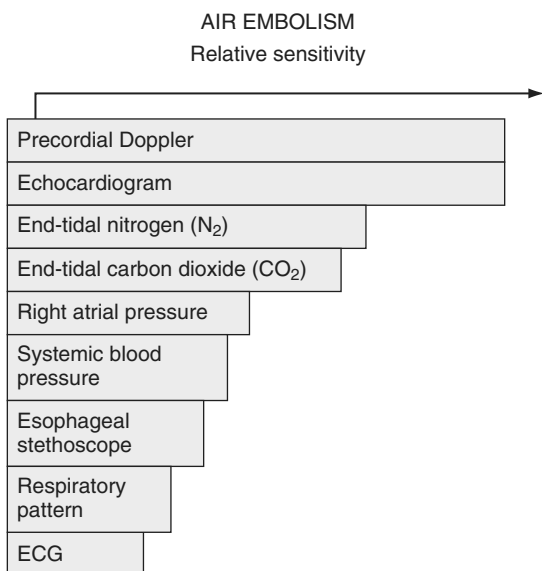

When air enters the central circulation, it can accumulate in the right atrium or the right ventricular outflow tract. Cardiac

output may be reduced, depending on the size of the air lock. If enough air is entrained into the circulation, the preload to the right ventricle decreases, or the right-sided heart afterload increases acutely, which can lead to cor pulmonale, acutely decreasing left ventricular preload and ultimately causing cardiovascular collapse. One study in dogs demonstrated that as little as 1 mL/kg of air could increase pulmonary artery pressure 200% to 300%.<sup>109</sup> Intracardiac shunts such as a patent foramen ovale, atrial or ventricular septal defects, and other congenital cardiac defects may allow air to access the systemic circulation, including the coronaries and brain. The risk of VAE is even greater in infants and children because potential intracardiac shunts exist in many otherwise healthy infants and children. They may become clinically important if pulmonary hypertension develops acutely after a large air embolism. Some clinicians recommend preoperative echocardiographic screening for patent foramen ovale in any child being considered for a sitting craniotomy; others regard a patent foramen ovale to be an absolute contraindication to the sitting position.<sup>110,111</sup>

Although the incidence of VAE is greatest in the sitting position, the lateral, supine, and prone positions are not free of risk. VAE have also been observed during craniotomy for craniosynostosis, even when the operating room table is flat and rarely when the surgery involved endoscopic strip craniectomy, although most occur without clinical sequelae.<sup>112,113</sup> The incidence of VAE in children undergoing suboccipital craniotomy in the sitting position is not significantly different from that in adults, but children appear to have a greater incidence of hypotension and a smaller likelihood of successful aspiration of central (intravascular) air.<sup>114</sup>

Several techniques may be used to detect VAE. Depending on the study design, the usual order of sensitivity of detecting air in the heart is transvenous intracardiac echocardiography (0.15 mL/kg) > transesophageal echocardiography (0.19 mL/kg) = precordial Doppler probe (0.24 mL/kg) > pulmonary artery pressure (0.61 mL/kg) = end-tidal CO<sub>2</sub> tension (0.63 mL/kg) = arterial O<sub>2</sub> tension > mean arterial pressure (1.16 mL/kg) = arterial CO<sub>2</sub> tension.<sup>115,116</sup> Transvenous intracardiac echocardiography is commonly used to guide catheters in cardiac ablation procedures or insertion of foramen ovale occlusion devices, but it is invasive and infrequently used in pediatric anesthesia. A precordial Doppler probe has been traditionally placed over the fourth or fifth intercostal space at the right sternal border to best monitor right heart sounds, although evidence suggests that placing the Doppler probe at the left parasternal border may be at least as sensitive (Fig. 24-6).<sup>117,118</sup> Appropriate Doppler positioning can be confirmed by listening for the characteristic change in sounds after rapid administration of a few milliliters of saline into a venous catheter. The precordial Doppler probe is particularly valuable because it is inexpensive, easy to use, benign, and non-invasive. Although transthoracic or transesophageal echocardiography is the most specific method for detecting small air emboli, it is not easily used intraoperatively, especially in children during neurosurgical procedures.<sup>110,119,120</sup>

Monitoring end-tidal gas tensions is important during neurosurgical procedures. When VAE occurs, there is a ventilation/perfusion mismatch caused by the air blocking passage of blood through the pulmonary circulation, increasing dead space ventilation with a sudden decrease in end-tidal CO<sub>2</sub> partial pressure and activation of complement resulting in pulmonary interstitial edema, neutrophil infiltration, and lung injury (Fig. 24-7).<sup>115</sup> The end-tidal CO<sub>2</sub> partial pressure remains a useful and cost-effective

**FIGURE 24-6** Relative sensitivities of air embolism-monitoring modalities. ECG, Electrocardiogram.

**FIGURE 24-7** Mechanism of decreased end-tidal carbon dioxide ( $ETCO_2$ ) after an air embolus. (Courtesy J. Drummond, MD.)

strategy in diagnosing massive VAE, although its sensitivity has been surpassed by other approaches (see Fig. 24-6). An increase in end-tidal nitrogen partial pressure during continuous monitoring is a specific sign of air emboli. Although slightly more sensitive than a decrease in end-tidal  $CO_2$ , an increase in end-tidal nitrogen is not detected by most infrared analyzers in practice and is usually of such small magnitude that it may be difficult to detect.

Less sensitive or more invasive methods to detect VAE include ECG changes, changes in heart rate, decreases in systemic blood pressure, and increases in right atrial and pulmonary arterial pressures. Right atrial and pulmonary artery pressures increase quickly after the emboli (within 30 seconds). The magnitude of these increases correlates with the size of emboli, although these findings should not be relied on alone for monitoring and diagnosis.

On suspicion or diagnosis of VAE, immediate measures must be taken by the surgeons and anesthesiologists to prevent continued entrainment of air and consequent hemodynamic deterioration. The surgeon should immediately flood the field with saline and apply bone wax to exposed bone edges. The

anesthesiologist should discontinue nitrous oxide and place the child in the Trendelenburg position, which has the effect of increasing cerebral venous pressure, stopping entrainment of air, augmenting the child's peripheral venous return, and increasing systemic blood pressure. Occlusion of the internal jugular veins in an attempt to increase cerebral venous pressure should be done with great care because occlusion of the carotid arteries can lead to cerebral ischemia. The application of positive end-expiratory pressure increases CVP but also decreases cardiac filling pressure, cardiac output, and blood pressure; extreme increases in positive end-expiratory pressure are usually unwarranted. Chest compressions, vasopressors, and aggressive fluid resuscitation may be required.

Aspiration of air from a central venous catheter is rarely successful unless massive amounts have been entrained. When central venous catheters are necessary, such as for a child in the sitting position or when massive blood loss is anticipated, an attempt should be made to place the tip at the junction of the superior vena cava and right atrium to provide the optimal location for aspiration of entrained air. More importantly, a central venous catheter is useful to estimate maintenance of circulating blood volume and to rapidly administer fluids and resuscitative medications when necessary. The position of a central venous catheter near the heart should be confirmed by radiograph, by transducing CVPs, or with the aid of ECG monitoring (i.e., biphasic P waves develop in a lead at the tip of the catheter). The threshold for aspirating air may be increased by properly positioning a multiple-orifice central venous catheter using a trans-venous intracardiac echocardiography probe.<sup>115</sup> Because erosion of the catheter tip through the heart causing fatal pericardial tamponade has occurred after surgery in small children, soft silicone catheters are recommended.<sup>121,122</sup>

## EMERGENCE

Protecting the brain is a major concern during neurosurgical procedures (Table 24-2). Emergence and extubation should be smooth and controlled to prevent fluctuations in ICP and in venous and arterial pressures.<sup>123</sup> To avoid vomiting during emergence, a multimodal antiemetic approach is advised.<sup>124</sup> Despite this approach, the incidence of PONV is high, which may be attributed to several factors: blood in the CSF is a potent emetic, opioids are often used to treat postoperative pain, and headache itself can precipitate emesis.

Intravenous lidocaine (1.0 to 1.5 mg/kg) given before extubation may help to suppress coughing and straining on the tracheal tube, although fentanyl appears to be equally effective and may be less sedating. Labetalol, an  $\alpha$ - and  $\beta$ -adrenergic blocking agent, can be administered incrementally for the control of blood pressure during the acute period of emergence, but this is rarely necessary in children who have received adequate doses of opioids during surgery. For adolescents, intravenous labetalol (0.1 to 0.4 mg/kg given every 5 to 10 minutes until desired effect is achieved) may be necessary, but this usually does not have to be repeated in the postoperative period. Esmolol is used by some practitioners and has been as effective as labetalol in controlling hypertension after intracranial surgery in adults.<sup>125</sup> However, esmolol should be used with caution in infants and smaller children because their cardiac output depends on heart rate. There are no studies evaluating the use of esmolol in children for such an application. Dexmedetomidine may be useful in facilitating a smooth emergence while still allowing evaluation of the child's neurologic status.

**TABLE 24-2** Maneuvers of Neuroprotection

Goals	Avoid cerebral edema
	Avoid cerebral hypoxia
	Avoid cerebral hypoperfusion
	Avoid cerebral hypermetabolism
	Avoid neuronal membrane damage
<b>Maneuvers</b>	
Head of bed at 30 degrees in midline	Increases cerebral venous drainage while maintaining CPP
Corticosteroids	May improve outcome in spinal cord injury
	Decrease vasogenic cerebral edema in children with tumors
	Stabilize neuronal membranes
	Free-radical scavengers
Controlled ventilation	Maintain $P_{aCO_2}$ at normal to slightly low levels: prevents both cerebral vasodilation and increased ICP
Muscle paralysis	Avoids coughing, straining, child movement, and other causes of increased ICP
Ventricular drainage	Decreases ICP
Antihypertensives	Prevent further cerebral edema, ischemia, and cerebral hemorrhage. Severe hypotension can significantly decrease CPP.
Anticonvulsants	Prevent seizure activity and increased ICP
Hypothermia	Decreases $CMRO_2$ and $CMRglu$ consumption
Barbiturate coma	Membrane-stabilizing effect
	Decreases CBF and $CMRO_2$

CBF, Cerebral blood flow;  $CMRglu$ , cerebral metabolic rate for glucose;  $CMRO_2$ , cerebral metabolic rate for oxygen; CPP, cerebral perfusion pressure; ICP, intracranial pressure;  $P_{aCO_2}$ , partial pressure of arterial carbon dioxide.

Neuromuscular blockade should be pharmacologically reversed because even the slightest residual weakness is poorly tolerated and may interfere with the neurologic examination. Adequate spontaneous ventilation and oxygenation and an awake mental status are required before extubation. If postoperative intracranial hypertension is possible or if the child does not meet respiratory or neurologic criteria for extubation, the tracheal tube should be left in place, sedation should be administered, and the child should be transported to an intensive care unit.

The child should be as fully alert as possible immediately after the operation to permit repeated neurologic examinations to assess recovery and to detect a deteriorating status. In unconscious children, ICP can be monitored invasively. CT scans can help to evaluate the cause of an increased ICP or deteriorating mental status.

Pain is usually not severe after a craniotomy, but it can be treated with incremental doses of opioids. Ketorolac is best avoided in the early postoperative period because of its effects on platelet function. Acetaminophen may be administered orally, rectally, or intravenously for mild pain.<sup>126</sup>

Diabetes insipidus or inappropriate secretion of antidiuretic hormone may complicate postoperative fluid and electrolyte management, particularly when surgery is in the region of the hypothalamus and pituitary gland. Careful observation of fluid status and repeated laboratory evaluation of blood and urine osmolality and sodium levels are important in this situation. When diabetes insipidus occurs, it can be managed

with a continuous infusion of dilute aqueous vasopressin (1 to 10 mU/kg/hr).<sup>127</sup> In such circumstances, large volumes of hypotonic intravenous solutions must be avoided because they may rapidly decrease the serum sodium level and osmolality. If normal saline is administered in strictly limited volumes, aqueous vasopressin can control the electrolyte and fluid balances of children with diabetes insipidus until they resume oral fluids. At that time, intranasal or oral desmopressin (DDAVP) can be substituted. When diabetes insipidus develops after surgery in the pituitary region (e.g., during resection of a craniopharyngioma), it may only be transient, and it is important to repeatedly assess the need for vasopressin.

Portable EEGs and evoked auditory, somatosensory, and less commonly, visual potentials may be helpful in assessing children who are deeply sedated or paralyzed. Observation in an intensive care unit capable of managing children is essential for the prevention or early detection and treatment of postoperative complications. CT and MRI are often performed 1 or 2 days after a craniotomy or earlier if neurologic deterioration develops.

## Special Situations

### TRAUMA

#### Head Injury

Among children, trauma is the primary cause of death, and head injuries produce most of this mortality and cause much of the morbidity in survivors.<sup>128-130</sup> Motor vehicle accidents continue to be the most frequent preventable cause of head injury, although domestic violence and sports-related head injury are also common in children (see Fig. 38-1). Assaults and suicide attempts have become increasingly common among adolescents.

Children with head trauma may have minimal neurologic abnormalities at the time of initial evaluation. However, increased ICP and neurologic deficits may progressively develop. They develop slowly because brain injuries occur in two stages. The primary insult that occurs at the time of impact results from the biomechanical forces that disrupt the cranium, neural tissue, and vasculature. The secondary insult is the parenchymal damage caused by the pathologic sequelae of the primary insult. These changes can result from hypotension, hypoxia, cerebral edema, or intracranial hypertension. Whereas prevention of primary injuries must be addressed in a sociopolitical forum such as through seatbelt laws, sports injury prevention, and domestic violence legislation, anesthesiologists are instrumental in preventing or minimizing secondary insults (see Chapter 38).

There are significant differences between children and adults in the pattern of CNS injuries. Although intracranial hematomas (i.e., epidural, subdural, or intraparenchymal) are common in adults, they are less common in children. In contrast, diffuse cerebral edema after blunt head trauma occurs more often in children than in adults.<sup>131</sup>

#### Scalp Injuries

One of the most common head injuries in children is the scalp laceration. Most can be managed in the emergency department, but more serious injuries may require the operating room to provide immobility and comfort. Children can lose a significant amount of blood from a scalp injury because a larger fraction of the cardiac output perfuses the head compared with adults. Infants younger than 1 year of age may become hemodynamically unstable from blood loss from a subgaleal hematoma alone, as in a closed scalp injury, and hypovolemia should always be

considered and treated before induction of anesthesia. Coexisting intracranial or other injuries must be considered, and a preoperative CT scan may be warranted.

### Skull Fractures

Skull fractures are a common manifestation of head trauma in children. Most are linear and do not require surgical treatment. These fractures are of concern primarily because the force required to produce them may damage the underlying brain and vasculature. A linear fracture over a major blood vessel (e.g., middle meningeal artery) or a large dural sinus may result in intracranial hemorrhage. Most children have an uneventful course after sustaining a simple skull fracture. A few develop a leptomeningeal cyst or growing fracture that eventually requires surgical treatment. Multiple skull fractures in the absence of documented major trauma should always raise the suspicion of child abuse (See Fig. 38-2), which is also referred to as *nonaccidental trauma*.

Depressed skull fractures often require surgical repair. They may occur even in the absence of a scalp laceration. However, displacement of the inner table of the skull requires greater force than that needed to produce a simple linear fracture and has greater potential to damage underlying tissues. Approximately one third of all depressed fractures are uncomplicated, another third are associated with dural lacerations, and the remaining third are associated with cortical lacerations. The extent of cortical injury is the primary determinant of morbidity and mortality. Surgical débridement and elevation of the depressed bone are usually performed as soon as possible after the injury (Fig. 24-8, *A*).

Basilar skull fractures are less common in children. Despite the force needed to produce these fractures, they typically have an excellent prognosis and rarely require surgical intervention. However, the possibility of a basilar skull fracture should be considered when caring for children with altered mental status, seizures, or associated trauma requiring surgery. Findings include periorbital ecchymoses ("raccoon eyes"), retroauricular ecchymosis (i.e., the Battle sign) (see Fig. 38-2, *B*), hemotympanum, clear rhinorrhea, or otorrhea. Unless absolutely necessary (e.g., mandibular wiring), nasotracheal intubation or passage of a nasogastric tube is best avoided because these tubes have inadvertently traversed these skull fractures and entered the cranium.<sup>132-134</sup> Complications of basilar skull fracture include meningitis from a CSF leak, cranial nerve damage, and anosmia.

### Epidural Hematoma

Epidural hematomas most commonly develop in the temporo-parietal region due to arterial bleeding from a severed middle meningeal artery. They can also develop in the posterior fossa as a result of bleeding from a venous sinus. Epidural hematomas are not necessarily associated with an overlying skull fracture. The classic natural history in adults is a "lucid interval" between the initial loss of consciousness and subsequent neurologic deterioration. Infants and children may not demonstrate an altered mental status in the early stages after the injury. However, as the hematoma expands, it can lead to a loss of consciousness, hemiparesis, and pupillary dilatation. This deterioration can be quite rapid once a mass effect occurs. Treatment is prompt surgical evacuation because delays are associated with increased morbidity. Medical therapy directed at decreasing ICP should be instituted as soon as a diagnosis is suspected but should not delay surgical repair (see Fig. 24-8, *B*). Children recover well after these

**FIGURE 24-8** *A*, This depressed skull fracture required surgical intervention. *B*, Children with severe head trauma (in this case, a shaken baby) may present with marked increases in intracranial pressure.

hemorrhages, although morbidity is usually a reflection of underlying brain injury or lengthy delay in treatment.

### Subdural Hematoma

Subdural hematomas are usually associated with cortical damage resulting from direct parenchymal contusion or laceration of venous blood vessels. Acute subdural hematomas are almost always traumatic and are frequently a result of abuse, such as shaking of small children, particularly those younger than 1 year of age. Shaken baby syndrome occurs when an infant is shaken so vigorously that significant neuronal disruption occurs and tears in the cortical bridging veins cause subdural hematomas.<sup>135-137</sup> These infants suffer significant brain damage complicated by episodes of apnea and further hypoxic insult.

Subdural hematomas occasionally result from birth trauma within the first hours of life. Vitamin K deficiency, congenital coagulopathies, and disseminated intravascular coagulation are considerations in these situations. Great force is required to produce a subdural hematoma, whether by direct impact, laceration of blood vessels, or traumatic separation of the brain and overlying dura. Cerebral edema, uncontrolled intracranial hypertension, and persistent neurologic deficits often characterize the postoperative course. Chronic subdural hematomas or effusions may also develop in infancy, although these children do not usually present with acute symptoms. Children are often diagnosed because they are irritable and vomiting or have an increased head circumference. Chronic subdural hematomas can increase

in size, causing slow but significant increases in ICP. Although a craniotomy is sometimes performed, most children undergo some form of hematoma drainage or shunting procedure as definitive treatment.

### Intracerebral Hematoma

Intracerebral hematomas are fortunately rare but have a poor prognosis. Deep parenchymal hematomas are most often extensions of cortical contusions in a child with severe neurologic injury. Rarely, a localized hematoma may be appropriate for surgical evacuation to decompress the brain. However, intraparenchymal hematomas are not evacuated for fear of damaging viable brain tissue. Anticonvulsants are usually administered prophylactically, and it is safest in the initial period after injury to avoid any medications that interfere with coagulation (e.g., ketorolac).

### Spinal Injury

Although isolated cervical spine injuries are uncommon in children, those with severe head trauma should always be managed as if they also have a cervical spine injury.<sup>138,139</sup> Different causes of spinal injuries are associated with specific age groups. Motor vehicle accidents produce the largest number of injuries in older children and adolescents, whereas birth injuries and falls are the most common cause in infants and young children.<sup>140</sup> Spinal cord injury itself may be caused by a variety of forces, including hyperflexion, hyperextension, rotation, vertical compression, flexion rotation, and shearing. The injury may involve bony, ligamentous, cartilaginous, vascular, or neural components of the spine or adjacent structures. The biomechanics and functional anatomy of the pediatric spine depend on the age of the child. Older children and teenagers are more likely to sustain injuries in the thoracolumbar region of the spine, whereas infants and younger children are more likely to suffer injuries in the high cervical region, particularly in the atlantoaxial region. The cervical spine is at greater risk in the infant and younger child because of the relatively weak and flexible neck muscles that support a proportionally large and heavy head, with the atlantooccipital area acting as a pivot point. Atlantooccipital dislocations are major neurologic injuries, leaving children neurologically devastated but not necessarily dead.

As with brain injury, spinal cord injury occurs in two phases. The primary insult results from biomechanical forces and bony fragments directly impacting the spinal cord. The secondary insult results from the pathologic sequelae of the primary insult: edema and ischemia due to cortical compression, hypotension, or hypoxia. Inappropriate manipulation of a child with an unstable fracture can exacerbate primary and secondary injuries. Anesthesiologists who provide care for a child with a potential cervical spine injury should be aware that spinal cord injuries in children commonly occur without actual evidence of spinal bone fractures on plain cervical radiographs. These injuries are known as spinal cord injuries without radiologic abnormality (SCIWORA).<sup>141</sup> Injuries to the cervical spine in particular are often difficult to recognize but may be identified by odontoid displacement or prevertebral swelling on radiographs. As a result, CT is frequently indicated when a spinal injury is initially suspected in a child with trauma. After a child with a potential spinal injury is determined to be medically stable, these studies should be obtained as soon as possible. The child's airway and cardiorespiratory function must be continuously and closely monitored until a spinal cord injury can be ruled out. Sometimes, as with brain injury,

there can be a delay in the onset of neurologic deficits with SCIWORA injuries.<sup>142</sup>

Respiratory failure is the most common cause of death after isolated cervical spine injury. The level of injury determines the degree of impairment. The phrenic nerve originates primarily from C4 but receives contributions of fibers from C3 and C5. Lesions at C5 leave partial diaphragmatic innervation but impair abdominal and intercostal accessory muscles. Lesions between C6 and T7 preserve diaphragmatic innervation but diminish accessory muscle function.

Children with a cervical spine injury may rapidly develop respiratory failure due to decreased vital capacity, increased dead space, retention of secretions, and respiratory muscle fatigue. Resultant hypercarbia and hypoxia aggravate the secondary injury to the brain and spinal cord. Respiratory status may be further impaired by associated trauma to the chest, causing pulmonary contusion or pneumothorax, or by aspiration of gastric contents.

Prompt airway management is essential to avoid hypoxia, ensure adequate respiratory mechanics, preserve neural function, and prevent extension of spinal injury (see Figs. 38-5 through 38-7). The head and neck must be immediately immobilized; restraint of the extremities may also be required. Various tracheal tubes and laryngoscope blades should be available, as well as equipment and personnel for an emergency tracheostomy. Insertion of a laryngeal mask airway may be lifesaving until a more secure airway can be achieved with fiberoptic or other means.<sup>143-148</sup> Small fiberoptic bronchoscopes (2.2-mm diameter) can fit through infant-sized tracheal tubes. Retrograde intubation using a guide-wire introduced through the cricothyroid membrane may be useful in older children or adolescents (see Chapter 12). However, an unstable infant or child whose airway cannot be secured by conventional means is probably best managed by an emergency tracheostomy. As a temporizing measure, a cricothyroidotomy can be performed (see Figs. 12-25 through 12-27).<sup>149</sup> This permits oxygenation (although inadequate ventilation) until personnel and equipment for tracheostomy are assembled. An emergent surgical airway can be extremely difficult to perform on a small child or infant, even by experienced and skilled hands.

Hemodynamic instability may be a problem due to hypovolemia from other injuries or severe head trauma. Other sites of bleeding such as long bone fractures and abdominal trauma should be ruled out. Children with spinal shock exhibit loss of vasomotor tone or loss of normal neurocardiac function with associated bradycardia and decreased myocardial contractility; intravenous fluids and vasopressors may be necessary.

Although there are few data for adults and children, corticosteroids are often administered with spinal injuries as soon as possible after the initial trauma in the hope of reducing the neurologic injury. The most commonly used drug is methylprednisolone; 30 mg/kg is administered over the first 15 minutes, followed by an infusion of 5.4 mg/kg/hr for the next 23 hours.<sup>150,151</sup> Methylprednisolone is thought to be effective through multiple mechanisms, including improved spinal blood flow, inhibition of the arachidonic acid cascade, and modulation of the local immune response.<sup>152</sup> Some evidence suggests that GM<sub>1</sub> ganglioside, with or without methylprednisolone, may be advantageous in decreasing demyelination and promoting neurologic recovery if administered soon after a spinal injury.<sup>153-159</sup>

If the spinal cord injury is more than 24 hours old, succinylcholine should be avoided because it can result in massive hyperkalemia.<sup>160</sup> Physiologic changes may result from autonomic

hyperreflexia, which frequently develops after cervical or high thoracic spinal lesions. Autonomic hyperreflexia can produce severe and life-threatening vasomotor instability with hypertension and arrhythmias.<sup>161,162</sup>

## CRANIOTOMY

### Tumors

Brain tumors are the most common solid tumors in children, exceeded only by the leukemias as the most common pediatric malignancy.<sup>163</sup> Between 1500 and 2000 new brain tumors are diagnosed annually in children in the United States. Unlike those in adults, most brain tumors in children are infratentorial in the posterior fossa. They include medulloblastomas, cerebellar astrocytomas, brainstem gliomas, and ependymomas of the fourth ventricle. Because posterior fossa tumors usually obstruct CSF flow, increased ICP occurs early. Presenting signs and symptoms include early morning vomiting and irritability or lethargy. Cranial nerve palsies and ataxia are also common findings, with respiratory and cardiac irregularities usually occurring late. Sedation or general anesthesia may be required for radiologic evaluation or radiation therapy.

Surgical resection of a posterior fossa tumor presents a number of anesthetic challenges. Children are usually positioned prone, although the lateral or sitting positions are used by some neurosurgeons. In any case, the head is flexed, and the position and patency of the tracheal tube must be meticulously ensured. In the event that the tracheal tube does become dislodged when the child is in a head holder and prone, successful emergent airway management has been described using a laryngeal mask airway.<sup>164</sup>

Arrhythmias and acute blood pressure changes may occur during surgical exploration, especially when the brainstem is manipulated. The electrocardiogram and arterial waveform should be closely monitored. Altered respiratory control may be masked by neuromuscular blocking drugs (NMBDs) and mechanical ventilation. Even when ICP is only marginally increased, intracranial compliance is presumed to have decreased. This warrants precautions against further increases in ICP. If ICP is markedly increased or acutely worsens, a ventricular catheter may be inserted before the tumor is resected. VAE is a potentially serious complication that is not eliminated by the prone or lateral position because head-up gradients of 10 to 20 degrees are frequently used to improve cerebral venous drainage. In infants and toddlers, large head size relative to body size accentuates this problem.

Supratentorial tumors in the midbrain include craniopharyngiomas, optic gliomas, pituitary adenomas, and hypothalamic tumors and account for approximately 15% of intracranial tumors. Hypothalamic tumors (i.e., hamartomas, gliomas, and teratomas) frequently manifest with precocious puberty in children who are large for their chronologic age. Craniopharyngiomas are the most common parasellar tumors in children and adolescents and may be associated with hypothalamic and pituitary dysfunction. Symptoms often include growth failure, visual impairment, and endocrine abnormalities.

Signs and symptoms of hypothyroidism should be sought and thyroid function measured. Corticosteroid replacement (i.e., dexamethasone or hydrocortisone) usually is administered because the integrity of the hypothalamic-pituitary-adrenal axis may be uncertain. Diabetes insipidus can occur preoperatively and is a common postoperative problem. The history usually reveals this condition preoperatively, especially if attention is focused on nocturnal drinking and enuresis. Evaluation of serum

electrolytes and osmolality, urine specific gravity, and urine output is helpful because hypernatremia and hyperosmolality, along with dilute urine, are typical findings. If diabetes insipidus does not exist preoperatively, it usually does not develop until the postoperative period because there is an adequate reserve of antidiuretic hormone in the posterior pituitary gland capable of functioning for many hours, even when the hypothalamic-pituitary stalk is damaged intraoperatively.

Postoperative diabetes insipidus is marked by a sudden large increase in dilute urine output associated with an increasing serum sodium concentration and osmolality. Protocols have been developed to guide intraoperative and postoperative management of diabetes insipidus (see Chapter 8).<sup>127</sup> Return of antidiuretic hormone activity a few days postoperatively may cause a marked decrease in urinary output, water intoxication, seizures, and cerebral edema if it is not recognized and fluid administration is not adjusted appropriately.

Transsphenoidal surgery typically is performed only in adolescents and older children with pituitary adenomas. However, it should be treated like other midbrain tumors in terms of monitoring and vascular access. Children are usually intubated orally to give the surgeon optimal access to the nasopharynx, and preparations for an emergent craniotomy should be anticipated in case unexpected massive bleeding develops. Because nasal packs are inserted at the end of surgery, the child should be fully awake before tracheal extubation.

Gliomas of the optic pathways occur with increased frequency in children with neurofibromatosis. Presenting symptoms include visual changes and proptosis; increased ICP and hypothalamic dysfunction are usually late findings. Neurofibromas tend to be highly vascular, and the anesthesiologist should be prepared for significant blood loss.

Approximately 25% of intracranial tumors in children involve the cerebral hemispheres. They are primarily astrocytomas, oligodendrogliomas, ependymomas, and glioblastomas. Neurologic symptoms are more likely to include a seizure disorder or focal deficits. Succinylcholine should be avoided if motor weakness is present because it can cause sudden severe hyperkalemia. Nondepolarizing NMBDs and opioids may be metabolized more rapidly than usual in children who are receiving chronic anticonvulsants. Choroid plexus papillomas are rare but occur most often in children younger than 3 years of age. They usually arise from the choroid plexus of the lateral ventricle and produce early hydrocephalus as a result of increased production of CSF and obstruction of CSF flow. Hydrocephalus usually resolves with surgical resection. When lesions lie near the motor or sensory strip, a special type of somatosensory evoked potential monitoring called *phase reversal* may be used to delineate the locations.<sup>165</sup> If cortical stimulation is planned to help identify motor areas, NMBDs must be permitted to wear off and the anesthetic technique adjusted to achieve immobilization without paralysis.

Stereotactic biopsies or craniotomies present special concerns regarding airway accessibility. Newer head frames have adjustable anterior positions so that the airway is readily accessible (E-Fig. 24-1). They are especially useful for stereotactic neurosurgery. It is more comfortable and less distressing for the child to be anesthetized before the head frame is applied, even though this means the anesthesiologist must induce anesthesia in the radiology suite and then transport the child from the CT scanner to the operating room. The wrench that is used to apply and remove the head frame should be taped to the frame at all times so that

**E-FIGURE 24-1** The modified Brown-Roberts-Wells stereotactic head frame has an adjustable face piece that provides enhanced access to the airway. (From Stokes MA, Soriano SG, Tarbell NJ, et al. Anesthesia for stereotactic radiosurgery in children. *J Neurosurg Anesthesiol* 1995;7:100-8.)

it is always readily available if emergent removal of the head frame becomes necessary (e.g., during transport).

## Vascular Anomalies

### Arteriovenous Malformations

Arteriovenous malformations consist of large arterial feeding vessels, dilated communicating vessels, and large draining veins carrying arterialized blood. Large malformations, especially those involving the posterior cerebral artery and vein of Galen, may manifest as congestive heart failure (i.e., high-output heart failure, often with pulmonary hypertension) in the neonate. The prognosis for these types of arteriovenous malformations is quite poor. Saccular dilation of the vein of Galen may manifest later in infancy or childhood as hydrocephalus due to obstruction of the aqueduct of Sylvius. Malformations not large enough to produce congestive heart failure usually remain clinically silent unless they cause seizures or a stroke or until the acute rupture of a communicating vessel results in subarachnoid or intracerebral hemorrhage.<sup>166</sup> Intracranial hemorrhages are the most common presentation in this population, with an associated mortality rate of 25%.

Treatment usually consists of embolization or irradiation of deep malformations, surgical excision (usually of the more superficial ones), or a combination of these modalities. Management for elective embolic procedures involves general anesthesia. Moderate hyperventilation may enhance visualization of abnormal blood vessels that do not respond with vasoconstriction. The anesthesiologist should be knowledgeable about the types of embolic agents that can be used and their potential complications. Anticonvulsant therapy is routine. Neonates in cardiac failure may be receiving inotropic agents. Bleeding, especially from the femoral arterial puncture site (which cannot always be visualized), should always be a consideration. Fluid overload result from the large amount of contrast agents administered, especially in a young infant who may already be in high-output cardiac failure. The anesthesiologist should be prepared for the possibility of an emergency craniotomy if a vessel ruptures.

### Aneurysms

Intracranial aneurysms most often result from a congenital malformation in an arterial wall. Children with coarctation of the aorta or polycystic kidney disease have an increased incidence of these aneurysms. They usually remain asymptomatic during childhood; most ruptures that occur in childhood are fatal. Symptoms of subarachnoid or intracerebral hemorrhage frequently appear suddenly in a previously healthy young adult. When technically feasible, surgical ligation or clipping constitutes the treatment of choice.<sup>167</sup>

Anesthesia for surgical resection of vascular malformations and aneurysms in children presents unique challenges, especially if the diagnosis has been preceded by an intracranial hemorrhage. Blood products should be in the operating room and verified before the start of the procedure. An adequate depth of anesthesia should be ensured before any invasive maneuver to prevent precipitous hypertension. Adequate venous access to respond to sudden and massive blood loss is crucial but can wait until after induction of anesthesia. A blood-warming device, such as a rapid transfusion device, should be immediately available.

Controlled hypotension may be valuable in some situations for brief periods to reduce tension in the abnormal blood vessels and improve the safety of surgical manipulation.<sup>168</sup> It is not clear, however, whether the benefits of controlled hypotension are

worth the risks, especially in small children (see Chapter 10). Controlled hypotension should not be used in children with increased ICP because of the risk of decreasing CPP, with resulting ischemia and further increased ICP. Although the absolute limits of acceptable hypotension are unknown, a mean blood pressure greater than 40 mm Hg for infants or 50 mm Hg for older children appears to be safe; teenagers should have a target mean arterial pressure no less than 55 mm Hg. At the conclusion of the procedure, the blood pressure is returned to normal, but before closing the dura, the operative site should be inspected for bleeding.

Hemodynamic stability is important during emergence to avoid bucking, coughing, straining, and hypertension during extubation. Excessive hypertension can result in postoperative bleeding, although in most cases of aneurysm clipping, a slightly increased blood pressure may be desirable postoperatively to minimize the risk of vasospasm. After resection of an arteriovenous malformation, there can be serious postoperative complications due to cerebral edema with increased ICP or hemorrhage. This *normal perfusion pressure breakthrough* is probably caused by hyperemia of the areas surrounding the previous arteriovenous malformation site, where vessels suffer from continued vasomotor paralysis and cannot vasoconstrict. Treatment is controversial but usually involves therapy for increased ICP (e.g., diuretics, moderate hyperventilation, head elevation) in addition to judicious use of moderate hypotension (while maintaining CPP) and moderate hypothermia. When surgery is completed, it is important that children are able to cooperate with a neurologic examination and that there is careful control of blood pressure in the intensive care unit.

### Moyamoya Disease

Moyamoya disease is an anomaly that results in progressive and life-threatening occlusion of intracranial vessels, primarily the internal carotid arteries near the circle of Willis.<sup>169</sup> An abnormal vascular network of collaterals develops at the base of the brain, and the appearance of these many, small vessels on angiography was originally described by the Japanese name *moyamoya*, which roughly translates as “puff of smoke.” The congenital form of the disease can involve the systemic vasculature, including pulmonary, coronary, and renal vessels; affected renal arteries are the most commonly identified angiographic lesion. The acquired variety (i.e., moyamoya syndrome) may be associated with meningitis, neurofibromatosis, chronic inflammation, connective tissue diseases, certain hematologic disorders, Down syndrome, or prior intracranial radiation. Some children with neurologic symptoms from sickle cell disease may also have moyamoya.<sup>170</sup> Moyamoya disease appears to be more common among children of Japanese ancestry. Associated intracranial aneurysms are rare in children but may occur in more than 10% of affected adult patients. Abnormal electrocardiographic findings have been described with the syndrome in adults.

Moyamoya disease usually manifests as transient ischemic attacks progressing to strokes and fixed neurologic deficits in children. The attacks may be precipitated by hyperventilation.<sup>171</sup> The morbidity and mortality rates are high if the condition is left untreated. Medical management consists of antiplatelet therapy, such as aspirin, or calcium channel blockers. The most common surgical operation for correction in children is pial synangiosis, which involves suturing a scalp artery (usually the superficial temporal artery) directly onto the pial surface of the brain to enhance angiogenesis (Fig. 24-9).<sup>172</sup>

**FIGURE 24-9** Moyamoya disease. **A**, The top angiogram shows the pattern of arterial filling after injection of the internal carotid artery in a child with moyamoya disease before pial synangiosis. Area A shows poor filling from the middle cerebral artery as a result of the disease process. Area B shows the characteristic hazy collaterals, or moyamoya vessels. The bottom angiogram is from the same child after pial synangiosis. The angiogram was obtained after injection of the superficial temporal artery, and it shows good filling in the middle cerebral artery distribution in area A. Area B does not fill from the middle cerebral artery. **B**, Pial synangiosis. The superficial temporal artery is prepared to be sutured to the pia of the cerebral cortex. After the craniotomy is completed, this artery can be sewn directly onto the underlying pia mater. The result of this procedure is improvement of blood flow to ischemic areas of the cerebral cortex.

Careful and continuous monitoring of end-tidal  $\text{CO}_2$  partial pressure is essential in anesthesia management.<sup>173</sup> Children with moyamoya disease have reduced hemispheric blood flow bilaterally, and hyperventilation may further reduce regional blood flow and cause significant EEG and neurologic changes.<sup>174</sup> Normocapnia must be maintained throughout all phases of the procedure, including induction of anesthesia. Adequate hydration and maintenance of baseline blood pressure are indispensable. Most of these children have an intravenous catheter inserted the night before surgery and are given 1.5 times the amount of maintenance fluids to avoid dehydration during the perioperative period. EEG monitoring during these procedures can detect and help to treat ischemia that appears to be a result of cerebral vasoconstriction in response to direct surgical manipulation of the brain.<sup>175</sup> Normothermia is maintained, particularly at the end of the procedure, to avoid postoperative shivering and an exaggerated stress response. As with most neurosurgical procedures, a smooth extubation without hypertension or crying is desirable. Although scant literature exists regarding intraoperative and postoperative complications during moyamoya surgery, it appears that most complications (e.g., strokes) occur postoperatively and are associated with dehydration and crying (i.e., hyperventilation) episodes.<sup>176</sup>

### Seizure Surgery

Epilepsy is one of the most common neurologic disorders of childhood. Despite the development of new drugs and regimens, the prevalence of pharmacologically intractable seizures remains high. Advances in neuroimaging and EEG monitoring provide epileptologists anatomic targets that mediate some medically intractable seizure disorders. Advances in pediatric neurosurgery have exploited these technologies and dramatically improved the outcomes for infants and children.<sup>177</sup>

Children presenting for surgical management of seizures take anticonvulsant medications, which can have serious side effects, including abnormalities of hematologic function such as abnormal coagulation, depression of red or white blood cell production, and decreased platelet counts. Other problems may arise from altered hepatic function. Specific anticonvulsant concentrations should be determined preoperatively to detect subtherapeutic or toxic concentrations. Many anticonvulsants enhance metabolism of nondepolarizing NMBDs and opioids, increasing (up to 50%) the amount of these drugs needed during a surgical procedure. The preoperative evaluation should detect underlying conditions that are causing the seizures and the disabilities that can result from progressive neurologic dysfunction.

A major concern during resection of seizure foci is avoiding harming brain tissue that controls vital functions, such as motion, sensation, speech, and memory (so-called eloquent cortex), especially if a seizure focus is adjacent to cortical areas controlling these functions. Cooperative adolescents and adults can assist in determination of the limits of safe cortical resection if they can be continually assessed during the surgical procedure. The technique of awake craniotomy is often performed in carefully selected adolescents. An awake craniotomy encompasses a wide variety of techniques whose common goal is to allow intraoperative assessment and feedback to determine if the eloquent cortex is at risk during resection.

Children are selected for this procedure on an individual basis. Most children younger than 12 years old and many teenagers cannot tolerate an awake craniotomy. However, selected individuals may do well. The anesthesiologist should have detailed

conversations with the child and parents to determine appropriateness before initiating such a procedure.

Some practitioners perform the entire procedure, including line placement, infiltration of local anesthetic, skull and dural opening, and resection, with the child completely awake or with minimal sedation. This particular approach requires an extremely motivated child. A variation on this technique uses short-acting sedatives and analgesics, such as propofol and fentanyl, titrated to induce unconsciousness but maintain spontaneous ventilation for instillation of local anesthetics, insertion of monitoring catheters, placement of head pins, and skull opening.<sup>178</sup> Subsequently, children can be allowed to awaken during surgical resection. They can then have sedatives and opioids reinstituted for the craniotomy closure.

Alternatively, some anesthesiologists use the asleep-awake-asleep technique. It consists of inducing general anesthesia and maintaining airway control with a supraglottic device (i.e., laryngeal mask airway). General anesthesia is maintained for line placement, placement of head pins, and skull and dural opening. The child is then awakened, the supraglottic airway is removed, and the surgeons proceed with resection. At the conclusion of the resection, general anesthesia is again induced and the supraglottic airway reinserted for closure of the dura, skull, and skin. There are several disadvantages to the asleep-awake-asleep approach. One of the major concerns when employing this approach is airway management during emergence and induction while the child is in head pins. If the child coughs or bucks while immobilized, cervical spine injuries or scalp lacerations can occur. Brain swelling is also a concern in a child who is breathing spontaneously under general anesthesia with an inhalational anesthetic and possibly with nitrous oxide.

Regardless of the technique chosen, the anesthesiologist must have an in-depth discussion with the child or adolescent about intraoperative needs and expectations. The preoperative period is the time to decide whether the child is a candidate for an awake craniotomy. There are no randomized, controlled trials comparing the safety or effectiveness of the techniques described.

Younger children (up to 12 years of age) or uncooperative children of any age do not tolerate this approach and require general anesthesia throughout. In these circumstances, intraoperative electrophysiologic studies, such as somatosensory evoked potentials, EEG, and motor stimulation, may be used to help localize and determine the function of the site of planned resection. If EEG studies are to be performed, the anesthetic technique should be adjusted to maximize EEG signals. If direct cortical motor stimulation is planned, NMBDs must be permitted to wear off. Occasionally, a seizure focus is difficult to identify intraoperatively. In these situations, hyperventilation or methohexital (in small doses, 0.25 to 0.5 mg/kg) may be helpful in lowering the seizure threshold and producing EEG seizure activity.<sup>179,180</sup>

In some children, the site of origin of generalized seizures is difficult to determine. When this occurs, evaluation with intracranial EEG monitoring ("grids and strips") may be accomplished with direct electrocorticography (E-Fig. 24-2). The leads are placed on the surface of the cortex after a craniotomy performed under general anesthesia. Intraoperative EEG monitoring is limited during these procedures to ensuring that all leads are functional; monitoring for seizures takes place over the next several days to identify a focus that is amenable to resection. These children need to be observed carefully in the postoperative period because complications can develop from having

intracranial electrodes in place. Because air frequently persists in the skull for up to 3 weeks after a craniotomy,<sup>86</sup> these children should not have nitrous oxide administered for a subsequent procedure (e.g., to resect a seizure focus, to remove the electrocorticography leads) until their dura has been opened to prevent the development of tension pneumocephalus.

When a focal resection is not possible, a lobectomy or corpus callosotomy may be attempted. However, children undergoing the latter procedure are often somnolent for the first few postoperative days, especially if a complete callosotomy is performed. This also occurs in children who have undergone insertion of multiple subdural grids and strips. Occasionally, small children undergo a hemispherectomy because their seizures are attributed to an abnormal hemisphere that is already severely dysfunctional, as when affected by hemiparesis. These can be challenging cases for the anesthesiologist because much blood can be lost (from one half to multiples of the estimated blood volume).<sup>181</sup> This procedure is usually performed when children are very young to permit the other hemisphere to take over the function of both sides. Large-bore intravenous access is necessary in these cases to facilitate rapid replacement of blood, crystalloid solutions, and medications. Arterial pressure monitoring is routine, and many practitioners also use CVP monitoring.

An advance in the treatment of epilepsy has been the development of the vagal nerve stimulator. Although its exact mechanism of action is not well understood, it appears to inhibit seizure activity at brainstem or cortical levels.<sup>182,183</sup> It is becoming a popular form of treatment because it has shown benefit with minimal side effects in many children who are disabled by intractable seizures. Large, randomized trials are being conducted to determine the overall efficacy of this treatment. There are few published series of vagal nerve stimulation in children, but it is estimated that there is a 60% to 70% improvement in seizure control, with the best results achieved in those with drop attacks.<sup>184,185</sup>

The vagal nerve stimulator is a programmable device that is similar to a cardiac pacemaker placed subcutaneously under the left anterior chest wall. Bipolar platinum stimulating electrode coils, which are implanted around the left vagus nerve, are connected to the generator by subcutaneously tunneled wires. The device automatically activates for up to 30 seconds every 5 minutes. Although stimulation of the vagal nerve in this manner may affect vocal cord function, sudden bradycardia or other side effects are uncommon.<sup>186</sup> When children with vagal nerve stimulators return for subsequent operations, it may be appropriate to deactivate the stimulator while the child is under general anesthesia to prevent repetitive vocal cord motion.

## HYDROCEPHALUS

Hydrocephalus is a condition involving a mismatch of CSF production and absorption, resulting in an increased intracranial CSF volume. It can be caused by a variety of pathologic processes, including arachnoid cysts (E-Fig. 24-3). Except for rare instances of excess CSF production, such as in choroid plexus papillomas, most cases of hydrocephalus result from some type of obstruction or an inability to absorb CSF appropriately. Commonly, this is a result of neonatal intraventricular or subarachnoid hemorrhage, congenital problems (e.g., aqueductal stenosis), trauma, infection, or tumors, especially those in the posterior fossa. Hydrocephalus can be classified as nonobstructive/communicating or obstructive/noncommunicating based on the ability of CSF to flow around the spinal cord in its usual manner.

**E-FIGURE 24-2** Skull radiograph of a child with intracranial electrocorticography grids in place.

**E-FIGURE 24-3** Arachnoid cysts can cause hydrocephalus in children. **A**, Before decompression, the mass effect is obvious. **B**, After fenestration of the cyst, cerebrospinal fluid has a path of egress from inside of the cyst to the normal cerebrospinal fluid circulation. The mass effect is resolved.

Intracranial hypertension or decreased intracranial compliance typically accompanies untreated hydrocephalus in children. How much intracranial compliance exists and how acutely hydrocephalus develops are both factors in how severe the signs and symptoms of hydrocephalus become. If hydrocephalus develops slowly in the young infant, the skull will expand and the cerebral cortical mantle will stretch until massive craniomegaly (often with irreversible neurologic damage) occurs. However, if the cranial bones are fused or the cranium cannot expand fast enough, neurologic signs and symptoms rapidly become apparent. The child may become progressively more lethargic and develop vomiting, cranial nerve dysfunction (i.e., setting sun sign), bradycardia, brain herniation, and death.

Unless the cause of the hydrocephalus can be definitively treated, treatment usually involves surgical placement of an extracranial shunt. Most shunts transport CSF from the lateral ventricles to the peritoneal cavity (i.e., ventriculoperitoneal shunts). The distal end of the shunt occasionally must be placed in the right atrium or pleural cavity, usually because of problems with the ability of the peritoneal cavity to absorb CSF. Newer shunt systems with programmable valves are being tried to reduce the need for shunt revisions.<sup>187</sup>

The use of a percutaneous flexible neuroendoscope through a burrhole in the skull has provided an alternative to extracranial shunt placement.<sup>188,189</sup> During these procedures, a ventriculostomy may be made to bypass an obstruction (e.g., aqueductal stenosis) by forming a communicating hole from one area of CSF flow to another using a blunt probe inserted through the neuroendoscope (Video 24-1). Common locations for a ventriculostomy are through the septum pellucidum (allowing lateral ventricles to communicate) or through the floor of the third ventricle into the adjacent CSF cisterns. Complications such as damage to the basilar artery or its branches or neural injuries can be life-threatening when they occur, and the anesthesiologist should be prepared for an emergency craniotomy during these procedures. Hemodynamic instability may occur intraoperatively if excessive cold irrigating solutions or large volumes are infused through the endoscope.

The anesthetic plan for a child with hydrocephalus should be directed at controlling ICP and relieving the obstruction as soon as possible. Children with an increased ICP are at risk for vomiting and pulmonary aspiration. Rapid-sequence induction and tracheal intubation should be performed. Ketamine is avoided in these children because of its potential to cause sudden massive intracranial hypertension.<sup>190</sup> Despite this concern, there is some evidence that ketamine may ameliorate the increased intracranial pressure in children.<sup>191,192</sup> In infants, hydrocephalus often produces large, dilated scalp veins, and they can be used for induction of anesthesia if necessary. If intravenous access cannot be established, induction with sevoflurane and gentle cricoid pressure may be an alternative, although less desirable, method of induction.<sup>193</sup> This method results in venodilation and usually facilitates establishment of intravenous access. After an intravenous catheter is inserted, the child may be paralyzed, the lungs ventilated, the trachea intubated, and the inhalational agent decreased or discontinued. The possibility of VAE during placement of the distal end of a ventriculoatrial shunt should always be considered. Postoperatively, children should be observed carefully because an altered mental status and recent peritoneal incision place them at increased risk for pulmonary aspiration after feeding begins. Analgesia may be provided with a variety of easily performed blocks of the head (see Figs. 41-15 and 41-16).

Anesthesiologists should be familiar with a few special situations involving shunts. Children who develop a shunt infection usually have the entire shunt system removed and external ventricular drainage established. They return to the operating room for insertion of a new shunt several days after the infection has been treated with antibiotics. While an external drain is in place, the operator must be careful not to dislodge the ventricular tubing. The height of the drainage bag should not be significantly changed in relation to the child's head to avoid sudden alterations in ICP. For example, suddenly lowering an open drainage bag can siphon CSF rapidly from the head, resulting in collapse of the ventricles and rupture of cortical veins. When transporting children with CSF drainage or when moving them from a stretcher to an operating room table, it is best to close off the ventriculostomy tubing during these brief periods.

Anesthesiologists should be aware of the condition known as slit ventricle syndrome (Fig. 24-10). This situation develops in 5% to 10% of children with CSF shunts and is associated with overdrainage of CSF and small, slitlike, lateral ventricular spaces. Children with this condition do not have the usual amount of intracranial CSF to compensate for alterations in brain or intracranial blood volume. Special attention should be paid when CT scans identify this condition. It is probably safest to avoid the administration of excess or hypotonic intravenous solutions in these situations in the intraoperative and postoperative periods to minimize the potential for brain swelling. Some of these children cannot accommodate to situations that otherwise healthy children can easily tolerate. Episodes of postoperative cerebral herniation have been reported after uneventful surgical procedures.<sup>45</sup>

## CONGENITAL ANOMALIES

Congenital CNS anomalies typically occur as midline defects. This dysraphism may occur anywhere along the neural axis, involving the head (i.e., encephalocele) or spine (i.e., meningocele) (Fig. 24-11, A). The defect may be relatively minor and affect only superficial bony and membranous structures, or it may include a large segment of malformed neural tissue.

### Encephalocele

Encephaloceles can occur anywhere from the occiput to the frontal area. They can even appear to be nasal polyps if they protrude through the cribriform plate. They are rarely filled with so much CSF that the defect can be almost as large as the head itself (see Fig. 24-11, B). Large defects may present challenges to tracheal intubation. Blood loss can be severe, especially if venous sinuses are involved. Adequate intravenous access should be ensured and blood products readily available. If hemodynamic instability is anticipated, an arterial catheter is indicated.

### Myelodysplasia

Defects in the spine are known as *spina bifida*. Meningoceles are lesions containing CSF without spinal tissue. When neural tissue is also present within the lesion, the defect is called a *meningocele*. Open neural tissue is known as *rachischisis*. Hydrocephalus is usually present and is often associated with a type II Chiari malformation.

Most children with a meningocele present for primary closure of the defect within the first 24 hours of life to minimize the risk of infection. Many are now scheduled electively before birth for repair because the defect is usually apparent on prenatal ultrasonography. Many neurosurgeons prefer to insert a

**FIGURE 24-10** Computed tomographic scans of children with normal-sized ventricles (A), untreated hydrocephalus (B), hydrocephalus treated with a ventricular shunt (C), and hydrocephalus treated with a ventricular shunt, resulting in slit ventricles (D). (Courtesy Ellen Grant, MD.)

ventriculoperitoneal shunt at the time of initial surgery. Alternatively, a shunt may be inserted a few days later or is occasionally deferred if there is no evidence of hydrocephalus at birth.

A major anesthesia consideration is positioning the neonate for induction at surgery. In most cases, tracheal intubation can be performed with the infant in the supine position and the uninvolved portion of the child's back supported with towels (or a donut ring) so there is no direct pressure on the meningocele. For very large defects, it is occasionally necessary to place the infant in the left lateral decubitus position for induction and tracheal intubation. Succinylcholine is rarely needed for tracheal intubation, although it is not associated with hyperkalemia because the defect develops early in gestation and is not associated with muscle denervation.<sup>194</sup> Airway management, mask fit, and intubation may be difficult in infants with massive hydrocephalus or very large defects. In such cases, awake intubation after preoxygenation and administration of atropine occasionally may be the safest alternative. Blood loss may be considerable during repair of a larger defect when skin is undermined to cover the defect.

Children with myelodysplasia are at high risk for latex sensitivity and possibly anaphylaxis.<sup>40</sup> This likely results from repeated

exposure to latex products encountered during frequent bladder catheterizations and multiple (usually more than five) surgical procedures, during which latex gloves have been in contact with large mucosal surfaces. These children should be managed in a latex-free environment from birth to minimize the chances for sensitization.<sup>195</sup> Latex allergy should be suspected if signs and symptoms of anaphylaxis develop during surgery. Suspected anaphylaxis should be treated with intravenous epinephrine in a dose of 1 to 10  $\mu\text{g}/\text{kg}$ , as required. Many hospitals have replaced most or all of their latex-containing supplies with nonlatex alternatives; this has resulted in complete elimination of latex anaphylactic reactions during anesthesia in some institutions.<sup>196</sup> Children who develop latex allergy exhibit cross-reactivity with some antibiotics<sup>197,198</sup> and foods, especially tropical fruits such as avocados, kiwis, and bananas.

Postoperatively, respiratory status should be carefully assessed. Pulse oximetry is valuable during recovery from anesthesia because breathing difficulties may occur after a tight skin closure and the ventilatory responses to hypoxia and hypercarbia may be diminished or absent when a Chiari malformation coexists.<sup>199</sup> Intrauterine surgery has been advocated as a way of diminishing the degree of damage caused by myelodysplasia.<sup>200-202</sup>

**FIGURE 24-11** **A**, An infant with an anterior encephalocele. **B**, An infant with a posterior encephalocele and myelomeningocele defects. Notice the large exposed surface areas that make this child prone to dehydration. Difficulty may be encountered in positioning for induction of anesthesia, and significant loss of blood and cerebrospinal fluid during surgical correction should be anticipated.

### Chiari Malformations

There are several types of Chiari malformations (Table 24-3). The Arnold-Chiari malformation (type II) usually coexists in children with myelodysplasia. This defect consists of a bony abnormality in the posterior fossa and upper cervical spine with caudal displacement of the cerebellar vermis, fourth ventricle, and lower brainstem below the plane of the foramen magnum. Medullary cervical cord compression can occur (Figs. 24-12 and 24-13). Vocal cord paralysis with stridor and respiratory distress, apnea, abnormal swallowing and pulmonary aspiration, opisthotonos, and cranial nerve deficits may be associated with the Arnold-Chiari malformation and usually manifests during infancy. Children

**TABLE 24-3** Types of Chiari Malformation

Type I	Caudal displacement of cerebellar tonsils below the plane of the foramen magnum
Type II (Arnold-Chiari; associated with myelomeningocele)	Caudal displacement of the cerebellar vermis, fourth ventricle, and lower brainstem below the plane of the foramen magnum Dysplastic brainstem with characteristic kink, elongation of the fourth ventricle, beaking of the quadrigeminal plate, hypoplastic tentorium with small posterior fossa, polymicrogyria, enlargement of the massa intermedia
Type III	Caudal displacement of the cerebellum and brainstem into a high cervical meningocele
Type IV	Cerebellar hypoplasia

with vocal cord paralysis or a diminished gag reflex may require tracheostomy and gastrostomy to secure the airway and to minimize chronic aspiration. Children of any age may have abnormal responses to hypoxia and hypercarbia because of cranial nerve and brainstem dysfunction.<sup>199,203</sup> Extreme head flexion may cause brainstem compression in otherwise asymptomatic children.

Type I Chiari malformations can occur in healthy children without myelodysplasia. These defects also involve caudal displacement of the cerebellar tonsils below the foramen magnum, but children usually have much milder symptoms, sometimes manifesting only as headache or neck pain.<sup>204</sup> Surgical treatment usually involves a decompressive suboccipital craniectomy with cervical laminectomies.

### Other Spinal Defects

Other spinal anomalies (e.g., lipomeningoceles, lipomyelomeningoceles, diastematomyelias, dermoid tracts) may manifest as tethered cords. Skin defects, typically over the lower lumbar region, may occur as dural sinus tracts or lipomeningoceles. Midline hair tufts, skin dimples, or fat pads may be associated with spinal defects. These anomalies sometimes manifest when toilet training or ambulation is observed to be abnormal or later in childhood when children complain of back pain. Children who have had a meningomyelocele repaired after birth may also develop an ascending neurologic deficit from a tethered spinal cord during growth. Early detection of a tethered cord is easily diagnosed with MRI. Prophylactic surgical untethering is common.

Anesthesia management for surgical release of a tethered cord usually entails monitoring the innervation of the lower extremities and bowel and bladder with nerve stimulators and rectal electromyograms or manometry. Muscle relaxants should be avoided or permitted to dissipate before intraoperative assessment.

### NEURORADIOLOGIC PROCEDURES

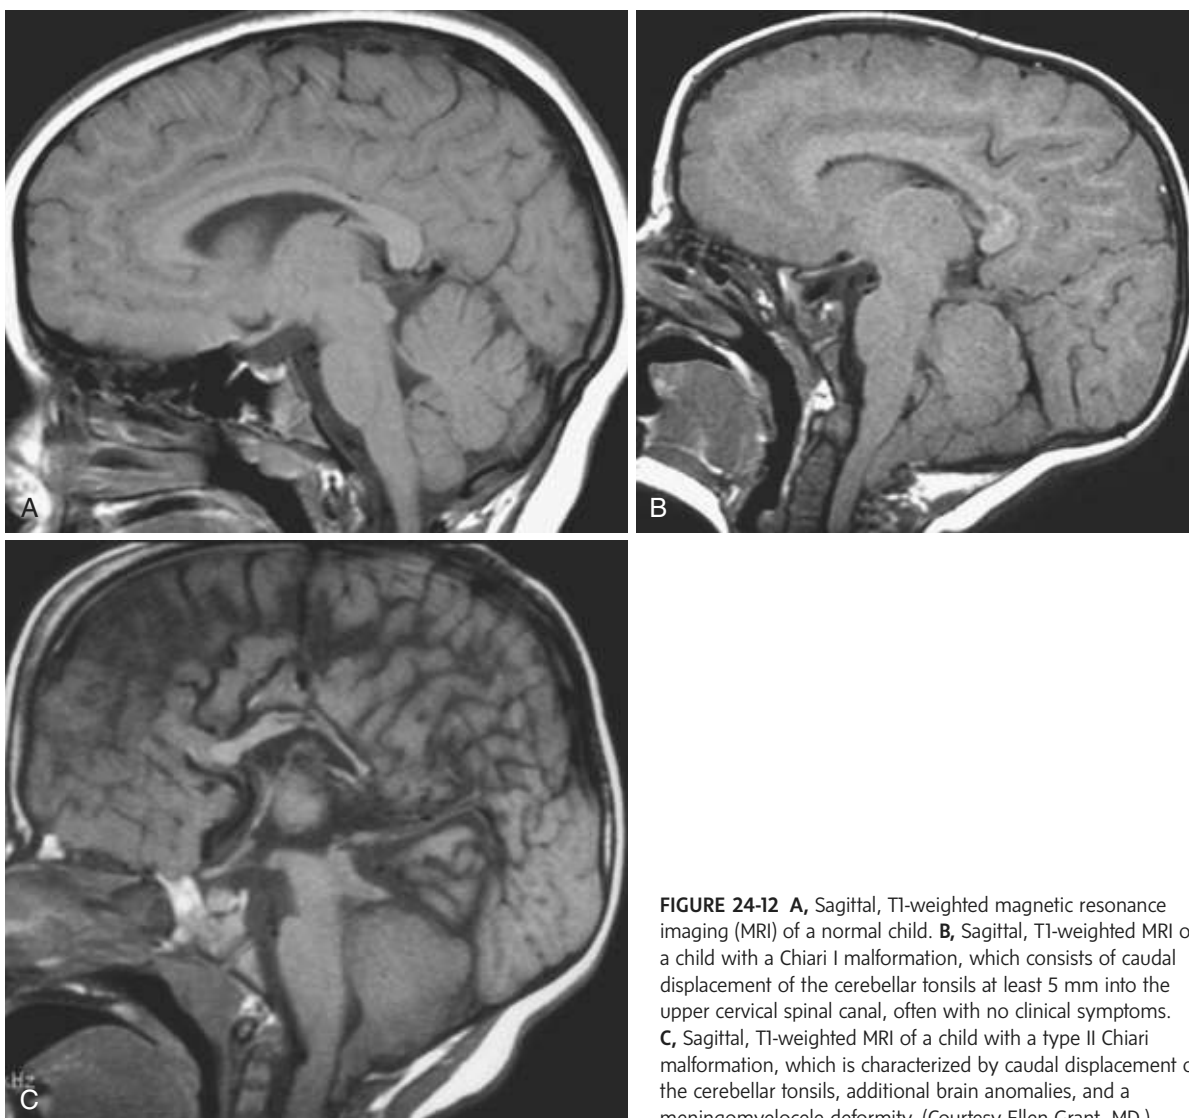

Many neuroradiologic procedures are performed in children. Anesthetic considerations for neurodiagnostic procedures (e.g., CT, MRI) are discussed elsewhere in this book (see Chapters 45 and 47), but certain therapeutic neuroradiologic procedures are addressed here.

To improve intraoperative navigation during intracranial procedures, the concept of intraoperative MRI was introduced in the mid-1990s. The technology has advanced to include a variety of operating room suite designs that encompass MRI machines (E-Fig. 24-4). These procedures present special challenges for

**E-FIGURE 24-4** Intraoperative magnetic resonance imaging (MRI) unit. A child undergoing a craniotomy for tumor resection is being prepared to undergo an intraoperative MRI to assess the extent of resection needed. The child currently has an open craniotomy. The surgical field is kept sterile under the clear plastic drape. The mobile, 1.5-T MRI unit is moving out over the child and will be completely over the child's head during imaging. The information provided by the intraoperative scan helps to guide intraoperative decision-making, such as the need for continued resection if residual tumor is found. Although this technology represents an advance in intraoperative navigation, the technical difficulties of anesthetizing a child for a major surgical procedure in a high-strength magnetic field environment are significant.

**FIGURE 24-12** **A**, Sagittal, T1-weighted magnetic resonance imaging (MRI) of a normal child. **B**, Sagittal, T1-weighted MRI of a child with a Chiari I malformation, which consists of caudal displacement of the cerebellar tonsils at least 5 mm into the upper cervical spinal canal, often with no clinical symptoms. **C**, Sagittal, T1-weighted MRI of a child with a type II Chiari malformation, which is characterized by caudal displacement of the cerebellar tonsils, additional brain anomalies, and a meningocele deformity. (Courtesy Ellen Grant, MD.)

**FIGURE 24-13** The images show the posterior fossa in a child with a Chiari II malformation before and after posterior fossa decompression. **A**, Notice the downward herniation of the cerebellar tonsils. **B**, Resolution of cerebellar tonsillar herniation after posterior fossa decompression.

neurosurgeons and anesthesiologists.<sup>205-209</sup> As with anesthesia for diagnostic MRI scans, special monitors, infusion pumps, and an MRI-safe or MRI-conditional anesthesia machine are required. It is challenging to do surgical procedures in this environment, especially because these procedures may take many hours, they may be associated with significant blood loss, and access to the child is severely limited. Some monitoring equipment found in conventional operating rooms (e.g., precordial Doppler ultrasonography, core temperature probes, fluid warmers) is not MRI safe or conditional. Nevertheless, numerous neurosurgical procedures have been safely performed in children in these MRI operating rooms, and the equipment for these procedures is rapidly evolving.

## ACKNOWLEDGMENTS

The authors wish to thank Veronica Miller, MD, and Elizabeth A. Eldredge, MD, for their prior contributions to this chapter.

## Diabetes Mellitus\*

The incidence of both type 1 and type 2 diabetes mellitus in children is increasing worldwide.<sup>1-6</sup> The use of insulin pumps and various multicomponent insulin regimens has increased the complexity of perioperative management of children with diabetes. Anesthesiologists must carefully consider the pathophysiology of the disease, as well as each child's specific diabetes treatment regimen, glycemic control, intended surgery, and anticipated postoperative course, when devising an appropriate perioperative management plan. Standardized algorithms for perioperative diabetes management improve care<sup>7-9</sup> without significantly increasing costs<sup>9</sup>; several guidelines and studies of perioperative management of children with diabetes are available in the literature and examples are included.<sup>10-15</sup>

### CLASSIFICATION AND EPIDEMIOLOGY IN CHILDREN

Type 1 and type 2 are the most common forms of diabetes.<sup>16,17</sup> Type 1 diabetes is characterized by absolute deficiency of insulin, which usually results from immune-mediated destruction of pancreatic beta cells.<sup>17</sup> In contrast, type 2 diabetes results from a

combination of insulin resistance and a relative deficiency of insulin.<sup>16,17</sup> Children with type 2 diabetes typically are overweight and frequently have a first- or second-degree relative with type 2 diabetes.<sup>16</sup> However, the increasing prevalence of obesity in children<sup>18</sup> has made distinction between type 1 and type 2 diabetes, at times, rather difficult. Children with phenotypic characteristics of type 2 diabetes may have pancreatic autoimmunity,<sup>19-21</sup> and approximately 35% of children with diabetes who require exogenous insulin at diagnosis are overweight or obese,<sup>22,23</sup> consistent with the prevalence of childhood overweight and obesity in the general U.S. pediatric population.<sup>24</sup> Other forms of diabetes may be less commonly encountered (Table 25-1). Additional modifications to the perioperative treatment regimen may be necessary when diabetes is associated with genetic syndromes and/or other endocrinopathies, such as adrenal insufficiency (see later discussion).

Although the worldwide incidence of type 1 diabetes is quite variable,<sup>25</sup> the incidence is increasing in almost all populations throughout the world.<sup>4</sup> In the United States, the SEARCH for Diabetes in Youth Study, which began in 2000, provides the most comprehensive estimates of the prevalence and incidence of type 1 and type 2 diabetes among youth less than 20 years of age in the United States.<sup>26-30</sup> Type 1 diabetes remains the most common form of diabetes observed among youth in the United States, with the greatest prevalence (2 per 1000) among non-Hispanic Caucasians.<sup>29</sup> The epidemic of obesity has also contributed to a

progressive increase in the incidence and prevalence of type 2 diabetes in U.S. children.<sup>1</sup> In the SEARCH study, the prevalence of type 2 diabetes in 10- to 19-year-old youth ranged from 0.18 per 1000 among non-Hispanic Caucasian youth to 1.45 per 1000 among Navajo youth, and the incidence ranged from 3.7 per 100,000 per year among non-Hispanic Caucasian youth to 27.7 per 100,000 per year among Navajo youth.<sup>29,30</sup> Increases in the incidence and prevalence of type 2 diabetes have been noted in other parts of the world.<sup>2,3,5,6,31-34</sup>

### GENERAL MANAGEMENT PRINCIPLES

Understanding both the pharmacokinetic and pharmacodynamic properties of different insulin preparations and antihyperglycemic medications is critical to developing an appropriate perioperative plan.

Type 1 diabetes always requires treatment with insulin. However, an increasing number of insulin preparations (Table 25-2) and delivery systems are available. The least complex insulin regimens consist of two or three insulin injections per day. They incorporate a combination of an intermediate-acting insulin (e.g., neutral protamine Hagedorn [NPH]) and/or a long-acting insulin (e.g., insulin detemir [Levemir] or insulin glargine [Lantus]) for basal coverage with a short- or rapid-acting insulin (e.g., regular, insulin aspart [NovoLog], insulin lispro [Humalog], or insulin glulisine [Apidra]) to provide prandial glycemic coverage. More intensive insulin regimens are being used with greater frequency and typically consist of insulin glargine, a long-acting insulin, which provides a relatively constant 24-hour basal concentration of circulating insulin without a pronounced peak, to simulate basal insulin secretion,<sup>35</sup> in conjunction with rapid-acting insulin administered with food. Some studies have demonstrated superior glycemic control with such regimens as compared with regimens using NPH insulin and regular insulin,<sup>36</sup> although the ideal insulin regimen for children with type 1

**TABLE 25-2** Insulin Preparations Classified according to Their Pharmacokinetic Profiles\*

	Onset (hours)	Peak (hours)	Duration (hours)
<b>Rapid-Acting<sup>†</sup></b>			
Insulin lispro (Humalog) <sup>‡</sup>	<0.25	0.5-2.5	≤5
Insulin aspart (Novolog) <sup>‡</sup>	<0.25	1-3	3-5

\*Times of onset, peak, and duration of action vary within and between patients and are affected by numerous factors, including dosage, site, depth of injection, dilution, temperature, and other factors.

<sup>†</sup>Premixed combinations of intermediate-acting and either rapid- or short-acting insulins are available whose pharmacodynamic profiles have a bimodal pattern reflecting the two insulin components.

<sup>‡</sup>Insulin analogue developed by modifying the amino acid sequence of the human insulin molecule.

diabetes remains controversial.<sup>37</sup> Another long-acting insulin, insulin detemir, may also be used in intensive insulin regimens and has demonstrated more predictable glucose-reducing effects than both NPH insulin<sup>38-40</sup> and insulin glargine.<sup>38</sup>

Many children with type 1 diabetes are managed with an insulin pump,<sup>41,42</sup> a device that administers a continuous subcutaneous infusion of insulin (typically a rapid-acting insulin, see Table 25-2) at a basal rate that is supplemented by bolus doses of insulin given with meals and snacks and to correct hyperglycemia. In appropriately selected children, pump therapy has shown superiority over injection regimens.<sup>43-46</sup> Standard insulin preparations are U100, meaning that there are 100 units of insulin per milliliter. However, very young patients with type 1 diabetes may require diluted insulin (e.g., U10) to achieve accurate dosing.<sup>47</sup> Parents of toddlers with type 1 diabetes should be specifically questioned about their use of diluted insulin.

Most children with type 2 diabetes are managed with insulin and/or oral metformin, the only oral agent approved for use in children with diabetes in the United States.<sup>48-50</sup> Metformin's primary action is to decrease hepatic glucose production and, secondarily, to increase insulin sensitivity in peripheral tissues. Occasionally, other oral agents, including sulfonylureas, which promote insulin secretion, and thiazolidinediones, which increase insulin sensitivity in muscle and adipose tissue, are used in adolescents.<sup>48,51</sup> Nutritional therapy is always included in the management of children with type 2 diabetes. Studies, such as the Treatment Options for Type 2 Diabetes in Adolescents and Youth (TODAY) trial,<sup>52,53</sup> are evaluating the optimal treatment for type 2 diabetes. Monotherapy with metformin was associated with durable glycemic control in approximately half of children and adolescents with type 2 diabetes. The addition of rosiglitazone, but not an intensive lifestyle intervention, was superior to metformin alone.

New medications introduced to manage adults with diabetes may eventually become available for use in children. Incretins, including glucose-dependent insulinotropic polypeptide and glucagon-like peptide-1 (GLP-1), are gastrointestinal hormones released after eating that stimulate insulin secretion and are necessary for normal glucose tolerance.<sup>54,55</sup> GLP-1 acts through a G protein-coupled receptor to promote glucose-dependent insulin secretion, suppression of glucagon secretion, slowing of gastric emptying, and reduction in food intake.<sup>54</sup> Exenatide (Byetta) is a GLP-1 receptor agonist widely used in adults with type 2 diabetes as an adjunctive therapy for those taking metformin and/or a sulfonylurea.<sup>56</sup> Inhibitors of dipeptidyl peptidase-IV,<sup>57</sup> the enzyme that degrades GLP-1, are also increasingly being used for the treatment of type 2 diabetes in adults, but have not been approved for use in children. Pramlintide acetate (Symlin) is a synthetic amylin receptor agonist that can be used as an adjunct to insulin therapy in adults with type 1 or type 2 diabetes.<sup>58-61</sup> Amylin, a 37-amino acid polypeptide islet hormone cosecreted with insulin from beta islet cells,<sup>54</sup> has three effects: delays gastric emptying, inhibits glucagon secretion, and modulates satiety.<sup>54</sup>

### METABOLIC RESPONSE TO SURGERY

Trauma of any kind, and surgery in particular, causes a complex neuroendocrine stress response, including suppression of insulin secretion and increased production of counter-regulatory hormones (frequently called “stress hormones” in the anesthesiology literature), particularly cortisol and catecholamines.<sup>62,63</sup> Insulin is the primary anabolic hormone that promotes glucose uptake in muscle and adipose tissue while suppressing glucose production (glycogenolysis and gluconeogenesis) by the liver.<sup>64</sup> The counter-regulatory hormones, which include epinephrine, glucagon, cortisol, and growth hormone, exert the opposite effects, resulting in resistance to insulin action<sup>65-67</sup> and an increase in blood glucose concentration by: (1) stimulating glycogenolysis and gluconeogenesis in the liver, (2) increasing lipolysis and ketogenesis, and (3) inhibiting glucose uptake and utilization in muscle and fat. Glucagon, secreted by alpha cells in the pancreatic islets, suppresses insulin secretion while stimulating hepatic glycogenolysis, gluconeogenesis, and ketogenesis.<sup>64,65</sup> Epinephrine, which acts via  $\beta_2$ - and  $\alpha_2$ -adrenergic receptors, stimulates glucagon production, increases glycogenolysis and gluconeogenesis, stimulates lipolysis, decreases insulin secretion, and decreases glucose utilization in insulin-sensitive tissues.<sup>64</sup> Cortisol stimulates gluconeogenesis, proteolysis, and lipolysis, and decreases glucose utilization.<sup>65,68</sup> Growth hormone augments glucose production, decreases glucose utilization, and accelerates lipolysis.<sup>69</sup> Pro-inflammatory cytokines may further stimulate secretion of counter-regulatory hormones and alter insulin receptor signaling.<sup>67</sup> These changes increase catabolism, as evidenced by increased hepatic glucose production and breakdown of protein and fat. In the diabetic patient with absolute or relative insulin deficiency, the enhanced catabolism resulting from surgical trauma can lead to marked hyperglycemia and even diabetic ketoacidosis.<sup>70</sup> These metabolic effects may be exacerbated by a prolonged fast before and during surgery.

### METABOLIC RESPONSE TO ANESTHESIA

Although adequate analgesia is essential to minimize the neuroendocrine stress response to surgery, some anesthetics may also independently contribute to perioperative hyperglycemia.<sup>10,71</sup> Inhalation anesthetics, such as isoflurane, may cause hyperglycemia by inhibiting insulin secretion<sup>72,73</sup>; the hyperglycemia results from both impaired glucose uptake and increased glucose

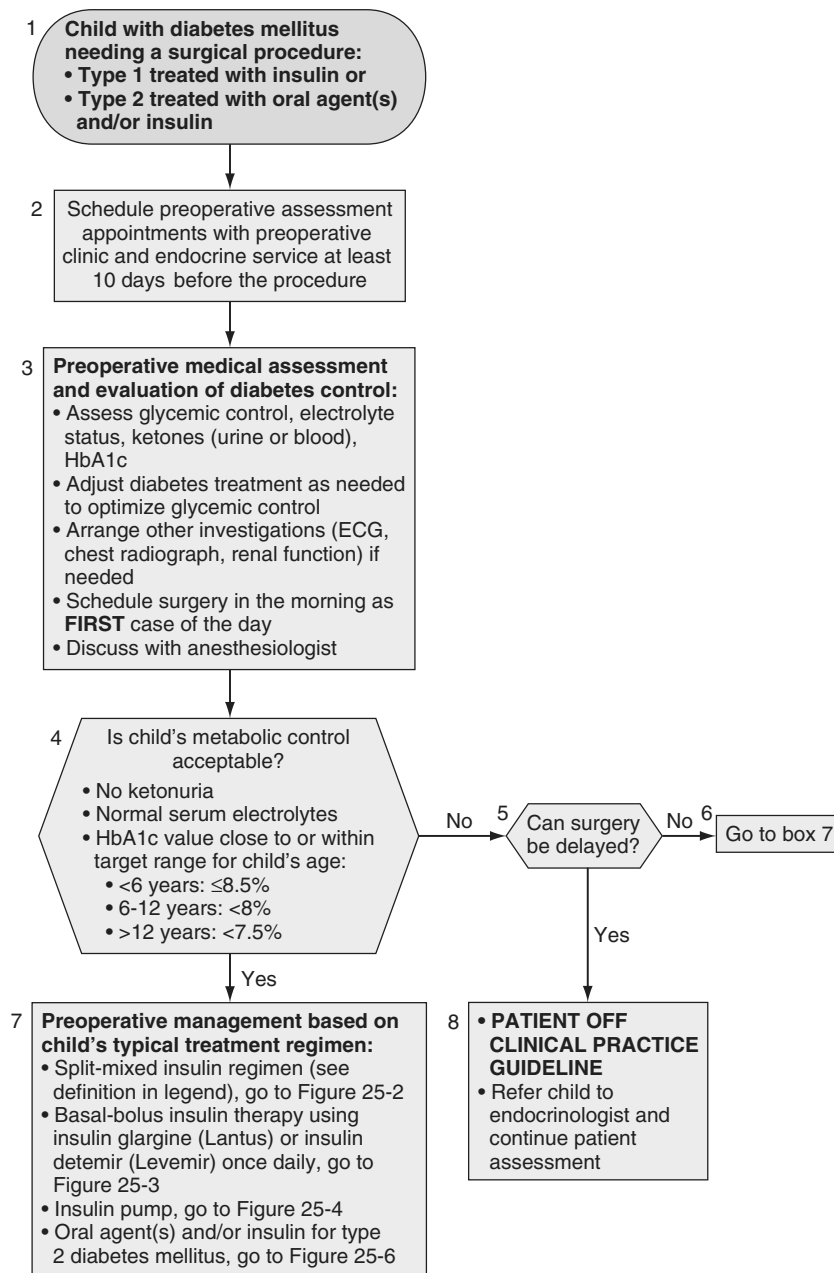

production.<sup>71</sup> In contrast, epidural analgesia with local anesthetics prevents this hyperglycemic effect<sup>74,75</sup> through an inhibitory effect on endogenous glucose production.<sup>71</sup> Similarly, intravenous (IV) anesthesia with opioids mitigates the hyperglycemic response of surgery<sup>71,76,77</sup> through its apparent neutral effect on endogenous glucose production but decrease in glucose clearance.<sup>71</sup> Although these differences are important to consider, the metabolic effects of anesthesia are relatively minor compared with the direct effects of surgery.<sup>10</sup>

### ADVERSE CONSEQUENCES OF HYPERGLYCEMIA

Hyperglycemia can impair wound healing by hindering collagen production, which may decrease the tensile strength of the surgical wound.<sup>78</sup> Hyperglycemia may also have adverse effects on neutrophil function, including decreased chemotaxis, phagocytosis, and bactericidal killing.<sup>79-82</sup> Evidence from controlled experimental studies in rabbits demonstrated that these effects may be reversed, in part, by glycemia-independent effects of insulin.<sup>83</sup> However, the overall benefits of intensive insulin therapy, including a reduction in mortality, were derived mainly from maintenance of normoglycemia, whereas glycemia-independent actions of insulin exert only minor, organ-specific effects.<sup>83</sup>

Clinical studies in humans have not consistently supported the relationship between perioperative glycemic control and short-term risk of infection or morbidity.<sup>84,85</sup> However, several studies in diabetic adults undergoing surgery have shown an association between postoperative hyperglycemia and infectious complications.<sup>86,87</sup> A meta-analysis showed that patients in surgical intensive care units (ICUs) appear to benefit from intensive insulin therapy, whereas patients in other ICU settings do not.<sup>88</sup> These outcomes have contributed to confusion regarding specific glycemic targets and the means for achieving them in both critically and noncritically ill patients. A recent consensus statement<sup>89</sup> recommended that an insulin infusion should be used to control hyperglycemia in the majority of critically ill patients in the ICU setting, with a starting threshold of no greater than 180 mg/dL. Once IV insulin therapy has been initiated, the glucose level should be maintained between 140 and 180 mg/dL. With no prospective, randomized controlled trial data for establishing specific guidelines in noncritically ill patients treated with insulin, pre-meal glucose targets should generally be less than 140 mg/dL and random blood glucose values less than 180 mg/dL, as long as these targets can be safely achieved. To avoid hypoglycemia, one should reassess the insulin regimen if blood glucose levels decline below 100 mg/dL. Modification of the insulin regimen is necessary when blood glucose values are less than 70 mg/dL, unless the event is easily explained by other factors (such as a missed meal).<sup>89</sup>

The single pediatric trial to date demonstrated shorter length of stay, attenuated inflammatory response, and decreased mortality in patients randomized to targeting of age-adjusted normoglycemia.<sup>90</sup> However, the rate of severe hypoglycemia (less than 40 mg/dL) in that study was too frequent, at 25% of the total cohort, making the implementation of this approach ill-advised without further evidence from ongoing multicenter pediatric trials. Other retrospective studies of critically ill children managed in pediatric ICUs have also demonstrated associations of hyperglycemia with morbidity and mortality.<sup>91-94</sup> In the 1980s and 1990s the dogma of tight glucose control replaced an era in which the mantra of caring for diabetic surgical patients was “keep them sweet,” but in more recent years glucose control has become controversial and is unresolved, with conflicting evidence;

**FIGURE 25-1** Clinical practice guideline for perioperative management of diabetes mellitus. Split-mixed insulin regimen refers to a regimen combining multiple daily injections of intermediate- or long-acting insulins (e.g., neutral protamine Hagedorn [NPH] or insulin detemir [Levemir]) and multiple injections of rapid- or short-acting insulins (regular, insulin lispro [Humalog], insulin aspart [NovoLog], or insulin glulisine [Apidra]). ECG, Electrocardiogram. (Modified from Rhodes ET, Ferrari LR, Wolfsdorf JI. Perioperative management of pediatric surgical patients with diabetes mellitus. *Anesth Analg* 2005;101:986-99.)

a systematic review of the literature concluded that there are insufficient data regarding the best strategy or regimen to attain target blood glucose levels in ambulatory surgical patients with diabetes mellitus.<sup>95</sup> The recommended practice for subspecialties, such as cardiac, neurosurgical, and solid organ transplant surgical patients, requires still more study, and it must be highlighted that few of the published investigations and meta-analyses have focused specifically on the pediatric age group.

#### PREOPERATIVE ASSESSMENT

When feasible, children with diabetes should not undergo elective surgery until they are metabolically stable (Fig. 25-1, box 4);

that is, there is no ketosis, serum electrolytes are normal, and the glycated hemoglobin (HbA1c) value is close to or within the ideal range for the child's age. Although there is no consensus regarding the ideal metabolic targets for control of diabetes in children,<sup>96</sup> the American Diabetes Association recommends an HbA1c less than or equal to 8.5% for children younger than 6 years of age; less than 8% for children 6 to 12 years of age; and less than 7.5% for 13 years of age or older, with a more stringent target of less than 7% to be considered in this last age group, for children in whom this can be achieved without excessive hypoglycemia,<sup>96</sup> as well as for those with type 2 diabetes.<sup>16</sup> The preoperative consultation to assess the adequacy of metabolic control

should be scheduled at least 10 days before the procedure (see Fig. 25-1, box 3). If metabolic control is poor, surgery should be delayed if possible. Both the endocrinology and anesthesiology services should participate in this assessment. Whenever possible, surgery for children with diabetes should be scheduled as the first case in the morning so that prolonged fasting is avoided and diabetes treatment regimens may be most easily adjusted.

Children who present for emergent surgery, for example, because of trauma or acute surgical conditions, require a multidisciplinary preoperative assessment with collaborative involvement of both the endocrinology and anesthesiology services. In these situations, surgery often cannot be delayed even if metabolic control is poor, as in the case of a child requiring emergent surgery who presents in diabetic ketoacidosis. This has implications for the intraoperative management of such children, as described later under “Special Surgical Situations.”

### PREOPERATIVE MANAGEMENT

The regimen for managing diabetes before, during, and after a surgical or diagnostic procedure that requires the child to fast should aim to maintain near-normoglycemia, that is, blood glucose levels of 100 to 200 mg/dL. In this blood glucose range there will be a reduced risk of osmotic diuresis, dehydration, electrolyte imbalance, metabolic acidosis, infection, and hypoglycemia in the sedated child who may be unaware of hypoglycemia or unable to communicate with staff.<sup>97</sup> The child need not be admitted before the day of surgery, but rather early on the same morning as the surgery or procedure. Parents should receive explicit written instructions regarding appropriate modifications of their child’s diabetes regimen before and for the day of surgery. On admission to the hospital, metabolic control should be assessed, including a preoperative determination of glucose concentration. On the morning of surgery, no rapid- or short-acting insulin should be administered *unless* the blood glucose level exceeds 250 mg/dL. However, admission to the hospital before *major* surgical procedures in children<sup>10</sup> and adults has been recommended if the metabolic status needs to be optimized preoperatively.<sup>65</sup> If the surgery must be delayed for any reason, frequent blood glucose monitoring is mandatory to prevent perioperative hypoglycemia or hyperglycemia.

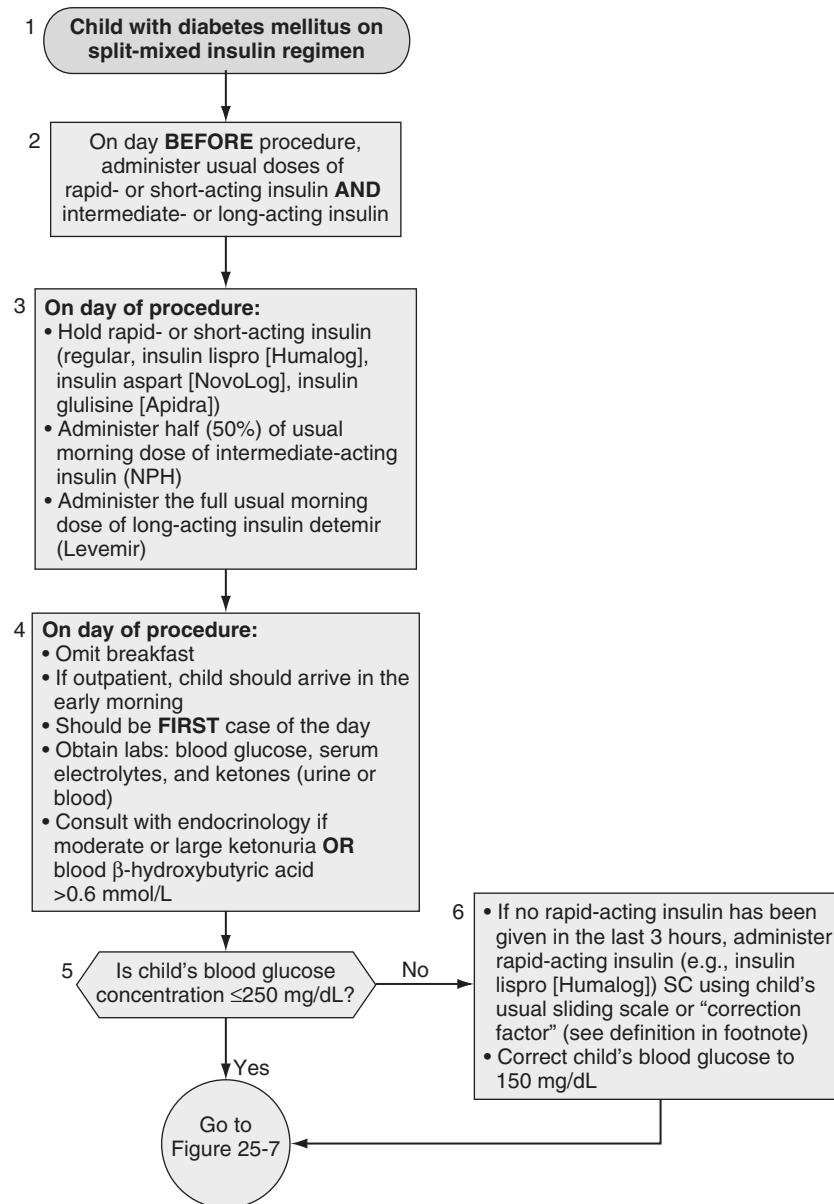

If the blood glucose exceeds 250 mg/dL, a conservative dose of rapid-acting insulin (e.g., insulin lispro or insulin aspart) or short-acting insulin (regular) is administered to restore near-normoglycemia. This is achieved using the child’s usual sliding scale or a “correction factor.” The insulin “correction factor” is the decrease in the blood glucose concentration expected after administering 1 unit of rapid- or short-acting insulin. This can be calculated using the “1500 rule”: divide 1500 by the child’s usual total daily dose (TDD) of insulin. For example, if a child typically receives 30 units of insulin daily, this child’s “correction factor” would be  $1500 \div 30 = 50$ . Therefore 1 unit of rapid- or short-acting insulin would be expected to decrease the child’s blood glucose concentration by approximately 50 mg/dL. Various correction factors have been described, including a “1500 rule” for short-acting insulin (regular) and an “1800 rule” for rapid-acting insulin, such as insulin lispro.<sup>91,98</sup> For simplicity and because of insulin resistance stimulated by surgical stress, the “1500 rule” is appropriate in this setting, even with the use of a rapid-acting insulin. To then calculate an appropriate corrective dose of insulin to restore near-normoglycemia, the anesthesiologist should aim for a target blood glucose concentration of 150 mg/dL.

The “correction factor” rather than a sliding scale is used to manage a child with hyperglycemia and restore the blood glucose concentration to 150 mg/dL. For example, if the child has a correction factor of 1 unit of rapid- or short-acting insulin to reduce the blood glucose concentration by about 50 mg/dL, and the current blood glucose value is 300 mg/dL, to reduce the blood glucose concentration from 300 mg/dL to 150 mg/dL, a total dose of  $(300 - 150)/50$  or 3 units of insulin would be required. At the start of the procedure, the “correction” dose may be administered subcutaneously (using rapid-acting insulin) or IV using short-acting (regular) insulin in those children who will be managed with an intravenous insulin infusion during the procedure. For children with type 2 diabetes who do *not* require insulin (but who are, by definition, insulin resistant), an insulin dose of 0.1 unit/kg of rapid-acting insulin may be administered subcutaneously to correct a blood glucose concentration greater than 250 mg/dL.

More detailed preoperative recommendations must be based on the individual child’s usual treatment regimen. For most children with diabetes undergoing minor outpatient surgical procedures, insulin can be provided perioperatively with subcutaneous injections. In adults, especially those with type 2 diabetes, this practice is commonly,<sup>97</sup> although not universally, preferred.<sup>99</sup> Others routinely recommend insulin infusions even for minor outpatient surgical procedures in children.<sup>10</sup> Several reports suggest that better glycemic control can be achieved in the perioperative period with a continuous intravenous infusion rather than subcutaneous insulin administration.<sup>12,100,101</sup> However, these studies were conducted before the availability of rapid-acting insulins whose rapid and reproducible effects after subcutaneous administration<sup>102</sup> may more closely match the ability to titrate IV-administered short-acting insulin. Subcutaneous insulin lispro has been shown to be as efficacious as regular IV insulin for treatment of uncomplicated diabetic ketoacidosis in children.<sup>103</sup> Whatever the management strategy for the diabetes, it is most important that it is coordinated between the anesthesiology and endocrinology services, and the modifications to the child’s diabetic regimen at home needs to be communicated clearly and in a timely manner to the family.

Split-mixed insulin regimens involve two to three injections per day with a combination of NPH or insulin detemir plus a rapid- or short-acting insulin. For children who use such a regimen, 50% of the usual morning dose of NPH or the full usual dose of insulin detemir should be administered on the morning of the procedure (Fig. 25-2). For the child whose basal insulin is once-daily insulin glargine or insulin detemir, no additional insulin is given on the morning of the surgery if the child received a dose in the evening of the previous day (Fig. 25-3). However, if insulin glargine or detemir is typically administered in the morning, the full dose should be administered on the morning of the procedure to prevent ketosis.

Management of the child on an insulin pump depends on the duration of the surgical procedure (Fig. 25-4). Those undergoing minor procedures expected to last less than 2 hours can continue to receive their usual basal rate via their insulin pump. However, this approach requires that the anesthesiologist is familiar and comfortable with the use of the pump in the operating room. Other protocols include transitioning patients who use an insulin pump to IV insulin infusion or subcutaneous insulin glargine.<sup>65</sup> For procedures longer than 2 hours, children should be transitioned to an IV insulin infusion, as described in the next section.

**FIGURE 25-2** Preoperative management for children with diabetes mellitus on split-mixed insulin regimens. The calculation for insulin "correction factor" is as follows:

1. Divide 1500 by child's total daily dose (TDD).

2. If daily dose varies (i.e., use of sliding scales), use the *average* daily dose in the past week to determine TDD.

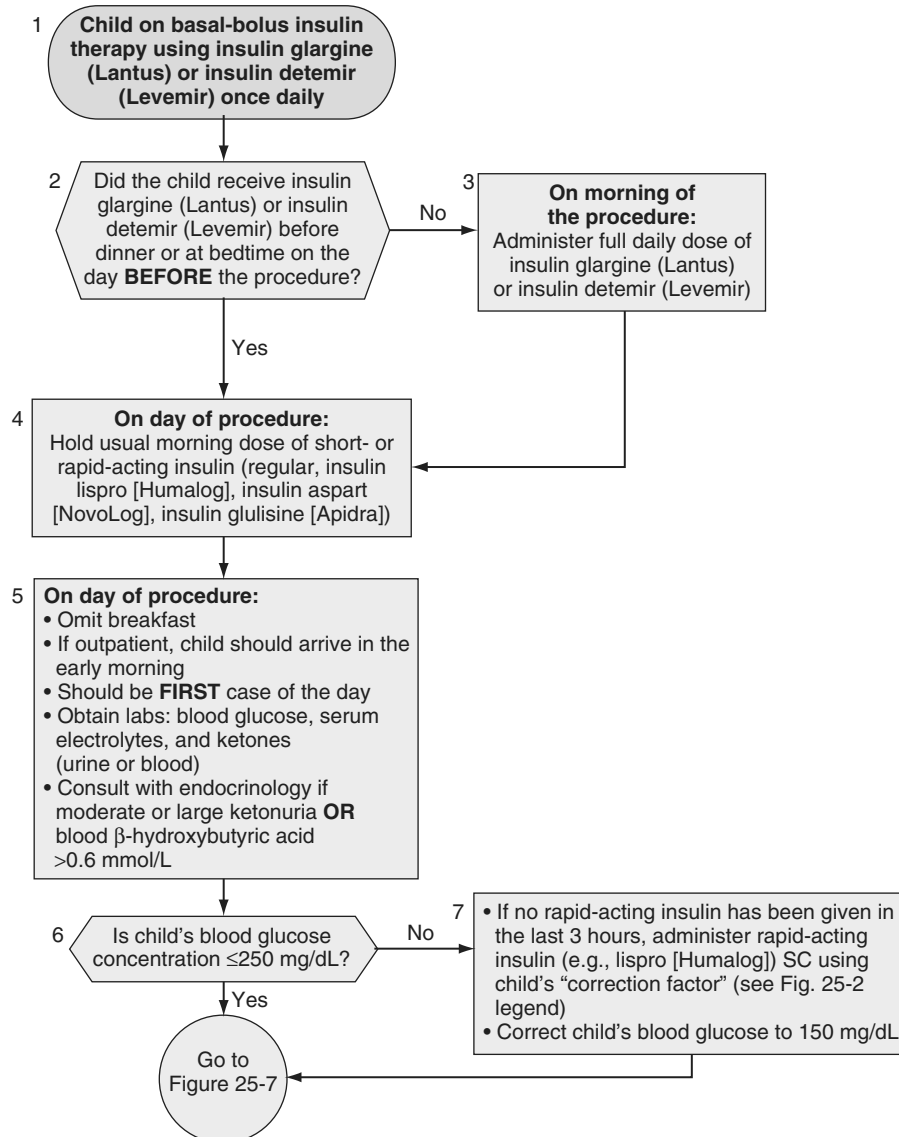

3. Example: if TDD = 50 units, then insulin correction factor is 1 unit insulin lispro (Humalog) to reduce blood glucose by 30 mg/dL.

NPH, Neutral protamine Hagedorn; SC, subcutaneous. (Modified from Rhodes ET, Ferrari LR, Wolfsdorf JL. Perioperative management of pediatric surgical patients with diabetes mellitus. *Anesth Analg* 2005;101:986-99.)

## MAJOR SURGERY AND INTRAVENOUS INSULIN INFUSIONS

For children who require major surgery, especially procedures anticipated to last more than 2 hours, an IV insulin infusion is the preferred perioperative diabetes management plan (Fig. 25-5). Studies in children<sup>12</sup> and adults<sup>7</sup> have demonstrated that glycemic control is superior with infusions of IV insulin compared with subcutaneous injections. These children should receive their usual doses of insulin on the day before the procedure. On the morning of the procedure, an IV infusion of 5% dextrose in half-normal saline should be started at a maintenance rate, and an IV insulin infusion should also be provided to accommodate

the dextrose infusion to maintain blood glucose in the target range of 100 to 200 mg/dL (see Fig. 25-5). The maintenance rate for IV fluids in a child depends on body size and can be calculated either based on body weight (4 mL/kg/hr for the first 10 kg body weight, 2 mL/kg/hr for 11 to 20 kg, and then 1 mL/kg/hr for each kg over 20 kg) or body surface area (1.5 L/m<sup>2</sup>/day). The insulin dose varies with the child's pubertal status; prepubertal children are relatively more sensitive to insulin than pubertal adolescents.<sup>104</sup> In prepubertal children with type 1 diabetes, after the remission (honeymoon) period, the insulin requirement is typically 0.6 to 0.8 unit/kg/day, whereas in adolescents, the

**FIGURE 25-3** Preoperative management for children with diabetes mellitus on once-daily insulin glargine (Lantus) or insulin detemir (Levemir) regimens. Note that insulin glargine and insulin detemir should not be mixed with any other insulin. SC, Subcutaneous. (Modified from Rhodes ET, Ferrari LR, Wolfsdorf JI. Perioperative management of pediatric surgical patients with diabetes mellitus. *Anesth Analg* 2005;101:986-99.)

requirement is 1 to 1.5 units/kg/day.<sup>105,106</sup> Children with type 2 diabetes may require even greater doses of insulin because of their insulin resistance. With IV insulin, a suitable initial ratio of insulin to dextrose may be estimated from the child's usual or average total daily insulin dose (TDD) using the formula  $500 \div \text{TDD}$ . For example, if the child typically receives 50 units of insulin daily, then  $500 \div 50 = 10$ . Therefore, in this example, 1 unit of insulin would be administered via a "piggyback infusion" for each 10 g of dextrose contained in the maintenance IV infusion to prevent hyperglycemia. Note that a maintenance IV solution of 5% dextrose contains 10 g of dextrose in every 200 mL. Only regular insulin should be used for IV infusions.

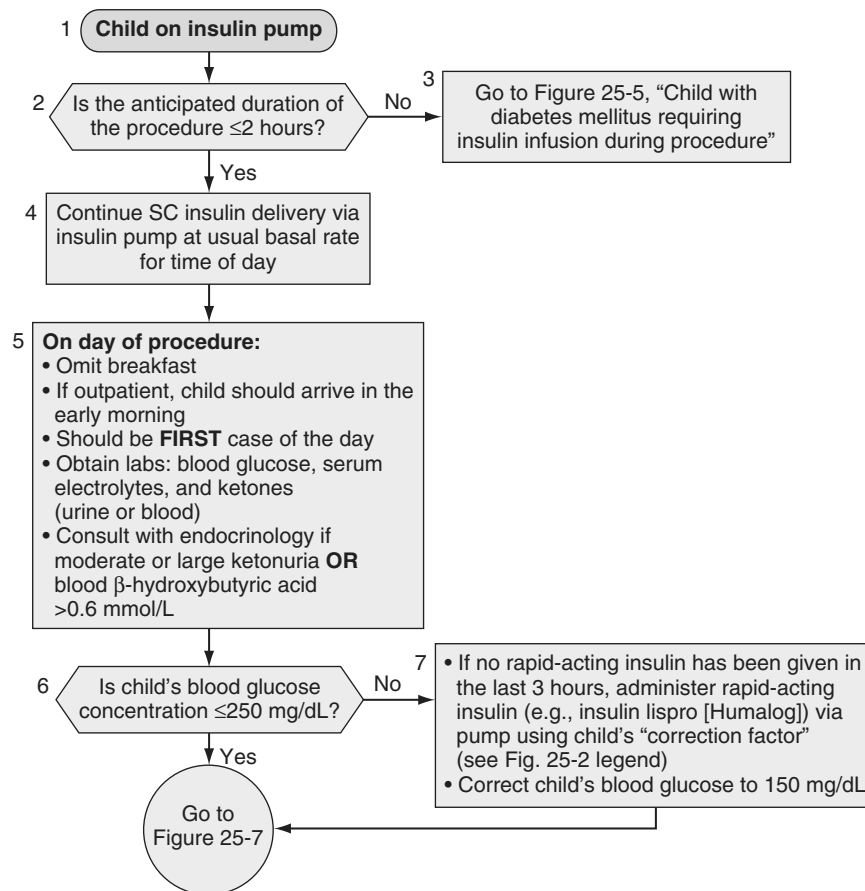

#### SPECIAL CONSIDERATIONS FOR PREOPERATIVE MANAGEMENT OF TYPE 2 DIABETES

Children with type 2 diabetes may require insulin or one of several oral antihyperglycemic agents (Fig. 25-6). Metformin should be discontinued 24 hours before a procedure because of

its long half-life and the risk of lactic acidosis in the presence of dehydration, hypoxemia, or poor tissue perfusion.<sup>107</sup> Other oral agents, such as sulfonylureas and thiazolidinediones, may be discontinued on the morning of the procedure. Figure 25-6 outlines additional recommendations for children with type 2 diabetes who use a split-mixed or basal-bolus insulin regimen. Adjustments for other insulin regimens or oral hypoglycemic agents in type 2 diabetes should be determined in consultation with an endocrinologist or diabetologist.

#### INTRAOPERATIVE MANAGEMENT

The insulin and fluid regimen during and after surgery depends on the duration of the procedure. If the procedure is likely to be brief (e.g.,  $\leq 1$  hour) and one can reasonably anticipate that the child will be able to drink soon after the procedure, it may not be necessary to start a glucose-containing IV infusion. If the duration of fasting is likely to be more prolonged, an IV infusion should be started at a maintenance rate as described

**FIGURE 25-4** Preoperative management for children with diabetes mellitus who are using an insulin pump. SC, Subcutaneous. (Modified from Rhodes ET, Ferrari LR, Wolfsdorf JL. Perioperative management of pediatric surgical patients with diabetes mellitus. *Anesth Analg* 2005;101:986-99.)

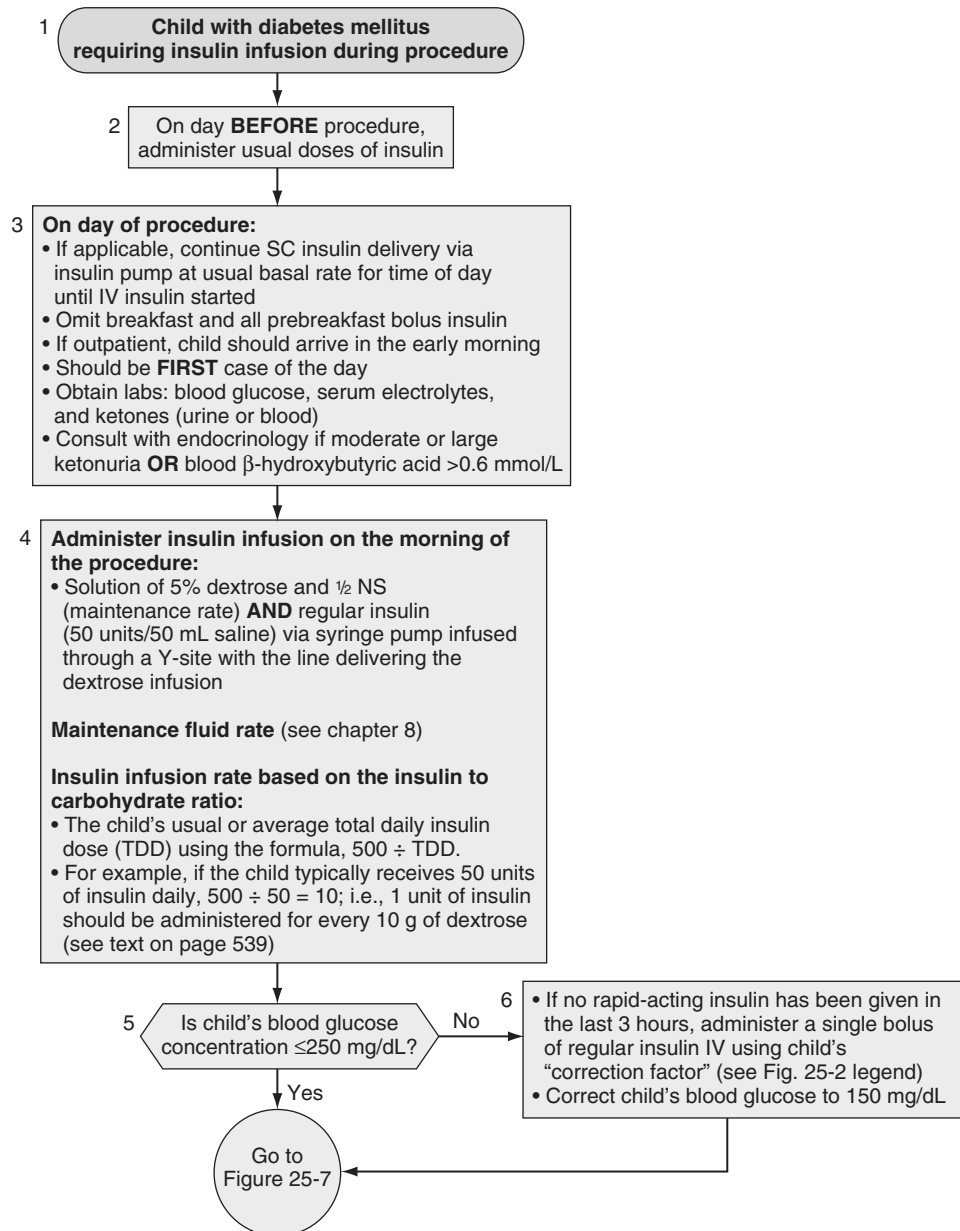

earlier (Fig. 25-7). Intraoperative maintenance fluid should then be replaced with a comparable glucose-containing solution. Replacement of insensible losses and intravascular volume owing to blood or other body fluid losses should be with an appropriate isotonic solution (e.g., lactated Ringer's solution or normal saline).

Although some protocols include potassium chloride in the maintenance IV fluid solution,<sup>10,65,97</sup> this practice should generally be avoided because of the danger of inadvertent intraoperative administration of large quantities of potassium during fluid resuscitation. Children undergoing a brief procedure with a baseline normal serum potassium concentration and well-controlled diabetes have a small risk of hypokalemia. Those undergoing more prolonged surgeries or emergent surgeries during which metabolic decompensation is more likely, require intraoperative assessment of electrolytes and appropriate adjustment of the electrolyte composition of their IV solution. *In all cases, blood glucose concentrations should be measured hourly and either insulin or dextrose adjusted, as necessary, to maintain blood glucose in the target range of 100 to 200 mg/dL.* If the blood glucose exceeds 250 mg/dL, urine or blood ketones should also be measured (see Fig. 25-7). Either an increase in the rate of continuous insulin infusion or subcutaneous administration of a rapid-acting insulin analog is used to correct intraoperative hyperglycemia. Intraoperative IV bolus of regular insulin is not recommended because this causes a rapid supraphysiologic increase in serum insulin concentration, which, owing to insulin's short half-life

(approximately 5 minutes), will have a short-lived effect on blood glucose levels. In contrast, subcutaneously administered rapid-acting insulin analogs have a typical and reproducible pharmacologic profile.

## POSTOPERATIVE MANAGEMENT

As soon as the child is able to resume drinking and eating normally, the usual diabetes regimen, including insulin and/or oral agents, may be reinstituted and the dextrose infusion discontinued, if applicable (Fig. 25-8). One exception to this approach is for children with type 2 diabetes who take metformin; metformin should be held for 48 hours and renal function must be within normal limits before its resumption. For children who are unable to eat or drink, IV dextrose and electrolyte solution should be continued until oral intake is restored. An infusion of IV short-acting insulin (regular) or intermittent subcutaneous rapid-acting insulin should be administered, not more than every 3 hours, to maintain blood glucose in the target range of 100 to 200 mg/dL. Frequent blood glucose monitoring and monitoring blood or urine ketones is essential because of the variable effects of surgical trauma, inactivity, pain, anxiety, nausea and/or vomiting with poor oral intake, medications, and postoperative infection. At the time of discharge from the hospital, children and their parents or care providers should be given appropriate guidelines regarding these issues. Those who are admitted to the hospital overnight after surgery should be managed in consultation with the

**FIGURE 25-5** Preoperative management for children with diabetes mellitus who require insulin infusions during surgery. IV, Intravenous; NS, normal saline; SC, subcutaneous. (Modified from Rhodes ET, Ferrari LR, Wolfsdorf JI. Perioperative management of pediatric surgical patients with diabetes mellitus. *Anesth Analg* 2005;101:986-99.)

endocrinology service, if possible, to coordinate appropriate scheduling and subsequent dosing of insulin.

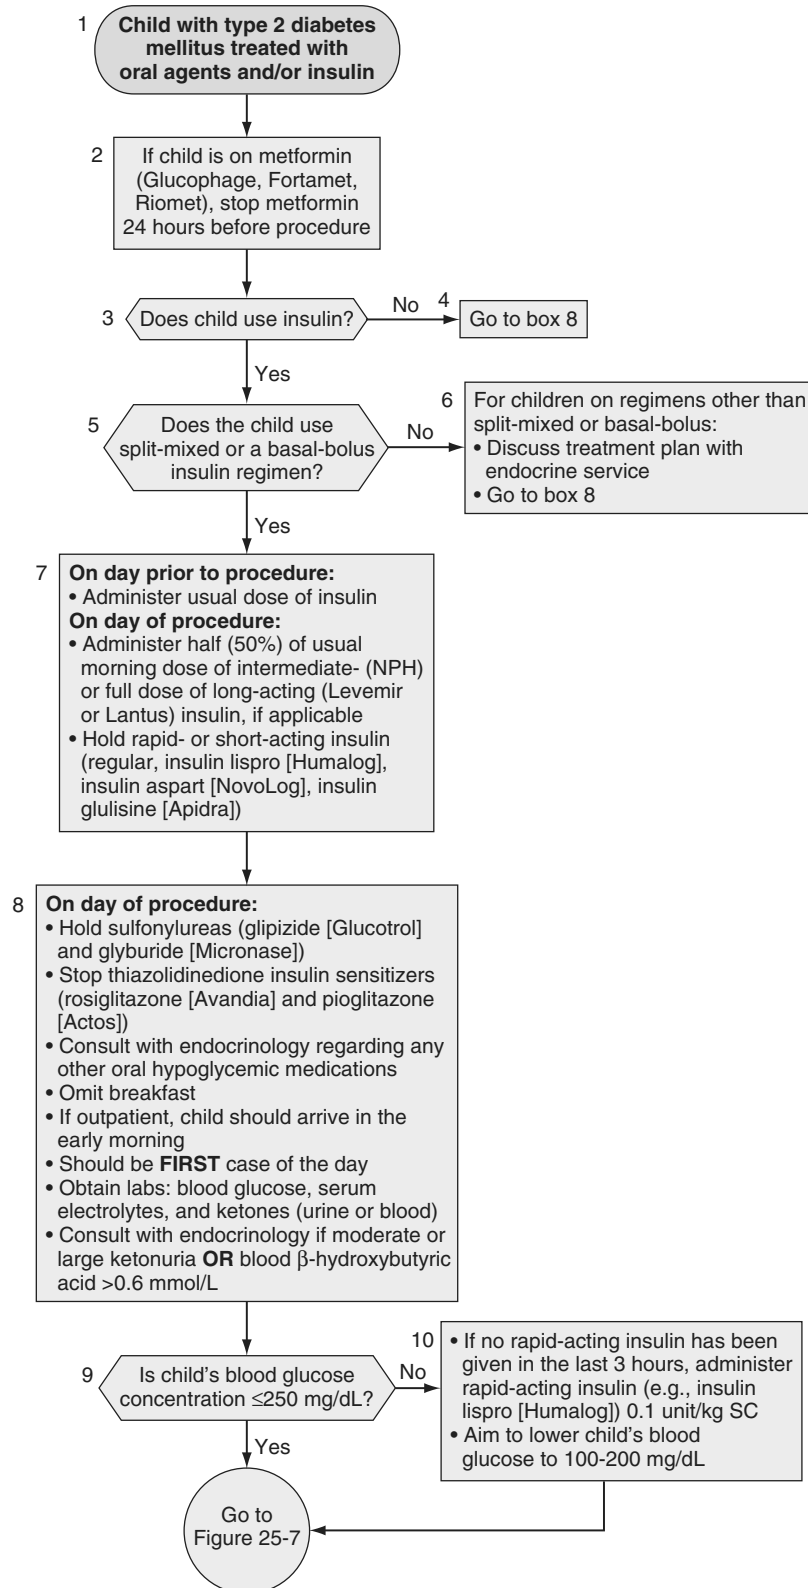

### SPECIAL SURGICAL SITUATIONS

Children with diabetes who need urgent surgery must have a full clinical and biochemical assessment. Frequently, the problem necessitating surgery may have led to metabolic decompensation that must first be corrected and stabilized, unless the need for surgery is immediate. These children are often dehydrated; in addition to administering insulin, rehydration and electrolyte replacement is critical to address their metabolic derangements and restore normal glomerular filtration rate and renal function. In most cases, these children require emergent surgery that should be managed with an IV infusion of insulin as described

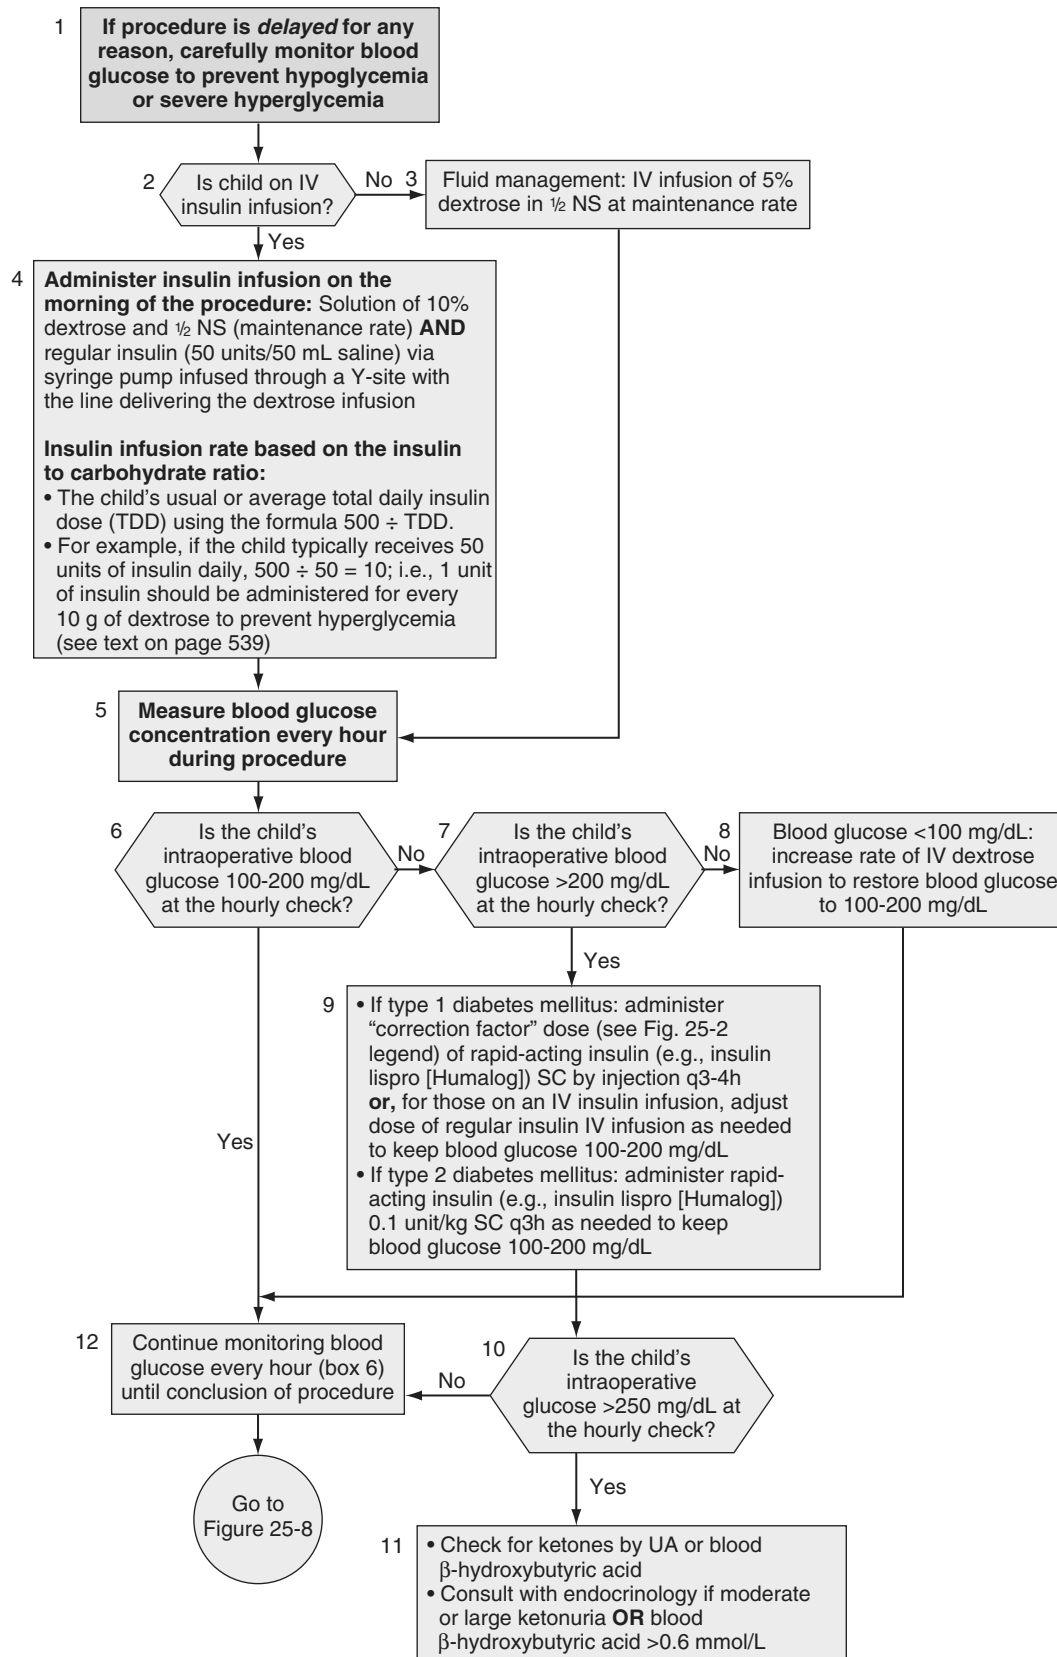

earlier (see Fig. 25-5). Children with diabetic ketoacidosis require close collaboration between the anesthesiology and endocrinology services.

### Diabetes Insipidus

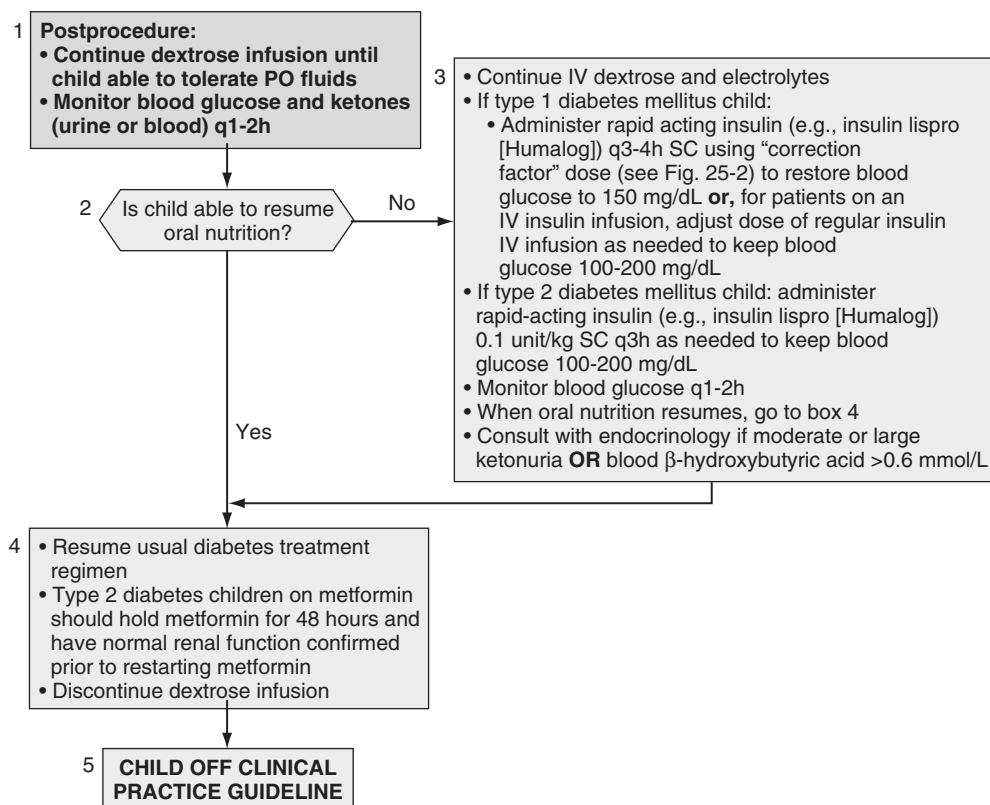

Children undergoing neurosurgical procedures for tumors in or near the pituitary gland, especially craniopharyngioma, often require management of diabetes insipidus (DI), as do children with known DI who require anesthesia for surgical or radiologic procedures. The perioperative management of these children is frequently complicated by either overhydration or underhydration and electrolyte disturbances.

**FIGURE 25-6** Preoperative management for children with type 2 diabetes who are using oral agents and/or insulin. *NPH*, Neutral protamine Hagedorn; *SC*, subcutaneous. (Modified from Rhodes ET, Ferrari LR, Wolfsdorf JL. Perioperative management of pediatric surgical patients with diabetes mellitus. *Anesth Analg* 2005;101:986-99.)

**FIGURE 25-7** Intraoperative management of children with diabetes mellitus. The management goal for the child with diabetes is near-normoglycemia (100-200 mg/dL). Maintenance fluid rate calculation is 4 mL/kg/hr for the first 10 kg of body weight, 2 mL/kg/hr for body weight between 11 and 20 kg, and 1 mL/kg/hr for every kg of body weight over 20 kg. IV, Intravenous; NS, normal saline; SC, subcutaneous; UA, urinalysis. (Modified from Rhodes ET, Ferrari LR, Wolfsdorf JL. Perioperative management of pediatric surgical patients with diabetes mellitus. *Anesth Analg* 2005;101:986-99.)

**FIGURE 25-8** Postoperative management of children with diabetes mellitus. IV, Intravenous; PO, postoperative; SC, subcutaneous. (Modified from Rhodes ET, Ferrari LR, Wolfsdorf JL. Perioperative management of pediatric surgical patients with diabetes mellitus. *Anesth Analg* 2005;101:986-99.)

DI is caused by a deficiency of the antidiuretic hormone arginine vasopressin, which acts on the distal tubule and collecting duct of the kidney to promote reabsorption of water. Central (hypothalamic, neurogenic, or vasopressin-sensitive) DI can be caused by disorders of vasopressin gene structure; accidental or surgical trauma to vasopressin neurons; congenital anatomic hypothalamic or pituitary defects; neoplasms; infiltrative, autoimmune, and infectious diseases affecting vasopressin neurons or fiber tracts; and increased metabolism of vasopressin. The etiology is unknown in approximately 50% of children with central DI.

#### DIAGNOSIS OF NEUROSURGICAL DIABETES INSIPIDUS: THE TRIPLE-PHASE RESPONSE

It is important to distinguish polyuria caused by the onset of acute postsurgical central DI from polyuria resulting from diuresis of fluids given during surgery. In both cases, children may have a large volume (exceeding 200 mL/m<sup>2</sup>/hr) of dilute urine. Serum osmolality will be increased in DI but will be normal in the child excreting excess salt and water. The normal child who excretes excess salt and water has a markedly increased urine osmolality. A meticulous examination of the intraoperative and postoperative records and careful bedside assessment of volume status (jugular venous distention, capillary refill) will help to distinguish between these two entities.

Of special interest is the triphasic pattern of vasopressin secretion, often, but not always, observed after neurosurgical procedures that interfere with the supraoptic-hypophyseal tract.<sup>108</sup> After surgery, an initial phase of transient DI may be observed,

lasting between 12 hours and 2 days. This may be explained by local edema that interferes with normal vasopressin secretion. If significant vasopressin-secreting cell damage has occurred, release of stored vasopressin from damaged neurons leads to a second phase that involves water retention. The syndrome of inappropriate antidiuretic hormone secretion (SIADH) may last up to 10 days. Finally, a third phase, permanent neurogenic DI, may follow if more than 90% of vasopressin cells are destroyed. Pronounced SIADH in the second phase generally portends permanent DI in the final phase of the triple response. In children with vasopressin and cortisol deficiency (e.g., in combined anterior and posterior hypopituitarism after neurosurgical treatment of craniopharyngioma), symptoms of DI may be masked because cortisol deficiency impairs renal free water clearance. Institution of glucocorticoid therapy may precipitate polyuria, leading to the diagnosis of DI (Fig. 25-9).

#### PERIOPERATIVE MANAGEMENT OF MINOR PROCEDURES

Children with preexisting DI who are scheduled for a minor procedure, i.e., a procedure without significant blood loss and not followed by a period of further fasting or fluid shifts (e.g., myringotomy, radiologic imaging, peripheral orthopedic procedures) are treated differently from those undergoing a more major procedure associated with blood loss or fluid shifts and delayed postoperative resumption of fluid intake (see Fig. 25-9).

Children undergoing minor procedures under anesthesia should receive their usual morning dose of desmopressin (DDAVP) (Table 25-3). The anesthetic technique is tailored to the procedure (e.g., IV sedation for MRI, general endotracheal

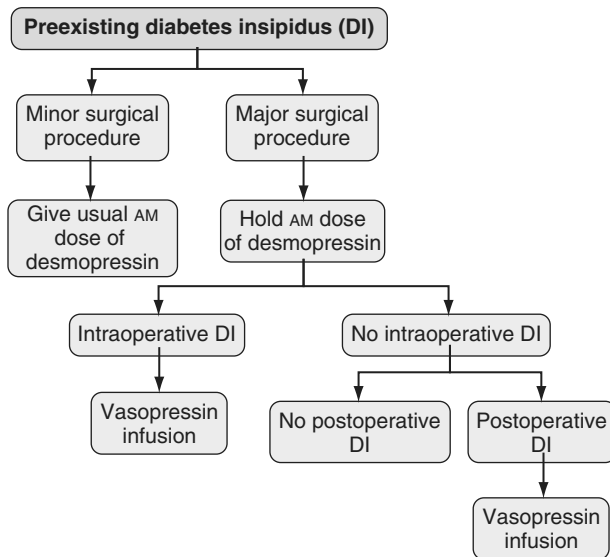

FIGURE 25-9 Perioperative management of diabetes insipidus.

TABLE 25-3 Medications for Management of Central Diabetes Insipidus

Desmopressin acetate (100-, 200- $\mu$ g tablets; nasal tube 10 $\mu$ g/0.1 mL; nasal spray 10 $\mu$ g/0.1 mL: delivers 0.1 mL/spray)	
Oral	Dose: 100-400 $\mu$ g q12h Oral doses are 10-20 times intranasal doses of desmopressin Onset of action: ~15-30 minutes Duration: 8-12 hours May develop tachyphylaxis
Intranasal	Dose: ~10-20 $\mu$ g/dose q12-24h Onset of action: 5-15 minutes Duration: 8-12 hours
Vasopressin (Pitressin) (20 units/mL; 0.5-mL, 1-mL, and 10-mL vials; conversion: 1 unit = 2.5 $\mu$ g)	
Intravenous	Dose: 1.5 milliunits/kg/hr Onset of action: minutes Half life: 5-10 minutes

anesthesia for tonsillectomy). Arterial and urinary catheters are not required, and recovery takes place in the postanesthesia care unit (PACU). Once the morning dose of desmopressin has been administered, intraoperative and postoperative fluids should be restricted to the rate of 1 L/m<sup>2</sup>/24 hours, i.e., to match insensible free water losses and obligatory urine output. Oral fluids may be offered once the child is awake. Although modern PACU policies often no longer require successful fluid intake before discharging the ambulatory patient, discharging the child with DI should be delayed until the child is able to freely take oral fluids without vomiting. Subsequent doses of desmopressin should be administered according to the child's usual preoperative schedule.

#### PERIOPERATIVE MANAGEMENT OF MAJOR PROCEDURES

A major surgical procedure is defined as an operation associated with the potential for significant blood loss; intraoperative or postoperative hemodynamic, neurologic, or respiratory instability; entry into a body cavity (e.g., craniotomy, abdominal surgery,

thoracic surgery); craniofacial or airway surgery; major orthopedic surgery (e.g., spine surgery, tumor resection or amputation, major osteotomies); and/or surgery followed by delayed resumption of unrestricted fluid intake. The child with DI should be scheduled as the first case of the day. On the day before the procedure, the child treated with desmopressin should receive the usual morning dose, but only 50% of the usual evening or bedtime dose (see Fig. 25-9). On the morning of the procedure, desmopressin is withheld. The child undergoing a major procedure should receive general anesthesia with conventional monitoring, as well as insertion of arterial and urinary catheters, and after surgery is admitted to the ICU. A central venous catheter for monitoring central venous pressure, although not indicated solely for the management of DI, is useful in the postoperative period.

At the start of the procedure, an infusion of aqueous vasopressin (20 units/1000 mL to yield a final concentration of 20 milliunits/mL) should be started at 1.5 milliunits/kg/hr (0.0015 unit/kg/hr). IV fluids, using normal saline with 5% dextrose, should total 1 L/m<sup>2</sup>/24 hours to approximate insensible losses and obligate urine output. Additional IV saline, isotonic fluid, or blood products may be given, as needed, to correct blood and surgical fluid loss, to correct third space fluid loss, and to maintain hemodynamic stability. Urine output should not routinely be replaced in the child receiving a vasopressin infusion.

#### NEW PERIOPERATIVE DIAGNOSIS

The new diagnosis of intraoperative or postoperative DI is based on clinical and laboratory findings, including serum sodium level greater than 145 mmol/L, polyuria (greater than 4 mL/kg/hr) for 30 minutes or more, increased plasma osmolality (greater than 300 mOsm/kg) in association with hypotonic urine (less than 300 mOsm/kg), and after excluding the presence of glycosuria and diuretic or mannitol administration as possible causes of polyuria.

When DI occurs, an infusion of aqueous vasopressin (20 units/1000 mL) is initiated at 1.5 milliunits/kg/hr (0.0015 unit/kg/hr) and the dose is doubled after 15 to 30 minutes if the child does not respond, until urine output decreases to less than 2 mL/kg/hr. Once a urine output of less than 2 mL/kg/hr is achieved, the vasopressin infusion is maintained at a constant rate.

IV desmopressin should *not* be used in the acute management of postoperative central DI because it offers no advantage over aqueous vasopressin and because its long half-life (8 to 12 hours) compared with that of vasopressin (5 to 10 minutes) increases the risk of water intoxication and precludes dose titration.

#### POSTOPERATIVE MANAGEMENT

The child with DI should be cared for in an ICU after major surgery. Fluid input and output, serum electrolytes and osmolality are monitored closely (hourly if necessary) in the intraoperative and postoperative periods. Until stability is achieved, it is important to have a urinary catheter in place to distinguish postoperative urinary retention from oliguria. The vasopressin infusion initiated intraoperatively is continued in the ICU. Fluid administration is *not* adjusted according to urine output; however, fluid deficits are replaced and blood pressure supported until antidiuresis (urine output of less than 2 mL/kg/hr) is clearly established. Total (oral and IV) maintenance fluids should not exceed insensible plus obligatory urinary losses of 1 L/m<sup>2</sup>/24 hours. In the postoperative period, appropriate maintenance fluid is generally 5% dextrose in half-normal saline with

0 to 40 mEq/L of potassium chloride (depending on the serum potassium concentration). Blood loss should be replaced with normal saline, 5% albumin, or blood products, as appropriate.

Aqueous vasopressin at a dose of 1.5 milliunits/kg/hr results in a supranormal blood vasopressin concentration of approximately 10 pg/mL, twice that needed for full antidiuretic activity.<sup>109</sup> The effect of vasopressin is maximal within 2 hours after starting an infusion.<sup>109</sup>

After hypothalamic, but not trans-sphenoidal surgery, greater initial concentrations of vasopressin are occasionally required to treat acute DI. This may be attributed to the release of a substance related to vasopressin from the damaged hypothalamo-neurohypophyseal system, which acts as an antagonist to normal vasopressin activity.<sup>110</sup> Much greater rates of vasopressin infusions, resulting in plasma concentrations greater than 1000 pg/mL, should be avoided because they may cause cutaneous necrosis,<sup>111</sup> rhabdomyolysis,<sup>111,112</sup> and cardiac rhythm disturbances.<sup>112</sup>

### POST-INTENSIVE CARE UNIT MANAGEMENT

Children treated with vasopressin for postneurosurgical DI should be switched from IV to oral fluid intake at the earliest opportunity. With an intact thirst mechanism and access to free water, the patient will better regulate blood osmolality. Once oral intake has been resumed without nausea and vomiting (often by the morning of the day after surgery), the vasopressin infusion should be stopped; all IV infusions should be stopped to avoid iatrogenic fluid overload, and oral fluids are permitted freely. Desmopressin is reinstituted (nasally or orally) in the child with preexisting DI or begun in the child who has new-onset DI (see Table 25-3).

## Syndrome of Inappropriate Antidiuretic Hormone Secretion

SIADH is characterized by hypotonic hyponatremia, urine osmolality in excess of plasma osmolality, natriuresis in the absence of edema and volume depletion, and normal renal and adrenal function.<sup>113</sup> The dilutional hyponatremia of SIADH develops because of persistent detectable or increased plasma arginine vasopressin (AVP; also known as antidiuretic hormone [ADH]) concentrations in the presence of continued fluid intake. Chronic hyponatremia, however, is the result of a combination of water retention and sodium excretion.<sup>114</sup> The major causes of SIADH are neurologic diseases, neoplasia, lung diseases, and medications (Table 25-4).<sup>115</sup> Inappropriate infusion of hypotonic fluids in the postoperative period is among the most common causes.<sup>116</sup> The clinical manifestations are principally neuromuscular (headache, nausea, vomiting, muscle cramps, lethargy, restlessness, disorientation, and depressed reflexes). The severity of symptoms is related to both the absolute serum sodium concentration (most patients with serum sodium greater than 125 mEq/L are asymptomatic) and its rate of decrease, especially if greater than 0.5 mEq/L/hr.

Although ADH secretion impairs water excretion, the mechanisms that regulate volume (renin-angiotensin-aldosterone system and atrial natriuretic peptide) are intact. Volume expansion activates natriuretic mechanisms (decreased proximal sodium reabsorption and decreased aldosterone production), resulting in sodium and water excretion and the restoration of near-euvolemia. With *chronic* SIADH, sodium loss is a more prominent feature

**TABLE 25-4 Causes of Syndrome of Inappropriate Antidiuretic Hormone Secretion (SIADH)**

#### Central Nervous System Disturbances

Head injury  
Brain tumor  
Subarachnoid hemorrhage  
Stroke  
Infection (meningitis, encephalitis)  
Acute psychosis

#### Drugs

Vasopressin, desmopressin  
Carbamazepine, oxcarbamazepine  
Cyclophosphamide  
Vinca alkaloids  
Cisplatin  
Phenothiazines  
Serotonin uptake inhibitors (e.g., fluoxetine, sertraline)  
Tricyclic antidepressants  
Monoamine oxidase inhibitors  
Methylenedioxymethamphetamine ("ecstasy")  
Nicotine

#### Major Surgery

Major abdominal or thoracic surgery  
Pituitary surgery  
Pain  
Severe nausea

#### Pulmonary Disease

Pneumonia, tuberculosis  
Asthma  
Atelectasis  
Pneumothorax  
Positive-pressure ventilation

#### Neoplasia

Carcinoma of lung (e.g., small cell carcinoma)  
Leukemia  
Thymoma  
Lymphoma  
Other tumors

#### Infection

Human immunodeficiency virus

#### Hereditary SIADH

Functional mutations in the gene for vasopressin-2 receptor

than is water retention. Severe hyponatremia increases cell size because of entry of water into the cell along its osmotic gradient, and may be associated with loss of intracellular potassium and other solutes in an attempt to restore cell volume.

### PERIOPERATIVE MANAGEMENT

Many of the causes of SIADH are transient and resolve as the underlying condition is corrected. Treatment of chronic SIADH consists of water restriction; that is, fluid intake is restricted to less than or equal to 1 L/m<sup>2</sup>/24 hours. Unless sodium intake is adequate, water restriction can lead to volume depletion in children with a sodium deficit. In asymptomatic chronic (more than 3 days) dilutional hyponatremia and in chronic SIADH, specific therapy may not be required.

Hypertonic (3%) saline should be used with caution in children. Rapid correction of chronic hyponatremia can lead to serious, permanent, and even fatal neurologic complications from osmotic demyelination (central pontine myelinolysis).<sup>117</sup> Only children with neurologic symptoms (e.g., altered level of consciousness, coma, or seizures) attributable to acute hyponatremia of less than 3 days' duration require rapid initial correction of the sodium deficit (use 3% hypertonic saline to deliver 5 mEq/kg per hour). The rate of increase of serum sodium concentration in states of chronic hyponatremia should not exceed 0.5 mEq/L/hr (or 8 to 10 mEq/L/24 hours).<sup>118,119</sup> The saline infusion should stop when the absolute concentration of serum sodium reaches 120 to 125 mEq/L. Hypertonic saline is usually combined with furosemide to limit treatment-induced expansion of the extracellular fluid volume.<sup>119</sup> Thereafter, treatment should consist of fluid restriction.

## Thyroid Disorders

Thyroid hormones play an important role in metabolic processes, growth, and development in children.<sup>120</sup> The thyroid gland develops from the embryonic pharyngeal floor and descends along the thyroglossal duct to its final position in the anterior neck. Thyroid hormone production is controlled by the hypothalamic-pituitary-thyroid axis. Two principal thyroid hormones are produced. Although thyroxine ( $T_4$ ) is the predominant circulating thyroid hormone, triiodothyronine ( $T_3$ ), primarily formed by peripheral conversion from  $T_4$  by a family of deiodinases, is the major physiologically active thyroid hormone. Serum  $T_3$  and  $T_4$  concentrations in turn regulate hypothalamic thyrotropin-releasing hormone (TRH) and pituitary thyroid stimulating hormone (TSH) secretion via negative feedback. Thyroid hormones are transported in the blood by carrier proteins, including thyroxine-binding globulin (TBG), prealbumin, and albumin. Protein-bound  $T_4$  and  $T_3$  are not biologically active. Only 0.03% of circulating  $T_4$  and 0.3% of  $T_3$  are unbound and active.<sup>121,122</sup>

### HYPOTHYROIDISM

#### Classification and Epidemiology

Hypothyroidism, the most common thyroid disorder in children, can range from subclinical to overt disease. In subclinical hypothyroidism, children maintain a normal  $T_4$  level by increasing TSH release. Over time, however, thyroid function can decompensate despite increased TSH stimulation and progress to overt thyroid hormone deficiency.<sup>123-125</sup> Iodine deficiency continues to be the foremost cause of hypothyroidism worldwide.<sup>126</sup> However, in the United States and other regions in which the intake of iodine is adequate, autoimmune thyroid disease is the most common cause of hypothyroidism.<sup>124</sup> Other less frequent causes of hypothyroidism include secondary and tertiary processes resulting from pituitary or hypothalamic insufficiency, respectively, which are relevant in many surgical situations, especially tumors of the central nervous system (CNS).

#### Biochemical Tests of Thyroid Function

In general, measurement of serum TSH and either total  $T_4$  or free  $T_4$  suffices for assessment of thyroid function. However, several conditions exist in which thyroid hormone levels appear abnormal yet the individual is clinically euthyroid. These conditions may lead to erroneous diagnosis and inappropriate treatment for hypothyroidism or hyperthyroidism. TSH is the most sensitive test for diagnosing primary thyroid disorders and generally

precedes noticeable changes in total  $T_4$  and  $T_3$  levels. Thyroid function can also be assessed by measurement of unbound or free  $T_4$ . When the total  $T_4$  level is reduced but free  $T_4$  and TSH values are normal, TBG deficiency is the most likely diagnosis. No treatment is required for TBG deficiency because these individuals have normal concentrations of free  $T_4$  and are euthyroid. Likewise, medical intervention is unnecessary for familial dysalbuminemic hyperthyroxinemia, which manifests with increased total  $T_4$  levels but normal free  $T_4$  and TSH values.<sup>127</sup>

Importantly, if the hypothalamic-pituitary axis is not intact, TSH becomes a useless measurement of thyroid function. Therefore, in cases of secondary or tertiary (central) thyroid disorders, diagnosis and treatment is based solely on serum  $T_4$  levels and clinical signs. During times of stress or acute illness, increased conversion of  $T_3$  to a metabolically inactive form (reverse  $T_3$ ) occurs. In addition,  $T_4$  and TSH values may both be reduced, reflecting a decreased metabolic state. Individuals are considered euthyroid based on non-elevated TSH values but the differential diagnosis includes central hypothyroidism, a distinction that often cannot be made by laboratory evaluation. Controversy still exists regarding possible benefits of using  $T_4$  or  $T_3$  to treat euthyroid sick syndrome, in which there are abnormal thyroid tests in the setting of a nonthyroid illness, such as a critical illness. Typically, children with euthyroid sick syndrome have a reduced  $T_4$  level with a normal or low-normal TSH level, indicating a decreased metabolic state.<sup>128-131</sup>

#### Clinical Manifestations

Because thyroid hormone affects all metabolically active cells, hormone deficiency leads to a wide array of systemic abnormalities. Classic signs and symptoms of hypothyroidism in children include short stature resulting from a decline in growth rate, fatigue, cold intolerance, weight gain, dry skin, hair loss, constipation, hoarse voice, and coarse facial features. Myxedema coma is a severe manifestation of hypothyroidism that can occur in profoundly hypothyroid individuals exposed to an external stress, such as infection, surgery, hypnotics, or cold temperature. Myxedema coma can result in severe life-threatening heart failure or coma<sup>132,133</sup> and should be considered in any postoperative child with unexplained cardiovascular dysfunction, difficulty weaning from ventilator support, or delirium.<sup>97</sup> Other medical conditions associated with hypothyroidism include anemia, hyperlipidemia, and pubertal disorders.

#### Neonatal Hypothyroidism

Congenital hypothyroidism remains the most frequent cause of preventable mental developmental delay. Thyroid dysgenesis or agenesis accounts for the majority of cases, whereas a smaller percentage results from thyroid dysmorphogenesis and secondary or tertiary hypothyroidism.<sup>134</sup> Because neonates do not exhibit the classic signs or symptoms of hypothyroidism, testing for congenital hypothyroidism occurs with the neonatal screen. Newborn screening programs that employ a strategy based on TSH thresholds detect only primary thyroid deficiency and not the central hypothyroidism that accompanies hypopituitarism or CNS anomalies, such as septo-optic dysplasia. Early detection and implementation of thyroid replacement are essential to avoid permanent neurologic sequelae. The classic syndrome includes macroglossia, umbilical hernia, constipation, hypothermia, a low hoarse cry, and neonatal jaundice (Fig. 25-10). In general, affected children who receive adequate thyroid replacement starting early in the neonatal period lead normal lives.

**FIGURE 25-10** An infant with congenital hypothyroidism. ("Congenital hypothyroidism," Wikipedia: The Free Encyclopedia. Wikimedia Foundation, Inc. 24 Feb 2012, as of 31 Mar. 2012. [http://en.wikipedia.org/wiki/Congenital\\_hypothyroidism](http://en.wikipedia.org/wiki/Congenital_hypothyroidism).)

### Treatment

The goal of thyroid replacement is to normalize  $T_4$  within 1-2 weeks and TSH within 4 weeks, and consequently reverse the metabolic derangements caused by hypothyroidism. In general, daily levothyroxine ( $LT_4$ ) replacement leads to normalization in  $T_4$  levels within a week but equilibration of TSH occurs more slowly, over 4 to 6 weeks.<sup>135</sup> The appropriate starting  $LT_4$  dose varies with age and disease state. For neonates, the starting dose is 10 to 15  $\mu\text{g}/\text{kg}/\text{day}$ , which is much greater than the conventional replacement dose of 2 to 4  $\mu\text{g}/\text{kg}/\text{day}$  in older children and adolescents.<sup>136</sup> In healthy children with acute hypothyroidism (e.g., post thyroidectomy), full  $LT_4$  replacement can be started immediately. However, symptomatic children with chronic hypothyroidism may develop pseudotumor cerebri or slipped capital femoral epiphysis if they are started on full  $LT_4$  doses. Therefore treatment should begin at one-fourth of the expected dose, with slow titration every 4 to 6 weeks.<sup>137,138</sup> After dose stabilization, children and adolescents should continue to have regular clinical examinations and TSH monitoring owing to increased dose requirements during puberty and pregnancy.<sup>139,140</sup> Thyroid replacement can be given parenterally if needed. The IV dose of  $LT_4$  is approximately half of the oral dose and should be given once daily.

### Preoperative Management

Because thyroid hormones play a critical role in regulating metabolism, children should be clinically and biochemically euthyroid before any type of elective surgery. Several case studies have shown decreased cardiac function, diminished breathing capacity, and increased sensitivity to anesthetic agents with moderate to severe hypothyroidism.<sup>141-143</sup> Children with known hypothyroidism should have documented normal thyroid function tests before surgery. For those with undiagnosed hypothyroidism,

a detailed history should be obtained regarding previous thyroid disorders, head and neck radiation, radioiodine therapy, thyroid surgery, and family history of thyroid disease.<sup>144</sup> In addition, children with autoimmune disorders, type 1 diabetes mellitus, celiac disease, and children with genetic syndromes such as trisomy 21 and Turner syndrome are at increased risk for developing autoimmune thyroiditis and should be screened if symptomatic.<sup>145-147</sup>

Children with subclinical or mild hypothyroidism often must undergo urgent surgery without delay. Thyroid replacement can be started and continued with the same regimen as described in the outpatient setting. For children with moderate to severe hypothyroidism, however, surgery should be postponed, if possible, until thyroid hormone levels normalize on replacement therapy. However, if urgent surgery is required, perioperative treatment with IV  $LT_4$  with or without glucocorticoids should be given to prevent myxedema coma.<sup>97,144</sup> An exception to this strategy applies to the child who is scheduled for cardiovascular surgery or cardiac catheterization in which thyroid replacement could precipitate or worsen unstable coronary syndromes. Several studies in adults reported no adverse outcomes in cardiac patients undergoing surgery without thyroid replacement.<sup>97,144,148</sup> Therefore thyroid replacement could be initiated postoperatively in children with cardiovascular disease undergoing cardiac surgery or cardiac evaluation.

## HYPERTHYROIDISM

### Classification and Epidemiology

Hyperthyroidism is a condition caused by excess circulating thyroid hormones resulting in an increase in metabolic activity of various peripheral tissues in the body. Almost all children with hyperthyroidism have suppressed serum TSH concentrations resulting from negative feedback by increased concentrations of  $T_4$  and  $T_3$ . Hyperthyroidism can be either overt or subclinical.<sup>149</sup> Overt hyperthyroidism is characterized by both clinical and biochemical manifestations of the disease. A child with subclinical hyperthyroidism typically is asymptomatic but with a suppressed TSH level.

Hyperthyroidism occurs less frequently than hypothyroidism in children and is nearly always caused by Graves disease. Other causes of childhood thyrotoxicosis include autoimmune thyroiditis (Hashimoto thyroiditis), infections of the thyroid gland, autonomously functioning thyroid nodules, iodine-induced hyperthyroidism, McCune-Albright syndrome, TSH-producing pituitary adenomas, and thyroid hormone ingestion.<sup>150</sup> A rare thyroid disorder that mimics hyperthyroidism is thyroid hormone resistance. However, unlike other causes of childhood thyrotoxicosis, thyroid hormone resistance should not be treated with antithyroid medications.<sup>151,152</sup>

### Graves Disease

Graves disease, an autoimmune disorder, is the most common cause of childhood hyperthyroidism. The pathophysiology of Graves disease involves thyroid-stimulating immunoglobulins that bind to the TSH receptor causing hyperstimulation of the thyroid gland. Most children with Graves disease have a diffuse goiter, and some develop autoimmune ophthalmopathy and myxedema. Because few children with Graves disease enter spontaneous remission, treatment of hyperthyroidism is required. Current treatment options include antithyroid medications (methimazole; propylthiouracil [PTU] is no longer recommended for treatment of Graves disease in children because of the risk of hepatotoxicity),

surgical removal of the thyroid gland, or radioiodine.<sup>153,154</sup> Although virtually all children enter remission during therapy with antithyroid drugs, side effects are relatively common (see later discussion) and the majority of children treated for 2 to 3 years relapse shortly after discontinuation of therapy.<sup>155,156</sup> Radioactive ablation is usually definitive and carries less risk than surgery.<sup>157</sup>

### Thyroiditis

The term *thyroiditis* is used to describe a heterogeneous group of disorders that result in inflammation of the thyroid gland with subsequent release of preformed thyroid hormone. Transient hyperthyroidism can result from the initial inflammatory process, but symptoms generally last up to about 8 weeks, until preformed stored thyroid hormone is depleted. Some children will develop hypothyroidism after the recovery phase because of lymphocytic infiltration of the gland and destruction of thyroid tissue. Treatment with antithyroid drugs (thioamides) that block formation of thyroid hormone is not indicated for transient hyperthyroidism, but for symptomatic children,  $\beta$ -blockers should be used during the thyrotoxic phase to control symptoms.<sup>158</sup>

Thyroiditis can also manifest as painful inflammation of the gland and fever owing to bacterial or viral infection. *Haemophilus influenzae*, group A streptococci, and *Staphylococcus* are the most frequent causes of acute thyroiditis, which can be associated with thyroid gland cutaneous fistulas.<sup>159</sup> Viral infections of the thyroid gland are less severe and result in subacute thyroiditis.<sup>160</sup> Owing to the difficulty in distinguishing bacterial from viral infections, all cases of infectious thyroiditis are treated with antibiotics.

### Clinical Manifestations

Most of the symptoms that children experience are the same regardless of the cause of hyperthyroidism. Classic signs and symptoms of hyperthyroidism include goiter, tachycardia and/or palpitations, tremor, brisk reflexes, heat intolerance, dyspnea, insomnia, diarrhea, nervousness, and weight loss despite a normal or increased appetite. Many children with hyperthyroidism have inability to concentrate, resulting in poor school performance, and may be initially mistaken to have attention deficit hyperactivity disorder. Other medical conditions associated with longstanding hyperthyroidism include osteoporosis and irregular menses.<sup>161</sup>

Individuals with Graves disease may develop additional autoimmune manifestations, such as ophthalmopathy and pretibial myxedema. Eye involvement in Graves disease is characterized by inflammation of the extraocular muscles, connective tissue, and orbital fat, which results in proptosis, restricted eye movement, and periorbital edema.<sup>162,163</sup> Children with Graves ophthalmopathy may complain of eye irritation or dryness because of lid retraction (Fig. 25-11). If left untreated, corneal ulceration may develop and lead to irreversible eye damage, including blindness. Unfortunately, ophthalmopathy usually persists in spite of treatment of the hyperthyroidism.<sup>153,164</sup>

### Treatment

Antithyroid medications remain the first line of treatment for many physicians, because one-third of children enter remission after several years of drug therapy.<sup>155,165</sup> Long-term remission rates are greater in pubertal than prepubertal children. Other favorable prognostic indicators include a small thyroid gland and normal levels of TSH receptor antibodies at the time of diagnosis.<sup>166,167</sup> Methimazole (a thioamide) is the mainstay of antithyroid therapy. Minor adverse effects occur in 25% of children treated with

**FIGURE 25-11** Proptosis of the eyes in a child with Graves disease. (With permission of author and publisher, HealthInfoTimes, Symptoms of Graves disease, 14 Feb 2012, <http://healthinfotimes.com/symptoms-of-graves-disease-in-children-14945.html>.)

thioamides and include increases in liver enzymes, neutropenia, rash, and lymphadenopathy. Serious adverse effects, such as agranulocytosis and liver failure, are rare, occurring in up to 1% of individuals.<sup>168</sup>

### Perioperative Management

For children who relapse after antithyroid drug therapy or who require immediate definitive therapy, radioiodine is a safe and effective alternative to thyroidectomy. Treatment consists of iodine-131 uptake in the thyroid gland, which leads to cell destruction by internal radiation. Several longitudinal studies have shown that children are not at increased risk for developing thyroid cancer if appropriate ablative doses of radioiodine are used.<sup>169,170</sup> In cases in which radioiodine is contraindicated, surgical removal of the entire thyroid gland can also cure the hyperthyroid state. Children should be euthyroid or slightly hypothyroid before surgery to avoid precipitation of thyroid storm. In addition, because of potential serious complications from neck surgery, only surgeons with expertise in performing thyroidectomies in children should perform the surgery.<sup>171</sup>

In special circumstances, perioperative rapid control of hyperthyroidism can be achieved by using large doses of oral iodine (Lugol solution or saturated potassium iodine), which inhibit thyroid hormone synthesis. The effect is short-lived (several days) because of eventual escape from the Wolff-Chaikoff effect (iodine inhibition of thyroid hormone release); therefore, the addition of a thioamide is necessary for long-term treatment. Rarely, untreated or undertreated hyperthyroidism can lead to thyroid storm (approximately 1 in 1,000,000 young children), a potentially lethal complication.<sup>172</sup> Thyroid storm may be difficult to differentiate from an acute malignant hyperthermia (MH) reaction.<sup>173,174</sup> However, in contrast to MH, thyroid storm has a varied onset (usually an insidious onset 6 to 18 hours postoperatively, although it may develop precipitously during surgery), it induces a less severe acidosis than MH, and the serum creatine phosphokinase remains unchanged. Because the serum creatine phosphokinase peaks at 12 to 18 hours after an MH reaction, it is a late sign to differentiate from MH. Interestingly, IV dantrolene will ameliorate some of the clinical manifestations of thyroid storm, including rigidity and hyperthermia.<sup>174,175</sup> Thyroid storm usually responds to symptomatic treatment, including parenteral  $\beta$ -blockers, large doses of glucocorticoids (block conversion of

**TABLE 25-5** Management of Hyperthyroid Crisis

Drug Class	Recommended Drug	Starting Dose	Mechanism of Action
Iodine	Potassium iodide (SSKI)	3-5 drops by mouth q6h	Blocks release of thyroid hormone from gland
	Lugol solution	4-8 drops by mouth q6-8h	Blocks release of thyroid hormone from gland
$\beta$ Blockers	Propranolol	Infant: 2 mg/kg/day by mouth divided q8-12h Child: 10-40 mg by mouth q6-8h	$\beta$ -adrenergic blockade; decreased $T_4$ to $T_3$ conversion
	Esmolol	100-200 $\mu$ g/kg/min IV infusion	$\beta$ -adrenergic blockade
Thioamide	Propylthiouracil	5-10 mg/kg/day by mouth divided q8h	Inhibits new hormone synthesis; decreases $T_4$ to $T_3$ conversion
	Methimazole	0.4 mg/kg/day by mouth divided q8-12h	Inhibits new hormone synthesis
Supportive treatment	Intravenous fluid	20-40 mL/kg normal saline	Replacement of increased insensible losses resulting from fever, diaphoresis, vomiting, and diarrhea
	Cooling blankets, ice packs		Reduce fever
	Acetaminophen	15 mg/kg/dose by mouth q4-6h or 40 mg/kg per rectum loading dose then 20 mg/kg/dose q6h Intravenous acetaminophen may be utilized in children with IV access.	
	Hydrocortisone	Adult: 100 mg IV q8h (no pediatric dose recommended)	Decreases $T_4$ to $T_3$ conversion; enhances vasomotor stability

SSKI, Saturated solution of potassium iodide.

$T_4$  to  $T_3$  and prevent relative adrenal insufficiency), and propylthiouracil, the last intervention administered with a nasogastric tube.<sup>173</sup> If left untreated, the mortality rate resulting from thyroid storm is 20% to 30%.<sup>172</sup> Several factors may precipitate thyroid storm, including surgery, infection, and stress. Because of the dramatically increased metabolic state, acute management of hyperthyroidism and targeted symptomatic treatment is essential to avoid death.<sup>132,150,173</sup> If the presentation proves difficult to distinguish from MH (both diseases may present with tachycardia, rigidity, and fever), it would be prudent to administer dantrolene 2.5 mg/kg IV in case the presumptive diagnosis of thyroid storm is incorrect.<sup>175</sup> However, if the hypermetabolic signs abate after dantrolene, one cannot conclude that the reaction was MH, as dantrolene does attenuate the hypermetabolic signs of thyroid storm.<sup>174</sup> The specific treatment for thyroid storm, however, remains a multidrug approach to (1) halt production and release of thyroid hormone, (2) prevent conversion of  $T_4$  to  $T_3$ , (3) antagonize the peripheral (adrenergic) effects of thyroid hormone, and (4) control systemic disturbances with supportive therapy (Table 25-5).<sup>133,153,168,176-179</sup>

## Parathyroid and Calcium Disorders

### PHYSIOLOGY OF CALCIUM HOMEOSTASIS

The four parathyroid glands are usually present in pairs on the posterior aspect of the superior and inferior poles of the thyroid gland, with the inferior pair occasionally ectopic elsewhere in the neck or chest. Parathyroid hormone (PTH) is released from secretory granules in response to a decrease in serum ionized calcium; its secretion is inhibited by hyperphosphatemia, profound hypomagnesemia or hypermagnesemia, or increased 1,25-dihydroxyvitamin D (calcitriol). The calcium-sensing receptor in the parathyroid mediates PTH release and also directly regulates calcium reabsorption in the distal tubule. Inactivating mutations in the calcium-sensing receptor gene result in a greater

serum calcium set point in familial hypocalciuric hypercalcemia, now a relatively common and incidental diagnosis that is benign unless homozygotic, whereas activating mutations result in autosomal dominant hypocalcemia with hypercalciuria.<sup>180,181</sup> PTH has three primary modes of increasing serum calcium: (1) calcium reabsorption in the proximal convoluted tubule, and concomitant phosphaturia in the proximal tubule; (2) upregulation of osteoclast-mediated calcium and phosphate release from bone; and (3) renal conversion of 25-hydroxyvitamin D to the active metabolite, calcitriol. In turn, calcitriol increases absorption of calcium and phosphate from the gut and has direct calcium-releasing effects on bone. Calcitonin is secreted by the thyroid C cells and has calcium-reducing properties via its own G protein-coupled receptor. It has no known physiologic role at this time.

### HYPOCALCEMIA

#### Neonatal Hypocalcemia

Neonatal hypocalcemia owing to prematurity and maternal diabetes is common but is typically transient. Rare causes include maternal hyperparathyroidism, excessive diuretic use or phosphate load, and transient neonatal hypoparathyroidism.<sup>182</sup> Neonatal hypocalcemia requires exclusion of 22q11.2 deletion syndrome (which includes DiGeorge syndrome, velocardiofacial syndrome [VCF], and other clinical manifestations) by genetic testing.<sup>183-185</sup> The hypocalcemia of VCF results from an incomplete hypoparathyroidism that tends to normalize eventually but may recur. Reduced PTH or PTH resistance (pseudohypoparathyroidism) cause hyperphosphatemia beyond the already increased normal range in neonates, whereas vitamin D deficiency or resistance is associated with low to normal serum phosphate levels. Maternal 25-hydroxyvitamin D deficiency is another common cause of early or late infantile hypocalcemia in the United States, regardless of the infant's dietary intake.<sup>186,187</sup> Childhood hypocalcemia with reduced PTH may be the first

endocrine sign of polyglandular autoimmune disease type I, now called autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED).<sup>188</sup>

### Childhood Hypocalcemia

Persistent hypocalcemia in infants and children can have many manifestations, including poor feeding, tetany, seizures, laryngospasm, paresthesias, and muscle cramping. Initial evaluation of hypocalcemia, regardless of age, includes measurement of serum calcium, phosphate, magnesium, alkaline phosphatase, creatinine, PTH, 25-hydroxyvitamin D, and 1,25-dihydroxyvitamin D, plus urine calcium, phosphate, and creatinine. Therapy for acute hypocalcemia includes parenteral calcium, followed by oral calcium supplementation and 25-hydroxyvitamin D if reduced,<sup>187</sup> and calcitriol as a substitute for PTH, because PTH itself, an anabolic bone agent in adults,<sup>189</sup> is contraindicated in children owing to concerns about its possible role in osteosarcoma.

### Perioperative Management

Hypocalcemia is most frequently managed by IV infusion of calcium in the form of calcium chloride or calcium gluconate, with frequent measurement of serum ionized calcium levels to guide therapy (see Chapter 10). Calcium salts release free calcium ions and should be given via a central venous catheter because their hypertonicity and the increase concentration of ionized calcium causes intense local vasoconstriction that may lead to necrosis of the skin and subcutaneous tissues and possible gangrene of the affected limb if administered via a peripheral IV cannula that becomes interstitial. In the postoperative period after the child is tolerating oral intake, IV calcium supplementation may be converted to oral supplementation.

### HYPERCALCEMIA

Hyperparathyroidism (HPT) is much less common in children than in adults.<sup>190</sup> In most cases of HPT in children, an adenoma is present that is unresponsive to the increased serum calcium level. Other uncommon causes of HPT in children include generalized parathyroid hyperplasia and, rarely, parathyroid carcinoma.<sup>191</sup>

Parathyroid hyperplasia occurs in familial forms of HPT, including multiple endocrine neoplasia type 1 (MEN 1), in which HPT is a nearly universal manifestation of the mutation of the *menin* gene; the hyperparathyroid abnormality occurs more commonly and earlier in presentation than the associated pancreatic, pituitary, and gastrointestinal neuroendocrine tumors associated with MEN 1.<sup>192,193</sup> HPT is a less common manifestation of MEN 2A, in which medullary thyroid carcinoma and pheochromocytoma occur as a result of the proto-oncogene mutation.<sup>194</sup> Secondary HPT with relatively normal calcium levels is a common pediatric phenomenon that accompanies renal failure, renal tubular acidosis, and hypophosphatemic rickets.<sup>195</sup> When hypercalcemia is present, the differential diagnosis includes Williams syndrome, vitamin A intoxication, vitamin D excess and conversion to 1,25-dihydroxyvitamin D in granulomatous disorders, and infantile subcutaneous fat necrosis.<sup>196</sup> Solid tumors may secrete increased concentrations of parathyroid hormone-related protein (PTHrP). Tumors, such as leukemias, lymphomas, and others, may release excess cytokines and osteoclast-activating factors, with the hypercalcemia leading to the tumor diagnosis.<sup>197,198</sup>

Signs and symptoms of hypercalcemia are usually nonspecific, such as nausea and vomiting, polyuria, and fatigue. Initial labora-

tory evaluation of hypercalcemia matches the list for hypocalcemia given earlier.<sup>199</sup>

Evaluation of unexplained hypercalcemia includes measurement of PTHrP for malignancy, and of parental calcium levels for familial hypocalciuric hypercalcemia, additional hormones or genetic testing for MEN syndromes, tumor markers, bone marrow biopsy, and relevant imaging. When HPT is found, ultrasonography is helpful to assess the parathyroid glands, but MRI or technetium-sestamibi scan is more precise, and intraoperative measurement of PTH levels can be provided for tumor localization.

### Perioperative Management

Management of acute hypercalcemia begins with isotonic rehydration and administration of furosemide to induce calciuria. Treatment then proceeds to administration of calcitonin, to which tachyphylaxis may occur within 1 or 2 days, or to glucocorticoids. In the absence of a definitive therapy, such as surgical excision of the pathologic source of PTH, chronic hypercalcemia is responsive to bisphosphonates, such as pamidronate, which can be given by infusion every 3 months.<sup>200,201</sup> Acute management after parathyroidectomy requires careful monitoring and replacement of calcium and possibly the use of calcitriol for persistent hypocalcemia. In isolated parathyroid hyperplasia, MEN, or secondary HPT, surgeons may elect to leave a portion of one gland in the forearm to avoid permanent hypoparathyroidism, which is challenging to manage.

## Adrenal Endocrinopathies

### PHYSIOLOGY

Adrenal steroidogenesis begins with cholesterol as precursor and results in three types of steroids: mineralocorticoids, glucocorticoids, and sex steroids (androgen precursors).<sup>202</sup> Most of the enzymes involved in adrenal (or gonadal) steroidogenesis are cytochrome P450s. The adrenal cortex comprises three zones: the outer zona glomerulosa exclusively synthesizes mineralocorticoids owing to localized expression of CYP11B2, whereas the zona fasciculata and reticularis synthesize glucocorticoid and androgens owing to localized expression of CYP17.<sup>203</sup> Cortisol, the end-product of the glucocorticoid pathway, is the primary regulator of the hypothalamic-pituitary-adrenal (HPA) axis, in which hypothalamic corticotropin-releasing hormone regulates pituitary adrenocorticotrophic hormone (ACTH) secretion and downstream adrenal production of all three categories of steroid. ACTH release follows a diurnal pattern with a peak at 0400 to 0800 hours and, most importantly, markedly increases in response to trauma, acute illness, high fever, and hypoglycemia.

Mineralocorticoid production is primarily controlled by the renin-angiotensin system, in which angiotensinogen secreted by the liver is cleaved by renin to angiotensin I, which is then converted to angiotensin II.<sup>204</sup> The mineralocorticoid pathway is also responsive to ACTH, as demonstrated by a rise in all mineralocorticoid precursors and the end-product aldosterone within minutes of exogenous ACTH stimulation. However, hypopituitarism does not lead to mineralocorticoid deficiency because an intact renin-angiotensin system independently stimulates aldosterone synthesis. Nevertheless, patients with ACTH deficiency may present with hyponatremia (glucocorticoids are required for free water excretion) and hypotension. The latter consequence of failure of the adrenal to release an adequate amount of glucocorticoid may be attributable to the role of

cortisol in enhancing vascular responsiveness to catecholamines and inotropic activity.<sup>205</sup> This essential aspect of glucocorticoid activity is the most lethal potential consequence of both primary adrenal insufficiency and hypothalamic-pituitary deficiency and requires the utmost caution on the part of pediatrician, endocrinologist, surgeon, or anesthesiologist. When any question regarding adequacy of the HPA arises, it is prudent to provide exogenous glucocorticoid, particularly perioperatively.<sup>206</sup>

### CAUSES OF ADRENAL INSUFFICIENCY

Primary adrenal insufficiency is suspected from features such as weight loss, nausea and vomiting, poor appetite, and, specifically, the characteristic skin hyperpigmentation that is secondary to melanocyte-stimulating hormone receptor cross-stimulation by ACTH (which is present in extraordinarily large concentrations).<sup>207</sup> Primary adrenal insufficiency is uncommon in countries with advanced health care systems now that infectious diseases, such as tuberculosis, are less prevalent, but adrenal hemorrhage still causes adrenal failure.<sup>208</sup> Autoimmune adrenal insufficiency, sometimes as part of a polyendocrinopathy syndrome, is now the most common cause and includes both glucocorticoid and mineralocorticoid deficiency. Glucocorticoid deficiency with or without mineralocorticoid loss is characteristic of congenital adrenal hyperplasia.<sup>209</sup> Rare disorders causing adrenal insufficiency include adrenoleukodystrophy,<sup>210</sup> congenital adrenal hypoplasia, X-linked adrenal hypoplasia congenita, and ACTH receptor defects.<sup>211</sup>

Congenital or acquired lesions of the hypothalamus or pituitary may lead to ACTH deficiency. In general, these lesions cause other pituitary deficiencies, particularly growth hormone or TSH deficiency; isolated ACTH deficiency is rare. Both growth hormone and ACTH deficiency may cause hypoglycemia in infancy. CNS malformations leading to ACTH deficiency are usually detectable by MRI. A notable CNS anomaly with hypopituitarism is septo-optic dysplasia,<sup>29,212-214</sup> which may be associated with an assortment of midline defects, such as an absent or underdeveloped septum pellucidum and optic nerve hypoplasia, but isolated pituitary agenesis or hypoplasia is more common. Acquired lesions leading to hypopituitarism include hydrocephalus, meningitis, infiltrative disorders,<sup>215</sup> and tumors such as craniopharyngioma or histiocytosis X.<sup>216</sup> Tumor resection, especially craniopharyngioma, cranial irradiation, and chemotherapy, can lead to multiple pituitary deficiencies, often evolving over many years.<sup>217</sup>

### TESTING FOR ADRENAL INSUFFICIENCY

Cortisol levels follow a diurnal pattern, with peak levels resulting from an ACTH surge in the early morning and trough levels later in the day. Although a morning serum cortisol level of less than 5 µg/dL is less than normal and suggestive of adrenal insufficiency, it may be difficult to interpret the significance of a random cortisol concentration. A reduced concentration at any other time of day is uninformative and should not be used to test for adrenal function. In contrast, laboratory confirmation of primary mineralocorticoid deficiency by obtaining a random serum sample will show a low aldosterone concentration despite markedly increased plasma renin activity.

Primary adrenal insufficiency may be effectively assessed in two ways,<sup>218</sup> either by simultaneous measurement of serum cortisol and plasma ACTH concentrations or by stimulating the adrenal with exogenous ACTH (cosyntropin [Cortrosyn], the biologically active fragment of ACTH containing the first

24 amino acids). A markedly increased random plasma ACTH concentration is definitive evidence of primary adrenal insufficiency, but levels can be moderately increased by the stress of phlebotomy itself. Therefore blood for plasma ACTH levels should be obtained from an indwelling catheter to avoid false-positive values.

Hypothalamic-pituitary insufficiency is more difficult to assess. The complete absence of ACTH levels, as in the obvious case of pituitary ablation or destruction, leads eventually to adrenal atrophy and complete unresponsiveness to cosyntropin stimulation, a finding that necessitates maintenance glucocorticoid replacement. However, an “adequate” response to cosyntropin implies only tonic ACTH secretion and does not guarantee the ability to generate a normal surge of ACTH during stress. As a consequence, any patient with a CNS lesion that might cause HPA deficiency should receive stress doses of glucocorticoid (see later discussion). In practical terms, a post-cosyntropin-treatment cortisol value of 10 to 20 µg/dL in an at-risk child suggests the need for stress coverage, whereas a value less than 10 µg/dL indicates long-term replacement.<sup>218,219</sup>

### PERIOPERATIVE MANAGEMENT OF ADRENAL INSUFFICIENCY

#### Glucocorticoid Dosing

Endogenous cortisol secretion is 6 to 8 mg/m<sup>2</sup>/day. Because a fraction of oral cortisol is degraded by the liver, the typical oral replacement dose is 10 to 12 mg/m<sup>2</sup>/day. A replacement dose of hydrocortisone depends on age and body size but might be 5.0 to 7.5 mg two to three times a day orally for an adolescent with chronic adrenal insufficiency. No dose monitoring is required, but the child's growth rate should be tracked according to age. With concomitant or isolated mineralocorticoid deficiency, replacement uses fludrocortisone (Florinef) at an approximate dose of 0.1 mg orally per day, independent of body size, with intermittent monitoring of blood pressure and plasma renin activity. When the primary goal of glucocorticoid therapy is not replacement but suppression of ACTH secretion, as in congenital adrenal hyperplasia, the daily hydrocortisone dose is generally 15 to 20 mg/m<sup>2</sup>, guided by monitoring of serum levels of 17-hydroxyprogesterone, androstenedione, dehydroepiandrosterone sulfate, and testosterone. Alternatives to hydrocortisone include prednisone, which is four to five times more potent than hydrocortisone. Dexamethasone is 30 to 40 times more potent than hydrocortisone, but has no mineralocorticoid activity and carries much more significant risk of adverse effects, such as osteopenia and aseptic necrosis of the femoral head, and so should not be used for chronic routine replacement therapy. Single-dose use of dexamethasone has not been associated with aseptic necrosis of the femoral head.

Conventional stress glucocorticoid coverage is 3 to 10 times the patient's usual replacement dose, depending on the severity of illness or trauma, although this practice is not evidence based.<sup>220</sup> Therefore, with little risk associated with the transient use of excess glucocorticoid, for children who are on oral replacement therapy we recommend exogenous glucocorticoid replacement using three to five times the patient's usual oral maintenance dose for intercurrent illness or fever (greater than 101° F) and five to ten times the oral maintenance dose for major surgery, during critical illness, or in major emergencies. For children who require stress glucocorticoid coverage but who do not take outpatient steroids, or who are unable to take medications by mouth, we recommend using parenteral cortisol (Solu-Cortef) at a dose

of 0.5 mg/kg/day every 12 hours for illness associated with nausea, vomiting, diarrhea, or fever (greater than 101° F) and 0.5 to 1 mg/kg every 6 hours for perioperative, intensive care, or emergency department indications for up to 72 hours.<sup>221</sup>

### Iatrogenic Adrenal Suppression and Tapering

Increased doses of exogenous glucocorticoids are used chronically for control of autoimmune disorders, suppression of transplant rejection, and control of inflammatory processes. Iatrogenic adrenal suppression depends on the duration and dose of glucocorticoid used. Periods of high-dose steroids up to 7 to 10 days do not suppress the HPA axis. Adrenal suppressive treatments lasting 3 to 6 weeks require a taper over 1 to 2 weeks to allow recovery of the HPA axis. Long-term high-dose treatment may require up to 6 to 9 months for complete return of HPA function and necessitates a taper during that period. At the termination of the taper, a repeat cosyntropin stimulation test should be performed to confirm recovery of function, and any repeat trauma or illness during the period of taper requires short-term stress coverage.

The glucocorticoid taper has two meanings. The tempo of therapeutic tapers of prednisone by gastroenterologists, rheumatologists, nephrologists, and oncologists, and of dexamethasone by surgeons, is entirely dependent on their assessment of the immune or inflammatory process. As long as the glucocorticoid dose is in excess of the replacement dose, and regardless of the dose, the HPA axis continues to be suppressed. It is only when the steroid dose is tapered down to the daily replacement dose (approximately 10 mg/m<sup>2</sup> hydrocortisone, 2 mg/m<sup>2</sup> prednisone, or less than 0.5 mg/m<sup>2</sup> dexamethasone) that the endocrine taper begins. At that point, the prednisone should be switched to hydrocortisone for ease of starting a gradual taper from replacement therapy to reduced doses while function of the HPA axis is reestablished. In the perioperative period, steroid coverage should be administered if there is any concern about the integrity of the HPA axis during a steroid taper (Table 25-6).

### HYPERCORTISOLISM (CUSHING SYNDROME)

Excess cortisol, whether exogenous or endogenous, results in muscle wasting, truncal obesity, moon facies, hypertension, hyperglycemia, osteopenia, and growth deceleration.<sup>222,223</sup> Iatrogenic hypercortisolism is common in pediatrics,<sup>224</sup> whereas Cushing disease or syndrome is rare.<sup>225</sup> Cushing disease refers to an ACTH-secreting pituitary adenoma. Cushing syndrome refers to other conditions of excess glucocorticoid, including ectopic ACTH-secreting tumors<sup>226</sup> and adrenal tumors that secrete cortisol.<sup>227</sup> An adrenal tumor (adenoma or carcinoma) is the most likely cause of hypercortisolism in a young child. These tumors can secrete any combination of steroids and commonly cosecrete

androgens, resulting in virilization.<sup>228</sup> A unilateral glucocorticoid-secreting tumor typically causes HPA axis suppression, requiring careful tapering of hydrocortisone replacement after resection to reestablish normal cortisol production in the contralateral adrenal gland.<sup>229</sup>

In a child with signs of hypercortisolism (and not simply obesity), screening tests include an overnight small dose dexamethasone suppression test, measurement of 24-hour urinary free cortisol and creatinine, and measurement of nocturnal salivary cortisol concentrations.<sup>230</sup> If screening tests suggest a diagnosis of hypercortisolism, additional adrenal steroids should be measured and an adrenal computed tomographic scan or magnetic resonance image obtained. In an adolescent with pure glucocorticoid effects and suspicious results of a corticotropin-releasing hormone stimulation test or longer dexamethasone suppression test<sup>231</sup> suggestive of a pituitary ACTH-secreting adenoma (Cushing disease), pituitary magnetic resonance imaging is warranted.<sup>232</sup> Because pituitary adenomas can be very small, bilateral inferior petrosal sinus sampling may be necessary to locate the adenoma.<sup>233</sup>

### PERIOPERATIVE MANAGEMENT OF HYPERCORTISOLISM

Therapy for Cushing disease and Cushing syndrome is surgical.<sup>234,235</sup> There are no specific anesthetic considerations except the supportive management of secondary manifestations, such as obesity and its attendant airway concerns, hypertension, and skin and bone fragility.

Medications

## Intraoperative Management

Special Considerations

Fluids and Blood Products

Anesthetic Agents

## Postoperative Concerns

THE ANESTHESIA PRACTITIONER IS OFTEN FACED with a patient who has acute kidney injury (AKI) or renal failure. Renal disease requires the practitioner to be vigilant about fluid homeostasis, acid-base balance, electrolyte management, choice of anesthetics, and potential complications. Maintaining a fine balance, particularly in the neonate and younger child, requires knowledge of the excretory and volume maintenance functions of the kidney. If not managed correctly, perioperative renal dysfunction can lead to multiorgan system compromise and significant morbidity or mortality. The anesthesia provider must understand renal physiology, appropriate preoperative preparation, intraoperative management, and postoperative care of the renal patient.

## Renal Physiology

The basic function of the kidney is to maintain fluid and electrolyte homeostasis. The first step in this tightly controlled process is the production of the glomerular filtrate from the renal plasma. The glomerular filtration rate (GFR) depends on renal plasma flow, which depends on blood pressure and circulating volume. The kidneys are the best perfused organs per gram of weight in the body. They receive 20% to 30% of the cardiac output maintained over a wide range of blood pressures through changes in renal vascular resistance. Numerous hormones play a role in this autoregulation, including vasodilators (i.e., prostaglandins E and I<sub>2</sub>, dopamine, and nitric oxide) and vasoconstrictors (i.e., angiotensin II, thromboxane, adrenergic stimulation, and endothelin). Congestive heart failure and volume contraction severely limit the ability of the kidney to maintain autoregulation during changes in blood pressure.

When renal blood flow is adjusted for body surface area, it doubles during the first 2 weeks of postnatal life and continues to increase until it reaches adult values by the age of 2 years (see Figs. 6-10 and 6-11).<sup>1,2</sup> Increased blood flow results from an increase in cardiac output and a decrease in renal vascular resistance. Paralleling these changes, the GFR, when adjusted for body surface area, also doubles over the first 2 weeks of postnatal life and continues to increase until it reaches adult values by the age of 1 to 2 years. The initial GFR and the rate of increase correlate with gestational age at birth. For example, the GFR of an infant of 28 weeks gestation is half of that of a full-term infant (see Figs. 6-10 and 6-11).<sup>3</sup> An estimate of GFR can be made from the serum creatinine concentration and the height of the child according to the following formula<sup>4,5</sup>:

$$\text{GFR (mL/min/1.73 m}^2\text{)} = \text{height (cm)} \times k / \text{serum creatinine}$$

In the equation, k is 0.45 for infants, 0.55 for children, and 0.7 for adolescent boys. The serum creatinine concentration, especially in the first days of life, reflects the maternal serum creatinine concentration and therefore cannot be used to predict neonatal renal function until at least 2 days after birth.<sup>6</sup>

## FLUIDS AND ELECTROLYTES

The kidney regulates total body sodium balance and maintains normal extracellular and circulating volumes.<sup>7</sup> The adult kidney filters 25,000 mEq of sodium per day, but it excretes less than 1% through extremely efficient resorption mechanisms along the nephron. The proximal tubule resorbs 50% to 70%, the ascending limb of the loop of Henle resorbs about 25%, and the distal

nephron accounts for 10% of the filtered load of sodium. Several hormones, including renin, angiotensin II, aldosterone, and atrial natriuretic peptide, and changes in circulating volume play roles in maintaining sodium balance.<sup>8</sup>

Serum osmolality is tightly regulated through changes in arginine vasopressin (AVP) release and the appreciation of thirst.<sup>9-11</sup> AVP, also called *antidiuretic hormone*, is synthesized in the hypothalamus and stored in the posterior pituitary, where it is released in response to an increasing plasma osmolality. AVP is also released in response to a decreased circulating volume or hypotension, including those responses to nausea, vomiting, and possibly opioids. AVP binds to receptors in the collecting duct, increasing the permeability of the tubules to water and leading to increased water resorption and concentrated urine. Neonates are much less able to conserve or excrete water compared with older children, rendering the fluid management and volume issues important tasks of the pediatric anesthesiologist in this young age-group.<sup>12</sup>

The regulation of serum potassium is managed by the kidney and depends on the concentration of plasma aldosterone. Aldosterone binds to receptors on cells in the distal nephron, increasing the secretion of potassium in the urine. Neonates are much less efficient at excreting potassium loads compared with adults, and the normal range of serum potassium concentrations is therefore greater in neonates; Table 26-1 provides the normal values.<sup>13</sup> Potassium regulation is affected by the acid-base status; excretion of potassium increases in the presence of alkalosis and decreases in the presence of acidosis. Causes of hyperkalemia and hypokalemia are presented in Tables 26-2 and 26-3, respectively.

## ACID-BASE BALANCE

The kidney is involved in the day-to-day regulation of acid-base balance and the response to the stress of illness. The kidney reclaims virtually all of the filtered bicarbonate in the proximal tubule. The kidney also regenerates the bicarbonate ( $\text{HCO}_3^-$ ) lost in the neutralization of acid generated by the normal combustion of food, especially protein, and the formation of bone. New bicarbonate is generated by the cells of the distal nephron by decomposing the carbonic acid ( $\text{H}_2\text{CO}_3$ ) formed from water ( $\text{H}_2\text{O}$ ) and carbon dioxide ( $\text{CO}_2$ ) by carbonic anhydrase. The protons ( $\text{H}^+$ ) that are generated from this process are pumped into the lumen of the collecting duct, where they combine with hydrogen phosphate ( $\text{HPO}_4^{2-}$ ) or ammonia ( $\text{NH}_3$ ) generated by the catabolism of amino acids, mainly glutamine, in the tubule cells.

Infants, especially neonates, maintain a slightly acidotic pH (7.37) and decreased plasma bicarbonate concentration (22 mEq/L) compared with older children and adults (pH = 7.39; plasma bicarbonate = 24 to 28 mEq/L).<sup>14</sup> Neonates can maintain acid-base homeostasis but are limited in their ability to respond to an acid load.<sup>15</sup> This is especially true for preterm infants. This reduced plasma  $\text{HCO}_3^-$  concentration in infants is the result of a reduced threshold, or the plasma concentration at which  $\text{HCO}_3^-$  is no longer completely resorbed by the kidney.

**TABLE 26-1** Normal Values of Serum Potassium

Age	Serum Potassium Range (mEq/L)
0-1 month	4.0-6.0
1 month-2 years	4.0-5.5
2-17 years	3.8-5.0
>18 years	3.2-4.8

 Bartter syndrome  
 Corticosteroids

### Decreased Intake

Malnutrition  
 Anorexia nervosa

## Disease States

The causes of and differences in renal diseases between children and adults are substantive. Adult renal disease usually results from longstanding diabetes mellitus or hypertension with an associated compromise in cardiovascular function. Children may also have renal failure due to diseases such as sickle cell anemia or systemic lupus erythematosus, but cardiovascular function is far less commonly compromised. Depending on the cause of the renal disease, management may be different.

## ACUTE RENAL FAILURE AND ACUTE KIDNEY INJURY

Acute renal failure (ARF) or acute renal insufficiency can be defined as an abrupt deterioration in the kidney's ability to clear nitrogenous wastes, such as urea and creatinine. Concomitantly, there is a loss of ability to excrete other solutes and maintain a normal water balance. This leads to the clinical presentation of acute renal insufficiency: edema, hypertension, hyperkalemia, and uremia.

*Acute kidney injury* (AKI) has almost replaced the traditional term *acute renal failure*, which was used in reference to the subset of patients with an acute need for dialysis. With the recognition that even modest increases in serum creatinine are associated with a dramatic impact on the risk for mortality, the clinical spectrum of acute decline in GFR is broader. The minor deteriorations in GFR and kidney injury are captured in a working clinical definition of kidney damage that allows early detection and intervention and uses AKI as a replacement for the term ARF. The term ARF is preferably restricted to patients who have AKI and need renal replacement therapy.<sup>16</sup> The prognosis of AKI is assessed in part by the use of the RIFLE criteria, which include three severity categories (i.e., Risk, Injury, and Failure) and two clinical outcome categories (Loss and End-stage renal disease) (Table 26-4).

The term ARF has often been incorrectly used interchangeably with *acute tubular necrosis*, which usually refers to a rapid deterioration in renal function occurring minutes to days after an ischemic or nephrotoxic event. Although acute tubular necrosis is an important cause of ARF, it is not the sole cause, and the terms are not synonymous. For the purposes of this chapter, AKI refers to the disease formerly called ARF.

### Etiology and Pathophysiology

AKI is often multifactorial in origin or the result of several distinct insults. To treat AKI, it is important to understand its causes and pathophysiology. The causes of AKI are varied but in general can be classified as follows (Table 26-5):

**TABLE 26-4 RIFLE Classification of Renal Failure and Kidney Injury**

RIFLE Factors	GFR Criteria	Urine Output Criteria	
Risk	Increased Cr $\times 1.5$ or decreased GFR $>25\%$	UOP $<0.5$ mL/kg/hr $\times 6$ hours	High sensitivity
Injury	Increased Cr $\times 2$ or GFR decrease $>50\%$	UOP $<0.5$ mL/kg/hr $\times 12$ hours	
Failure	Increased Cr $\times 3$ or GFR decrease of $75\%$ or Cr $\geq 4$ mg/dL Acute rise $\geq 0.5$ mg/dL	UOP $<0.3$ mL/kg/hr $\times 24$ hours or anuria $\times 12$ hours	
Loss	Persistent ARF: complete loss of kidney function $>4$ weeks		High specificity
ESKD	End-stage kidney disease ( $>3$ months)		

Modified from Bellomo R, Ronco C, Kellum JA, Mehta RL, Palevsky P; Acute Dialysis Quality Initiative Workgroup. Acute renal failure—definition, outcome measures, animal models, fluid therapy and information technology needs: the Second International Consensus Conference of the Acute Dialysis Quality Initiative (ADQI) Group. *Crit Care* 2004;8:R204-12.

ARF, Acute renal failure; Cr, creatinine; ESKD, end-stage kidney disease; GFR, glomerular filtration rate; RIFLE, Risk of renal dysfunction, Injury to the kidney, Failure of kidney function, Loss of kidney function, and End-stage kidney disease; UOP, urine output.

- *Prerenal* implies poor renal perfusion.
- *Renal* implies intrinsic renal disease or damage.
- *Postrenal* implies an obstruction to urine excretion.

Prerenal insults are a common cause of AKI, accounting for up to 70% of all cases. Prerenal failure usually results from extracellular fluid loss, such as from gastroenteritis, burns, hemorrhage, or excessive diuresis. It also occurs in the setting of cardiac failure or sepsis. The common feature of this condition is diminished renal perfusion. In response to the reduction in flow, there is a compensatory increase in afferent tone, which decreases the GFR and increases the retention of salt and water. The net effect of these events is a drastic reduction in urine volume, often resulting in oliguria. If the underlying problem is recognized and treated aggressively, progressive renal insufficiency may be averted. Nonsteroidal antiinflammatory drugs, angiotensin-converting enzyme (ACE) inhibitors, and angiotensin receptor blockers can aggravate prerenal azotemia by further reducing glomerular capillary pressure and the GFR.<sup>17</sup>

AKI resulting from parenchymal disease or injury accounts for 20% to 30% of cases of abrupt renal insufficiency. Common causes in infants include birth asphyxia, sepsis, and cardiac surgery. Important causes of AKI in older children include trauma, sepsis, and the hemolytic uremic syndrome. Prolonged prerenal azotemia may result in overt renal injury. Similarly, intrarenal obstruction to blood flow from thrombi or vasculitis may cause renal failure. Drugs such as aminoglycosides or amphotericin B or other nephrotoxins, including radiocontrast agents, may induce AKI through tubular injury or cause interstitial injury as a result of allergic reactions, as can be seen with penicillins. Acute glomerulonephritis is another cause of AKI in children. Rarely, pyelonephritis can lead to AKI.

The remaining causes of AKI result from the obstruction to urine flow. In total, these conditions account for less than 10% of all cases of AKI and lead to obstruction of both kidneys. Complete cessation of urine may be a clue to a postrenal cause. The obstruction can occur within the collecting system of the kidney (intrarenal), in the ureter, or in the urethra (extrarenal). Intrarenal obstruction may occur with the tumor lysis syndrome with the deposition of uric acid crystals or from medications such as acyclovir and cidofovir. Extrarenal obstruction can be caused by the presence of stones in the ureters or from external compression due to lymph nodes or tumor. As with other forms of AKI, prompt recognition and appropriate intervention to relieve an obstruction may prevent a permanent reduction in renal function.

The exact pathophysiology of AKI remains unclear, but several factors have been identified.<sup>18</sup> There is a profound vasoconstriction in the initial phase of AKI that contributes to the reduced GFR (Fig. 26-1). Factors implicated in increased vasoconstriction include increased activity of the renin-angiotensin and the adrenergic systems and endothelial dysfunction with increased endothelin release and decreased nitric oxide synthesis. However, therapeutic interventions to increase vasodilatation, such as prostaglandin and dopamine infusions, ACE inhibitors, calcium channel blockers, and endothelin receptor antagonists, have not significantly improved established AKI.<sup>19</sup>

Another factor in the pathogenesis of AKI is renal tubule cell injury that is a direct result of a nephrotoxic agent or from an ischemic insult (Fig. 26-2). Cellular injury leads to sloughing of the brush border, swelling, mitochondrial condensation, disruption of cellular architecture, and loss of adhesion to the basement membrane with shedding of cells into the tubular lumen.<sup>20</sup> These changes, which occur within minutes of an ischemic event,

TABLE 26-5 Causes of Acute Renal Failure

Prerenal Failure	Renal Failure	Postrenal Failure
Hypovolemia Volume loss Gastrointestinal, renal losses Sequestration (burns, postoperative)	Acute glomerulonephritis Postinfectious Membranoproliferative glomerulonephritis Rapidly progressive glomerulonephritis Glomerulonephritis due to systemic disease (e.g., HUS, DIC, SLE)	Obstruction Intrinsic (papillary necrosis due to diabetes, sickle cell disease, or analgesic nephropathy) Intrarenal abnormalities, ureteral obstruction, obstruction of the bladder or urethra Extrinsic (tumor compression, lymphadenopathy)
Hypotension Shock Vasodilators	Acute interstitial nephritis Drug-induced hypersensitivity (penicillin) Infections

contribute to the decreased GFR by obstructing the lumen of the tubule.<sup>21</sup> These cellular changes allow the filtrate to leak back into the peritubular blood, reducing the excretion of solutes and the effective GFR.

Some of these cell derangements in AKI, such as a decrease in ATP concentrations,<sup>21</sup> cell membrane injury by reactive oxygen molecules,<sup>22</sup> and increased intracellular calcium levels from changes in membrane phospholipid metabolism, lead to cell death. Reactive oxygen molecules also stimulate the production of cytokines and chemokines that play a role in cell injury and vasoconstriction.

Infiltrating neutrophils, recruited during reperfusion injury after renal ischemia, mediate parenchymal damage.<sup>23</sup> Reperfusion injury increases intracellular adhesion molecule 1 (ICAM-1) on endothelial cells promoting the adhesion of circulating neutrophils and their eventual infiltration into the parenchyma. Neutrophils then release reactive oxygen molecules, elastases, proteases, and other enzymes that lead to further tissue injury.

### Diagnostic Procedures

A thorough history and physical examination can yield important clues to the possible cause of renal failure. The initial laboratory assessment of a child with AKI should include the measurement of serum urea, creatinine, and electrolytes and a urinalysis. Prerenal azotemia is typically associated with a ratio of blood urea nitrogen (BUN) to creatinine that is usually greater

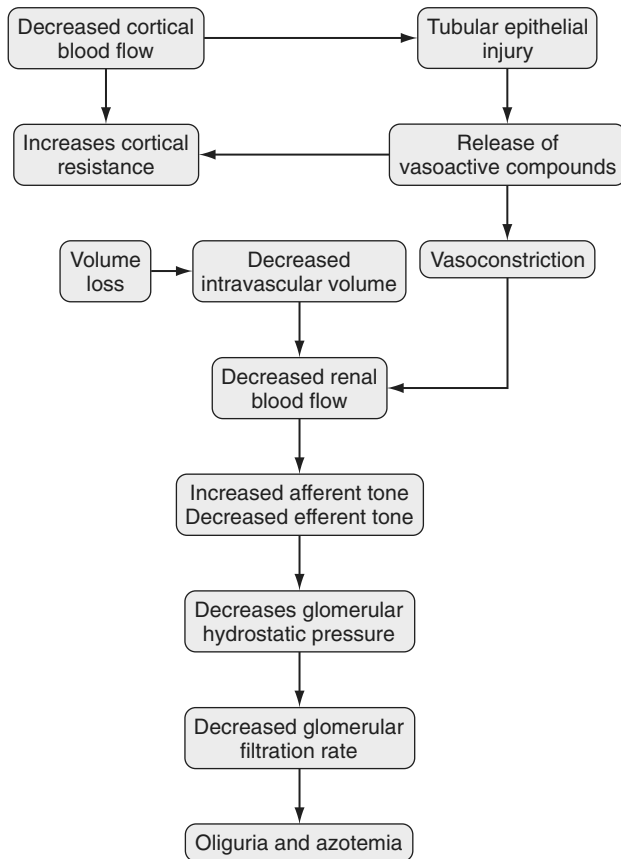

than 20. In cases of renal parenchymal dysfunction, this ratio is approximately 10. Hematuria and proteinuria are seen in all causes of AKI, but the presence of cellular casts, especially red blood cell casts, in the urinary sediment suggests glomerulonephritis. Granular casts may be seen in prerenal azotemia.

One test to distinguish prerenal azotemia from established renal failure from ischemia or nephrotoxins is the fractional excretion of sodium (FE<sub>Na</sub>). The FE<sub>Na</sub> is calculated using the following equation:

$$FE_{Na} = \frac{U_{Na}}{S_{Na}} \frac{S_{Cr}}{U_{Cr}} \times 100\%$$

U<sub>Na</sub> and S<sub>Na</sub> are urine and serum sodium concentrations, and U<sub>Cr</sub> and S<sub>Cr</sub> are the urine and serum creatinine concentrations, respectively. In prerenal azotemia, the FE<sub>Na</sub> is usually less than 1% for adults and children and less than 2.5% for infants. In established AKI from ischemia and nephrotoxins, but not acute glomerulonephritis, the FE<sub>Na</sub> is usually increased above 1%. Diuretics confound the interpretation of this test.

The initial radiologic assessment of children with AKI is ultrasonography. Renal ultrasound does not depend on renal function and can define renal anatomy, changes in parenchymal density, and possible obstruction by demonstrating dilation of the urinary tract. Doppler interrogation of the renal vessels provides information on vascular flow. Further radiographic studies, such as voiding cystourethrography, nuclear renal flow scanning, and

**FIGURE 26-1** Hemodynamic factors in the pathogenesis of acute renal failure.

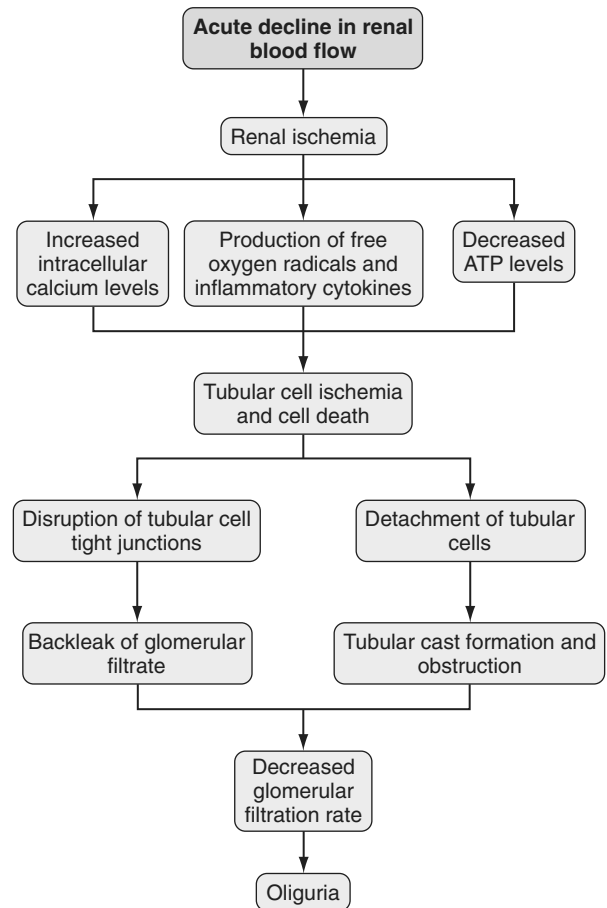

abdominal computed tomography (CT) may be indicated in selected children.

### Therapeutic Interventions

Therapeutic interventions in children with AKI should be aimed at the underlying cause and at improving renal function and urine flow. Children with AKI due to hypovolemia should be fluid resuscitated with at least 20 mL/kg over 30 to 60 minutes of normal saline or a balanced salt solution. For children with significant hypotension, an alternative choice is a colloid-containing solution. Children with oliguria due to hypovolemia usually respond within 4 to 6 hours with increased urine output. Although there are anecdotal reports supporting low-dose dopamine in AKI, clinical trials have not shown a benefit from dopamine in preventing or improving AKI.<sup>24</sup>

Diuretics have been commonly used to treat oliguric AKI. There are several theoretical reasons why mannitol, furosemide, or other loop diuretics may ameliorate AKI. Diuretics may convert oliguric AKI to nonoliguric AKI. Loop diuretics decrease energy-driven transport in the loop of Henle, and this may protect cells in regions of hypoperfusion. However, neither mannitol nor loop diuretics can predictably convert an oliguric patient with AKI to a polyuric patient. Diuretics have not been shown in clinical studies to influence renal recovery, need for dialysis, or survival in patients with AKI.<sup>25,26</sup> Diuretics should be used only after the circulating volume has been adequately restored and should be stopped if there is no early response.

Dopamine has been widely used to prevent and manage AKI. In low doses (0.5 to 2.0 µg/kg/min), dopamine increases renal

**FIGURE 26-2** Influences of specific injuries on the nephron in the pathogenesis of acute renal failure. ATP, Adenosine triphosphate.

plasma flow, GFR, and renal sodium excretion by activating dopaminergic receptors. Infusion rates in excess of 3 µg/kg/min stimulate α-adrenergic receptors on systemic arterial resistance vasculature causing vasoconstriction; cardiac β<sub>1</sub>-adrenergic receptors increasing cardiac contractility, heart rate, and cardiac index; and β<sub>2</sub>-adrenergic receptors on systemic arterial resistance vasculature causing vasodilatation. In a meta-analysis of 24 studies and 854 patients, dopamine did not prevent renal failure, alter the need for dialysis, or change the mortality rate.<sup>27</sup> In a randomized clinical trial of low-dose dopamine in 328 critically ill patients, dopamine did not change the duration or severity of the renal failure, need for dialysis, or mortality.<sup>28</sup> From these data, the routine use of low-dose dopamine in patients with AKI cannot be supported.

Several other agents that were useful in experimental models of AKI have been investigated but not shown clinical success. Atrial natriuretic peptide increases GFR in animal models of AKI by increasing renal perfusion pressure and sodium excretion. Initial studies demonstrated some benefit in patients with AKI,<sup>29</sup> especially oliguric AKI,<sup>30</sup> but a subsequent study of 222 patients with oliguric AKI revealed no statistical difference between patients treated with atrial natriuretic peptide and placebo in terms of the need for dialysis or mortality.<sup>31</sup> Insulin-like growth factor 1 has been beneficial in animal models of AKI, presumably by potentiating cell regeneration. However, in a multicenter, placebo-controlled trial enrolling 72 patients with AKI, insulin-like growth factor 1 did not speed recovery, decrease the need

for dialysis, or alter the mortality rate.<sup>32</sup> Thyroxine abbreviates the course of experimental acute renal failure but had no effect on the duration of renal failure in patients and increased mortality threefold (by suppression of thyroid-stimulating hormone).<sup>33</sup>

In patients with severe AKI, renal replacement therapy through dialysis is life sustaining. The indications for initiation of dialytic therapy are persistent hyperkalemia, volume overload refractory to diuretics, severe metabolic acidosis, and overt signs and symptoms of uremia such as pericarditis and encephalopathy. Many nephrologists advocate for initiation of dialysis if the BUN value approaches 100 mg/dL or even earlier, especially in the oliguric patient, although this has not proved to alter outcome. A retrospective study that compared early (BUN <60 mg/dL) versus late (BUN >60 mg/dL) initiation of dialysis in 100 adult patients suggested that early initiation improved survival.<sup>34</sup> However, the timing of the initiation of dialysis remains an unresolved question.

The three modalities of renal replacement for the support of critically ill children and adults are hemodialysis, peritoneal dialysis, and a variation of continuous replacement therapies, such as venovenous hemofiltration (CVVH), hemodialysis (CVVHD), and hemodiafiltration (CVVHDF). No form of replacement therapy has been clearly superior to the others. However, in the individual child, one form may be more practical than the others. Hemodialysis is technically more difficult than peritoneal dialysis in the infant and hemodynamically unstable child. Continuous replacement therapies appear to cause less hemodynamic instability compared with hemodialysis but offer more predictable solute and fluid removal than peritoneal dialysis. Hemodialysis and continuous replacement therapies require large-bore vascular access to achieve the high blood flow rates necessary for these modalities.

Although the modalities are technically different, they are based on the same principles (Fig. 26-3). The aim of all renal replacement therapies is to promote the removal of nitrogenous

**FIGURE 26-3** Principles of dialysis. Solute (pink circles) moves from the blood to the dialysate (broken arrows) in response to a concentration gradient (i.e., diffusion). The obligate passive movement of water (blue circles) attempts to maintain appropriate osmolarity. This flux of solute and water (i.e., ultrafiltration) may be enhanced by increased osmotic pressure (i.e., glucose in peritoneal dialysis fluid) or by increased hydrostatic pressure, which is created mechanically as transmembrane pressure in hemodialysis.

wastes (i.e., urea), excess fluid, and excess solute, especially potassium. This is achieved by exposing blood to a salt solution (i.e., dialysate), with the two separated by a semipermeable membrane. The movement of solute occurs by diffusion (i.e., solute moves across the membrane in response to a concentration gradient) and ultrafiltration (i.e., osmotic or hydrostatic pressures). The rate of removal of water and solute waste depends on membrane characteristics (i.e., pore size and selectivity), diffusion, and ultrafiltration.<sup>35</sup>

The permeability characteristics and surface areas are known for specific dialyzers used in hemodialysis and hemofiltration. The peritoneum serves as the dialysis membrane in peritoneal dialysis and remains physically unalterable, but changes in dialysate composition and length of time the dialysate is exposed to the peritoneal membrane changes the amount of solute and water removed. In all forms of renal replacement therapy, the therapeutic prescription is individualized for the child.

### Hemodialysis

Hemodialysis is useful for AKI and is the best modality for the rapid removal of toxins, such as drug overdoses or other ingestions. Hemodialysis is very efficient, with the ability to reduce the BUN by 60% to 70%, normalize the serum potassium concentration, and remove fluid equal to 5% to 10% of the body weight in 3 to 4 hours. To accomplish this, rapid blood flows are necessary (5 to 10 mL/kg/min), which requires large-vessel venous access, but this can usually be achieved even in infants by the insertion of a double-lumen catheter into the subclavian, internal jugular, or femoral vein. In small infants, two single-lumen catheters placed in different sites may be necessary for access and return of blood. Rarely, a single-lumen catheter is used for outflow and return of blood. Modern hemodialysis machines have microprocessors that can accurately measure fluid removal, allowing precise volumes of fluid to be removed.

Hemodialysis usually requires systemic anticoagulation with heparin, the effectiveness of which can be monitored by the activated clotting time. Hemodialysis can be done without the use of an anticoagulant in the child at significant risk for bleeding by using a rapid blood flow rate and frequent rinsing of the blood circuit with saline. However, clotting of the circuit with subsequent loss of the extracorporeal blood is common.

In addition to the risk of bleeding, hemodialysis is associated with several other complications. The most common side effect is hypotension, which is usually related to aggressive volume removal but can be caused by sepsis or the release of cytokines and autokines from blood passage over the hemodialysis filter surface. Muscle cramps, headache, nausea, and vomiting are also common complaints. A more serious complication of hemodialysis is the disequilibrium syndrome that is related to rapid removal of solute from the bloodstream with slow equilibration with the tissues, particularly in the brain. This can cause cerebral edema, manifested by headache, obtundation, seizures, or coma. The disequilibrium syndrome is usually reported in children undergoing dialysis for the first time. This can be avoided by short, frequent dialysis sessions initially, especially if the BUN concentration is increased substantially. Infection of the dialysis catheter is another common problem and can be minimized with sterile central line technique.

### Peritoneal Dialysis

Peritoneal dialysis has a long history as a renal replacement therapy in children.<sup>36</sup> It is relatively simple and easily performed

even in small infants. Although not as efficient as hemodialysis, it is best done continuously to control solute and water balance. In contrast to hemodialysis, it is much less likely to cause hemodynamic instability. Peritoneal dialysis involves instilling dialysate fluid into the peritoneum for a set period and then draining the fluid and replacing it with fresh dialysate. This cycling removes waste products by diffusion and water by ultrafiltration as a consequence of a high glucose concentration in the dialysate. The efficacy of peritoneal dialysis depends on the volume instilled and the number of cycles per day. Most children with acute renal failure can be managed with 1- to 2-hour cycles of 5- to 30-mL/kg dwell volumes. Children with chronic renal failure are managed with greater cycle times and larger dwell volumes. The amount of fluid removed can be varied by changing the concentration of the glucose in the dialysate. Short-term peritoneal dialysis can be accomplished with a nontunneled catheter, but dialysis that should continue beyond 3 to 5 days is best achieved with a subcutaneously tunneled cuffed catheter to minimize the risk of peritonitis.

The principal complications of peritoneal dialysis are infection and mechanical problems related to the catheter. It is not uncommon to find poor drainage from the catheter, usually from fibrin occlusion of the catheter or from omentum or bowel covering the inlet holes. The catheter may leak at its point of insertion. Hernias, especially inguinal hernias in boys, may develop as a consequence of the increased abdominal pressure from the infused dialysate. Mild hyponatremia may develop in infants because of the relatively low sodium concentration (130 mEq/L) in commercial dialysate. Less common but serious complications include bowel injury and intraabdominal hemorrhage from catheter insertion and peritonitis.

### CHRONIC RENAL FAILURE

The loss of functioning renal mass results in a compensatory increase in filtration by the remaining renal tissue.<sup>37</sup> For example, after a unilateral nephrectomy, there is a demonstrable increase in the GFR and evidence of contralateral renal hypertrophy within the first 48 hours. By 2 to 4 weeks, the GFR has returned to 80% of normal, and there is no clinical evidence of renal dysfunction. With the loss of 50% to 75% of renal mass, there is an increase in the residual function to 50% to 80% of normal and often little evidence of clinical renal insufficiency. When the residual renal function decreases to 30% to 50% of normal, the term *chronic renal insufficiency* applies. At this point, acute illness and other stress states may result in acidosis, hyperkalemia, and dehydration. It is only when the residual function decreases to less than 30% of normal that the term *chronic renal failure* is used. At this point, electrolyte abnormalities begin to appear, and more importantly, there is limited ability of the kidney to adjust to variations in fluid and electrolyte homeostasis. The term *uremia* refers to the symptoms of anorexia, nausea, lethargy, and somnolence that develop as a result of chronic renal failure. Uremia ultimately results in death unless dialysis therapy or renal transplantation is performed. Initiating dialysis or transplanting a kidney is referred to as end-stage renal disease care.

Chronic renal insufficiency and chronic renal failure are both categories within the larger schema of chronic kidney disease (CKD). Although the stages are defined by categorizing continuous measures of function (i.e., GFR) and therefore are somewhat arbitrary, they do provide a context for the evaluation and management of kidney disease. There are six stages of CKD:

- Stage I: The GFR is normal ( $>90$  mL/min/1.73 m<sup>2</sup>), but there may be evidence of chronic renal disease, including an abnormal urinalysis, hypertension, or abnormal renal ultrasound results.
- Stage II: The GFR of 60 to 89 mL/min/1.73 m<sup>2</sup> indicates mild kidney damage with a reduction in the GFR.
- Stage III: The GFR of 30 to 59 mL/min/1.73 m<sup>2</sup> indicates a moderate reduction in the GFR.
- Stage IV: The GFR of 15 to 29 mL/min/1.73 m<sup>2</sup> indicates a severe decline in the GFR, often accompanied by electrolyte or metabolic derangements.
- Stage V: The GFR of less than 15 mL/min/1.73 m<sup>2</sup> indicates kidney failure requiring renal replacement therapy.
- Stage VI: Patients are receiving dialysis or are transplant recipients.

Despite losses of up to 90% of renal function, sodium homeostasis usually is well maintained in chronic renal failure. With large decreases in the GFR, the kidney maintains normal serum sodium by increasing the  $FE_{Na}$  from less than 1% up to 25% to 30%, largely through decreases in distal tubular resorption. Some of the hormonal factors involved in this adaptation include aldosterone, atrial natriuretic factor, and a poorly characterized natriuretic hormone that inhibits  $Na^+/K^+$ -ATPase. With chronic renal failure, the ability of the kidney to handle a wide range of sodium intake, from 1 to 250 mEq/m<sup>2</sup>/day, is lost. Instead, the kidney may be able to handle an intake of only 50 to 100 mEq/m<sup>2</sup>/day. It may be possible to decrease this obligatory excretion of sodium to 5 to 20 mEq/m<sup>2</sup>/day, although only after weeks of decreasing the sodium intake slowly. Certain children with renal disease, especially those with obstructive uropathy or tubulointerstitial disease, may be unable to adjust to a decreased sodium intake and display a salt-losing nephropathy. These children are prone to dehydration with salt restriction and may need salt supplementation for normal growth. In others, a regular diet may lead to sodium retention, volume overload, and hypertension; sodium intake must be individualized to fit the limitations of each child.

Water balance also is affected by chronic renal failure. There is an obligatory total osmolar excretion that limits the ability of the kidney to excrete free water. The concentrating ability of the kidney is affected, limiting its ability to make a maximally concentrated or dilute urine. These limitations may result in water retention and hyponatremia or dehydration if water is administered in amounts exceeding the kidney's capabilities. These limitations must be considered in the treatment of children with chronic renal failure, particularly before surgery when free access to water is restricted.

In patients with chronic renal failure, normal serum potassium concentrations usually are maintained until the GFR is less than 10% of normal. Potassium excretion in normal and uremic states is maintained by potassium secretion in the distal nephron. In response to an increase in potassium intake or loss of renal mass, there is an increase in  $Na^+/K^+$ -ATPase in the remaining collecting tubules that seems to be partly responsible for augmented excretion of potassium per nephron. In uremic animals, potassium is excreted from the renal tubules at a rate sixfold greater than in nonuremic animals and 1.5 times the filtered potassium load. Partial adaptation can occur in the absence of aldosterone, but aldosterone plays an important role in the maintenance of normal potassium homeostasis. This is demonstrated by the presence of hyperkalemia in children with hyporeninemic hypoaldosteronism or in those treated with the aldosterone antagonist spironolactone.

The colon normally is responsible for the excretion of less than 13% of dietary potassium. In patients with chronic renal failure, this can increase to 50% by the activation of colonic  $\text{Na}^+/\text{K}^+$ -ATPase. Aldosterone augments the activity of colonic  $\text{Na}^+/\text{K}^+$ -ATPase. An additional mechanism that plays an essential role in the adaptation to an acute potassium load is the redistribution of potassium from the extracellular to the intracellular compartment, which depends on insulin,  $\beta$ -adrenergic catecholamines, aldosterone, and pH. Despite the presence of total body potassium depletion in uremia, the uptake of potassium into the cells is impaired. This contributes to the intolerance to an acute potassium load in uremia despite the ability to excrete a potassium load.
