Hyperkalemia is a major problem in chronic renal failure.<sup>38</sup> In contrast, significant hypokalemia is unusual in the absence of potassium restriction, alkalosis, or diuretic therapy. Hyperkalemia can result from an extrinsic potassium load, but it also can be caused by fasting or acidosis, in which case the source of the potassium is the intracellular compartment. This can be a particular problem when a child is fasted before surgery and can be ameliorated by an infusion of glucose and insulin. Drugs that can cause hyperkalemia in renal failure include spironolactone,  $\beta$ -adrenergic blockers, and ACE inhibitors. When clinically significant hyperkalemia develops in a child with chronic renal failure, the first-line therapy is to stabilize the myocardium with exogenous calcium and then to redistribute the potassium into the intracellular compartment with insulin and glucose. To deliver the same dose of ionized calcium, three times as much calcium gluconate (mg/kg) must be given than calcium chloride. All doses of calcium are optimally delivered through a central venous access line because calcium infusions are irritating to peripheral veins and can cause necrosis of the skin if extravasation occurs. More definitive correction of hyperkalemia is accomplished by removing potassium from the body using dialysis or Kayexalate. At eight times the usual asthma dose, nebulized albuterol has been effective in redistributing potassium intracellularly, whereas sodium bicarbonate ( $\text{NaHCO}_3$ ) administration has not been effective (Table 26-6).

**TABLE 26-6 Treatment of Hyperkalemia**

Treatment	Dosage
<b>Stabilization of Myocardium</b>	
Calcium and bicarbonate	Calcium gluconate: 10% 30-100 mg/kg IV or Calcium chloride: 10% 10-33 mg/kg IV Sodium bicarbonate: 1 mEq/kg IV if acidotic
<b>Shifting of Potassium to Intracellular Space</b>	
Insulin and glucose	Insulin: 0.1-0.3 unit/kg or 0.1 unit/kg/hr infusion Glucose: $\text{D}_{50}$ 1-2 mL/kg or $\text{D}_{25}$ 2-4 mL/kg IV or $\text{D}_5$ 1-2 mL/kg/hr
Albuterol	Albuterol: 2.5-5 mg/mL nebulization
<b>Decreasing Total Body Potassium</b>	
Sodium polystyrene sulfonate (Kayexalate)	1 g/kg up to 40 g every 4 hours PO or PR
Furosemide (diuretic)	0.5 mg/kg up to 40 mg

*D*, Dextrose; *IV*, intravenous; *PO*, per os (oral); *PR*, per rectum (suppository).

Metabolic acidosis is common in patients with chronic renal failure.<sup>39</sup> The metabolic acidosis is associated with a normal anion gap in moderate renal insufficiency, but with severe renal insufficiency, there is retention of phosphate, sulfate, and organic acids, resulting in an elevated anion gap. The primary cause of metabolic acidosis in chronic renal failure is the inability of the remaining proximal renal tubules to increase ammonium formation to keep pace with the loss of renal mass. The kidney becomes unable to generate the 1 to 3 mEq/kg/day of new bicarbonate that is necessary to compensate for that lost to buffer endogenous acid production. Previous studies have suggested a major role for decreased resorption of bicarbonate by the proximal renal tubule in chronic renal failure. Although this may occur in the presence of volume overload, severe secondary hyperparathyroidism, and disorders such as Fanconi syndrome, it is not a major mechanism causing acidosis in chronic renal failure. Except for severe phosphate depletion, decreased excretion of phosphate as a titratable acid normally does not contribute to metabolic acidosis.

One of the earliest manifestations of chronic renal failure is secondary hyperparathyroidism.<sup>40</sup> Secondary hyperparathyroidism, which results from inadequate formation of 1,25-(OH)<sub>2</sub> vitamin D (i.e., 1,25-dihydroxyvitamin D<sub>3</sub> or calcitriol), develops in moderate renal insufficiency in the presence of normal serum concentrations of calcium and phosphorus. With more severe renal insufficiency, overt hypocalcemia and hyperphosphatemia often develop. Hypocalcemia is caused by decreased calcium absorption from the gastrointestinal tract as a result of a true deficiency of 1,25-(OH)<sub>2</sub> vitamin D. Diminished release of calcium from bone occurs as a result of resistance to the action of parathyroid hormone, and calcium and phosphate are deposited in soft tissues as a consequence of hyperphosphatemia.

The kidney plays a key role in the maintenance of phosphate homeostasis by regulating its excretion. In the presence of a normal GFR, the kidney excretes 5% to 15% of the filtered load of phosphate, whereas in chronic renal failure, the kidney can increase its fractional excretion of phosphate to 60% to 80%. Through this adaptation, the kidneys are able to maintain a phosphate balance in chronic renal failure, but they do so at an increased serum phosphate concentration. At the same time, the kidneys have no reserve with which to increase phosphate excretion in response to a phosphate load. In children with chronic renal failure, a large phosphate load, such as can occur with the administration of a phosphate-containing enema, can lead to life-threatening hyperphosphatemia and hypocalcemia.

### Hematologic Problems

One of the most common manifestations of chronic renal failure is anemia. The anemia of chronic renal failure results from impaired erythropoiesis, hemolysis, and bleeding. Of these, impaired erythropoiesis is most important and usually the result of a deficiency of erythropoietin production. Erythropoietin is synthesized and secreted by peritubular cells in the renal cortex in response to decreased tissue oxygenation. It acts on receptors on the erythroid burst-forming units and erythroid colony-forming units. With loss of renal mass, erythropoietin secretion does not respond adequately to hypoxia, and anemia results. Children with chronic renal failure are now routinely treated with recombinant erythropoietin.<sup>41,42</sup> Current recommendations are to treat children with chronic renal failure in whom the hematocrit is less than 30%, starting at a dosage of 50 to 150 units/kg intravenously three times per week. When a target hematocrit of

36% is reached, a maintenance dosage of about 75 units/kg is instituted. Subcutaneous administration of erythropoietin is also effective, can be given only once each week, and obviates the need for intravenous injections. Doses greater than 150 units/kg increase the hematocrit faster than smaller doses, but both therapies take 4 to 8 weeks to reach target hematocrit values of 33% to 36%. The most common cause for failure of erythropoietin is concurrent iron deficiency. Children who are scheduled for erythropoietin therapy should begin oral iron, vitamin C, and folic acid 2 to 3 weeks in advance to ensure adequate iron and folic acid stores to facilitate erythropoiesis. Current recommendations are to maintain serum ferritin concentrations above 250 ng/mL and transferrin saturation above 25%. Other causes for failure of erythropoietin to increase or maintain the hematocrit are occult infections, hemolysis, aluminum overload, severe hyperparathyroidism, and occult bleeding. Complications of erythropoietin therapy include worsening of hypertension and a possible increased incidence of thrombosis of polytetrafluoroethylene vascular grafts.

The other major hematologic problem in chronic renal failure is bleeding. This is a classic and lethal complication in children with terminal uremia and results from platelet dysfunction in the presence of a normal coagulation profile and normal platelet counts. The best indicator of platelet dysfunction in children with chronic renal failure is a prolonged bleeding time. The platelet dysfunction is the result of poorly described abnormalities attributed to the uremic environment, and platelet transfusions are ineffective. Dialysis improves the platelet dysfunction, as does improvement in the hematocrit with transfusion or erythropoietin therapy. Preoperative intravenous desmopressin acetate (1-deamino-8-D-arginine vasopressin [DDAVP]) (0.3 µg/kg) has been shown to be effective in improving the bleeding time in children with uremia.

### Cardiovascular Complications

Hypertension is one of the most common complications of chronic renal failure and contributes significantly to the morbidity and mortality of these children. The cause is multifactorial and includes volume overload and hormonal abnormalities, such as increased secretion of renin, that result from the underlying renal disorder. In children who are being dialyzed, volume overload is the result of inadequate removal of volume by the process of ultrafiltration during dialysis. The goal of ultrafiltration is to remove sufficient salt and water to achieve the dry weight that is appropriate for each child. The *dry weight* is the weight at which the child has no signs of volume overload but below which the child has hypotension. The initial response to volume overload is to increase the cardiac output. Later, the cardiac output returns to normal, but the peripheral resistance increases because of peripheral vasoconstriction, resulting in hypertension. These children may have no other signs of volume overload, such as edema, but with a reduction in total body salt and water content, the blood pressure can be controlled with little or no antihypertensive medication.

In other children, intrinsic renal abnormalities play a primary role in hypertension. In these children, bilateral nephrectomy may be necessary to control severe refractory hypertension, although usually it can be controlled with oral antihypertensive agents. Of the mechanisms that cause hypertension in these children, increased renin secretion is the best understood. Renin activates the formation of angiotensin I, which is then converted to angiotensin II, a powerful vasoconstrictor. Children with

renin-dependent hypertension respond poorly to control of blood pressure by salt and water removal alone but respond well to ACE inhibitors such as captopril.

Cardiovascular disease is the most common cause of death in patients receiving long-term dialysis, including children.<sup>43</sup> Patients with chronic renal failure can have abnormalities of the pericardium, myocardium, cardiac valves, and coronary arteries. Another cardiac manifestation, pericarditis, has long been recognized as a complication of uremia. Pericarditis was once considered a sign of the terminal phase of uremia, but it occurs in 15% of children receiving dialysis and can be symptomatic or clinically silent. In nondialyzed uremic patients with pericarditis, intensive dialysis often results in its resolution within about 2 weeks. Some children require surgical procedures such as pericardiocentesis, pericardial drainage with a catheter or through a pericardial window, or pericardiectomy.

Left ventricular failure is also a common complication of chronic renal failure. In older patients, coronary artery disease may lead to myocardial dysfunction, severely limiting cardiac output. Volume overload and hypertension, which increase preload and afterload, respectively, are important causes of heart failure. With proper fluid management and antihypertensive medication, these abnormalities can be controlled. Anemia is another contributing factor that can be controlled with the use of erythropoietin. An array of metabolic abnormalities associated with chronic renal failure, such as secondary hyperparathyroidism, electrolyte and acid-base imbalances, and the accumulation of nonspecific uremic toxins, contribute to abnormal myocardial function.

### Causes of Chronic Renal Failure

The causes of chronic renal insufficiency and failure can be correlated with age (Table 26-7). The chronic renal failure that is commonly encountered in early infancy results largely from congenital anomalies or perinatal asphyxia. Later in childhood, renal

**TABLE 26-7 Causes of Chronic Renal Failure**

Infancy (Congenital Anomalies)	Childhood	Adolescence
Prune-belly syndrome	Dysplasia	Focal segmental glomerulosclerosis
Congenital obstruction	Agenesis	Membranoproliferative glomerulonephritis
Posterior urethral valves	Autosomal dominant PKD	Secondary glomerulonephritis
Multicystic dysplasia	Reflux nephropathy	Systemic lupus erythematosus
Agenesis	Obstruction	Sickle cell disease
Autosomal recessive PKD	Focal segmental glomerulosclerosis	HIV-associated nephropathy
Reflux nephropathy	Membranoproliferative glomerulonephritis	Diabetes mellitus Vasculitis Hemolytic uremic syndrome Henoch-Schönlein purpura Interstitial nephritis Malignancy

HIV, Human immunodeficiency virus; PKD, polycystic kidney disease.

failure may result from dysplasia, or acquired lesions, whereas those affected in adolescence may have deterioration of function related to acquired disease, manifestation of inherited disease, or secondary lesions resulting from other illnesses (e.g., systemic lupus erythematosus, sickle cell disease) or their treatments.

## Preoperative Preparation of the Child with Renal Dysfunction

The preoperative preparation of the renal patient depends on the type of renal disease and the presence of hypertension. Renal diseases that may affect the choice of anesthetic agents include renal failure, nephrotic syndrome, and tubular disorders. In children with known renal disease, careful delineation of the type of renal disease and a knowledge of the child's medications should be reviewed at the time of the preoperative visit to anticipate potential problems during the procedure. Identification of children with occult renal disease can be difficult. Clues to the presence of renal disease include edema, hypertension, failure to thrive, anemia, and rickets.

Children with tubular disorders, obstructive uropathy, or hypoplastic/dysplastic kidneys may have fixed polyuria and are at risk for dehydration if oral intake is restricted (NPO) for long periods. Following the American Society of Anesthesiologists (ASA) guidelines and allowing liberal amounts of clear fluids until 2 hours before the procedure may avoid potential dehydration and alleviate anxiety in a fasting child. Alternatively, for the in-house patient, maintenance intravenous fluids should be continued while the child is NPO.

Perioperative renal dysfunction may occur in children with normal renal function when subjected to perioperative insults such as hypoperfusion from hypotension or hypovolemia. Preexisting renal insufficiency compounds this risk, and precautions to preserve renal perfusion must be taken.<sup>44</sup> Associated risk factors include hypovolemia leading to vasoconstriction, nephrotoxic agents such as contrast media, embolic events in cases involving arterial vessel cross-clamping, renal ischemia, and inflammation. Perioperative renal failure is associated with mortality rates of 60% to 90%, and it is therefore important to avoid factors that may augment preexisting renal dysfunction.<sup>45,46</sup> A large national database has shown that 1% of all adult patients who underwent general surgical procedures developed postoperative AKI<sup>47</sup>; the patients at greatest risk were older men ( $\geq 56$  years old). These data may not be applicable to children, but an increased incidence of AKI among children with congestive heart failure, hypertension, preoperative renal insufficiency, or ascites may help to identify children who are also at risk. Identification of those at risk is not a trivial exercise because postoperative AKI increased postoperative morbidity threefold and postoperative mortality fivefold.

### PREOPERATIVE LABORATORY EVALUATION

Several preoperative laboratory tests should be assessed before surgery in a child with renal insufficiency. This allows the practitioner to determine the severity of the presenting disease and provides a baseline that may be compared with intraoperative and postoperative laboratory values to ensure proper protective renal care.

Children with known renal failure, especially those with a significant reduction in renal function, require preoperative

serum electrolyte and calcium concentrations and hemoglobin levels measured within 24 hours of the procedure and on the morning of the procedure if a known lability exists. Although the serum creatinine concentration is typically used as a marker for renal function, the value is not indicative of the degree of injury.

Abnormal potassium concentrations often occur in children with renal failure; acceptable limits depend on the status of the child and the trends in the potassium concentration over time. Chronic hypokalemic or hyperkalemic states are less likely to have cardiac effects than acute changes. Acute hypokalemia reduces arrhythmia threshold and increases cardiac excitability. Acute hyperkalemia may result in life-threatening arrhythmias from electrical conduction suppression. A child with chronic renal failure whose serum potassium concentrations are chronically 5.5 to 6.0 mEq/L does not need correction of the hyperkalemia, whereas a child with an acute increase to a potassium concentration greater than 5.5 mEq/L requires intervention before the surgical procedure and anesthesia. Existing acidosis must be taken into consideration in determining total body potassium concentrations, with the understanding that acute acidosis promotes extracellular hyperkalemia at a rate of 0.5 mEq/L for every decrease in pH of 0.1 unit. Treatment of hyperkalemia has several options (see Table 26-6).

Hypomagnesemia likewise predisposes a child to the risks of supraventricular and ventricular arrhythmias and should be corrected preoperatively. Hypermagnesemia or hypophosphatemia may cause muscle weakness and potentiate the action of muscle relaxants. Administration of calcium is helpful in treating hyperkalemia or hypermagnesemia.

Hemoglobin, hematocrit, and platelet counts should be part of the preoperative evaluation. Anemia is a common finding in children with renal disease, and morbidity and mortality are associated with hemoglobin concentrations less than 11 g/dL in adult patients with renal failure.<sup>48,49</sup> This relationship was based on the effect of anemia on the incidence of left ventricular hypertrophy and associated morbidity and may be less of a concern in children. Recombinant erythropoietin reduces the risks of cardiac compromise from left ventricular hypertrophy by increasing the hemoglobin to normal values.<sup>50,51</sup> Blood transfusion is generally not indicated if the hematocrit is more than 25%.

Platelet counts, although typically normal in children with renal failure, are not predictive of platelet dysfunction. The best indicator of platelet dysfunction in children with chronic renal failure is a prolonged bleeding time. Signs of coagulopathy such as petechiae should alert the practitioner of abnormal platelet function, which does not necessarily improve with platelet transfusion. Dialysis, red blood cell transfusion, and erythropoietin improve platelet dysfunction. Desmopressin (0.3  $\mu$ g/kg given intravenously over 15 to 20 minutes) can improve the bleeding time in children with uremia and can minimize hypotension when given 1 hour before surgery. It releases endothelial von Willebrand factor/factor VIII complex and improves platelet function for 6 to 12 hours. Cryoprecipitate is an alternative that should be used in children who have received desmopressin and continue to have coagulopathy.

A preoperative urinalysis can be useful in identifying children with unknown renal disease, although a normal result does not always exclude the possibility that a child has significant renal disease. The use of an  $FE_{Na}$  estimate assists differentiating pre-renal azotemia from acute tubular necrosis.

Depending on the degree of renal failure and suspected cardiac involvement, additional testing, including an electrocardiogram, a chest radiograph, and an echocardiogram, should be considered. These tests can help the practitioner determine evidence of left ventricular hypertrophy, arrhythmias, and presence or absence of pericardial effusions.

Although not proved to be reliable markers of renal injury, concentrations of serum cystatin C, which reflects the GFR better than serum creatinine, and urinary neutrophil gelatinase-associated lipocalin, which is produced in response to injury by tubular cells, may be used more in the future to provide information preoperatively.<sup>52,53</sup>

### PERIOPERATIVE DIALYSIS

In the child with renal failure, dialysis is used to prevent hyperkalemia and remove excess water. However, excessive or overly aggressive dialysis may lead to electrolyte abnormalities and hypovolemia. Accordingly, the timing of this therapy or need for the therapy should be discussed with the child's nephrologist. Ideally, renal failure patients on *intermittent* hemodialysis should be dialyzed the day before surgery to optimize their fluid and electrolyte status and minimize problems with acute fluid shifts with hypotension, hypokalemia, and anticoagulation that may occur if hemodialysis occurs the day of surgery. Children being treated with peritoneal dialysis can be dialyzed up until the day of surgery. Peritoneal dialysis should be resumed with the consideration that the child's pulmonary function must be able to tolerate the increased abdominal distention. Consultation with the child's nephrologist is recommended to optimize the child's clinical status before the procedure and to arrange the appropriate timing of the peritoneal dialysis.

### MEDICATIONS

Children with renal failure may require that their medications be adjusted in the perioperative period. These medications typically include antihypertensives, and although proceeding with elective surgery with moderate hypertension may be acceptable, severe or labile hypertension should be controlled before surgery. Induction of anesthesia may cause hypotension in children with chronic hypertension, although preloading with balanced salt solution may offset this effect. There is a temporal relationship between adults who take ACE inhibitors for blood pressure control on the day of surgery and hypotension at induction of anesthesia and cardiac arrest.<sup>54</sup> Moderate hypotension was significantly more frequent in patients who discontinued their ACE inhibitor within 10 hours of their anesthetic induction compared with those who had not taken their medication for more than 10 hours before induction.<sup>54</sup> Additional studies and opinion leaders suggest that ACE inhibitors should be stopped the day before surgery to prevent hypotension after induction of anesthesia, although the hypotension can be easily managed, especially during total intravenous anesthesia in adults.<sup>55-57</sup> All other antihypertensives, immunosuppressives, and steroids should be continued. Most other medications can be safely held until they can be resumed postoperatively.

If acute hypertension is diagnosed before an urgent procedure, clonidine should be considered. Because of the risk of rebound hypertension when it is discontinued, oral therapy should be started as soon as the child can tolerate oral intake, or alternatively, a transdermal clonidine patch may be applied to avoid postoperative rebound hypertension.

## Intraoperative Management

### SPECIAL CONSIDERATIONS

Children with chronic renal failure frequently present with serious medical problems that complicate anesthesia when surgery is required.<sup>58,59</sup> These problems stem mainly from fluid and electrolyte abnormalities, complications of chronic renal failure such as anemia and hypertension, and differences in the pharmacokinetics of anesthetic agents in children with renal failure. Although several empirical measures have been advocated for renal protection in the perioperative period, a Cochrane review concluded that no interventions, whether pharmacologic or otherwise, protected the kidney in the perioperative period.<sup>60</sup>

In addition to routine monitoring, consideration should be given to the absolute need for arterial access because it may affect future shunt sites, careful positioning of children with renal osteodystrophy, and careful antiseptic techniques for vascular line placements due to the increased risk of infection. Strategies to maintain normothermia, including increasing the room temperature and application of a forced-air warming blanket, should be considered to avoid hypothermia. An arterial line may be useful to monitor blood pressure that may be labile during the perioperative period. An arterial or central line also facilitates checking laboratory values during prolonged procedures in children with large fluid shifts and in the severely compromised renal patient. Serum potassium concentrations must be monitored and corrected to avoid arrhythmias or conduction problems. Central venous monitoring may be valuable in this population for several reasons; peripheral venous access may be challenging due to their chronic disease, fluid management is more easily guided using central venous pressure monitoring when urine output cannot be used as an indicator of hydration status, and it ensures safe and reliable delivery of vasoactive medications and calcium.

### FLUIDS AND BLOOD PRODUCTS

In the child with renal insufficiency, fluid management requires a balanced approach. The child must receive adequate hydration to prevent further renal deterioration in an otherwise injured kidney. Children with renal failure and a history of hypertension are at risk for hypotension and hypertension and require some degree of fluid resuscitation for stability. However, they also may have hypoalbuminemia with low oncotic pressure that puts them at risk for pulmonary edema. Ideally, if the child is euvoletic, standard fluid therapy based on typical surgical fluid management may ensue. Fluid overload must be avoided in all anuric children and in outpatients. Although common sense and years of practice suggest that normal saline is preferable to lactated Ringer solution due to the potassium load in the latter, there is evidence to the contrary. In a series of adults who underwent kidney transplantation with normal saline or lactated Ringer solution, 19% of the patients in the saline group had a potassium concentration of 6 mEq/L and 31% had a metabolic acidosis that required treatment, compared with none for both metabolic disorders in the lactated Ringer group.<sup>61</sup> Consideration should be given to returning to lactated Ringer solution for renal failure patients.

In a child with AKI and low urine output, it is tempting to administer diuretics to increase renal blood flow and flush the renal tubules. However, the use of diuretics in a patient with renal disease may worsen renal failure by causing hypovolemia and decreased renal perfusion.

Because of the risk of bleeding in children with significant renal failure, hemoglobin concentrations should be followed closely. This is a classic and lethal complication in children with terminal uremia that results from platelet dysfunction in the presence of a normal coagulation profile and normal platelet counts. Blood and component therapy may be used in accordance with surgical losses and to keep the hemoglobin concentration greater than 11 g/dL. Other components that may be effective to alleviate surgical oozing or occult bleeding should be given based on clinical need because results of coagulation studies may not be true indicators of the coagulation status in children with platelet dysfunction.

### ANESTHETIC AGENTS

The pharmacokinetics and pharmacodynamics of anesthetic agents and perioperative medications may be altered in children with renal failure. The medications most likely to be affected are those that depend on renal excretion, such as the hydrophilic, highly ionized agents. Repeated doses of medications that depend primarily on renal excretion for elimination should be administered at longer intervals or in smaller doses than they are given otherwise. Examples of commonly used perioperative medications that primarily depend on renal elimination are penicillins, cephalosporins, aminoglycosides, vancomycin, and digoxin. Anesthetic agents should be tailored according to the circumstances and child. For example, the duration of action of medications that are delivered as a single bolus depends more on redistribution than on elimination. If the volume of distribution of the medication is unchanged, the single bolus dose should be unchanged. Medications that depend only in part on renal elimination have a normal duration of action when delivered as a bolus or short-term infusion. Many anesthetics depend in part on renal elimination, including pancuronium, vecuronium, atropine, glycopyrrolate, and neostigmine. The vasoactive agents milrinone and amrinone also belong to this group. Long-acting medications and infusions must be used with caution in renal failure patients due to the risk for drug accumulation.

Because uremic children are more susceptible to excessive sedation, premedication should be kept to a minimum in these children. However, a short-acting anxiolytic such as midazolam may be used with caution in the anxious child, but if the child is encephalopathic, no premedicant should be used.

Induction of anesthesia may be carried out safely as long as the child is euvoletic and the pharmacokinetics and pharmacodynamics of the induction agent are understood and accounted for. Anesthetic agents may be affected by the presence of anemia, acidosis, and altered drug binding due to hypoproteinemia in children with renal disease. Antihypertensives such as ACE inhibitors, particularly in combination with diuretics, may lead to profound hypotension.<sup>62</sup>

The dose of propofol to induce anesthesia using the bispectral index and clinical signs to indicate the state of hypnosis in adult patients with renal failure were significantly greater than in those without renal disease.<sup>63</sup> This was attributed to a larger volume of distribution in renal failure patients, consistent with previous studies of thiopental.<sup>64</sup> Anemia is another contributing factor. It may indirectly cause a greater plasma volume and greater cardiac output. When propofol is delivered as an infusion, no significant differences in pharmacokinetic or pharmacodynamic parameters have been observed.<sup>65</sup>

There are insufficient data on the use of inhalational anesthetics for induction in children with renal impairment. For

maintenance of anesthesia in adults, desflurane and isoflurane do not further impair renal function in those with preexisting renal disease.<sup>66</sup> Sevoflurane at low flows is associated with increased circuit concentrations of compound A, which is nephrotoxic in rats.<sup>67,68</sup> In adult patients with normal renal function, low-flow sevoflurane anesthesia has been associated with mild, transient proteinuria but no changes in BUN, creatinine level, or creatinine clearance.<sup>69</sup> In adults with renal insufficiency, low-flow sevoflurane has been shown to be as safe as low-flow isoflurane in terms of kidney function.<sup>68</sup> Overall, sevoflurane is considered safe in patients with renal disease, but low flows should be avoided. Because desflurane is minimally metabolized (rate of 0.2%) *in vivo*, it may be preferred even at very low flows (1 L/min).

Neuromuscular blocking drugs (NMBDs) have evolved over the years to provide a choice of relaxants for use in children with renal disease. Children with chronic renal failure may have existing autonomic neuropathy and associated delayed gastric emptying that puts them at risk for aspiration. Along with renal implications, aspiration should be anticipated when choosing a NMBD for airway management. Succinylcholine is often avoided in children with renal failure because of its well-known propensity for increasing serum potassium. However, succinylcholine does not increase the plasma potassium concentration in patients with renal failure any more than in patients with normal renal function (0.5 to 0.8 mEq/L of potassium).<sup>70,71</sup> Plasma potassium concentration is chronically increased in renal failure, which means that the intracellular and extracellular potassium concentrations are in equilibrium. This contrasts with patients with acute hyperkalemia in whom the intracellular and extracellular potassium concentrations are not in equilibrium, which predisposes them to ventricular arrhythmias if succinylcholine is given. In the latter case, succinylcholine is relatively contraindicated, whereas in the former case, it is not contraindicated.

The pharmacodynamics of NMBDs in children with renal insufficiency merit consideration. The onset time of rocuronium in children with renal failure (139 seconds) was significantly greater than in the control children (87.3 seconds). This difference was attributed to a greater volume of distribution and decreased serum albumin concentrations and possibly to a reduced cardiac output in children with renal failure who were taking antihypertensives. The slower onset time of rocuronium in children with renal failure must be considered when a rapid-sequence intubation is required. The duration of action of rocuronium in children with end-stage renal disease and normal renal function is similar.<sup>72</sup> The time to recover a train-of-four ratio of 70% in children with renal failure was 28.9 minutes, and in those without renal failure, it was 29.4 minutes. The clearance of rocuronium is decreased in children with renal failure.<sup>73</sup> Vecuronium has an increased duration of action in adults with renal failure.<sup>74</sup>

NMBDs such as atracurium and cisatracurium are ideal choices for children with renal insufficiency because their elimination is independent of the kidney. Despite the fact that atracurium and cisatracurium undergo spontaneous degradation by plasma esterase and Hofmann elimination, neuromuscular blockade should be monitored.<sup>75</sup> With appropriate monitoring and dosing, atracurium, cisatracurium, vecuronium, and rocuronium are acceptable NMBDs in children with renal disease and provide reliable durations of action after a single bolus dose. However, depending on how rocuronium and vecuronium are administered during a case, their accumulation may ultimately affect their duration of action.<sup>75</sup>

If a prolonged neuromuscular blockade occurs, hypermagnesemia should be ruled out. In this case, calcium may be administered to help antagonize the blockade. The elimination of neostigmine may be delayed beyond elimination of atropine or glycopyrrolate, and muscarinic effects such as bradycardia, increased secretions, or bronchospasm may occur postoperatively after antagonism. Sugammadex, a selective relaxant binding agent, has reduced clearance in adults with severe renal failure.<sup>76</sup> The clearance of sugammadex was only 5.5 mL/min in renal failure patients but 95.2 mL/min in the control group. Despite this difference in pharmacokinetics, sugammadex can rapidly and effectively reverse the effects of rocuronium in patients with renal failure.<sup>77</sup>

Remifentanyl may be a preferred choice for a maintenance opioid in the intraoperative period in children with renal insufficiency because of its rapid metabolism by nonspecific blood and tissue esterases. The pharmacokinetics and pharmacodynamics of remifentanyl are not altered in patients with renal disease, but the principal metabolite of remifentanyl has reduced elimination,<sup>78,79</sup> which is not expected to be clinically important. Doses of other opioids should be reduced by 30% to 50% to avoid unexpected respiratory depression in children with chronic renal failure. Active metabolites of morphine and meperidine can likewise accumulate in patients with renal failure, whereas those of fentanyl and sufentanil do not. The latter opioids are preferable on that basis alone.<sup>80-84</sup> Prolonged antagonism of opioid effects with naloxone can be expected in renal failure patients.

Esmolol or labetalol are useful to control tachycardia and hypertension, but large doses may exacerbate hyperkalemia by blocking intracellular potassium flux. Nicardipine is an effective, short-acting antihypertensive agent that does not affect serum potassium.

Delayed emergence, vomiting and aspiration, hypertension, respiratory depression, and pulmonary edema are potential problems that should be anticipated with anesthetic emergence. Hyperkalemia as a consequence of tissue injury, catabolism, blood transfusion, and acidosis is common. Children with chronic renal failure usually have chronic metabolic acidosis with limited buffer reserve. Modest hypercapnia with emergence may lead to significant acidosis and hyperkalemia. Careful attention should be given to the fluid needs of the child postoperatively to minimize volume overload and pulmonary edema.

Regional anesthesia is a viable alternative to general anesthesia or an adjunct in many cases. The anesthesia team must pay particular attention to coagulation studies and signs of coagulopathy before embarking on any central block because abnormal platelet function puts the renal failure patient at risk for epidural hematoma.

## Postoperative Concerns

The postoperative care of the child with renal disease must take into account the level of renal function, anemia, and preexistence of hypertension. In the child with limited ability to excrete a salt and water load, care must be given to the rate and amount of postoperative fluids administered, with consideration of the volume given during the procedure and operative losses. In children with renal insufficiency, nephrotic syndrome, or tubular disorders (especially those with concentration impairments), it is common to administer fluid volumes that approximate anticipated output and insensible needs. This volume needs to be

**TABLE 26-8** Management of Acute Malignant Hypertension

Drug	Dose	Side Effects
Sodium nitroprusside	1-10 µg/kg/min	Possible cyanide and thiocyanate toxicity, acute hypotension
Enalaprilat*	0.01-0.06 mg/kg/day every 6 hours	Hypotension, angioedema, anaphylactoid reaction
Labetalol	0.4-3 mg/kg/hr or 0.2-1 mg/kg every 10 minutes	Bradycardia
Nicardipine	0.5-5 µg/kg/min	Acute hypotension

\*Intravenous angiotensin-converting enzyme inhibitor.

adjusted for third spacing, ongoing losses, and the administration of blood and blood products.

For children with known renal disease, care must be taken to identify medications that need to be resumed in the immediate postoperative period. Children who have been on chronic antihypertensive medications may be able to resume oral medications when awake. It may be necessary to treat isolated hypertensive episodes with intravenous medications during the postoperative period. It is important to assess the contribution of pain and anxiety to increased blood pressures to avoid overtreatment.

Because of ischemic tissue injury, it is possible that preexisting metabolic acidosis and hyperkalemia may worsen in the postoperative period. In children who have renal failure, careful monitoring of electrolytes during and after the procedure may prevent untoward emergencies. When clinically significant hyperkalemia develops in a child with chronic renal failure, treatment is imperative (see Table 26-6).

Acute hypertension can be treated with a variety of intravenous and oral medications (Table 26-8). Because the therapy for acute symptomatic hypertension should be directed toward rapid normalization of blood pressure, prompt and effective therapy must be initiated, often before the cause has been discerned. The rate of change of blood pressure can be just as important as its absolute level in the pathogenesis of hypertensive emergencies. Blood pressure itself may be a poor determinant of the severity of the clinical situation and the need for aggressive parenteral therapy. The decision to use aggressive parenteral therapy should be based on an absolute number and on clinical findings that define the situation as emergent. When it is determined that aggressive therapy is indicated, several antihypertensive agents can be used safely in children in the acute setting. The drugs most often chosen are potent vasodilators, such as hydralazine, diazoxide, or nitroprusside. There has been widespread use of nicardipine for acute hypertension in children, and they have the advantages of intravenous administration, safety, and rapid onset of action.

Hemodialysis or peritoneal dialysis can be safely resumed on the first postoperative day, with the exception of the occasional child who has operative placement of a dialysis access port for more emergent therapy. In these children, timing of renal replacement therapy must be individualized in consultation with the child's nephrologist.

Uremic encephalopathy may occur and should be considered in the child who exhibits confusion or prolonged sedation in the postanesthesia care unit. These children should be transferred to an intensive care setting for stabilization and airway management during further workup.

By careful preoperative assessment and review of preexisting disease, many postoperative complications can be anticipated and avoided. Hypervigilance during the entire perioperative period allows children with renal disease to be managed in a safe manner.

**ABDOMINAL SURGERY AND UROLOGIC** interventions after infancy make up a large fraction of anesthetic practice for the pediatric anesthesiologist. The field is rapidly evolving, with increased use of laparoscopic surgery, including robot-assisted procedures.<sup>1</sup> This chapter focuses on the specific issues related to abdominal and urologic surgery, particularly in young children. The management of infants for pyloromyotomy and other neonatal abdominal procedures is discussed in Chapter 36.

## General Principles of Abdominal Surgery

### "THE FULL STOMACH": THE RISK FOR PULMONARY ASPIRATION OF GASTRIC CONTENTS

A large number of abdominal surgeries are emergency procedures that require a rapid induction of anesthesia and protection of the airway to prevent regurgitation and aspiration. Children who present with these emergencies should be considered to be at risk for vomiting and/or regurgitation and aspiration during induction of and emergence from anesthesia. Adhering to fasting guidelines for elective surgery<sup>2</sup> does not ensure that the stomachs of children with acute abdomens are empty of liquids and solids. The only metric that has been associated with gastric emptying after an acute emergency in children is the time interval

between the last food ingested and the occurrence of the pathologic event or trauma.<sup>2</sup> However, there is no firm fasting interval after a trauma that predicts a zero risk of regurgitation and aspiration. In a postal survey, 83% of anesthesiologists use a rapid-sequence induction (RSI) for children with a forearm fracture within 2 hours of feeding and after opioid administration, whereas fewer than 20% use an RSI for this fracture if the child had not eaten for 6 hours since the injury.<sup>3</sup> The presence or absence of bowel sounds is also not predictive of gastric emptying or of the risk of regurgitation. Preoperatively, some children with acute abdomens are administered oral contrast agent before abdominal ultrasonography and/or computed tomography, in order to visualize the stomach contents and to estimate their volumes. However, these radiologic tools may not provide reliable estimates of the volume of the gastric contents.<sup>4,5</sup> Indeed, the absence of gastric contents in these scans does not eliminate the risk of vomiting and regurgitation. Consequently, there is no evidence that delaying the surgical procedure for the express purpose of emptying the stomach will reduce the risk of regurgitation; it cannot predict when the risk of regurgitation will be zero and may actually increase the risk of complications by delaying surgical attention to the acute abdomen.

## RAPID-SEQUENCE INDUCTION

RSI is recommended for children with a full stomach, to quickly secure the airway. This approach is intended to minimize the risk of aspiration, although it is not evidence based. The strategy is to predetermine the drug doses and have all the required airway equipment ready to use. Predetermined drug doses are administered in a rapid sequence and when muscle relaxation is present, the trachea is intubated and the cuff (if used) inflated. Many clinicians include cricoid pressure to occlude the esophageal lumen during RSI, although no randomized studies have demonstrated that this combination prevents regurgitation and aspiration compared with an inhalational or slow IV induction. This lack of evidence, combined with both theoretical and actual complications associated with RSI and cricoid pressure in children, has generated skepticism regarding their role in preventing vomiting in children who are at risk.<sup>6</sup> Only 74% of anesthesiologists in Northern Ireland perform RSI for children scheduled for appendectomy, 78% in the United States use it for pyloromyotomy and 83% in England use it for forearm fractures within 2 hours of eating and after recent opioid administration.<sup>3,7,8</sup> In two surveys, 16% and 28% of anesthesiologists in the United States and UK, respectively, reported that a number of children with full stomachs had experienced gastric regurgitation despite using RSI with cricoid pressure, and several of them had progressed to serious harm and even death.<sup>7,9</sup> Despite the lack of evidence that RSI is effective in children with full stomachs, we continue to recommend this approach for the majority of children at risk. Whether cricoid pressure contributes substantively to preventing regurgitation when RSI is performed remains unclear. Complications of RSI, for the most part, relate to improperly performed RSI (e.g., excessive cricoid pressure distorting the anatomy of the airway,<sup>10</sup> causing difficulty in securing the airway) or poor selection of patients (those with a known difficult airway, where a more measured approach must take precedence over concerns for possible aspiration).

RSI in infants and children requires more planning than it does in older children and adults for several reasons. First, the induction drugs should be flushed into the child's veins using a separate flush syringe, to ensure a rapid bolus administration of the drugs. Succinylcholine remains useful for rapid-sequence tracheal intubation for brief procedures. The introduction of intermediate-acting neuromuscular blocking drugs (NMBDs) with rapid onset, coupled with concerns about the risk of hyperkalemia after succinylcholine in children with undiagnosed neuromuscular diseases (especially males less than 8 years of age), have dramatically reduced the use of succinylcholine in elective surgery. With the shift from succinylcholine to nondepolarizing NMBDs for rapid paralysis in young children, inability to intubate and prolonged paralysis may present serious, possible life-threatening problems. Although sugammadex reverses some NMBDs, its effectiveness is limited to rocuronium and vecuronium and is not always available.<sup>11-13</sup> Second, preoxygenation is often difficult in infants and children because they commonly resist the tight application of the face mask needed to deliver high concentrations of oxygen. Failure to ventilate the lungs after induction and before tracheal intubation may result in desaturation more rapidly in young infants and children than older children, and in those with upper respiratory tract infections or other causes of a limited oxygen reserve.<sup>14,15</sup> During laryngoscopy and intubation, mask ventilation with 100% oxygen should begin when the saturation decreases to 95%, to attenuate the nadir in oxygen saturation that follows.<sup>14</sup> Third,

the force needed to occlude the esophagus when applying cricoid pressure to infants and children is poorly understood and poorly applied, can distort the view of the larynx during laryngoscopy, may not occlude the lumen of the esophagus, and may actually deform the lumen of the trachea if excessive force is applied.<sup>6,10,16</sup> Conversely, effective cricoid pressure that occludes the esophagus in children, may permit bag mask ventilation with up to 40 cm H<sub>2</sub>O peak inspiratory pressure without gastric insufflation.<sup>17</sup> This is known as a modified RSI. Thus, if the first attempt at tracheal intubation fails or the child desaturates during laryngoscopy, properly maintained cricoid pressure allows bag and mask ventilation of the lungs to restore oxygenation, without increasing the risk of regurgitation.

## INDICATIONS FOR PREOPERATIVE NASOGASTRIC TUBE PLACEMENT

Although there are no published guidelines on this subject, it is reasonable to insert a nasogastric tube preoperatively to allow drainage of gastrointestinal fluids in cases of documented bowel obstruction (e.g., ileus, strangulated bowel, pyloric obstruction) or in other situations in which aspiration is judged to be a substantial risk. The child may experience discomfort while a nasogastric tube is inserted, but this must be balanced against the need to decompress the stomach and reduce the risk of regurgitation during induction of anesthesia. In the remaining cases, the placement of a nasogastric tube can wait until after tracheal intubation. It should be noted that placement of a nasogastric tube may decrease lower esophageal sphincter tone, increase the risk for reflux, and reduce the ability to clear refluxed gastric contents from the distal esophagus.<sup>18,19</sup> Thus the anesthesiologist is faced with the dilemma of whether or not to remove the nasogastric tube before induction. It is reasonable to apply suction to the nasogastric tube, evacuate all of the gastric contents before induction, and to remove the nasogastric tube before induction, because it is unclear if even properly applied cricoid pressure can prevent wicking of gastric contents along the path created by the nasogastric tube. It should be further noted that placing a nasogastric tube, although comforting, does not ensure an empty stomach.

## FLUID BALANCE

Many acute abdominal emergencies are associated with pronounced shifts in fluid balance, mainly in the form of dehydration, electrolyte losses, third space fluid shifts, and hypovolemia. Adequate correction of these derangements is mandatory, in most instances, before proceeding with anesthesia and surgery. However, when a large fraction of the bowel becomes strangulated and ischemic, large volumes of fluid may be sequestered in the bowel. In these cases, hypovolemia should be suspected and resuscitation initiated as anesthesia is rapidly induced. In some elective cases (e.g., bowel resection because of inflammatory bowel disease), fluid and electrolyte resuscitation should routinely be a focus of special interest, because the child may not be fully compensated at the time of surgery.

To date, published studies indicate that resuscitation with crystalloid fluids yields similar results to that with colloids.<sup>20</sup> In most children, initial resuscitation is undertaken with balanced salt solutions. Although colloid therapy may result in less tissue edema and less volume infused, the added expense of colloids may not justify their routine use in children.

### POTENTIAL FOR STRANGULATED OR ISCHEMIC BOWEL

The need for anesthesia and surgery becomes more urgent when the bowel is suspected of being ischemic and/or necrotic. For example, if true volvulus is suspected, immediate action is necessary; otherwise the child is at risk for massive bowel resection with subsequent short bowel syndrome, a condition associated with serious lifelong medical problems. Even if the child is far from optimally resuscitated, anesthesia must be induced and maintained, preferably with anesthetics that do not depress the circulation excessively, while simultaneously correcting the dehydration (or hypovolemia) and electrolyte imbalance. The situation is somewhat less critical in the child with an incarcerated inguinal hernia, although delay of even this surgery should be minimized.

Translocation of bacteria from the intestinal tract and subsequent septicemia are possible with ischemic bowel. Ischemic bowel may release a host of mediators that can cause severe hemodynamic instability. Thus when a substantial segment of the bowel is becoming ischemic, the anesthesiologist must be prepared to maintain anesthesia without depressing the circulation excessively, acutely resuscitate the child with appropriate fluids, and administer inotropic and/or vasoactive medications as needed. It should be noted that hemodynamic instability might acutely worsen when reperfusion of the bowel is established or with simple opening of the abdomen. Close communication with the surgeon is paramount in these cases.

### PRESENCE OF CONCOMITANT SEPTICEMIA

Children with acute intraabdominal disease should always be regarded as being at risk for bacterial translocation with subsequent septicemia. Children with overt sepsis are usually easy to identify and may already be admitted to the pediatric intensive care unit. However, incipient or early sepsis may not exhibit overt signs, therefore signs of sepsis should be actively sought. If septicemia is present or suspected, appropriate intravenous (IV) antibiotics should be administered without delay, preferably before anesthesia and surgery. Septic or preseptic children can be extremely unstable; the possible need to administer inotropic and/or vasoactive drugs should be anticipated. Hemodynamic compromise may be dramatically revealed following anesthetic induction and loss of vascular sympathetic tone. Additionally, their lungs may be difficult to ventilate because of established or developing acute lung injury. Thus the anesthesiologist needs to be prepared to provide invasive monitoring (arterial and central venous pressures) and an anesthetic machine capable of providing positive end-expiratory pressure; in some situations an intensive care unit ventilator may be needed in the operating room.

### PRESENCE OF ABDOMINAL COMPARTMENT SYNDROME

Acute intraabdominal disease processes may lead to a critically increased intraabdominal pressure (IAP).<sup>21</sup> If the IAP increases above the capillary perfusion pressure of the intraabdominal organs, an abdominal compartment syndrome can develop. Organ perfusion will become compromised and ischemia and/or necrosis may develop. The most commonly affected organs in this situation are the bowels, kidneys, and liver. Abdominal compartment syndrome occurs less frequently in children than in adults.<sup>22</sup> Causes of abdominal compartment syndrome include burns, extracorporeal membrane oxygenation,<sup>23</sup> closure of gastroschisis or omphalocele,<sup>24</sup> abdominal trauma,<sup>25,26</sup> abdominal surgery,<sup>27</sup> and a variety of other intraabdominal pathologies, including necrotizing enterocolitis, Hirschsprung enterocolitis,

perforated bowel, diaphragmatic hernia, and Wilms tumor.<sup>23,28,29</sup> Insufficient perfusion of the bowel may cause an ileus, translocation of bacteria, lactate accumulation, and production of mediators that cause hemodynamic instability. Increased IAP can reduce liver blood flow that will reduce hepatic function,<sup>30</sup> mainly manifested as an inability to metabolize lactate, a delay in drug metabolism,<sup>30,31</sup> and, in severe cases, impaired synthesis of coagulation factors. Because the pressure is also transmitted to the retroperitoneal space, renal function may become impaired, resulting in oliguria or anuria and reduced excretion of drugs.<sup>28</sup> In addition, cranial displacement of the abdominal contents and splinting of the diaphragm may seriously compromise ventilation.<sup>32</sup>

If acute intraabdominal compartment syndrome is suspected, then the IAP should be measured to determine if it exceeds the critical threshold of 20 to 25 mm Hg. Some suspect a compartment syndrome when the vesicular (bladder) pressure exceeds 10 to 12 mm Hg.<sup>33,34</sup> These pressures can be measured either via a nasogastric tube or bladder catheter.<sup>35</sup> The diagnosis of intraabdominal compartment syndrome should be suspected when the triad of (1) massive abdominal distention, (2) increased bladder pressures and increased peak inspiratory airway pressures, and (3) evidence of renal and/or cardiac dysfunction are present.<sup>29,36,37</sup>

Children with acute intraabdominal compartment syndrome can become extremely hemodynamically unstable. Although decompression of the abdomen by a laparotomy will immediately normalize the IAP, reperfusion of the ischemic tissues almost always releases a host of biologically active substances that cause serious hypotension. These substances may also precipitate acute renal failure and lead to a disseminated intravascular coagulopathy. As in the case of sepsis, the anesthesiologist must be fully prepared to address these challenges by having blood products in the operating room and vasopressors available before induction of anesthesia. Some children will require a patch abdominoplasty as a temporizing measure to protect abdominal organs with primary closure of the anterior abdominal wall at some time in the future.<sup>29,36</sup>

### PREOPERATIVE LABORATORY TESTING AND INVESTIGATIONS

Most minor elective cases (e.g., umbilical or inguinal hernia repair) do not require any further preoperative work-up beyond a basic history and physical examination. Many centers require a preoperative urine (or hemoglobin) screen for pregnancy in females who have reached menarche.<sup>38</sup> More complex elective cases may warrant additional laboratory testing, including basic hematology screening and electrolyte profile.

Preoperative laboratory testing is strongly advised in more critically ill children. Liver and renal function tests, coagulation profile, and serum albumin concentration should be assessed and blood typed and crossmatched. In children who are septic or who have an acute intraabdominal compartment syndrome, a preoperative chest radiograph may indicate the severity of pulmonary involvement. An echocardiogram may be needed to assess myocardial contractility and volume status if there is evidence of cardiac dysfunction.

### MONITORING REQUIREMENTS

Routine elective cases rarely require more than standard monitoring equipment. In children undergoing major intraabdominal procedures, invasive arterial and central venous blood pressure monitoring may be indicated. A multiple-lumen central venous

line inserted at the beginning of the procedure will facilitate administration of inotropic and/or vasoactive drugs, in addition to measuring central venous pressure; ultrasound-guided insertion is strongly recommended.<sup>39</sup> These lines are of great value in the immediate postoperative period for blood sampling, drug administration, ongoing assessment of intravascular volume status, and parenteral nutrition. Transesophageal echocardiographic or transesophageal Doppler evaluation may provide valuable intraoperative and postoperative information regarding the child's volume status, as well as cardiac contractility.<sup>40-50</sup>

A urinary catheter with a pediatric urinometer (i.e., a graduated collection receptacle), which provides an accurate measure of urine output is a useful monitor for most intraabdominal procedures. The measurement of hourly urine output safeguards against the development of hypovolemia and possible prerenal azotemia (see the section on laparoscopy for discussion of changes in urine output with increased IAP).

Monitoring IAP is important during laparoscopic surgery, although it will be of minimal value in omphalocele and gastroschisis surgeries, as long as the abdomen remains open. Once the abdomen is closed however, IAP will provide useful prognostic information regarding intraabdominal organ blood flow, circulatory stability, and respiratory embarrassment (see Chapter 36).<sup>32</sup>

### CHOICE OF ANESTHETIC

The anesthesiologist may use his or her personal preference of anesthetic technique for the management of both elective and emergency intraabdominal surgery in children. However, airway management associated with intraabdominal surgery requires careful consideration. Even when the child is not at increased risk for regurgitation and aspiration, the risk of regurgitation can be increased if the surgeon manipulates the bowel, when the child is positioned head down, and if gas is insufflated into the peritoneal cavity (as occurs in laparoscopic procedures). A particular concern arises when the surgeon decides to decompress distended bowel. One method is to perform an enterotomy and directly drain the fluid, whereas the other is to massage (strip) the bowel in a retrograde direction until the contents can be vented with a nasogastric tube. The latter method has caused massive intestinal regurgitation that exceeded the capacity of the nasogastric tube, required clearance of the mouth with a Yankauer suction tip, and caused pulmonary aspiration.<sup>51</sup> The laryngeal mask airway should not be used during intraabdominal surgery in general, and instead we strongly recommend the use of tracheal intubation with a cuffed tracheal tube as the standard in the majority of these cases.

Regional anesthetic techniques may be useful adjuncts in children undergoing both minor and major abdominal surgery. However, in critically unstable or septic children, the use of epidural anesthesia is not recommended, because sympathetic blockade may further exacerbate the hemodynamic instability, and there is an increased risk of epidural abscess formation. Simple local infiltration of the port insertion sites contributes to adequate postoperative analgesia in most children who have had laparoscopic procedures,<sup>52</sup> whereas those who have had an open procedure will require IV opioids (see Chapter 43). Analgesia is commonly supplemented with NSAIDs and acetaminophen.

## General Principles of Urologic Surgery

With the exception of acute drainage of urinary obstruction (i.e., ultrasound-guided nephrostomy or cystostomy procedures) and

torsion of the testis, most pediatric urologic surgeries are elective. In the vast majority of cases, these children are otherwise healthy or with stable medical conditions that do not require more than a careful history, physical examination, and review of the child's medical record. Children who undergo urologic procedures may be suffering from emotional disturbance because of repeated interventions and sensitivity of the surgical site. This mandates special psychological attention before and after anesthesia. The occurrence of anaphylaxis resulting from exposure to latex-related products is of special concern in children with chronic urologic disorders.<sup>53-56</sup> Children with spina bifida are at greater risk for latex allergy than those without spina bifida,<sup>57-60</sup> presumably because of early and repeated exposure to latex urethral catheters, although every child with congenital malformations of the urinary tract and repeat latex exposure to mucous membranes beginning in the neonatal period is at significant risk for developing latex hypersensitivity.<sup>61,62</sup> Thus latex-free management is highly recommended in this population.<sup>63-65</sup>

### REDUCED RENAL FUNCTION

Children with chronic renal disease have impaired renal function, which may affect drug dosing and disposition, as well as cause secondary effects on the cardiovascular system. In the most severe cases, the child may require dialysis to balance fluids and electrolytes. In children with renal disease, it is essential to determine the degree of renal impairment by consulting the child's nephrologist and reviewing the serum creatinine, blood urea nitrogen, sodium, and potassium concentrations (see also Chapter 26). Because renal impairment may also affect clotting, a coagulation profile, including platelet count, should be reviewed preoperatively if substantial blood loss is anticipated. These children are prone to fluid overload, particularly those who are anuric and dialysis dependent. Apart from clinical signs associated with fluid overload, measuring the child's weight and comparing it with their normal weight is a simple means to assess the child's current volume status. If cardiac function or volume status remains in doubt, an echocardiogram should be obtained. Children with chronic renal insufficiency often have impaired left ventricular function even before they require dialysis, so a preoperative echocardiogram may be indicated<sup>66-70</sup>; pericardial effusion is also a concern in these children.<sup>67,71,72</sup>

For children who are dialyzed, the most recent date of dialysis should be documented. Overhydration and/or hypervolemia should be corrected preoperatively with dialysis. Although dialysis corrects hyperkalemia and overhydration, and may transiently improve platelet function (peritoneal dialysis yielding more consistent improvement than hemodialysis), it is best to not perform dialysis within 12 hours of anesthesia, so as to avoid a relative hypovolemia and to allow sufficient time for body fluids to re-equilibrate (see Chapter 26).<sup>73,74</sup> Postdialysis laboratory indices of serum electrolytes (particularly potassium), hemoglobin or hematocrit, renal function (creatinine and blood urea nitrogen), and the child's weight loss should be recorded. For children who undergo hemodialysis, IV access should not be established in the extremity ipsilateral to the arteriovenous fistula.

### SYSTEMIC HYPERTENSION

Systemic hypertension is common in renal insufficiency in adults, but far less common in children. Nonetheless, some children with urologic disorders develop significant systemic hypertension associated with disturbances in the renin-angiotensin system.<sup>75-78</sup> As in adults, it is important to control systemic hypertension

before induction to avoid wide swings in blood pressure. In contrast to adults, however, hypervolemia is an important cause of hypertension in children with renal insufficiency and should be considered and treated preoperatively. Children and adults are often treated with similar antihypertensive medications.<sup>77,78</sup> These medications should be continued up to and including the morning of surgery to maintain intraoperative and postoperative hemodynamic stability. However, angiotensin-converting enzyme inhibitors are exceptions to this rule<sup>79</sup>: consideration should be given to holding the medication at least 1 day before surgery to avoid intraoperative hypotension<sup>80,81</sup>; conversely, holding the medication may be associated with rebound hypertension postoperatively. If these medications are not withheld, vasopressors may be required during anesthesia to stabilize the blood pressure.<sup>82</sup> Because therapy-resistant renal hypertension is an indication for nephrectomy, one should anticipate and be prepared to treat wide fluctuations in blood pressure, including severe hypertension during the first stage of the operation and profound hypotension when the responsible kidney is removed. As a consequence, long-acting antihypertensive agents are best avoided during the early stages of a nephrectomy in a child.

### CORTICOSTEROID MEDICATIONS

Children with renal disease may be chronically treated with corticosteroids as part of their medical management (e.g., children with proteinuria or who have undergone previous renal transplant surgery). In such cases, a stress dose of parenteral corticosteroids during surgery is indicated, with continued supplementation until the child resumes his or her normal corticosteroid medication by the enteral route. In more complex situations, consultation with a pediatric nephrologist or endocrinologist is warranted to optimize corticosteroid supplementation, although in more straightforward cases, a dose of 2.5 mg/kg of IV hydrocortisone two to three times each day is usually adequate (see Chapter 25).

### INFECTION OR SEPSIS

Obstructive urinary tract disease or chronic renal insufficiency increases the risk for urinary tract infections. If treated properly, the infection is usually well controlled and should not interfere with anesthesia. However, in children who demonstrate overt signs of systemic illness or septicemia, the anesthetic and postoperative course may be difficult.

### MONITORING REQUIREMENTS

Standard noninvasive monitoring is adequate for the vast majority of urologic procedures in children, as they are of minor or moderate magnitude (e.g., circumcision, orchiopexy, pyeloplasty, and ureter neimplantation). The anesthetic care that is required for infants and children undergoing penile surgery is routine, including a forced-air heating mattress to prevent hypothermia in surgeries lasting more than 1 hour. However, recognizing the minimal amount of skin that is exposed during this type of surgery, the child's temperature often increases steadily during the surgery necessitating close monitoring of the child's temperature to avoid iatrogenic overheating.

Invasive monitors (i.e., invasive blood pressure monitoring, central venous access for pressure measurements and administration of vasoactive drugs) are indicated for major surgical interventions, and in cases with concomitant problems (e.g., decreased renal function, significant hypertension, associated cardiac dysfunction, sepsis). If central venous access is deemed to be

necessary, the coagulation status of the child should be evaluated, because platelet function may be substantially compromised. Ultrasound guidance improves safety in securing central venous access in cases in which a coagulopathy is present or suspected on clinical grounds (see Chapter 48). In the unstable child, even more complex monitoring (e.g., esophageal Doppler monitoring or transesophageal echocardiography) should be considered.

It is important to monitor urine output, although the volume of urine may not reflect renal homeostasis. During surgery that involves the bladder or in children who are anuric, urine output will not be available for part or all of the surgery. Hence, other indices of fluid status and perfusion must be used. Heart rate and systolic blood pressure are reliable indices of volume status and perfusion in most children, although central venous pressure and invasive arterial pressure measurement may be indicated in special cases. Surgeons may be heartened to observe urine flowing into the bladder after reimplantation of ureters and kidney transplantation. Preloading with an IV balanced salt solution may be useful in such circumstances; occasionally a loop diuretic is requested.

## Laparoscopic Surgery

Although laparoscopic surgery was introduced more than 80 years ago, its role in pediatric surgery has only become notable in the past 10 to 15 years. To a large extent, this has been due to improved technology in optics and miniaturization of the instruments. An increasing number of general and urologic surgical procedures (including appendectomy, cholecystectomy, and splenectomy, as well as those to treat inguinal hernia and undescended testicles) are performed either laparoscopically or using robotic techniques in children of all ages, including neonates (Figs. 27-1 to 27-4).<sup>83-91</sup> More sophisticated laparoscopic techniques have enabled the performance of complex surgical procedures, including Nissen fundoplication, colectomy, pyeloplasty, bowel pull-through, and removal of large organs, including the kidney and spleen.<sup>89,92-95</sup> Technological advances now permit laparoscopic surgery in neonates and small infants, including those with hypoplastic left heart syndrome after stage 1 or 2 repair.<sup>91,96-98</sup>

**FIGURE 27-1** A child undergoing laparoscopic appendectomy, presented as a paradigm for the surgical set-up for any multiple trocar laparoscopic surgery. Three incisions were made, two in the anterior abdominal wall and the third in the umbilicus. The first two trocars carry instruments to manipulate the appendix, while the third holds the camera for viewing by all personnel in the operating room. All cables swing widely off the surgical field.

**FIGURE 27-2** Wide-angle view of the operating room with surgeon and scrub nurse viewing the appendix being held by the grasper, shown on the overhead monitor.

**FIGURE 27-3** Inside the abdominal cavity with a view of the inflamed appendix that has been mobilized. The peritoneal attachments must be peeled off the appendix before it is ligated and removed.

**FIGURE 27-4** The appendix is ligated and inserted into a plastic container and withdrawn usually through the trocar or incision site without contaminating adjacent tissues. The appendix is shown in the surgeon's hand after removal.

It must be noted however that laparoscopic surgery in children with cyanotic heart disease carries with it a substantial risk that exceeds most other populations having this form of surgery. Although several reports suggest that infants and children of all ages, at all stages of palliative repair of their cyanotic heart

disease, tolerate laparoscopic surgery,<sup>98-100</sup> the risk for those with Fontan physiology undergoing laparoscopic surgery is substantial. It is essential to understand that in Fontan physiology, pulmonary blood flow is passive, and decreases in venous return (whether from increases in intrathoracic pressure or head-up positioning) or increases in pulmonary vascular resistance (because of carbon dioxide absorption or decreased minute ventilation) could severely reduce the cardiac output.<sup>101</sup> Creating a pneumoperitoneum, as in the case in laparoscopic surgery, and extreme positions increase IAP and arterial carbon dioxide tensions (increasing pulmonary artery pressure), reduce venous return, and increase the risk of reducing the cardiac output in children with Fontan physiology (see later discussion). Successful management of these children during laparoscopic surgery requires a multidisciplinary team that functions in concert to optimize the child's outcome (1) by optimizing the child's condition preoperatively and identifying any cardiac issues, (2) by recruiting surgeons who can complete the surgery quickly and efficiently, (3) by maintaining the children in the supine position throughout the surgery, (4) by maintaining normocapnia, (5) by monitoring the child with a transesophageal echo probe as needed, as well as with an arterial invasive pressure monitor for blood gas analysis, and (6) by insufflating the abdomen to the lowest (less than 8 mm Hg) IAP that is surgically feasible. Larger studies are required before children with cyanotic heart disease, particularly those with Fontan physiology, can routinely undergo laparoscopic surgery in any center except those with specialized teams to manage these children.

Laparoscopic surgery offers a number of advantages over open surgery, including more rapid emergence from anesthesia, faster ambulation, earlier discharge from the hospital, and reduced perioperative complications.<sup>102-105</sup> Robot-assisted surgical technology is discussed later.

Laparoscopic surgery involves the insufflation of gas into the abdominal cavity in order to visualize the intraabdominal organs. When preparing for laparoscopic surgery, if the surgery involves the upper abdomen, the stomach should be decompressed using a nasogastric or orogastric tube whereas if the surgery involves the lower abdomen, the bladder should be emptied using a urinary catheter. Surgical access to the peritoneal cavity is achieved with trocars introduced through three (or more) small (3 to 10 mm in diameter) incisions. Through the trocars, the laparoscopic instruments and a camera are then passed. Recently a laparo-endoscopic single site (LESS), single port, single incision laparoscopic surgery (SILS), single incision multiport laparoscopy (SIMPL), or "belly button" surgery has been developed, in which all instruments pass through a single incision and a single large trocar (often in the umbilicus).<sup>106-109</sup> Through the single trocar, the instruments and a camera are inserted.<sup>109a</sup> (E-Figs. 27-1 through 27-3). "Clashing" (or colliding of objects) is a common problem because of the close proximity of the cables exiting the single trocar, as well as the proximity of the multiple hands performing the procedure. The clashing of cables has been resolved by fusing them into a single cable as they exit the trocar.

Pneumoperitoneal pressure is a major concern for all laparoscopic approaches. Experimental evidence in adult and newborn pigs demonstrated that the risks of cardiorespiratory consequences and potentially fatal emboli were directly related to the peak pneumoperitoneal pressure.<sup>110,111</sup> In infants and children, the optimal pneumoperitoneal pressure is the least pressure that enables adequate surgical access. Carbon dioxide should be insufflated through one of the trocars until the IAP reaches 6 to

**E-FIGURE 27-1** The “poor man’s” SIMPL device. Through a flap lifted in the umbilicus, a collapsible sheath is passed into the peritoneal cavity that opens once inside the abdomen to stabilize the sheath. On the skin surface, a ring stabilizes the sheath, over which a surgical glove is affixed. A finger tip on the glove is nicked and the gas insufflator (carbon dioxide feed) is inserted. The peritoneal cavity is then inflated to the desired pressure. Through adjacent finger tips, the camera and operating instruments are passed to perform the surgery. (Courtesy Dr. K. Vali, Pediatric Surgery, Women and Children’s Hospital of Buffalo, Buffalo, N.Y.)

**E-FIGURE 27-2** A commercially available SIMPL device for a child in which a single sheath is inserted through a flap lifted in the umbilicus. The ports and gas insufflator are mounted on the outside. For more information see Reference 109a. (Courtesy Dr. K. Vali, Pediatric Surgery, Women and Children’s Hospital of Buffalo, Buffalo, N.Y.)

**E-FIGURE 27-3** A commercially available SIMPL device in a child through which the camera and two laparoscopic instruments have access to the abdominal cavity. This is achieved through the umbilicus with one surgical incision. For more information, see Reference 109a. (Courtesy Dr. K. Vali, Pediatric Surgery, Women and Children’s Hospital of Buffalo, Buffalo, N.Y.)

15 mm Hg; most surgeons currently limit the IAP in neonates and young infants to 6 to 8 mm Hg and in children to 10 to 12 mm Hg.<sup>112</sup> The IAP is maintained throughout the surgery by intermittently insufflating additional CO<sub>2</sub>. Although carbon dioxide is most commonly used, a number of gases have been investigated (see later discussion).<sup>113</sup> Carbon dioxide is the preferred gas because it does not support combustion, is rapidly cleared from the peritoneal cavity at the end of surgery, and does not expand into bubbles or spaces.<sup>93,114,115</sup> However, the increased IAP may cause mechanical difficulties, such as circulatory or respiratory depression, hypothermia due to dry gas leakage, pneumothorax or subcutaneous emphysema, endobronchial intubation resulting from the upward shift of tracheal bifurcation, and injury due to paracentesis. The major disadvantage of CO<sub>2</sub> is that it is rapidly absorbed from the peritoneum, with the absorption and washout of CO<sub>2</sub> being more rapid and the peak end-tidal partial pressure of CO<sub>2</sub> (PETCO<sub>2</sub>) less in infants than in older children.<sup>116,117</sup> The inverse relationship between age and rate of CO<sub>2</sub> absorption from the abdomen has been attributed to the thinner peritoneum and the reduced peritoneal fat deposits in the abdomen of infants compared with older children.<sup>117</sup> Evidence indicates that only 10% to 20% of the PETCO<sub>2</sub> originates from the insufflated CO<sub>2</sub> after 10 to 20 minutes of insufflation at an IAP of 10 to 15 mm Hg.<sup>118</sup> During CO<sub>2</sub> insufflation, both the PETCO<sub>2</sub> and PaCO<sub>2</sub> increase up to 20 mm Hg or 20% to 50% above baseline.<sup>94,112,114,116,119</sup> Hypercapnia may occur if surgery lasts more than 1 hour, particularly in neonates,<sup>120</sup> necessitating an increase in minute ventilation of 50% to 100% to maintain a physiologic pH.<sup>93,121</sup> Again, it must be emphasized that all of these adverse physiologic changes that occur with laparoscopic surgery could have catastrophic implications for children with Fontan physiology and that consideration to performing an open procedure may be the safest approach.

The difference between the partial pressures of arterial and end-tidal CO<sub>2</sub> (Pa–PETCO<sub>2</sub>) often increases during insufflation of CO<sub>2</sub>,<sup>119,121</sup> although a number of studies reported negative Pa–PETCO<sub>2</sub> gradients, particularly in infants. The explanation for these negative gradients has been elusive, but may be due to sampling or technical errors or ventilation-perfusion mismatch.<sup>119,121</sup> The Pa–PETCO<sub>2</sub> gradient before and after pneumoperitoneum increases from a mean of 5.7 mm Hg to 13.4 mm Hg.<sup>122</sup> In neonates and in children with cyanotic congenital heart disease, the PETCO<sub>2</sub> may not reliably track the PaCO<sub>2</sub> during CO<sub>2</sub> insufflation, leading some to recommend arterial blood gas monitoring to validate the PETCO<sub>2</sub> measurements.<sup>119,122,123</sup>

Increased PaCO<sub>2</sub> may also trigger spontaneous respiratory efforts that could interfere with surgery. Additionally it may also initiate a sympathetic response, including an increase in the heart rate, blood pressure, and cerebral blood flow, as well as ventricular arrhythmias, although this occurs rarely today because sevoflurane has replaced halothane in many countries. A sudden increase in PETCO<sub>2</sub> may also suggest a diagnosis of malignant hyperthermia. If this diagnosis proves to be difficult to confirm or reject (see Chapter 40), it may be necessary to desufflate the abdomen and determine if the clinical and laboratory findings suggestive of MH resolve. Insufflated CO<sub>2</sub> originating from the abdomen continues to be exhaled for the first 30 minutes after desufflation.<sup>118</sup>

Gas emboli have been reported in several laparoscopic studies, most of which were interesting curiosities of no clinical consequence, although in several, the result was profound cardiovascular collapse. Most consider the emboli to be intravascular

CO<sub>2</sub> bubbles. Intravascular embolization of CO<sub>2</sub> may occur when the insufflation pressure exceeds the venous pressure, forcing CO<sub>2</sub> bubbles into the venous circulation, resulting in sudden cardiovascular collapse.<sup>124</sup> Continuous precordial Doppler or CO<sub>2</sub> partial pressure are effective in detecting a gas embolus, although the Doppler may be overly sensitive, with numerous false-positives. It has been suggested that many episodes of subclinical gas embolisms are unrecognized because the symptoms are mild and nonspecific. However, children with right-to-left shunts or potential right-to-left shunts, such as a patent foramen ovale, are vulnerable to the systemic effects of these emboli. Although CO<sub>2</sub> is soluble in blood and rapidly buffered, CO<sub>2</sub> emboli dissolve slowly in blood, taking 2 to 3 minutes to disappear.<sup>125</sup> Hence, large emboli may block blood flow in the heart for several minutes or more, before they dissolve. The minimum rate of infusion of CO<sub>2</sub> into blood that triggers cardiovascular collapse in pigs is 1.2 mL/kg/min<sup>125</sup>; comparable data in humans are lacking. Anesthesiologists should be aware of the high-risk conditions that predispose to CO<sub>2</sub> emboli (e.g., increased abdominal insufflation pressure, hypovolemia and reduced venous pressure, spontaneous respirations, and resection of vessel-rich parenchymatous organs) and correct the condition or warn the surgeons.

Some investigators suggest that clinically important gas emboli are actually nitrogen, not carbon dioxide gas emboli.<sup>124</sup> Whereas transient emboli are thought to be composed of CO<sub>2</sub>, emboli that persist may be nitrogen gas.<sup>124</sup> Nitrogen is insoluble in blood (blood/gas partition coefficient of 0.014), which explains its persistence as an embolus in blood. These emboli may arise from air either present in or entrained by the trocar during insufflation of the peritoneum, that is forced into a transected blood vessel while the carboperitoneum is pressurized.<sup>124</sup> This mechanism is a rare source for gas in the circulation, which may explain, in part, why the emboli that occur during laparoscopy very rarely result in cardiovascular instability and arrest.

In contrast to CO<sub>2</sub>, insufflation with oxygen, air, and nitrous oxide for laparoscopic surgery has been eschewed because they all support combustion. However, repeat desufflations of the pneumoperitoneal gas during laparoscopy in pigs whose lungs were ventilated with 66% nitrous oxide in oxygen, has been shown to prevent concentrations of nitrous oxide from exceeding 10% in the pneumoperitoneal cavity.<sup>126</sup> Nitrous oxide is still not recommended for either insufflation or as an adjunctive anesthetic gas during laparoscopy, because it also expands into gas-filled cavities should gas emboli appear in the circulation.<sup>114</sup> Its use during laparoscopic surgery may distend the bowel in bowel obstruction and obscure the surgeon's view, as well as expand any CO<sub>2</sub> emboli that develop.

The inert gases argon and helium were also candidate gases for insufflation to create a pneumoperitoneum as they cannot be oxidized (and therefore ignited), although they are much more expensive than CO<sub>2</sub>. When argon was used to create a pneumoperitoneum in pigs, embolization occurred more frequently than with CO<sub>2</sub>.<sup>127</sup> In theory, both argon and helium can cause serious sequelae if embolized into the vascular system because they are insoluble in blood (blood/gas solubility of helium is 0.007 and argon is 0.029) and are likely to persist.<sup>93,114,115,127</sup>

## PULMONARY EFFECTS

As the pressure within the peritoneal cavity increases, so too do the possible adverse respiratory effects, particularly at IAP greater than 15 cm H<sub>2</sub>O. The respiratory manifestations of increased IAP

include cephalad displacement of the diaphragm, decreased excursion of the diaphragm, and decreases in pulmonary and thoracic compliance, vital capacity, functional residual capacity, and closing volume.<sup>128</sup> Cephalad displacement of the diaphragm shifts ventilation to the nondependent parts of the lungs, creating ventilation-perfusion mismatch which may require that minute ventilation is increased from 50% to 100% to offset these effects. With a small functional residual capacity in children, cephalad displacement of the diaphragm further compresses the lungs, causing collapse of the small airways, ventilation-perfusion mismatch, and possibly hypoxemia. Pulmonary mechanics after insufflation of a pneumoperitoneum increases peak inspiratory pressures by 27% and decreases compliance by about 39%.<sup>129</sup> These physiologic changes are compounded by the extreme body tilting (i.e., extreme head-up or head-down positions) often requested by surgeons.<sup>114,130</sup> Positioning the child head down (i.e., Trendelenburg position) decreases compliance by 17% and pneumoperitoneum decreases compliance by 27%, requiring increases in peak inflation pressures of 19% and 32%, respectively.<sup>131</sup> Pulmonary function appears to be restored more readily after laparoscopic than open surgery.<sup>93</sup> In some instances, the pneumoperitoneum and the extreme position shift the tracheal tube in a rostral direction, as far as 1.2 to 2.7 cm, possibly impacting on the carina or passing into a bronchus.<sup>132</sup> With these changes, inspired oxygen concentrations in excess of 30% may be required, along with positive end-expiratory pressure to restore adequate oxygenation. A persistent 5% decrease in oxygen saturation has been associated with partial or intermittent endobronchial intubation.<sup>133</sup>

Securing the airway for laparoscopic surgery requires particular attention. Cuffed tracheal tubes are preferred over uncuffed tubes to maintain an adequate minute ventilation.<sup>123</sup> If the child has a mature tracheotomy, the air leak around the tracheotomy must be assessed before surgery. If the leak is excessive, then the IAP may prevent adequate ventilation during surgery. In such a situation, the tracheotomy should be replaced with a cuffed tracheotomy or an armored (cuffed) tracheal tube. If the air leak around the tracheotomy is insignificant, then ventilation should be adequate in the presence of increased IAP during laparoscopic surgery.

Excessive IAP may cause gas to track across the diaphragm, causing a pneumomediastinum or pneumothorax.<sup>115</sup> This is more common in hiatus hernia surgery and Nissen fundoplication, during which dissection of the esophagus may create passages for gas to traverse the diaphragm. Pneumomediastinum should be suspected if subcutaneous emphysema appears. If surgery creates a transdiaphragmatic passage for CO<sub>2</sub> to accumulate in the pleural space, the resulting pneumothorax may produce cardiorespiratory manifestations. A chest radiograph should be obtained if subcutaneous emphysema appears during or after surgery, or if there is a high index of suspicion that a pneumothorax has formed. In laparoscopic surgeries that are brief (less than 30 minutes), both laryngeal mask airways and ProSeal supraglottic airways have been used without complications, although most clinicians prefer cuffed tracheal tubes.<sup>115,134</sup> Both pressure- and volume-controlled ventilation have been used during laparoscopic abdominal surgery in infants and children. In a single randomized study, both ventilation strategies with 5 mm Hg positive end-expiratory pressure maintained effective ventilation and gas exchange.<sup>135</sup>

Although pneumoperitoneum offers the surgeons excellent operating conditions, it is a source of cardiorespiratory

compromise. An alternative to insufflating CO<sub>2</sub> to create a pneumoperitoneum is the gasless laparoscopic approach. This requires lifting the anterior abdominal wall to create an intra-abdominal tent.<sup>115,136</sup> Implementation of the gasless approach in pediatric medicine has been rather slow, presumably because of technical difficulties and the scarcity of instruments for infants and children.

## CARDIOVASCULAR EFFECTS

A pneumoperitoneum can adversely affect cardiovascular indices.<sup>115,136</sup> Three major factors contribute to cardiovascular changes: (1) IAP, (2) position (i.e., steep head-up or reverse Trendelenburg), and (3) release of neurohumoral vasoactive substances.<sup>128</sup> Increased IAP exerts a biphasic effect on venous return and cardiac output (CO). In neonatal pigs, the cardiac index (CI) decreased 55% when IAP exceeded 20 mm Hg.<sup>115</sup> The magnitude of the increase in IAP determines the degree to which the circulation is depressed.<sup>123,137</sup> For example, at IAP less than 15 mm Hg, blood is compressed out of the splanchnic circulation increasing venous return which either increases or results in no effect on CO. In contrast, at IAP greater than 15 mm Hg, the inferior vena cava is compressed, reducing venous return and therefore CO. Studies in children yielded similar results. When the IAP exceeded 12 mm Hg, myocardial contractility<sup>138</sup> and venous return<sup>114</sup> decreased mildly. In both infants and children, CO<sub>2</sub> insufflation to IAP 10 to 13 mm Hg decreased CI approximately 13%.<sup>139-141</sup> However, an IAP less than or equal to 5 mm Hg maintained the CI in infants during a CO<sub>2</sub> pneumoperitoneum.<sup>142</sup> In all of the studies in infants and children in which the CI decreased during increased IAP (10 to 12 mm Hg), the CI returned to preinsufflation values when the abdomen was desufflated.<sup>138,139,141</sup> Left ventricular systolic function was diminished and septal wall motion abnormalities have been reported with an IAP of 10 to 12 mm Hg in children with a CO<sub>2</sub> pneumoperitoneum.<sup>138,139</sup> No significant changes in echocardiographic indices of left ventricular work, preload or afterload, have been noted if the IAP was less than 10 mm Hg during the pneumoperitoneum.<sup>112</sup> When standard indices of hemodynamics were measured in infants and young children during laparoscopic Nissen fundoplication, IAP less than or equal to 10 mm Hg yielded no significant changes in heart rate and blood pressure but a slight increase in CI.<sup>142,143</sup> If IAP is maintained at less than or equal to 10 mm Hg, then the impact on hemodynamics (and in particular, CO) should be clinically insignificant, because venous return is enhanced as a result of displacement of blood from the splanchnic bed, and afterload is not increased.<sup>114,123,142</sup>

Body position during laparoscopic surgery may exaggerate cardiovascular changes. For Nissen fundoplication, a steep head-up position (greater than 20-degree incline) has been used, which reduces venous return.<sup>130</sup> In adult pigs, laparoscopic surgery for Nissen fundoplication increased pleural and mediastinal pressures that in turn, reduced CO episodically at an IAP of 15 mm Hg.<sup>144</sup> These decreases in CO were manifested by episodes of hypotension and hypoxia. When children were positioned in the steep head-up position, they developed transient hypotension and bradycardia that were reversed immediately with fluid loading and atropine.<sup>145</sup>

It is imperative to continuously monitor IAP to minimize the cardiorespiratory effects of laparoscopic surgery and to avoid excessive insufflation pressures. In adults, induction of anesthesia, IAP to 14 mm Hg, and 10-degree head-up tilt decreased the CI more than 50%.<sup>146</sup> Some clinicians recommend a maximum

IAP during laparoscopy in children of 6 to 8 mm Hg to limit the cardiorespiratory effects,<sup>147</sup> although the consensus appears to be closer to pressures of 10 to 12 mm Hg. In neonates and infants, 6 to 8 mm Hg appears to be the accepted peak IAP. Based on the current literature, the net cardiovascular effects of insufflating the abdomen to pressures less than or equal to 12 mm Hg, combined with the head-up position, are likely to be well-tolerated if adequate hydration is maintained and bradycardia is avoided.<sup>145</sup>

### CENTRAL NERVOUS SYSTEM EFFECTS

Laparoscopic surgery must be carefully evaluated if planned for a child with increased intracranial pressure, or in the presence of a ventriculoperitoneal (VP) shunt. The combination of increased IAP, increased systemic vascular resistance, increased PaCO<sub>2</sub> tension, and Trendelenburg position (as in lower abdominal surgery) may dramatically increase intracranial pressure. In adults during extreme head-down position (40 degrees) for prolonged periods, such as in robot-assisted surgery in the pelvis, cerebral tissue oxygen saturation is well-maintained, as evidenced by near-infrared spectroscopy.<sup>148</sup> Under similar surgical conditions, intracranial pressure increased 100%, and scleral edema and blurred vision may develop.<sup>149</sup>

Patency of a VP shunt should be evaluated before the procedure to prevent sudden increases in intracranial pressure during the procedure. Children with reduced brain compliance may sustain dramatic increases in intracranial pressure if the IAP is sufficient to attenuate the drainage of cerebrospinal fluid into the abdominal cavity. In these children, laparoscopic surgery may be relatively contraindicated.<sup>130</sup> The risks should be thoroughly explored and discussed with the neurosurgeon, general surgeon, anesthesiologist, and the family. Studies have reported a range of responses to laparoscopy in children with VP shunts, from dramatic increases in intracranial pressure to no change at all.<sup>128,150,151</sup> Accordingly, some advocate externalizing the shunt and clamping the distal (intraabdominal) end of the shunt before surgery to prevent carbon dioxide from passing retrograde up the shunt or from the laparoscopic pressure disrupting the shunt valve, although an IAP of 80 mm Hg is required for this to occur.<sup>153</sup> Others discourage externalizing the shunt as sequelae have been reported, and instead recommend monitoring the intracranial pressure to prevent and detect increases in intracranial pressure, and further recommend retraction of abdominal tissue during the laparoscopic surgery.<sup>153</sup> For the surgeon, using a SILS approach to laparoscopic surgery in these children reduces the risk of both traumatizing and infecting the VP shunt.<sup>152</sup> A recent review demonstrated that laparoscopy in children with VP shunts is safe and not associated with an increased risk of shunt infection.<sup>153</sup> No single strategy can provide the optimal management for every child with a VP shunt undergoing laparoscopic surgery.

### RENAL FUNCTION AND FLUID REQUIREMENTS

Increased IAP decreases renal blood flow, renal function (creatinine clearance and glomerular filtration rate), and urine output.<sup>123,128,154</sup> The effects on renal function and renal filtration are poorly understood. Decreases in urine output during laparoscopic surgery in children vary, in part, with the age of the child: oliguria occurs in older children and anuria in infants less than 1 year of age.<sup>128,130,155</sup> The etiology of the renal dysfunction and oliguria is multifactorial, but includes direct and indirect effects of IAP on renal perfusion, antidiuretic hormone (ADH), endothelin, and nitric oxide (NO).<sup>128,156</sup> ADH concentrations

increase as a result of reduced renal blood flow, resorbing water, and decreasing urine output. IAP increases renal endothelin (endothelin-1), resulting in renal vasoconstriction, which reduces renal blood flow and urine output.<sup>128,156</sup> Inhibiting endogenous NO exacerbates the renal dysfunction during pneumoperitoneum through several mechanisms, including reduced renal perfusion and increased salt and water resorption (e.g., oliguria).<sup>156</sup> Thus pretreating patients with an NO donor (such as L-arginine or nondepressor doses of nitroglycerine) may attenuate the detrimental effects of a pneumoperitoneum on renal dysfunction, a supposition that awaits human studies.<sup>156</sup> Renal tubular injury does not contribute to the renal dysfunction associated with increased IAP.<sup>157</sup> In adult donor nephrectomy patients, an overnight infusion of fluids followed by a colloid bolus immediately before the pneumoperitoneum attenuated the adverse hemodynamic effects and reduced the magnitude of changes in creatinine clearance associated with increased IAP.<sup>158</sup> Comparable data in children have not been forthcoming.

Fluid administration during laparoscopic surgery should be carefully monitored. Open abdominal surgeries may require 10 to 15 mL/kg/hr to account for "third space fluid" losses resulting from extensive bowel manipulation. Although the existence of and manipulation of a real "third space" are debated, the conceptual fluid shift is real. During laparoscopic surgery, however, these fluid requirements are reduced because little fluid is lost and the bowels are minimally manipulated. In fact, care must be taken to avoid fluid overload during these surgeries. Urine output is often used as an index of preload in children undergoing abdominal surgery, but 88% of infants (less than 1 year of age) and 33% of children develop anuria or oliguria during laparoscopic surgery. Because these completely resolve within several hours of desufflation, it is not necessary to fluid challenge these children, as fluid overload is a real possibility.<sup>155</sup> Transient oliguria in children after laparoscopic surgery should not be viewed as an early indicator of impending renal dysfunction.

### PAIN MANAGEMENT

Postoperative pain after open general and urologic surgery is primarily directed at the pain from the skin and muscle incisions. With the small incisions used during laparoscopic surgery, perioperative pain is less than with open surgery.<sup>159-161</sup> Pain after laparoscopic surgery arises from several sources, including the incision sites, residual gas in the abdomen, referred pain from the diaphragm, and stretch on nerves from peculiar patient positions. A long-acting local anesthetic should be infiltrated around the incision sites at the end of laparoscopic surgery to prevent postoperative incisional pain. Some children develop pain after laparoscopic surgery, including back and shoulder pain. In these instances, multimodal pain therapy, including acetaminophen, nonsteroidal antiinflammatory agents, and (less commonly) opioids, are effective.<sup>94,95,115</sup> Recent evidence suggests that SIMPL for appendectomy causes less pain than surgery with a multiport system.<sup>162</sup>

### Robot-Assisted Surgery

Robot-assisted surgery is relatively new to pediatric surgery and urology, with only limited experience reported, although it has been used extensively in adults since the late 1990s to facilitate minimally invasive endoscopic surgery. Enhanced with three-dimensional magnifying views and feedback-controlled enhanced motions of human hands, robot-assisted surgery enables very fine

manipulation of surgical instruments without natural human tremor, in a way that was not possible in the past. It has great potential as the future direction for pediatric surgery and urology.<sup>1,148,163,164</sup>

Initially introduced as a tool for remote battlefield surgery, robotic surgery is now available to assist pediatric surgeons in performing complex surgery, with less tissue and organ damage on extremely small surgical targets. Most of the information that is currently available is limited to one product (da Vinci Surgical System, Intuitive Surgical, Sunnyvale, Calif.) and to adult urologic procedures. However, rapid innovation and miniaturization of equipment has resulted in several pediatric centers undertaking robot-assisted laparoscopic surgery, with excellent outcomes (Videos 27-1 and 27-2). Concerns from the anesthesiologist's perspective regarding this relatively new approach are summarized in Table 27-1. Most of the perceived problems relate to the steep Trendelenburg position used, although numerous surgeries have been performed without this position.<sup>148,163</sup>

**TABLE 27-1** Issues Regarding Current Robotic-Assisted Procedures from the Anesthetist's Perspective

**Dependence on Extreme Body Position, such as Extreme Trendelenburg Position (Because of Absence of Adequate Surgical Assistance for Surgical Field Exposure), May Lead to:**

Increased intracranial pressure, ocular pressure, and impairment of cerebral perfusion  
 Optic nerve or retinal morbidity  
 Cerebro-facial congestion, airway edema, vocal cord palsy, delayed awakening  
 Possible overstretching of nerves passing through the axilla and nerve plexus damage  
 Extended lithotomy leading to compartment syndrome in the lower legs  
 Tendency to apply greater intraabdominal pressure  
 Circulatory depression and respiratory depression  
 Carbon dioxide insufflation related complications

**Absence of Touch, Traction, and Compression Sensations of Holding Instruments or Tissues**

All the manipulations are dependent exclusively on the visual sense  
 Inability to know the events occurring in an invisible place, overt tissue damage  
 Possibility of overlooking overt bleeding or tissue damage

**Absence of Robot Legs and Easy Movability**

Once fixed, it is hard to change the position of the robot or body position  
 Difficulty to check intravenous access sites or the airway

**Unlimited and Unexpected Surgical Approaches**

Exploration of new surgical approaches and complex tasks at awkward angles  
 Longer surgical time and longer setting up time, hypothermia, pressure sores  
 Unpredictable movement of robot and camera arms,  
 Hitting or compressing the child's face  
 Organization of all tubing and cables, including intravenous tubing and breathing hoses.

**Need for Emergency Undocking of the Robot in Case of Mechanical Failure or Critical Events**

## Specific General Surgical and Urologic Conditions

### NISSEN FUNDOPLICATION

This surgery is indicated for children with documented gastric fluid reflux that failed medical management. It involves mobilizing the muscles around the esophagus and suturing them tightly around the esophagus at the level of the lower esophageal sphincter. This surgery requires general anesthesia and tracheal intubation, and is usually performed laparoscopically.

Children who require a Nissen fundoplication often have a cerebral neurologic injury (i.e., cerebral palsy) that causes esophageal dysmotility. This dysmotility heralds esophageal reflux that, if severe, may result in aspiration pneumonia. If medical and gastric tube therapies fail, a Nissen fundoplication may be considered. The anesthetic considerations are few because this surgery is not associated with postoperative pain, large fluid shifts, or large blood loss. Positioning a bougie within the esophagus during surgery allows the surgeons to gauge how tight to tie the muscles around the esophagus; without a bougie, the muscles around the esophagus may be overtightened, causing an esophageal obstruction. Care must be taken to avoid dislodging the tracheal tube in the perioperative period. At the end of the procedure, it is common for the surgeon to request that 50 to 60 mL of air be insufflated into the stomach via the gastric tube to ensure that there are no anastomotic leaks. In general, this surgery is completed in less than 1 hour in experienced hands, with a complication rate of about 10% and an average hospital stay of about 1.6 days. Postoperative pain is easily managed.<sup>165,166</sup>

### PECTUS EXCAVATUM

Although this is a deformity of the chest wall, pediatric surgeons most often carry out the corrective procedure. Correction of the pectus excavatum by the classic approach involves an open procedure with fracture of the sternum, removal of multiple costal cartilages, and lifting of the sternum anteriorly with fixation, using one or two stainless steel bars. The Nuss procedure, a less invasive technique,<sup>167,168</sup> was initially a technique whereby a U-shaped bar was blindly passed through the thorax hugging the undersurface of the sternum. Once across the chest, the bar was flipped, through which process the sternum was pushed anteriorly without fracturing it, thus avoiding the creation of a flail chest by the removal of the costal cartilages. This procedure has since been modified, whereby the bar is passed through the thorax under direct vision, using thoracoscopy to reduce possible perforation of major structures (e.g., the heart or lungs).<sup>169-171</sup> Although the risk of this complication is reduced when the Nuss procedure is performed under direct vision, it may still occur.<sup>172-174</sup> Both blind and thoracoscopic approaches cause significant postoperative pain, which may be treated with patient-controlled analgesia, a thoracic epidural catheter, or a lumbar epidural catheter and epidural morphine (see Chapters 41 to 44).<sup>175</sup> Because these procedures are generally performed in teenagers, the thoracic epidural is preferably placed with the teenager awake but sedated. Compliance with inserting the epidural catheter while awake may be difficult in less mature teenagers. It is unclear whether the thoracic epidural provides improved analgesia compared with standard patient-controlled analgesia for this procedure.<sup>176</sup> It should be noted that these children will return for removal of the pectus bar after several years. Occasionally, the bar has become adherent to the pericardium or lung, resulting in a severe, sudden, and catastrophic rupture of a major vessel or chamber in the heart

when the pectus bar is removed.<sup>177</sup> It would be prudent to establish ample IV access to provide the means to rapidly transfuse fluids and blood should a catastrophic blood loss occur.

## PHEOCHROMOCYTOMA

*Pheochromocytoma* is a rare but potentially life-threatening neuroendocrine tumor that arises from the chromaffin cells of the adrenal medulla in 80% of cases, or extraadrenal paraganglionic tissue in 20% of cases.<sup>178,179</sup> Intraabdominal tumors are most commonly found around renal blood vessels or the corpora paraaortica (organs of Zu), which displays the largest collection of chromaffin tissue. Extraadrenal paragangliomas may occur anywhere in the body from the base of the skull to the pelvis.<sup>180</sup> Only cells that stain positive for chromaffin secrete catecholamines. These tumors derive their name from the dark grey-brown immunostaining of chromogranin A by chromium salts.<sup>180</sup> The Greek word “pheo,” meaning twilight, refers to the dark grey or twilight-colored immunostaining.

The incidence of pheochromocytoma in the general population is approximately 0.3 to 1 per million per year.<sup>180</sup> In children, the incidence of benign pheochromocytoma is 1 per 10 million and of the malignant form, 1 per 50 million. Approximately 10% to 20% of all pheochromocytomas are diagnosed in childhood, with an average age at the time of onset of 11 years.<sup>179,180</sup> In childhood, there is a preponderance of males, whereas during the reproductive years, there is a preponderance of females. The net effect throughout childhood is an equal distribution in the sexes.<sup>181</sup> In contrast to adults, pheochromocytomas in children are more often benign, bilateral, multiple in number, and extraadrenal.<sup>180</sup> With adequate preparation preoperatively and close monitoring intraoperatively, the mortality associated with extirpation of the tumor is less than 3% in children.<sup>178</sup>

Most of these tumors are benign, with only 5% to 10% malignant (although some reports suggest a malignancy rate as great as 50%). Malignancies of pheochromocytomas have been found in the bones, lungs, lymph nodes, and liver.<sup>178,179</sup> A diagnosis of pheochromocytoma can be confirmed by positive staining for chromaffin cells. The paraganglioma tumors with mutations in succinate dehydrogenase subgroup B (see later discussion) are most likely to metastasize.<sup>178</sup> Malignant tumors are more likely to secrete dopamine than benign ones.<sup>178</sup> The 5-year survival of metastatic pheochromocytoma is 50%, with no effective treatment.<sup>178</sup> In adults, radical surgery and iobenguane I 123 therapy have been effective in 80% of adults, although only 5% go into remission.<sup>182</sup>

In children, 40% to 60% of pheochromocytomas are inherited<sup>179,180</sup> in an autosomal dominant pattern,<sup>179,180</sup> with the remainder occurring spontaneously. Four hereditary syndromes associated with pheochromocytomas have been identified in five genes' mutations<sup>178,183-185</sup>: von Hippel-Lindau type 2, multiglandular multiple endocrine neoplasia (MEN) type 2, neurofibromatosis 1, and paraganglionic syndromes (mitochondrial complex II succinate dehydrogenase type B and D). Two additional (nonhereditary) syndromes have also been associated with pheochromocytomas: Tuberous sclerosis and Carney triad. The gene defect responsible for the MEN syndromes is located on chromosome 10q11.2.<sup>179</sup> MEN type 2A (Sipple syndrome) includes medullary thyroid cancer, parathyroid adenoma, and pheochromocytoma. MEN type 2B includes medullary thyroid cancer, multiple neuromas, Marfan habitus, and pheochromocytoma. Pheochromocytomas associated with MEN secrete both epinephrine and norepinephrine.<sup>178</sup> These tumors are bilateral in 50% to 80% of cases, but rarely metastasize.<sup>178</sup> The

von Hippel-Lindau syndrome type 2 (type 1 does not involve pheochromocytomas) is the most common cause of familial pheochromocytoma.<sup>180</sup> The von Hippel-Lindau gene is located on 3p25-26.<sup>178,179</sup> Pheochromocytoma is present in 10% to 20% of children with the gene. Three subtypes of the gene are distinguished by their association with other organs: type 2A involves hemangioblastomas of the central nervous system, endolymphatic sac tumors, and ependymal cystadenomas; type 2B involves all the organs in type 2A, as well as renal cell and pancreatic cysts and tumors. The only tissues associated with type 2C are pheochromocytomas. When associated with the von Hippel-Lindau gene, pheochromocytomas secrete exclusively norepinephrine.<sup>178</sup> These tumors occur bilaterally in the adrenal glands, but rarely metastasize.<sup>179</sup> Neurofibromatosis type 1 involves neurofibromas and café au lait spots. The genetic mutation is found on chromosome 17q11.2.<sup>178</sup> Pheochromocytomas occur in less than 5% of children with neurofibromatosis.<sup>179</sup>

Paraganglioma syndromes arise from mutations in the gene that codes for succinate dehydrogenase on cytochrome oxidase II in the respiratory chain of mitochondria. Two genetic mutations involve pheochromocytomas: subgroup B, which is coded on chromosome 1p36 and subgroup D, which is coded on chromosome 11q23.<sup>178,179</sup> These mutations present with paragangliomas of the adrenal, extra-adrenal, and head and neck regions. Subgroup B occurs more commonly in children (approximately 20% of pheochromocytomas bear this mutation), with a 30% to 50% metastatic rate. Subgroup D is inherited strictly along paternal lines.<sup>179</sup>

Tuberous sclerosis presents with the clinical findings of epilepsy, neurocognitive dysfunction, polycystic renal disease, and retinal phakomas. Tuberous sclerosis arises from two gene mutations located on chromosomes 9q34 and 16p13.3, which code for the production of hamartin and tuberlin, respectively. The wild types of these proteins suppress tumor production.

Carney triad, which usually occurs in young women, comprises gastric leiomyosarcoma (currently recognized as gastrointestinal stromal tumors), pulmonary chondroma, and extra-adrenal pheochromocytoma.

Pheochromocytomas can secrete epinephrine, norepinephrine, and/or dopamine. Most pheochromocytomas secrete norepinephrine as the predominant hormone; only 10% to 20% secrete epinephrine and dopamine as the predominant hormones. Hypertension is the most common presenting sign of this tumor. It is often accompanied by regular, intermittent headaches that are associated with nausea and vomiting. In children, nausea is a common presenting finding. The classic triad of headaches, sweating and palpitations, along with hypertension constitute the presenting signs in greater than 90% of patients with pheochromocytomas. Sustained hypertension is present in 60% to 90% of children with the tumor, but is not a requirement for the diagnosis.<sup>186</sup> In fact, there is no relationship between circulating catecholamine concentrations and overt symptoms. Epinephrine-secreting tumors can present as circulatory shock due to decreased intravascular volume, as a result of sustained high concentrations of catecholamines and their effects on vascular resistance. Tumors that secrete predominantly dopamine do not usually present with hypertension.

Other presenting findings include weight loss, nausea and vomiting, polyuria, visual disturbances, and anxiety.<sup>186</sup> Presenting signs may include pallor, orthostatic hypotension, tremor, and syncope, as well as abdominal pain, diarrhea and other gastrointestinal manifestations, hyperglycemia, low-grade fever, and behavioral disturbances. On occasion, catecholamine release may

be triggered by anesthesia, micturition (as in a urinary bladder pheochromocytoma), foods, and drugs, such as metoclopramide, tricyclic antidepressants, glucagon, and radiology contrast dye. Pheochromocytomas have been described as the great mimic, giving support to a differential diagnosis that includes acute coronary infarction, carcinoid tumor, thyroid storm, and cocaine (or other amphetamine-like drug) overdose. In other emergent circumstances, surgery undertaken for acute appendicitis with an undiagnosed pheochromocytoma has been terminated prematurely once the diagnosis of a pheochromocytoma was strongly suspected. The acute appendicitis resolved with conservative nonoperative management while the pheochromocytoma was investigated, the patient was treated with  $\alpha$ -adrenergic blocking agents, and the pheochromocytoma removed electively.<sup>187</sup>

Surgical resection of pheochromocytoma is optimally managed on an elective basis, after the child's medical status has been properly investigated, medical conditions are stabilized, the location of the tumor(s) determined and the  $\alpha$ -adrenergic receptors completely blocked. Preoperative  $\alpha$ -adrenergic blockade is critical, as its routine use has reduced perioperative complications during pheochromocytoma resection from 60% to 3%.<sup>188</sup> It must be emphasized that  $\beta$ -adrenergic blockade should NEVER be introduced until  $\alpha$ -adrenergic blockade has been well-established, because this could cause unopposed paroxysmal systemic hypertension, acute coronary or stroke signs, and death. Thus preoperative preparation of these children first requires the institution of a noncompetitive  $\alpha$ -adrenergic blocker, such as phenoxybenzamine. Phenoxybenzamine irreversibly alkylates  $\alpha$ -adrenergic receptors reducing the risk of an  $\alpha$ -adrenergic mediated paroxysmal increase in blood pressure during surgery. Phenoxybenzamine may be administered either orally or IV.<sup>183</sup> Oral doses between 0.25 and 1.0 mg/kg/day in divided doses are most common, although doses as great as 2 mg/kg/day have been used.<sup>180,183</sup> Oral bioavailability of phenoxybenzamine is only 20% to 30% with a 24-hour onset of action.<sup>183</sup> Children are usually treated for 3 to 15 days with oral phenoxybenzamine before surgery, although there is no means to reliably assess the completeness of  $\alpha$ -adrenergic blockade.<sup>183</sup> Some think that  $\alpha$ -adrenergic blockade has been established when the systolic blood pressure returns to normal limits for the child's age.<sup>179</sup> Alternatively, IV phenoxybenzamine has been used to more rapidly and reliably block  $\alpha_1$  receptors, although aggressive monitoring for peripheral vasodilatation, decreases in blood pressure, and relative hypovolemia must be followed until the hemodynamics have equilibrated. The action of phenoxybenzamine is terminated only by synthesizing new  $\alpha$ -adrenergic receptors. The disadvantage of irreversibly blocking  $\alpha$ -adrenergic receptors, as conferred by phenoxybenzamine, is that reactive hypotension may follow removal of the tumor, with resistance to interventions that are intended to increase the peripheral vascular resistance. In contrast, phentolamine has also been used because it has a much shorter half-life than does phenoxybenzamine and it is reversible. Competitive  $\alpha$ -adrenergic blockade with doxazosin, which also has a brief duration of action when compared with phenoxybenzamine, may be displaced from the  $\alpha$ -adrenergic receptors by increased concentrations of circulating catecholamines.<sup>178</sup> It is important to reemphasize that  $\beta$ -adrenergic blockade should only be introduced once  $\alpha$ -adrenergic receptor blockade has been established.

Perioperative fluid and electrolyte management in children as  $\alpha$ -adrenergic blockade develops requires close monitoring. It is tempting to administer generous volumes of balanced salt

solutions preoperatively to prevent hypotension, but this should be tempered with the understanding that children are at increased risk for catecholamine-induced pulmonary edema.<sup>183</sup> The plasma potassium concentration should be monitored closely as hypokalemia may develop as a result of increased renin concentrations.<sup>179</sup> Postoperative hypotension, a direct consequence of  $\alpha$ -adrenergic receptor blockade, may be attenuated by augmenting the sodium intake in the diet preoperatively, and by the judicious use of IV balanced salt solutions in the perioperative period.<sup>180</sup>

### Perioperative Evaluation

The pretreatment blood pressure should be compared with their supine blood pressure after  $\alpha$ -adrenergic blockade. The current blood pressure (and heart rate) should be within normal limits. If orthostatic hypotension is present, it should be treated with fluid boluses to render the child euvoletic. If the heart rate is not normal or within 20% of normal after  $\alpha$ -adrenergic receptor blockade, boluses of balanced salt solutions (20 mL/kg, IV) should be administered until the tachycardia abates. A recent electrocardiogram and echocardiogram should be reviewed to rule out arrhythmias and myocardial dysfunction. Thyroid function tests and serum calcium and blood glucose concentrations should be evaluated, as indicated by the associated endocrinopathies present. The child should be examined for café au lait spots to rule out neurofibromatosis. If café au lait spots are present, a history and physical examination should focus on the presence of neurofibromas, particularly in the form of a pulmonic flow murmur (intracardiac tumor) or a change in the child's voice (suggesting a laryngeal neurofibroma).

Preparation should be made for general anesthesia with invasive arterial and central venous catheters, together with transesophageal echocardiogram, if deemed necessary. Infusions to manage hypertensive crises should be available, including sodium nitroprusside, magnesium sulfate, and esmolol. Magnesium causes vasodilation by inhibiting catecholamine receptors and catecholamine release as well as antagonizing endogenous calcium effects.<sup>189</sup> Vasopressors, including ephedrine and vasopressin, may be required to restore the blood pressure if hypotension occurs, especially postoperatively.<sup>178,189,190</sup>

### Laboratory Findings

Biochemical testing for pheochromocytoma should be performed in children who present with signs suggestive of pheochromocytoma, whether a primary tumor or a recurrence. The most accurate biochemical tests are those for free plasma metanephrine and normetanephrine concentrations, and 24-hour urine for fractionated metanephrines,<sup>191</sup> although even these tests are not without problems.<sup>178,183,184</sup> These tests have supplanted 24-hour urinary and plasma epinephrine, norepinephrine, and dopamine concentrations, and the degradation product, urinary vanillylmandelic acid. Reference standards for metanephrine must be adjusted for the child's age, because the concentrations may be up to 33% less than those in adults. The current tests are much more reliable than older methods (vanillylmandelic acid concentration) for establishing a diagnosis of a pheochromocytoma. Plasma catecholamine concentrations correlate well with the urine concentrations during sustained tumor catecholamine secretion, although they may be exaggerated during episodes of cardiovascular instability. In both sporadic and familial pheochromocytoma, the test with the greatest sensitivity for normetanephrine and metanephrine is the measurement of plasma free

concentrations.<sup>191</sup> Plasma metanephrines are present in 99% of sporadic pheochromocytomas. However, this test may be difficult to perform in children because they must remain supine and relaxed for 30 minutes before sampling. The presence of increased urine and plasma catecholamine concentrations can be attributed to numerous physiologic and pathologic conditions, as well as to medications (e.g., acetaminophen, tricyclic antidepressants,  $\beta$ -adrenergic blockers, and calcium channel blockers). However, when the upper reference limits are adjusted, sensitivities of 100% and specificities of 80% to 94% can be obtained (sensitivities for familial forms are less than for sporadic forms, whereas specificities for familial forms are greater than for sporadic forms).<sup>178,184</sup> Concentrations of metanephrine and normetanephrine (as determined by high pressure liquid chromatography) that exceed the 99th percentile upper limit for normal levels, and thus suggest a “likely” diagnosis of a pheochromocytoma are: blood, free metanephrines greater than 0.42 nmol/L and normetanephrine greater than 1.4 nmol/L; urine, metanephrine greater than 2880 nmol per 24 hours and normetanephrine greater than 6550 nmol per 24 hours.<sup>178</sup> In some cases, results of the biochemical tests for diagnosing a pheochromocytoma are borderline. In such cases, oral clonidine may be administered as a suppression test, suppressing the release of norepinephrine. If clonidine suppresses the concentration of plasma normetanephrine greater than 40% below the upper reference limit, then a diagnosis of a pheochromocytoma may be excluded.<sup>192</sup> Caution should be exercised when administering clonidine, as  $\alpha_2$ -adrenoceptor agonists may cause substantial hypotension and bradycardia in children. Suppression tests are infrequently used today because of the sensitivity and specificity of the current catecholamine assays.

Preoperative hemoglobin and hematocrit should be determined, to gauge the adequacy of fluid replacement during  $\alpha$ -adrenergic blockade. Careful examination of the biochemical profile preoperatively will confirm the involvement of other organs. Hypokalemia may be present if hyperaldosteronism is diagnosed. Excess catecholamines associated with pheochromocytomas may increase fasting glucose concentrations or cause an abnormal glucose-tolerance test. This may be exacerbated by hypoinsulinemia caused by  $\alpha$ -adrenergic suppression of pancreatic insulin release. Testing should include total and ionized calcium concentrations to determine whether the parathyroid glands are involved, suggesting MEN syndrome.

Chronic exposure to increased circulating catecholamine concentrations may lead to a cardiomyopathy, congestive heart failure, and arrhythmias. Preoperatively, an electrocardiogram, chest radiograph, and echocardiogram should be performed.<sup>183</sup> The electrocardiogram may reveal arrhythmias, evidence of myocardial ischemia, or ventricular hypertrophy. The chest radiograph may show an increased cardiothoracic ratio suggestive of a cardiomyopathy or heart failure. Echocardiography will identify reduced cardiac function, heart failure, cardiomyopathy, or simply ventricular hypertrophy. Cardiac function should be optimized medically before embarking on general anesthesia. Transesophageal echocardiography and central venous pressure and arterial pressure monitoring may be indicated.

Once the biochemical diagnostic tests have been completed and the presence of a pheochromocytoma has been confirmed, the tumor(s) must be located. The most common location in children is in the abdomen, both within and without the adrenal gland; computed axial tomography (CAT) and magnetic resonance imaging (MRI) are used to locate these tumors in children.<sup>183</sup> CAT scans are very rapid, but they expose the children to

radiation. MRI studies are slower and require general anesthesia, but they avoid radiation exposure. The accuracy of locating a pheochromocytoma with these two techniques is similar.<sup>183</sup> 96% to 100%, although both may, on occasion, have difficulty distinguishing a pheochromocytoma from other intraabdominal lesions, especially with small tumors (less than 1 cm in diameter). For small tumors or for extraadrenal tumors, a supplementary radiologic investigation known as the iobenguane I-123 test may be used. Studies with iobenguane yield positive responses with both pheochromocytomas and neuroblastomas, necessitating additional studies to distinguish between the two.<sup>179</sup> Iobenguane uptake by the tumor may be impaired in the presence of labetalol and tricyclic antidepressants. Although metastatic paragangliomas may lose their ability to take up iobenguane, the combination of a positive MRI and iobenguane uptake usually confirms the diagnosis. In cases where iobenguane cannot be used or yields negative results, or when the tumor remains elusive, positron emission tomography with fluorodeoxyglucose F-18 may be used. The latter test offers greater sensitivity and possibly specificity than does the iobenguane I-123 test, especially during investigation for a metastatic pheochromocytoma.

### Anesthetic Management

Anxiolytics (such as midazolam) are useful to maintain circulatory homeostasis before surgical resection of pheochromocytomas. General anesthesia and tracheal intubation is required whether the tumor is resected using an open laparotomy or a laparoscopy. Induction of anesthesia may be undertaken with IV anesthetics, while avoiding sympathomimetics (e.g., ketamine). Steroidal muscle relaxants (e.g., vecuronium), benzodiazepines, opioids, and inhalational anesthetics may be used. Some have suggested succinylcholine may trigger a sympathetic response via stimulation of the sympathetic ganglia or fasciculations, although the evidence for such a response is weak.<sup>193</sup> Surges in blood pressure may be managed with propofol, increasing the concentration of the inhalational anesthetic, or administering vasodilators (magnesium or sodium nitroprusside infusions). Most pheochromocytomas are resected using an open laparotomy approach, although more recently, laparoscopic surgery has found favor.<sup>194</sup> The latter approach reduces the duration of surgery and speeds recovery. However, insufflation of the abdomen with carbon dioxide may precipitate a sympathetic response and a decrease in venous return. If the child was not euvoletic before insufflating the abdomen, a rapid decrease in venous return and blood pressure may ensue. This should be treated aggressively, using balanced salt solutions while relieving the intraabdominal pressure until the blood pressure stabilizes. If abdominal insufflation triggers a sympathetic response, an IV bolus of propofol should be administered, the concentration of inhaled anesthetic increased, and/or antihypertensives administered as needed. Contraindications to laparoscopic surgery include large tumors (greater than 15 cm), coagulopathy, and invasive metastatic disease.

For those undergoing a laparotomy, an epidural catheter may be placed after induction of anesthesia and dosed only for perioperative analgesia after the tumor has been removed. This eliminates the contribution of the epidural analgesic and vasodilation to hypotension that may occur. If an epidural is not medically indicated or the parents refuse, then patient-controlled analgesia may be used.

Emergency surgery is a hotly debated subject; the vast majority of these tumors are scheduled for elective removal after  $\alpha$ -adrenergic blockade has been pharmacologically established.

Rare instances of multiorgan failure from pheochromocytoma-associated “catecholamine crisis” have been reported. The crisis includes cardiomyopathy and congestive heart failure, hypertension, encephalopathy (with seizures), fever, and end-organ damage that required life-saving resection of the tumor to prevent a fatal outcome. In such situations, aggressive  $\alpha$ -adrenergic blockade while concurrently supporting an adequate CO take precedence.

### Potential Perioperative Problems

Hypertension can occur during the surgery, before or during manipulation of the tumor, despite  $\alpha$ -adrenergic blockade. Measures that may be used to control the blood pressure include increasing the inspired concentration of inhalational anesthetic, IV propofol (bolus or infusion), sodium nitroprusside infusion (0.5–8  $\mu\text{g/kg/min}$ ), IV magnesium sulfate (30 mg/kg loading dose over 30 minutes, followed by an infusion of 10 mg/kg/hr),  $\alpha$ -adrenergic blockers (e.g., phentolamine) and calcium channel blockers (e.g., diltiazem or nicardipine).<sup>189</sup>

Tachycardia may occur in response to tumor manipulation, antihypertensive treatment or hypovolemia.  $\beta$ -adrenergic blockers should never be used without first blocking  $\alpha_1$  adrenoceptors. Cautious use of  $\beta$ -adrenergic blockers is advised particularly in the presence of myocardial dysfunction. The preferred  $\beta$ -adrenergic blocker is esmolol (100–300  $\mu\text{g/kg/min}$ ) because of its very brief duration of action.

Hypotension can occur once the tumor has been extirpated, as a result of the sudden removal of the source of catecholamines and/or irreversible  $\alpha$ -adrenergic blockade by phenoxybenzamine. Hypotension may continue for several days postoperatively. Supportive treatment with fluids and vasopressors (including vasopressin) may be effective in restoring normal blood pressure.<sup>189</sup>

Fluid overload and left ventricular failure may present with the sudden onset of hemoglobin desaturation, increased airway pressures and pulmonary edema fluid in the tracheal tube. This should be prevented by the careful and judicious administration of balanced salt solution throughout the surgery and the avoidance of myocardial depressants. In the presence of a cardiomyopathy, it may be prudent to have a measure of central venous pressure or transesophageal echocardiography to assess for evidence of left ventricular decompensation during surgery.

Reactive hypoglycemia may occur upon removal of the source of catecholamines and relatively excess insulin levels. Blood glucose concentrations should be measured perioperatively until stabilized.

If bilateral adrenalectomy has been performed, steroid replacement may be required postoperatively. It is possible that after such surgery, the lack of an adequate concentration of steroids contributes to the development of hypotension, however, a much more likely cause for the hypotension is hypovolemia.

### CIRCUMCISION

Circumcision is performed in neonates, infants, children, and adults under local, regional, or general anesthesia. The indications for circumcision include phimosis, recurrent balanitis, religious beliefs, or parental preference. Inhalational anesthesia with additional regional analgesia is preferred. Classic circumcision involves cutting the foreskin and cauterizing and suturing the skin edges. The duration of surgery is usually less than 1 hour. The type of anesthetic and airway management do not significantly affect perioperative outcomes. The most common complication arising from circumcision is bleeding.

In infants and children, circumcision is performed under general anesthesia. Multimodal pain therapy includes acetaminophen 30 to 40 mg/kg rectally or 10 to 15 mg/kg IV, parenteral opioids (i.e., morphine 0.05–0.1 mg/kg), and/or local anesthetic without epinephrine (dorsal penile block, caudal block, subcutaneous ring block, and topical lidocaine–prilocaine [EMLA]) (see Chapter 41).<sup>195</sup> A comparison of a subcutaneous ring block of the penis with a suprapubic penile block, showed the latter provided better analgesia.<sup>196</sup> When a caudal block was compared with penile blocks and parenteral analgesics, a Cochrane review concluded that, with a caudal block, both rescue analgesia and nausea and vomiting were reduced compared with parenteral analgesics, although the analysis was limited because of a dearth of studies.<sup>197</sup>

### HYPOSPADIAS AND CHORDEE

This congenital malformation occurs in 1 of 250 liveborn males. It often occurs in isolation, without other congenital anomalies. *Hypospadias* refers to a malposition of the meatus of the urethra: rather than opening at the distal tip of the penis, the urethra opens along the undersurface of the penis anywhere from just proximal to the glans to the scrotum (Fig. 27-5). The majority of hypospadias defects are distal, occurring near or at the glans of the penis. Between 15% and 50% of hypospadii have an associated chordee, whereas 8% have an undescended testis. A small number of children with hypospadias have urethral openings remote from the glans of the penis, including the scrotum (Fig. 27-6, E-Figs. 27-4 and 27-5).

Surgery is undertaken with an expected duration of between 1 and 4 hours depending on the severity of the hypospadias. It is important to establish an understanding with the urologist

**FIGURE 27-5** Classic hypospadias. Saline is injected to perform an erection test before surgical correction of the hypospadias. (Courtesy Dr. P. Williot, Pediatric Urology, Women and Children's Hospital of Buffalo, Buffalo, N.Y.)

**E-FIGURE 27-4** A penoscrotal hypospadias with the urethra opening at what is the fusion of the penis and the scrotum. (Courtesy Dr. P. Williot, Pediatric Urology, Women and Children's Hospital of Buffalo, Buffalo, N.Y.)

**E-FIGURE 27-5** Urethral hypoplasia and hypospadias. The ultrathin tissue of the urethra presents a surgical problem for providing sufficient tissue to correct the hypospadias. (Courtesy Dr. P. Williot, Pediatric Urology, Women and Children's Hospital of Buffalo, Buffalo, N.Y.)

**FIGURE 27-6** Scrotal hypospadias with the urethra opening in the midline of the scrotum. (Courtesy Dr. P. Williot, Pediatric Urology, Women and Children's Hospital of Buffalo, Buffalo, N.Y.)

of the type of regional block that will suit the extent of surgery: those requiring a minor hypospadias repair (single-stage procedure, i.e., MAGPI [meatal advancement and glanuloplasty technique] or Mathieu repair) may be managed with a facemask, laryngeal mask airway, or tracheal tube. The anesthetic is at the discretion of the anesthesiologist; the children are outpatients and receive either a penile block or a single-shot caudal block. Those with more extensive hypospadias who require longer surgery will require either a laryngeal mask airway or a tracheal tube. They will be admitted to a hospital for one to two nights and need a strategy for continuous postoperative analgesia. For the latter, either a caudal catheter or a lumbar epidural catheter can be used during surgery to reduce the anesthetic requirements and postoperatively for analgesia. If opioids are avoided, a caudal-epidural block consisting of only local anesthetic does not cause delayed micturition after the urinary catheter has been removed.<sup>198</sup>

#### CRYPTORCHIDISM AND HERNIAS: INGUINAL AND UMBILICAL

These surgeries, together with hydrocele repair, are common outpatient procedures. *Orchiopexy* refers to mobilizing the undescended testis that is either in the inguinal canal or, less commonly, within the abdominal cavity (Fig. 27-7), and securing it firmly in the scrotum. Approximately 33% of preterm infant males are born with one undescended testis, whereas only 3% of full-term males are similarly afflicted. Although the incidence of undescended testis decreases to 1% by 3 months of age, the incidence remains at 1% thereafter. Cryptorchidism usually occurs in isolation, although it is associated with a number of conditions, including Prader-Willi syndrome, Noonan syndrome, and cloacal exstrophy.

Undescended testes are categorized, based on physical examination, to include testes that are truly undescended, those that are ectopic, and those that are retracted. The retracted ones are not true undescended testis because they can be massaged into the scrotum and require no further treatment. In the case of true undescended testes, the testes must be located, mobilized, and then fixed within the scrotal sac to ensure viability. Failure to

**FIGURE 27-7** Intraabdominal testis in the hernia ring, discovered during laparoscopy for an undescended testicle. (Courtesy Dr. P. Williot, Pediatric Urology, Women and Children's Hospital of Buffalo, Buffalo, N.Y.)

mobilize the testes out of the inguinal canal or abdomen may result in atrophy, torsion, testicular cancer, or hernias.

An *inguinal hernia* in a child is a congenital failure of the processus vaginalis to obliterate. In this case, a loop of bowel protrudes beyond the internal ring, causing a bulge in the inguinal region or scrotum. These protuberances may appear periodically, with complete resolution in the interim. On occasion, a small sac of fluid is present in the scrotum, known as a *hydrocele*, and is confused for a loop of bowel in the scrotum (E-Fig. 27-6). Hydroceles are removed electively with the same approach as for an inguinal hernia. On occasion, the loop of bowel does not reduce spontaneously from the hernia and remains trapped in the canal, necessitating a visit to the emergency department. A surgeon is often required to manually reduce the trapped bowel. In these cases, the hernia repair is then scheduled as an urgent or elective surgery, depending on whether there is suspicion of persistent or potential recurrent ischemia to the bowel. In some cases, the entrapped bowel cannot be reduced and an incarcerated hernia or obstructed bowel is diagnosed. Incarcerated hernias and bowel obstructions are surgical emergencies that require general anesthesia, and muscle relaxation to reduce the strangulated bowel. The emergency nature of the surgery requires careful questioning regarding the time interval between the last meal and the onset of abdominal pain and strangulated bowel. It is usually assumed that these children have a full stomach. At the time of open reduction, if the bowel does not appear to have adequate perfusion, a segment of the ischemic or necrotic bowel may have to be resected.

Management of cryptorchidism and inguinal hernia requires general anesthesia (facemask, laryngeal mask airway, or tracheal tube) and an adequate pain management strategy. Multimodal pain therapy, as described earlier, may be used together with a regional block. When the surgeon pulls on the foreskin, hernia sac, or testis during surgery, laryngospasm may occur if the depth of anesthesia is inadequate. Anesthesia can be deepened most rapidly by an IV bolus of propofol, although some increase the inspired concentration of inhalational anesthetic. Regional blocks (ilioinguinal, iliohypogastric, scrotal block; caudal-epidural block; or transversus abdominis plane block) are used for both orchiopexy and inguinal hernia surgery, using either a landmark-based or ultrasound-guided method<sup>199</sup> (see Chapter 41).

**E-FIGURE 27-6** Right hydrocele in the scrotum, evidenced by the swollen right sac. (Courtesy Dr. P. Williot, Pediatric Urology, Women and Children's Hospital of Buffalo, Buffalo, N.Y.)

An *umbilical hernia* is a 1- to 5-cm defect in the anterior abdominal wall (usually halfway between the umbilicus and the xiphisternal junction), with intermittent protuberance of bowel through the defect. This defect occurs in 15% of children, more commonly in children of African rather than European descent, and equally in males and females. Many resolve spontaneously in the first year of life. It also occurs frequently in preterm and low birth weight infants. If the defect is small, then a laryngeal mask airway may be sufficient to manage the airway, provided a deep level of anesthesia is maintained when the suture needles pass through each side of the rectus muscle. If the defect is large, tracheal intubation and, depending on the surgeon, muscle relaxation may be required. Deepening anesthesia while the defect is being closed by increasing the inspired concentration of inhalational anesthetic or administering an IV bolus of propofol (1 to 2 mg/kg) provides adequate relaxation to reduce the defect in most cases.

### TORSION OF THE TESTIS

Presentation of a male with sudden onset of acute scrotal pain in the absence of trauma requires immediate investigation and possible surgery to preserve a potentially viable testis. The differential diagnosis of acute onset of torsion of the testis (Fig. 27-8) includes torsion of the testicular appendix, torsion of the spermatic cord, epididymitis, and incarcerated hernia. The majority of testes can be saved if surgery is performed within 6 hours of the onset of pain if the diagnosis is confirmed by Doppler ultrasonography or suspected on clinical grounds.<sup>200</sup> The salvage rate for the testis decreases to 50% if surgery is undertaken 6 to 12 hours after the onset of pain. Children with suspected acute testicular torsion are assumed to have a full stomach and require RSI and tracheal intubation. Although pain at the time of induction of anesthesia may be intense, when the torsion is relieved, the pain abates. Hence, at the conclusion of surgery many of these children no longer have substantive pain that warrants aggressive treatment.

### POSTERIOR URETHRAL VALVES

Posterior urethral valves (PUV) is a spectrum of urethral obstruction that varies from mild to severe. The diagnosis is often made

**FIGURE 27-8** Torsion of the newborn testis. (Courtesy Dr. Daniel P. Doody, MD, Pediatric Surgery, MassGeneral Hospital for Children, Boston.)

antenatally (preferably by 24 weeks gestation) by ultrasound identification of bladder distention, megaureters, and hydronephrosis. When PUV is diagnosed antenatally, the severity of the disease tends to be greater.<sup>201</sup> Decompression of the urogenital system may be achieved by a vesicoamniotic shunt in utero. Although some recommend that an intervention should be undertaken as quickly as possible to minimize the impact on renal function, evidence suggests that early intervention does not substantively affect the outcome, because renal damage may have already occurred in utero.<sup>202,203</sup>

Postnatally, a lack of or decrease in urine output, urinary retention, or a poor urine stream may be the only indications of the presence of these valves.<sup>204</sup> Affected children can have associated renal insufficiency resulting from congenital renal dysplasia and urethral valve obstruction. Because the renal concentrating mechanism is often impaired, these infants commonly present with greater than normal urine output. Consequently, careful monitoring of urine output and balanced salt solution infusion rate is necessary. Primary valve ablation is required to decompress the urogenital system.

Several indices have been postulated as predictors of poor long-term renal function in infants with PUV, including a creatinine 0.8 mg/dL or greater at birth, antenatal diagnosis, proteinuria, moderate or severe hydronephrosis, and renal dysplasia.<sup>201,205</sup> A recent analysis indicated that a nadir creatinine greater than 1 mg/dL and bladder dysfunction were the only independent predictors of long-term renal dysfunction.<sup>206</sup>

Children with PUV are scheduled for elective surgery. A general anesthetic is required, with the specific management left to the discretion of the anesthesiologist. There are few special considerations needed.

### PRUNE-BELLY SYNDROME

Prune-belly syndrome is a disorder that occurs predominantly (97% of the time) in males, with an incidence of 1 in 40,000 births. Affected infants present with a range of findings, from stillborn to a full-term neonate, with a host of possible organ and chromosomal abnormalities.<sup>205</sup> Affected organs may involve orthopedic in 50% (congenital hip dislocation and scoliosis), gastrointestinal in 30% (malrotation and volvulus), congenital heart disease in 10% (tetralogy of Fallot and ventricular septal defect), and chromosomal defects (trisomy 18 and trisomy 21).<sup>205</sup>

In utero, the child's abdomen often swells with fluid (in the presence of oligohydramnios) that is resorbed by birth, leaving the characteristic wrinkled redundant abdominal wall (Fig. 27-9 and E-Fig. 27-7). The pathophysiology of this syndrome is unclear, but it has been suggested that a urethral obstruction in utero leads to dilatation of the urethra (megaurethra is a common finding), which, combined with bladder distention and ascites, causes distention of the abdomen in utero. This ultimately leads to vesicoureteral reflux and ureteral dilatation in 80% of affected children.

Abdominal overdistention in utero causes weak rectus abdominis muscles that undermine the child's ability to exhale forcefully, and to generate a strong cough to clear secretions. As a result, chronic aspiration pneumonia may contribute to an early demise. Some have suggested that aggressive intervention to correct the weak rectus muscles by plication and muscle transfer may improve respiratory function,<sup>207,208</sup> reduce back strain and pain, decreased bladder volume, and arrest scoliosis.<sup>209</sup> However, this view is not shared by others who prefer to observe the child for signs of regurgitation and aspiration before intervening.<sup>210</sup>

**E-FIGURE 27-7** View of the distended, weak-muscled abdomen in a child with prune-belly syndrome. The muscle wall is so thin that bowel peristalsis may be visualized on the abdominal surface. (Courtesy Dr. P. Williot, Pediatric Urology, Women and Children's Hospital of Buffalo, Buffalo, N.Y.)

**FIGURE 27-9** Prune-belly syndrome. View of the distended, weak muscled abdomen in a child with prune-belly syndrome. The muscle wall is so thin that the abdominal surface is bulging in front of the bowels. (Courtesy Dr. P. Williot, Pediatric Urology, Women and Children's Hospital of Buffalo, Buffalo, N.Y.)

Controlling the type of feeds, preventing gastrointestinal reflux disease, and using antibiotics to treat pneumonia permit the child to grow. Constipation is a frequent problem that may be exacerbated by their inability to increase their IAP during defecation. Stool softeners are often prescribed to prevent constipation and abdominal distention. Pneumonia must be aggressively treated and completely resolved before entertaining surgery. Percutaneous endoscopic gastroscopy tubes are generally eschewed in these children when feeding is a problem, as abdominal wall surgery is difficult. These children often require urologic surgery to correct vesicoureteral reflux and orchiopexy. Urethral obstruction may be due to the angulation of the urethra within the prostate.

Trisomy 18, the second most common autosomal trisomy, occurs in 1 in approximately 7,000 live births, and is associated with prune-belly syndrome. In contrast to the simple prune-belly syndrome, 60% to 80% of these infants are female. Trisomy 18 is characterized by severe neurologic developmental problems (including microcephaly), micrognathia and/or retrognathia, microstomia, auricular abnormalities, and others. In fact, 95% die in utero, with only 5% to 10% surviving 1 year and only 1% reaching 10 years of age. Mortality results from cardiac anomalies (90% of affected children have a ventricular septal defect, valvular heart defect, atrial septal defect, hypoplastic left heart syndrome, tetralogy of Fallot, or other cardiac defect), renal anomalies, failure to thrive, and apnea.<sup>211,212</sup> Additional findings include pulmonary hypoplasia and gastrointestinal anomalies (including prune-belly syndrome, omphalocele, ileal atresia, and esophageal atresia).

General anesthesia with tracheal intubation is required for most surgeries in these children. Controlled ventilation is recommended, because of the variability in the strength of the abdominal muscles. It is prudent to suction the lungs once the trachea has been intubated, in order to assess the severity of secretions. As little muscle relaxant as possible should be used during the surgery, with preferably no muscle relaxant administered during the last hour, to ensure the child's strength has had time to recover to have a successful extubation. Although opioids should be used cautiously, regional anesthesia may be preferred, in view of their difficulty with clearing secretions from the tracheobronchial tree.<sup>213</sup>

## URETERAL REIMPLANTATION

Vesicoureteral reflux, in which urine passes retrograde up the ureter, is a congenital disorder affecting 0.5% to 2% of children. Recurrent episodes of pyelonephritis may occur, leading to renal scarring and reduced renal function, depending on the severity of the reflux. The pathology is thought to be an anatomically abnormal insertion of the ureter into the bladder that fails to close tight when the bladder fills and contracts. A voiding cystourethrogram is the test required to diagnose the reflux and assess its severity. Mild forms of vesicoureteral reflux are managed with daily antibiotics until the child outgrows the reflux. However, more severe forms or those who develop kidney infections despite antibiotic therapy, require surgical correction. The classic surgical approach for vesicoureteral reflux is an open procedure in which the affected ureters are reimplanted into the bladder wall, re-creating a normal muscle flap valve.<sup>214</sup> This involves a lower abdominal incision and 3 to 4 hours of surgery. Postoperatively, the pain is often intense, necessitating 2 to 3 days of continuous infusion of local anesthetic via an indwelling caudal or epidural catheter.

More recently, laparoscopic techniques have been developed, with and without robotic control, for reimplantation of the ureters.<sup>214</sup> Preliminary evidence suggests an excellent success rate (greater than 90%) for this approach,<sup>215</sup> although the time for the surgery is more than twice the open technique and more complications were identified in children with small bladders.

Surgical alternatives in the past 20 years have spawned a number of compounds for injection into the terminal submucosal tract of the ureter, by passing a needle through a specially designed cystoscope. Initially, polytetrafluoroethylene (Teflon) was injected endoscopically, but a safer, more durable polymer has been developed over the past 20 years that is a mixture of dextranomer and hyaluronic acid (Deflux). In this way, surgeons create a swelling just inferior to the opening of the ureter into the bladder that prevents urine from refluxing (Fig. 27-10, before and after injection of polymer). The technique is successful in 80% of cases after one injection and in greater than 90% after two injections. Although this procedure still requires general anesthesia, its advantages far outweigh any disadvantages, in that the duration of the procedure is very brief (usually 15 to 30 minutes), the procedure avoids an abdominal incision, causes no postoperative pain, and its greatest advantage is that the child can be an outpatient. However, the results of this injection

**FIGURE 27-10** A female with ureteral reflux. Preinjection (at left) with the bladder orifice wide open. There is no valve to prevent the backwash of urine up the ureter. Polymer was injected into the submucosa of the bladder, raising a mound to seal off the orifice of that ureter. Postinjection (at right) with the orifice now appearing as a dimple on the peak of the mound (arrow). (Courtesy Dr. P. Williot, Pediatric Urology, Women and Children's Hospital of Buffalo, Buffalo, N.Y.)

technique continue to be monitored because long-term outcomes and sequelae have not been determined.

### PYELOPLASTY

Pyeloplasty is performed to decompress the renal pelvis either because of intrinsic (congenital) or extrinsic (major vessel) compression of the ureter. A distended renal pelvis is often diagnosed antenatally and, in some instances, decompressed in utero by percutaneous nephrostomy. The ureteric narrowing often occurs at the ureteropelvic junction, where the ureter exits the renal pelvis. Surgery involves disconnecting the ureter at the renal pelvis, reshaping it, and then reinserting it into the kidney. Such surgery is often performed in the lateral or prone position, with the table jackknifed. The duration of this surgery is approximately 2 hours, with a success rate of approximately 95%. Dissection is often retroperitoneal, but the incision is placed immediately below the rib cage. This procedure has been performed laparoscopically and with the use of robotics.<sup>105,215b</sup>

Anesthetic considerations include the prone or lateral decubitus position (complicated by placing the table in the “jackknife position”), postoperative pain, and adequate fluid resuscitation. IV access should be established in an upper extremity to maintain adequate atrial filling pressures. If the table is placed in the jackknife position, it is very important to measure the child’s blood pressure before and after the table is jackknifed, because venous return may become severely compromised, necessitating reducing the extent of the jackknife and resuscitating the child with fluid. The laparoscopic approach to pyeloplasty in children is new. In renal surgery, CO<sub>2</sub> is insufflated in the retroperitoneal space to provide surgical access.<sup>216</sup> Because of the anatomic differences between the retroperitoneal and intraperitoneal spaces, greater pressures may be required to provide adequate surgical visibility. A mean retroperitoneal pressure of 12 mm Hg increases PETCO<sub>2</sub> and peak inspiratory pressures, and decreases blood pressure.<sup>217</sup> Early evidence indicates that laparoscopic surgery yields similar outcomes to the open approach, although the duration of surgery is approximately one-third greater.<sup>218,219</sup> In part, this has been attributed to the learning curve of this technique. Evidence suggests that the laparoscopic approach decreases the length of hospital stay and may decrease postoperative pain<sup>105,219</sup> (see previous discussion of pain management after laparoscopic surgery).

### NEPHRECTOMY

Indications for nephrectomy and partial nephrectomy in children include nonfunctioning kidney, dysplastic kidney, urolithiasis, Wilms or other tumor, end-stage renal failure (pretransplantation or to control hypertension), hemolytic uremic syndrome, and polycystic disease. Children who require a nephrectomy will require a thorough preoperative assessment in terms of history, physical examination, and laboratory testing, depending on their underlying pathology. These children are often anemic because of chronic disease and possibly decreased erythropoietin concentrations. If the child is being staged for kidney transplant, the nephrologists may prefer to avoid blood transfusions at this time. If time is available and the patient is anemic, oral FeSO<sub>4</sub> and vitamin C should be commenced 3 to 6 weeks before surgery (vitamin C increases gut absorption of FeSO<sub>4</sub>) to increase the hemoglobin concentration, particularly if erythropoietin supplementation is planned.<sup>220,221</sup> These children are often small in size and this should be considered when preparing the anesthetic equipment.

Nephrectomies are commonly performed using a retroperitoneal approach with the child in the lateral decubitus position and the table jackknifed. The incision is usually large and located just subcostal to the twelfth rib. If an open approach is planned, a low thoracic epidural catheter may be placed before positioning the child. If, however, a laparoscopic or robotic-assisted approach is planned,<sup>89</sup> then no neuraxial block is necessary but the same surgical approach occurs. Outcomes after laparoscopic nephrectomy in children are similar to those after an open procedure, according to the experience from one center,<sup>222</sup> although recent evidence points to less pain and earlier discharge from the hospital.<sup>89</sup>

### NEUROBLASTOMA

The adrenal glands are located in the retroperitoneal space, adjacent to the superior pole of the kidneys. Masses that arise in the adrenal gland may be tumors, hemorrhage, infections, or cysts. The tumors in the adrenal glands may arise from the cortex (as in adenoma) or medulla (including the sympathetic chain, as in neuroblastoma or ganglioneuroma), and may be either hyperfunctioning or nonfunctioning.

Neuroblastoma is the most common extracranial solid tumor that presents in childhood, comprising 10% of all tumors and 15% of all deaths from tumors.<sup>223</sup> It is the second most common abdominal tumor, after Wilms tumor. Its incidence is approximately 1 in 100,000 children in the United States.<sup>224,225</sup> Neuroblastomas arise in the abdomen in 75% of cases and along the sympathetic chain anywhere from the neck to the pelvis in 25%. Only one-third of those that arise in the abdomen arise in the adrenal glands. The median age at presentation is 2 years, with up to 90% occurring in children under 5 years of age. In some series, up to 50% of the cases appear in the first month of life, with some diagnosed antenatally. This tumor occurs equally in boys and girls. Reports of familial neuroblastoma are rare. However, these tumors may be associated with other disorders, including Beckwith-Wiedemann syndrome, neurofibromatosis, Hirschsprung disease, and central hypoventilation syndrome.<sup>223</sup>

Most neuroblastomas are first detected as palpable masses in the abdomen. Symptomatic presentation may present as local pressure on adjacent organs or structures (liver, kidney, or spine), as metastases (lymph nodes, bone marrow, liver, and skin), or with manifestations of excess neurohumoral production (i.e., from catecholamine [e.g., systemic hypertension] or vasoactive intestine polypeptides [e.g., diarrhea]).<sup>223</sup> Urinary catecholamines are increased in greater than 90% of children (more than 1 year of age) with neuroblastoma. In a minority of instances, the diagnosis is made through incidental examination, either by radiography or ultrasonography.

Staging of these tumors follows two protocols.<sup>224</sup> The International Neuroblastoma Staging System depends on tumor resectability, lymph node involvement, and metastases. However, if patients are not surgical candidates, the staging score holds little relevance. To further stage these tumors, a second scoring system was developed, the International Neuroblastoma Risk Group classification system, which is based on the preoperative radiologic findings only. Survival likelihood depends on a low score, extraabdominal (as opposed to intraabdominal) primary tumor, and younger age. Therapeutic intervention is tailored to the staging of the tumor at presentation and the size of the tumor. Those with favorable tumor biology, no distant metastases, and younger than 18 months of age, are often curable with surgical resection alone. Those with less favorable tumor biology, metastases, and a large tumor size that may present a challenge

surgically, are ideally treated with a combination of chemotherapy, radiation, and/or bone marrow transplantation to reduce the tumor size first, and then with surgical resection. Patients with less favorable biology present a challenge for surgical resection because of local infiltration, large tumor size, and vascular extension. Debulking the tumor with incomplete resection has been met with mixed reviews. The most promising treatments for neuroblastomas with poor prognoses include molecular profiling of the tumor.<sup>224</sup> The long-term survival after treating these tumors is 88% for infants and children less than 18 months of age, 49% for children 18 months to 12 years of age, and 10% for those 12 years old or older.<sup>226</sup> Preoperative assessment requires a general systems review, with particular focus on the organ systems involved with the tumor. These tumors may present as a large intra-abdominal mass that compromises respiration, most commonly manifested as tachypnea. Those with catecholamine-secreting tumors may also present with chronic hypertension. This is mitigated to a large extent if the tumor is shrunk preoperatively, but intraoperative hypertensive episodes still occur in 25% of the children (with urinary catecholamines) during surgery. Children with catecholamine-secreting neuroblastomas should have both  $\alpha$ -adrenergic and  $\beta$ -adrenergic blockades established preoperatively (see previous discussion of pheochromocytoma) to avoid swings in blood pressure during manipulation of the tumor.<sup>227</sup> Less frequently, chronic diarrhea from vasoactive intestine polypeptides may cause chronic dehydration and electrolyte derangements that require correction.

The anesthetic plan depends on the nature and extent of the surgery. A general anesthetic with tracheal intubation and controlled respiration, as well as standard anesthetic monitors, is required. These should be supplemented with invasive monitoring, including arterial and central venous access for catecholamine-secreting tumors, large tumors, and those that are expected to bleed excessively. Anticipation of massive blood loss will necessitate using large bore upper extremity IV access, blood warmers, and possibly a rapid transfusion device. No specific anesthetic regimen has been recommended for these surgeries.

Although the blood pressure may be controlled with established  $\alpha$ -adrenergic blockade, manipulation and squeezing of the tumor during its removal may cause a surge in catecholamine release, necessitating the use of antihypertensive medications intraoperatively (see previous discussion of pheochromocytoma).<sup>227</sup> Labetalol may be effective in children with hypertension during resection of neuroblastomas<sup>227</sup>; however, it may cause paroxysmal hypertension and heart failure in children who have only  $\beta$ -adrenergic blockade established, because of the predominant  $\beta$ -adrenergic blocking action of labetalol.

## WILMS TUMOR

Renal tumors comprise 2.5% to 7% of tumors in children. Wilms tumor is the most common abdominal tumor in children, with an incidence of 8 in 1,000,000 children less than 15 years old, and the most common solid renal tumor beyond the first year of life.<sup>225,228</sup> These tumors arise from persistent immature parenchymal renal tissue (referred to as Wilms tumorlet cells) often in the periphery of the kidney (as opposed to the collecting ducts), enclosed by a pseudocapsule (Fig. 27-11). They may achieve a large size before detection, often compressing adjacent renal parenchyma. Histologically, the tumor often includes up to three distinct tissue cell lines: epithelial, blastemal, and stromal cells.<sup>228</sup> The presence of anaplastic cells (in 4% of Wilms tumors) and, more specifically, whether the cells are focal or diffuse in the

**FIGURE 27-11** A Wilms tumor was mobilized and exteriorized from the abdomen. Note that it is encapsulated and contiguous with the left kidney. (Courtesy Daniel P. Doody, MD, Pediatric Surgery, MassGeneral Hospital for Children, Boston.)

tumor, and older age at the time of presentation suggests a less favorable response to chemotherapy and less favorable long-term prognosis.<sup>228</sup> With tailored multimodal therapy, the survival from Wilms tumor in the past several decades has increased dramatically, from 30% to 90%.

Eighty percent of the children with Wilms tumor present between 1 and 5 years of age (peaking at 3 to 4 years of age), with no gender or racial bias.<sup>225,228</sup> Presentation of Wilms tumor is similar to that of other intraabdominal tumors in the form of an incidental mass on physical examination; approximately 6% are bilateral. Congenital anomalies coexist with Wilms tumors in 12% of children, notably in genitourinary anomalies (5%), hemihypertrophy (2.5%), and aniridia (1%).<sup>228</sup> A number of genetic syndromes predispose to Wilms tumors, including Beckwith-Wiedemann syndrome.<sup>225</sup> Wilms tumors occur twice as frequently in children with horseshoe kidneys than in those with normal kidneys, and is also more frequent in those with multicystic dysplastic kidneys.

Preoperatively, most children with Wilms tumors appear well, presenting with constitutional findings, including weight loss, loss of appetite, and malaise. Occasionally, they have an associated syndrome that should be detailed. Physical examination includes a palpable abdominal mass in 75% to 90% of children. Laboratory investigations before nephrectomy include routine complete blood count, electrolytes, renal function, as well as coagulation indices. Polycythemia may be present from tumor-induced excess erythropoietin production. Acquired Von Willebrand disease is present in less than 10% of these children.<sup>225</sup> Blood should be cross-matched for the surgery. Microscopic hematuria occurs in 25% of children whereas gross hematuria is rare,<sup>228</sup> suggesting tumor invasion of the collecting ducts. Systemic hypertension is present in 25% of children, presumably as a result of hyperreninemia. Preoperative investigations should include radiography and ultrasonography, the latter highlighting hyperechogenic structures within the kidney. Tumor extension into the ipsilateral renal vein and inferior vena cava must be examined before embarking on surgery, as chemotherapy may lead to involution of these tumors (Fig. 27-12).<sup>225</sup> Magnetic resonance imaging and computed tomography are valuable tools for delimiting the tumor borders within the kidney, as well as metastases in the lungs or other organs.<sup>225</sup> Most recent summaries of

**FIGURE 27-12** Coronal view of the CT scan of a Wilms tumor. Note the massive tumor enveloping the inferior vena cava, as the vena cava is only visible where it enters the liver in the upper midportion of the radiograph (arrow). (Radiograph courtesy Daniel P. Doody, MD, Pediatric Surgery, MassGeneral Hospital for Children, Boston.)

the radiologic investigations may determine the need for additional interventions, including echocardiogram and lung scan to determine the presence of tumor in the heart and lungs, respectively. An echocardiogram may be specifically required to evaluate myocardial function if doxorubicin and other anthracycline chemotherapeutic agents had been administered.<sup>225</sup>

Anesthetic management of children with Wilms tumor is similar to that with neuroblastoma. No specific anesthetic regimen is preferred. Invasive monitoring and large bore IV access (upper extremities to avoid interference from tumor extension into the inferior vena cava) with adequate blood warming capability is mandatory. Anesthesia may be further complicated by hypertension (precipitated by tumor handling), coagulopathy (acquired von Willebrand disease), extension of the tumor into the proximal inferior vena cava or right atrium, pulmonary tumor emboli, acute right heart failure, and considerations concerning preoperative or previous treatment with chemotherapeutic drugs.<sup>225</sup> These drugs may impair hepatic or hematopoietic function (actinomycin D), cause inappropriate antidiuretic hormone release (vincristine), or myocardial damage (doxorubicin).<sup>225</sup> Pain may be controlled using either IV or regional anesthesia, though the risk of a coagulopathy must be ruled out before administering an epidural block.

### BLADDER AND CLOACAL EXSTROPHY

Bladder exstrophy is a rare congenital anomaly of the genitourinary tract occurring in 1 in 50,000 births with a 2:1 male to female ratio.<sup>229</sup> It occurs as a failure of the abdominal wall to close during fetal development and results in defects of the anterior wall of the bladder and overlying midline abdominal wall. Bladder exstrophy may present with a spectrum of anomalies,

**FIGURE 27-13** Bladder exstrophy in a neonate. Note the open anterior abdominal wall, protuberant bladder, distorted genitalia, and splayed hips.

including widening of the symphysis pubis, and genital anomalies, such as epispadias, bifid clitoris, and undescended testes (Fig. 27-13). Some regard bladder and cloacal exstrophies as distinct entities, whereas others consider them both extremes in a continuum of antenatal defects. Cloacal exstrophy includes features of bladder exstrophy plus an omphalocele and spinal defects, and always includes imperforate anus. Because the antenatal diagnosis of bladder exstrophy using ultrasound may be technically difficult, and thus dependent on indirect signs (absence of bladder filling, a low-set umbilicus, widening of the pubic ramus, small external genitalia, or a lower abdominal mass), the diagnosis is confirmed at birth when the anterior abdominal wall defect with the exposed bladder mucosa are evident.

Therapy is aimed at the surgical reconstruction of the bladder with preservation of renal function while achieving urinary continence and satisfactory appearance of the external genitalia. Surgical repair is usually achieved via a planned surgical approach.<sup>230,231</sup> In a very carefully selected group of infants, surgical management may be carried out as a single-stage procedure.<sup>232</sup> Alternatively, a planned staged surgical repair may be chosen with management directed at closure of the bladder, posterior urethra, and abdominal wall. In addition, a bilateral iliac osteotomy is often performed to facilitate surgical closure, decrease the stress on the midline soft tissues, and reduce the risk of postoperative wound dehiscence.

Wound dehiscence, bladder prolapse, and multiple attempts at bladder closure are among the risk factors for decreased bladder growth and the inability for the later development of continence.<sup>233</sup> In addition to the immediate postoperative complications, children who have undergone surgical repair of bladder exstrophy carry an increased risk for the development of renal, bladder, and colon adenocarcinoma.<sup>234</sup> Children who require frequent bladder catheterizations or repeat surgeries are at risk for developing latex allergy if latex products are used.<sup>56</sup> Today, most bladder catheters exclude latex.

Surgical management of the epispadias is usually performed at 6 to 12 months of age, and reconstruction of the bladder neck by 5 years, the latter to allow for bladder training. After the initial surgical repair, children are immobilized for 4 to 6 weeks,<sup>235</sup> with a successful outcome likely when a modified Buck traction with an external fixator or a modified Bryant traction<sup>236</sup> and adequate postoperative analgesia are used.<sup>237</sup>

The preoperative assessment should evaluate the presence and severity of all congenital anomalies, particularly cardiac abnormalities. Signs or symptoms of renal insufficiency and electrolyte balance may be present. If the child has renal insufficiency, the dose and frequency of administration of potentially nephrotoxic drugs, as well as the commonly used anesthetic drugs, must be carefully evaluated. Typically, surgery is performed with the child in the supine and lithotomy positions. The duration of surgery is often prolonged, requiring alternating urologic and orthopedic teams for their respective segment of the surgery, and repositioning the child depending on the stage of the surgery. These neonates require judicious management of fluids, blood loss, and temperature control, as is typical for surgical procedures in the neonatal period. In formulating the anesthetic plan, the anesthesiologist must partner with the surgical teams to ensure an optimal strategy for balanced salt solutions, colloids, and blood products. This allows for optimal intraoperative management, as well as planning for a multimodal perioperative pain management strategy and postoperative ventilatory support, if needed. After applying the standard monitors, anesthesia may be induced either by inhalation or IV; after induction, at least one large bore peripheral IV should be placed. A second IV may be placed, or a central venous catheter and possibly an arterial catheter. In general, if blood loss occurs, it is slow and steady, but if posterior iliac osteotomies are performed, the blood loss may become brisk, requiring aggressive fluid resuscitation and administration of blood products. Beat-to-beat variability of arterial blood pressure and serial laboratory evaluations are valuable during goal directed resuscitation. Appropriate padding, a fluid warmer, and a forced-air heating system should be standard. The anesthetic plan varies according to the age of the child and whether the surgery is completed in a single or staged repair. Postoperatively, children are transferred directly to the pediatric intensive care unit for recovery. Careful attention must be paid to maintain fluid and electrolyte homeostasis, to prevent reduced oxygen carrying capacity, and to assure adequate analgesia.

A general anesthetic in combination with an epidural or caudal continuous infusion technique is often used if there are no associated spine abnormalities.<sup>238</sup> Opioids (other than remifentanyl) have had a limited role in neonates because of their potential to cause postoperative respiratory depression, although pediatric anesthesiologists today are much more aggressive in anticipating pain and administering opioids to neonates and infants, even if it delays extubation.

Maintenance of anesthesia may be achieved using an inhalation anesthetic, small doses of opioids, and intermittent boluses (0.5 to 1 mL/kg) or continuous infusions of bupivacaine (0.125% to 0.25%) or ropivacaine (0.2%) with or without epinephrine through a lumbar or caudal epidural catheter. Caudal or epidural analgesia may be provided by advancing the catheter to the appropriate surgical dermatomal level after induction of anesthesia. The catheter is either secured directly to the skin or tunneled using the epidural insertion needle.<sup>239</sup> A continuous infusion of a local anesthetic may be used and maintained for up to 3 days to provide analgesia and a mild motor blockade that favors immobility. However, care must be taken to avoid systemic toxicity. Neonates are at increased risk for developing local anesthetic toxicity because of their low serum protein concentration and metabolism. Albumin and  $\alpha$ 1-acid glycoprotein are reduced in this age group,<sup>240</sup> which reduces protein binding and increases the free-fraction of bupivacaine. This free form is metabolized to a lesser extent in the neonate because of immature metabolic

pathways, and contributes to an increased risk of cardiac and systemic toxicity.<sup>241,242</sup> This is especially true of the amide local anesthetics. If the epidural infusion is maintained beyond 48 to 72 hours, serum concentrations of local anesthetic should be sampled once or twice a day to guide therapy and minimize the risk of complications. Because serum concentrations of bupivacaine increase after only 48 hours of a continuous epidural infusion,<sup>241</sup> and serum concentrations are difficult to assay, lidocaine 0.1% (0.8 mg/kg/hr) may be preferable. Ropivacaine is also currently being used for infusions that last less than 72 hours.<sup>243</sup>

The outcome of this complex surgery is determined primarily by the surgical expertise. Urologic incontinence, bladder prolapse, and epispadias revisions will require additional urologic surgery, as well as possible osteotomies, for satisfactory closure and surgical outcomes. Renal function is usually well-maintained throughout. Complications of complete repair are reported to be similar to those of the staged repair, but usually involve additional soft tissue defects.<sup>244</sup>

Summary

## Anatomy

THE LIVER AND BILIARY TREE are derived from the endoderm of the dorsal foregut during the late third to the early fourth week of gestation. By the sixth week, the fetal liver primarily serves as a hematopoietic organ, while critical biologic functions such as glycolysis, bile acid synthesis, and metabolic waste processing are managed by the maternal liver through the fetoplacental circulation. Oxygenated blood is shunted from the placenta to the right atrium through the ductus venosus. Functional closure of the ductus begins immediately after birth, with complete functional closure occurring in up to 95% of infants by 2 weeks of age and anatomic closure taking place shortly thereafter.

Hepatic developmental changes occur throughout gestation. Hepatic hematopoiesis develops in utero at 5 to 6 weeks gestation, followed closely by protein synthesis.<sup>1</sup> The ability to metabolize carbohydrates and lipids begins by 10 weeks gestation, followed closely by the development of drug metabolizing systems.

At the time of delivery, the liver weighs between 120 and 160 g but remains structurally and physiologically immature. Peripheral branches of the intrahepatic biliary system require an additional 4 to 8 weeks before portal bile ducts can be identified histologically. The liver is composed of eight structurally independent segments, and each contains a feeding hepatic artery, portal vein, draining hepatic vein, and bile duct. Segment 1 is the caudate lobe. Segments 2 and 3 form the left lateral segment, and with segment 4, the left lobe of the liver is defined. Segments 5, 6, 7, and 8 constitute the right lobe of the liver.

The liver receives blood from two sources: the portal vein, which drains the spleen and intestine, and the hepatic artery, which provides systemic oxygenated blood directly to biliary epithelium and to the hepatic sinusoids. The portal vein accounts for approximately 70% of the blood flow to the liver. In the sinusoids, the hepatic arterial and portal venous blood mix and intercalate among the hepatocytes, fenestrated sinusoidal cells, and a host of resident immune cells (e.g., Kupffer cells). Sinusoids drain into terminal hepatic venules, which eventually coalesce to form the left and right hepatic veins. The veins merge into the

inferior vena cava immediately before entering the right atrium. At any time, the liver contains approximately 13% of the circulating blood volume.

During the neonatal period, liver function is immature in its ability to metabolize and clear xenobiotics. Factors believed to affect the clearance of medications include hepatic blood flow and the developmental status of hepatic transport and enzyme systems. Size alone does not account for this observed degree of immaturity, because the fetal and neonatal liver account for a greater percentage of body weight than the adult counterpart (3.6% of body weight versus 2.4% in adults).<sup>2</sup> The neonatal liver contains approximately 20% fewer hepatocytes than the adult liver, and the cells are almost one half of the size of adult hepatocytes. These structural features may play some role in the functional deficiencies exhibited by infant livers. Cellular growth and hypertrophy of the liver continue at a rapid pace into young adulthood.

The structural unit of the liver parenchyma is the lobule, a hub-and-spoke structure with the central vein serving as the hub that is bordered by portal tracts, which contain a bile duct and tributaries of the portal vein and hepatic artery. While the mixed venous and arterial blood flows from the portal tract to the central vein, bile flows in the opposite direction through a canalicular matrix that then enters the bile ductule in the portal tract. The functional unit of the liver is the hepatic acinus, which is centered on the portal track and extends in three concentric zones (i.e., zones of Rappaport) outward to the central vein (Fig. 28-1). The more central zones (zones 1 and 2) are most active in oxidative processes, whereas the distal zone 3, which is closer to the central vein, is more dependent on glycolysis and more susceptible to ischemic and toxic injury.

## Principles of Hepatic Drug Metabolism

Lipid solubility, an important and desired feature of most administered drugs, allows passive diffusion across cellular membranes. Lipophilic drugs are also difficult to excrete. They have a propensity to accumulate in the body's fat stores and are bound to proteins in plasma, thereby limiting renal excretion. Renal and

**FIGURE 28-1** Blood flows from the hepatic arteries and portal vein along the sinusoids toward the central vein. The hepatic triad consists of the bile duct, a branch of the portal vein, and the hepatic artery, with zone 1 (white) surrounding the triad, followed by zone 2 (pink), and zone 3 (red). Cytochrome P-450 expression is higher in zone 3, which has more extensive drug metabolism. (From Oinonen T, Lindros KO. Zonation of hepatic cytochrome P-450 expression and regulation. *Biochem J* 1998;329:17-35.)

biliary excretion of lipid-soluble compounds can result in their resorption across their respective membranes. A major role of the liver is to transform lipid-soluble drugs into water-soluble compounds that become easily excreted metabolites. An interesting example of the need for this biotransformation is the anesthetic compound thiopental, which if not transformed into its less lipophilic counterpart would have a plasma half-life of approximately 25 years.<sup>1</sup>

The primary family of liver enzymes assigned the task of metabolizing these exogenous substances is the cytochrome P-450 (CYP) family. *P* designates a red *pigment*, which is related to a heme molecule and absorbs light at a wavelength of 450 nm.<sup>3</sup> The primary reactions involved in the drug biotransformation and metabolism are hydroxylation and conjugation. Hydroxylation prepares the metabolite for conjugation (i.e., phase II reaction). The CYP family of enzymes is responsible for most phase I reactions, and the members were first thought to be chemically similar to mitochondrial cytochromes.

### PHASE I REACTIONS

The CYP enzymes likely evolved as a mechanism by which the host was able to protect itself from toxins ingested from the environment. Most enzymes involved in hepatic drug metabolism are categorized in three distinct families: CYP1, CYP2, and CYP3. Each family is further divided into subfamilies that are designated with capital letters and numbered in the order in which they were discovered. The CYP enzymes are generally conserved across species, but their regulation and catalytic activity vary among species, which highlights the challenges associated with laboratory analysis of drug metabolism.<sup>3</sup>

Genetic and nongenetic factors contribute to the variability in the enzymatic activity seen across all CYP enzymes.<sup>4</sup> Approximately 5% of Caucasian populations lack CYP2D6 activity, which is associated with altered metabolism of some drugs.<sup>5</sup> For

example, a lack of CYP2D6 activity enhances the effect of drugs such as haloperidol and metoprolol that require the enzyme for efficient metabolism, whereas codeine, which is metabolized to morphine by CYP2D6, provides little analgesia in a child with CYP2D6 deficiency.<sup>6</sup>

Nongenetic factors that influence CYP activity include concomitant disease states, malnutrition,<sup>7</sup> and exposure to a host of pharmacologic and naturally occurring compounds. Many drugs can inhibit or stimulate the enzyme system (Table 28-1). Inhibition of the CYPs occurs when drugs compete for the same enzyme. The degree to which this competition becomes clinically significant depends on five factors: the relative amount of the specific CYP, the concentrations of each drug, the degree of pharmacologically active metabolite generated through this system, the importance of the enzyme in elimination of the drugs, and the therapeutic index of the drug.<sup>3</sup>

Enhanced CYP expression occurs after amplified transcription of the specific gene that is induced by a variety of compounds. For example, rifampin and phenytoin induce CYP3A4 by binding the cytosolic human pregnenolone-X receptor (hPXR) or the steroid xenobiotic receptor (SXR).<sup>8</sup> The activated receptor translocates into the nucleus, where it binds the regulator elements of the *CYP3A4* gene and promotes increased transcription of CYP3A4, which can lead to toxic levels of intermediate

**TABLE 28-1** Major Human Liver Forms of Cytochrome P-450

P-450	Substrate	Inhibitors	Inducers
CYP1A2	Caffeine Clozapine Estradiol Theophylline	Fluvoxamine Furafylline	Omeprazole Tobacco smoke
CYP2A6	Halothane Nicotine	Methoxsalen

compounds, as is the case with erythromycin, or to subtherapeutic levels of cyclosporine in transplant recipients.<sup>9</sup>

### CYTOCHROME P-450 ACTIVITY

The superfamily of CYP enzymes is divided into subfamilies based on sequence homology and on demonstration of broad substrate specificities. An important example is the CYP3A subfamily, which is the most abundant group of cytochromes involved in the metabolism of xenobiotics. The three identified isoforms are CYP3A4, CYP3A5, and CYP3A7. CYP3A4 is the most abundant single enzyme in the human liver, accounting for the metabolism of approximately 50% of clinically used pharmaceuticals.<sup>10</sup> CYP3A5 is more commonly found in the kidneys and lungs and to a lesser degree in the liver. CYP3A7 is the predominant isoform in the neonatal liver but is replaced after birth by CYP3A4. Given its critical involvement in hepatic biotransformation of xenobiotics, the CYP3A family of enzymes is used to study and estimate hepatic drug clearance in various age and gender groups.

Changes in the distribution and activity of the CYP enzyme systems occur with hepatic growth and maturation (Fig. 28-2). The CYP3A family is homogeneously distributed across the liver parenchyma in the fetal liver and shortly after birth. However, during postnatal growth, expression of the CYP3A protein shifts toward the centrilobular region of the acinus (i.e., Rappaport zone 1). By adulthood, expression of CYP2A becomes increasingly limited to the zone 1 and zone 2 hepatocytes, with sparse expression occurring in zone 3.<sup>11</sup> Other examples of developmental changes in the CYP system include the CYP2C and CYP3A3/4 subfamilies, which have negligible expression in the fetus but have increased expression in the first few weeks of life.<sup>12,13</sup> CYP2D6 reaches adult activity levels within 1 month chronological age; variability thereafter is determined primarily by genetic polymorphisms.<sup>13a</sup>

Changes in activity of CYP enzyme families and subfamilies have correlated with drug clearance. For example, midazolam clearance correlates with changes in CYP3A4 activity, with decreased clearance in fetal and neonatal livers and with adult clearance rates achieved by 3 months of age.<sup>14,15</sup> In contrast,

CYP3A7 activity peaks at about 1 week postpartum and steadily diminishes during the first year of life, reaching approximately 10% of fetal liver activity by adulthood.

### PHASE II REACTIONS

Conjugation of lipophilic compounds decreases their lipid solubility and facilitates renal excretion.<sup>16,17</sup> Conjugation reactions (i.e., glucuronidation, sulfation, glutathione conjugation, acetylation, and methylation) are decreased in infants compared with adults.<sup>18</sup>

Glucuronidation is catalyzed by uridine 5'-diphosphate (UDP)-glucuronosyltransferase (UGT) family of enzymes, which are derived from assimilation of proteins from separate genes or alternate splicing from single-gene transcripts.<sup>19</sup> UGT enzymes are responsible for the metabolism of several drugs, including phenols, estrogens, and opioids (see Chapter 6). As with the CYP enzymes, individual UGT enzymes demonstrate substrate specificity and can act in concert to metabolize single compounds. Glucuronidation is not fully active in infants and can place this population at risk for toxic drug accumulation.<sup>20</sup> Hepatic UGT enzyme concentrations are reduced during fetal and early postnatal development. At 3 months of age, the levels of many UGTs are 25% of those in adults.<sup>21</sup>

UGT1A enzyme activity, which is involved in the conjugation of bilirubin and ethinylestradiol, is decreased in the fetus, but it increases to adult levels within 3 to 6 months after a term delivery.<sup>22</sup> UGT1A6, which conjugates acetaminophen and naproxen, has 10% of adult activity in the fetus and neonate, and it achieves only 50% of adult activity by 6 months of age.<sup>18</sup> UGT2B7 is active in the metabolism of the nonsteroidal antiinflammatory drugs naloxone, codeine, and lorazepam. Fetal activity of this enzyme approaches 10% to 20% of adult levels, with a rapid increase to adult levels by 2 months of age.<sup>23</sup>

Sulfation is accomplished by sulfotransferases, a family of cytosolic enzymes that are divided into two categories: catechol and phenol sulfotransferase. These enzymes conjugate inorganic sulfate from 3'-phosphoadenosine-5'-sulfophosphate (PAPS) with compounds containing functional hydroxyl groups.<sup>16</sup> The catechol transferases develop earlier in fetal life than the phenol counterparts and appear to exhibit decreased activity in the developing neonate. Although specific sulfotransferase substrates require identification, the activity of these enzymes is increased in fetuses and neonates and theorized to be an efficient conjugation pathway in this age group.

Glutathione *S*-transferases (GSTs) conjugate glutathione with a broad spectrum of lipophilic and electrophilic compounds. The family of GSTs is composed of up to five different groups in various classes designated  $\mu$ ,  $\alpha$ ,  $\theta$ , and  $\pi$ , which are derived from at least three genetic loci.<sup>24</sup> Tissue-specific expression of these enzymes has been demonstrated, with the liver expressing the greatest amount of protein. Variable time-dependent expression has also been shown, with  $\alpha$ - and  $\pi$ -class GSTs having enhanced expression between 16 and 24 weeks gestation, whereas only the  $\alpha$ -class enzymes predominate in the neonate and adult liver.<sup>25</sup> The hepatic  $\pi$ -class enzymes disappear from their hepatocellular location by 6 months of age and can be found only in the epithelial cells of the biliary canaliculi. Variations in the developmental expression of this class of enzymes have made it challenging to fully appreciate what is likely a multitude of clinical interactions.<sup>25</sup>

Acetylation reactions are catalyzed by *N*-acetyltransferases, which transfer an acetyl group from acetyl coenzyme A to a

**FIGURE 28-2** Changes in metabolic capacity versus percentage of adult activity. (Modified from Kearns G, Abdel-Rahman SM, Alander SW, et al. Developmental pharmacology—drug disposition, action, and therapy in infants and children. *N Engl J Med* 2003;349:1157-67.)

variety of substrates (e.g., *p*-aminobenzoic acid, *p*-aminosalicylic acid, procainamide). Two genes, *NAT1* and *NAT2*, are responsible for yielding two specific enzymes with different allelic forms. Despite having 87% sequence homology, these enzymes exhibit different substrate specificities.<sup>26</sup> Both are cytosolic enzymes involved in the biotransformation of several drugs and the bioactivation of several human carcinogens. *NAT1* is present in multiple fetal and postnatal tissues and accounts for the most *N*-acetyltransferase substrate metabolism in children younger than 1 year of age. *NAT2* is located primarily in the liver and becomes the dominant acetylator after 1 year of age. *NAT2* has polymorphisms with enzyme kinetics that differentiate patients with slow or rapid acetylation capabilities. Infants younger than 1 year of age usually are slow acetylators; subsequent age-dependent alterations lead an individual's targeted acetylator status.<sup>27</sup> Individuals who are genetically destined for rapid acetylation manifest this feature by 2 to 4 years of age.

## Anesthetic Agents

### INHALATIONAL ANESTHETIC METABOLISM

Inhalational anesthetics are poorly metabolized, with 15% to 20% of halothane undergoing biotransformation. Although both oxidative and reductive pathways are involved, the primary pathway of metabolism of halothane is through oxidation to a reactive intermediate, trifluoroacetyl chloride,<sup>28</sup> which then undergoes glutathione conjugation.<sup>29</sup>

Isoflurane is metabolized by CYP2E1 to a limited extent (0.2%).<sup>30</sup> Isoflurane is excreted as inorganic fluoride and trifluoroacetic acid after oxidative metabolism in the liver.<sup>31</sup> Desflurane is the least metabolized (0.02%) of the volatile anesthetics, which is approximately 10% of the rate of isoflurane.<sup>32</sup> Both are metabolized in the liver along similar paths because the urinary metabolite for desflurane, trifluoroacetic acid, is the same as for isoflurane.

Only 2% to 5% of inhaled sevoflurane is metabolized in humans by means of the hepatic CYP2E1 enzyme, as occurs for the other ether anesthetics.<sup>33</sup> Oxidation of sevoflurane generates the intermediate formyl fluoride, a highly reactive species thought to generate liver protein adducts. Carbon dioxide and inorganic fluoride are released through this oxidative mechanism, and the final product is hexafluoroisopropanol, which undergoes glucuronide conjugation and is further excreted in the urine (see Chapter 6).<sup>34</sup>

### NEUROMUSCULAR BLOCKING DRUGS

Neuromuscular blockade is achieved by depolarizing or nondepolarizing neuromuscular blocking agents (see Chapter 6). The only depolarizing agent still in use is short-acting suxamethonium (i.e., succinylcholine).<sup>35</sup> Succinylcholine is hydrolyzed completely by plasma cholinesterases, which are synthesized by the liver.<sup>36</sup> Enzyme activity varies with age, but it is decreased in liver disease and has been used as a metric of liver prognosis.<sup>37</sup>

Nondepolarizing muscle relaxants are divided into aminosteroids (i.e., pipecuronium, pancuronium, vecuronium, and rocuronium) and benzylisoquinolinium diesters (i.e., doxacurium, atracurium, and cisatracurium besylate). Renal and hepatic diseases affect their safety and efficacy.<sup>38</sup> Hepatic elimination depends on protein binding, hepatic blood flow, and drug extraction. The volume of drug distribution is increased in hepatic disease, leading to a slower onset and prolonged effect. In children with cholestatic liver disease, such as biliary atresia, uptake of

these compounds by the liver is decreased, which decreases plasma clearance and prolongs their effects.<sup>39,40</sup> Approximately 75% of the administered dose is bound to plasma proteins, with most bound to albumin. Despite these problems, children with liver disease and a correspondingly low albumin concentration are at minimal risk for the adverse effects from this group of drugs.<sup>41</sup>

Rocuronium is an analogue of vecuronium with a more rapid onset of action. Unlike other aminosteroids, which largely undergo renal excretion, only 12% to 22% of rocuronium is cleared through the kidney.<sup>42</sup> In patients with hepatic disease, the volume of distribution of rocuronium increased by 33% compared with healthy controls.<sup>43</sup> In patients undergoing liver transplantation, the clearance of rocuronium was only slightly reduced by the diseased native liver compared with the functioning allograft and healthy individuals.<sup>44</sup> Reduced infusion requirements of rocuronium during liver transplantation may indicate graft dysfunction.<sup>45</sup>

Hepatic elimination of the benzyl isoquinolinium agents is poorly understood, but hepatic dysfunction has been observed to affect their efficacy. Despite increased concentrations in biliary secretions, the pharmacokinetics of doxacurium are unchanged in the presence of hepatocellular injury, but recovery indices are prolonged.<sup>46</sup> Although no longer available in the United States, mivacurium is a mixture of three stereoisomers. Clearance of the *trans-trans* and *cis-trans* isomers is reduced in patients with liver disease,<sup>47</sup> whereas clearance of the *cis-cis* isomer is unchanged. Prolonged recovery occurs as a result of a decrease in plasma cholinesterases in significant liver disease.<sup>47</sup> Clearance of cisatracurium is decreased, although patients with liver disease experience no delay in recovery and minimal delay in onset of action. Children with liver disease, regardless of cause, usually tolerate this class of compounds, and there is no observed toxicity.<sup>48</sup>

### SEDATIVES, OPIOIDS, AND LIVER DISEASE

The commonly used sedatives midazolam, propofol, and ketamine undergo hepatic metabolism through oxidation and conjugation. These compounds are all lipid soluble, and their effects are altered by liver disease.<sup>49</sup> Midazolam has an increased clearance rate that depends in part on hepatic blood flow. In children with cirrhosis, the clearance of midazolam is halved with a corresponding doubling of the half-life compared with healthy controls.<sup>50</sup> With 95% to 97% bound to albumin, diseases that decrease the concentration of albumin dramatically increase the free fraction of drug, which leads to a greater effect.<sup>51,52</sup> Propofol is eliminated primarily (>88%) in the urine, and hepatocellular injury does not alter its pharmacokinetics.<sup>53</sup> Ketamine is also highly lipophilic and undergoes metabolism in the liver. However, unlike the other drugs described, it does so through methylation, and its clearance is minimally affected by liver dysfunction.<sup>54</sup>

Clinical effects from opioids result from their binding to opioid receptors. A greater serum concentration of opioid binds a greater number of receptors, resulting in a correspondingly greater opioid effect. Hepatic clearance and protein binding govern the serum concentration of an opioid.<sup>55</sup> Most opioids are oxidized in the liver. However, morphine and buprenorphine undergo glucuronidation, and remifentanyl is metabolized by plasma and tissue esterases, enzymes that are mature in term neonates. The ability of the diseased liver to oxidize opioids is diminished, leading to increased oral bioavailability due to decreased first-pass metabolism and decreased drug clearance. The clearance of morphine, despite being metabolized by glucuronidation, is also negatively affected by the presence of cirrhosis.<sup>56</sup>

Clearance of drugs that are highly extracted by the liver, such as meperidine and morphine, depend on hepatic blood flow.<sup>57,58</sup> Clearance (CL) is a function of hepatic blood flow ( $Q_H$ ) and the extraction ratio ( $E_H$ ), describing the ability of the liver to efficiently remove the drug from the circulation:

$$CL_H = Q_H \cdot E_H$$

When  $E_H$  is greater than 0.7, as with meperidine, lidocaine, and pentazocine,  $CL_H$  approaches  $Q_H$ . Conditions that alter hepatic blood flow, such as cirrhosis, portal vein thrombosis, and portacaval shunting, significantly alter opioid clearance. Drugs with a low  $E_H$ , such as methadone and naproxen, do not depend on hepatic blood flow. The metabolic activity of the liver and the plasma protein-binding fraction affect the clearance to a greater degree. The hepatic clearance of these drugs is described by the following equation:

$$CL_H = CL_{INT} \cdot f_u$$

In the formula,  $f_u$  is the fraction of unbound drug and  $CL_{INT}$  describes the metabolic activity. When  $f_u$  is small as with methadone (<0.1), clearance is mainly affected by reduced enzyme capacity.<sup>55</sup>

The pharmacology of the opioids is variably affected by liver disease. The analgesic effect of codeine, obtained after its demethylation to morphine, is reduced in the presence of liver disease. Liver disease can affect glucuronidation and thereby decrease clearance and prolong the half-life of morphine.<sup>59</sup> The protein binding and clearance of alfentanil are reduced in the presence of hepatic dysfunction,<sup>60,61</sup> whereas the half-life and volume of distribution of methadone are increased.<sup>62</sup> The pharmacokinetics of fentanyl, remifentanyl, and sufentanil are unchanged in the presence of significant hepatic dysfunction.<sup>63-65</sup> Because the degree of hepatic dysfunction exhibits interindividual variability, the level of adverse events of these medications also varies. Careful monitoring of children with liver disease is required when administering opioids.

## Anesthetic Effects on Hepatic Cellular Functions

### CARBOHYDRATES

Glucose metabolism is influenced by the availability of the substrate, the rate of entry into cells, and the ability of the target organ to convert glucose into energy or to use it to synthesize fats. In healthy individuals, hepatic glucose production accounts for most whole-body glucose production and is narrowly regulated directly and indirectly by insulin.<sup>66</sup> Insulin directly inhibits gluconeogenesis and glycogenolysis by binding to insulin receptors in the liver, thereby diminishing hepatic glucose production.<sup>67</sup> Of the glucose available to the liver, about 50% undergoes glycolysis and is converted to energy. Between 30% and 40% is converted to fat for storage, and 10% to 20% is shunted to glycogen.<sup>68</sup> Anesthetics inhibit glucose uptake by hepatocytes, an action referred to as the *anti-insulin effect of anesthesia*.<sup>69</sup> Although all inhalational anesthetics exhibit this tendency, halothane has the greatest impact on serum glucose, with isoflurane and sevoflurane having lesser effects.<sup>70</sup> Inhalational anesthetics at 1 to 2 minimal alveolar concentrations (MACs) inhibit glucose uptake by up to 50%. The combined effects of anesthetics and stress from surgery or trauma increase the serum glucose concentration,

which is one reason why glucose-containing intravenous fluids are no longer recommended for most healthy children undergoing elective surgery.

### PROTEIN SYNTHESIS

The impact of anesthesia and surgery on protein synthesis and metabolism is poorly understood. Albumin, a large, soluble, single polypeptide protein with a molecular weight of 66 kD, is an important protein synthesized by the liver. Between 6 and 12 g of albumin are produced each day, and production can increase twofold to threefold according to the individual's needs. Albumin functions as a binding and transport protein and maintains colloid oncotic pressure. Hepatic dysfunction may result in decreased synthesis of albumin and other proteins. Anesthetics may also inhibit protein synthesis. Diethyl ether causes reversible inhibition of protein synthesis in rat hepatocytes,<sup>71</sup> whereas halothane and enflurane block protein synthesis in a dose-dependent manner.<sup>72</sup> Halothane, sevoflurane, and enflurane inhibit protein synthesis and secretion, which may be an early indicator of hepatic cytotoxic injury.

### BILIRUBIN METABOLISM

Bilirubin, the end product of heme metabolism, is converted to unconjugated bilirubin by macrophages in the spleen and bone marrow and transported to the liver bound to plasma albumin. Unconjugated bilirubin is transported into the hepatocyte by bile acids and bacterial endotoxins. In the hepatocyte, bilirubin is conjugated with glucuronate, taurine, and to a lesser extent, glucose by glucuronyl transferase. Deficiencies of glucuronyl transferase manifest clinically in Gilbert syndrome, with more severe forms seen in Crigler-Najjar syndrome types I and II. Gilbert syndrome affects 2% to 13% of individuals, who have increases in bilirubin associated with stress or fasting. Although postoperative jaundice has been described, Gilbert syndrome has not been associated with serious adverse effects in the perioperative anesthesia period.<sup>73</sup> Patients with Crigler-Najjar syndrome can be managed safely by minimizing their exposure to drugs that may displace bilirubin from albumin and by using anesthetics that undergo minimal hepatic metabolism.<sup>74</sup>

### HEPATOTOXICITY

Increases in serum aminotransferase concentrations and bilirubin up to two times the upper limit of normal occur commonly in the postoperative period.<sup>75,76</sup> These increases are typically self-limited and inconsequential. However, serious liver injury can be caused by anesthetics.<sup>77</sup> The Drug-Induced Liver Injury Network, established by the National Institutes of Health in 2003, has and continues to standardize the nomenclature and causality assessment of drug-induced liver injury (DILI).<sup>78</sup> Diagnosis of DILI is entertained when increases in alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase,  $\gamma$ -glutamyl transferase (GGT), and bilirubin occur coincident with xenobiotic exposure. Patterns of injury are classified as hepatocellular, with predominantly increased ALT and AST levels; cholestatic, with increases in alkaline phosphatase, GGT, and bilirubin; and mixed pattern, with features of both hepatocellular and cholestatic injury. Differences between predictable and unpredictable DILI and the associated clinical and histologic variability led to the clinical pearl known as the *Hy rule*, named after Hyman Zimmerman: If increased serum aminotransferase

levels (greater than three times the upper limit of normal) and cholestasis (bilirubin greater than two times the upper limit of normal) without evidence of biliary obstruction occur at the same time in the setting of DILI, a mortality rate of at least 10% can be expected.<sup>79</sup>

In the absence of a unique test to assess liver function, surrogate markers for liver dysfunction include a prolonged prothrombin time (PT) greater than 15 seconds or an international normalized ratio (INR) greater than 1.5, or both. Other clinical and biochemical markers, such as hypoalbuminemia, hypoglycemia, and an altered mental status, should be included in the assessment of hepatic dysfunction, but they can also result from conditions not related to liver function, such as malnutrition, protein-losing enteropathy or nephropathy, or medications for sedation or pain management.

Halothane hepatitis is well described and used as a model for hepatotoxicity of all inhalational anesthetics.<sup>80-85</sup> Patients who develop halothane hepatitis typically have no history of preexisting liver disease, alcohol use, or concurrent exposure to other hepatotoxic drugs. The incidence is small, with 1 case reported for every 10,000 to 30,000 patients, making it difficult to clinically establish a causal link between exposure to halothane and the development of liver injury. Although halothane hepatitis can occur in all age-groups, the most common demographic is the obese, middle-aged woman. Although liver injury can occur after a single exposure, recurrent exposure to halothane, particularly when the interval between exposures is brief, increases the risk of liver injury and, in some cases, of liver failure. Health care workers exposed to halothane are also at increased risk through occupational exposure.<sup>86</sup>

The clinical symptoms observed in patients with halothane-induced liver injury are nonspecific and include malaise, fatigue, and anorexia. Patients may have subtle gastrointestinal symptoms such as nausea and abdominal pain. Some patients develop fever (albeit delayed), nonspecific rash, and arthralgias. Increases in serum transaminases are observed after exposure, with some patients becoming jaundiced. Jaundice can occur as late as 28 days after exposure. Many who develop halothane hepatitis do not progress to liver failure, and the inflammation usually resolves.<sup>87</sup> If continued exposure to halothane does not occur, chronic liver disease usually does not develop. However, in a few selected patients, fulminant hepatic failure does occur, and the mortality rate associated with developing halothane-induced hepatic necrosis is 20% to 50%.<sup>88</sup> A mild form of DILI occurs in up to 30% of patients after exposure. They tend to be asymptomatic and have increased transaminase levels, but they lack the serologic markers for immune activation, a feature common among those who develop significant liver disease.<sup>84-86,89-90</sup>

Histologic findings associated with halothane hepatitis include primarily centrilobular necrosis, although a range of findings from multifocal necrosis to massive fulminant necrosis is described. Ballooning degeneration, steatosis, and fibrosis have also been documented; in a small subset of patients, there are electron microscopic findings of mitochondrial injury. The histology of halothane hepatitis has a significant overlap with features of acute viral hepatitis and toxic hepatitis from other pharmaceutical exposures.<sup>91</sup>

Patient-specific metabolic and immunologic factors combine to account for this unpredictable hepatotoxicity. Variable expression and activation of CYP2E1 and the GSTs likely account

for the different degrees of liver injury. Immunologic factors probably play a role in this process and may account for the individual variability in effects. The halothane-induced liver injury is associated with circulating antibodies to tissue antigens, peripheral eosinophilia, and the finding of halothane-induced liver neoantigens.<sup>92-94</sup>

Evidence suggests that molecular mimicry exists between the trifluoroacetylated proteins and the lipoyl-lysine regions of the E2 subunits (i.e., dihydrolipoyl transacetylase) of the mitochondrial pyruvate dehydrogenase complex because they are epitopes recognized by the antibodies in patients with halothane hepatitis.<sup>95,96</sup> Molecular mimicry may account for immunologic tolerance to the trifluoroacetylated proteins resulting from anesthetic metabolism, providing an explanation for the lack of tissue-specific injury observed in most patients exposed to these compounds.<sup>97</sup> Various levels of expression of the E2 component of the pyruvate dehydrogenase complex have been observed, with abnormally low levels seen in tissue specimens from patients with halothane hepatitis. It is postulated that individuals with low levels of the E2 subunit of the pyruvate dehydrogenase complex are more likely to develop injury because of a decrease in immune tolerance of triacetylated proteins.<sup>97</sup> However, many thousands of children have been safely anesthetized with halothane, and its use has proved to be very safe for most children. Concern about the rare occurrence of halothane hepatitis should not discourage the use of this anesthetic agent in children.

The obesity epidemic and associated nonalcoholic fatty liver disease and nonalcoholic steatohepatitis have raised concerns that these patients may be at increased risk for DILI.<sup>98</sup> Obesity and hypercholesterolemia can induce CYP2E1, which may facilitate development of liver injury.<sup>99</sup> Few data are available to inform the best practice of anesthesia management for the obese child, and adequately powered prospective studies are needed.<sup>100</sup>

Enflurane, isoflurane, desflurane, and sevoflurane have also been associated with liver injury. Agents such as enflurane, isoflurane, and desflurane are associated with a lesser degree of toxic hepatitis, possibly because they are metabolized to a lesser extent than halothane.<sup>101</sup> Case reports have documented that each is capable of producing liver injury. Enflurane, for example, was associated with the development of severe liver disease, with an estimated incidence of 1 case per 800,000 exposed patients. The clinicopathologic features are similar when compared with halothane-induced disease, including histologic findings, delayed onset of jaundice, and a history of previous exposure to the anesthetic. There is also a correspondingly high mortality rate.<sup>102</sup> It is thought that previous exposure to halothane leads to an increased risk of disease, occurring through previous cross-sensitization among chemicals.

Isoflurane has been associated with development of liver disease, although significantly less frequently than other agents. Features of isoflurane hepatic injury mimic those found with halothane. Detection of hepatic metabolite-modified neoantigens that occur in a small percentage of patients demonstrates an immune-mediated pathogenesis similar to that of halothane.<sup>103</sup> Desflurane-associated liver injury has been described, and the finding of modified liver neoantigens supports an immune-mediated mechanism of injury similar to that of the other inhalation anesthetics.<sup>104,105</sup> Hepatic disease after exposure to sevoflurane has been reported, but an immunologic correlation, as seen with the other inhalational drugs, has not been established.<sup>106</sup>

## Perioperative Considerations in Liver Disease

Patients with known or suspected liver disease should be assessed for hepatocellular and bile duct injury, coagulopathy, ascites, and encephalopathy. Hepatopulmonary syndrome and portopulmonary hypertension are rare but important complications in children with known chronic liver disease, and they may serve as relative or absolute contraindications to elective surgery.<sup>107</sup> Perioperative mortality is greatest among those who have acute hepatitis compared with those with chronic liver disease.<sup>108-110</sup> The physiologic stress associated with surgical procedures decreases portal blood flow. Liver disease may decrease the degree to which hepatic artery blood flow can compensate for reduced portal blood flow,<sup>111</sup> which can increase the risk of developing ischemic injury.

Parenteral nutrition–associated liver disease (PNALD) occurs in children requiring parenteral nutrition for longer than 60 days. Children with short bowel syndrome are at greatest risk for PNALD. Aside from the disturbances to hepatic and portal blood flows seen in children with liver disease, those exposed to total parenteral nutrition (TPN) are at increased risk for perioperative glucose derangements.<sup>112-114</sup> Frequent perioperative glucose monitoring with adjustment of dextrose infusion appears to be the standard of care, which is associated with various rates of TPN discontinuation. A survey administered to members of the Study Group of Pediatric Anesthesia found that approximately 50% of respondents checked glucose levels as often as every 1 to 2 hours.<sup>115</sup> They also found that 19% discontinued TPN and administered a glucose-containing solution, whereas 35% decreased the fluids to one half of maintenance rates and 33% continued maintenance rates unchanged.<sup>115</sup>

## Summary

Understanding the basics of hepatic biotransformation is crucial in providing effective and safe care to children with or without

evidence of liver disease. Hepatic injuries and hepatic dysfunction can alter baseline processes and increase the risk of toxicity and complications from sedatives and anesthetics. Drugs directly metabolized by the liver should be used with caution in the setting of hepatic injury. However, a multitude of drugs that undergo extrahepatic metabolism or are bound to plasma proteins may also be affected by hepatic injury. Assessing hepatic function before sedation or anesthesia and monitoring those parameters throughout treatment can diminish the risk of injury and increase the targeted effect of the medication.

## **Liver Transplantation**

The first successful liver transplant was performed by Dr. Tom Starzl in a child in 1967, but the history of liver transplantation begins in 1955, with Stuart Welch in Albany, and Jack Cannon at UCLA. Welch was the first to describe auxiliary liver transplantation in the dog and Cannon was the first to attempt orthotopic liver transplantation in dogs. Unfortunately, none of the dogs survived the operation.<sup>1</sup> Francis Moore and Tom Starzl continued the research in the dog model. From 1958 to 1959, they each were able to successfully transplant the liver in the dog but the animals all died from rejection within 4 to 20 days. These deaths highlighted the barriers that prevented the first application in humans.

In the early stages of animal experimentation with liver transplantation, the main barriers to success involved surgical technique, organ preservation, and immunosuppression. Regarding organ preservation, the liver used to be preserved with chilled electrolyte solutions like lactated ringers and normal saline. Preservation time with these solutions was only 5 to 6 hours. In 1987, the University of Wisconsin developed a solution which increased the preservation time of livers to 18 to 24 hours. The third barrier, immunosuppression, was the most significant and likely explained most of the canine deaths. Medawar discovered the role of the immune system in organ rejection in 1944. Since that time, several unsuccessful attempts to deliberately weaken the immune system and control rejection failed. It was not until an animal

model demonstrated that the combination of azathioprine and prednisone were synergistic and ameliorated rejection. This combination was first used in human kidney transplants, and then expanded to liver transplantation. Later, in 1967, antilymphocyte globulin was introduced, providing lymphoid depletion, and supplemented azathioprine and prednisone, providing better immunosuppression.<sup>2</sup>

The first human liver transplantation was performed in 1963 on a 3-year-old boy with biliary atresia. This attempt ended in failure secondary to fatal intraoperative hemorrhage from venous collaterals. Six more attempts at three different institutions (Denver, Boston, and Paris) produced the same results. Attempts to control the intraoperative hemorrhage with coagulation factor replacement and  $\epsilon$ -aminocaproic acid resulted in clots and fatal pulmonary emboli in the venovenous bypass system. Inadequate immunosuppression played a significant role in these fatalities as well. At this time a self-imposed moratorium was established. Thymoglobulin, a lymphoid depleting agent was introduced into the immunosuppression regimen in 1967 and Starzl successfully transplanted a liver in a 1 year old with hepatoblastoma; this child survived 13 months.

Despite the initial success of the first pediatric liver transplant, the 1-year survival rate in subsequent transplant patients remained no greater than 50%. In 1979, with the introduction of cyclosporine, the 1-year patient survival increased to 70%.<sup>3,4</sup> FK-506 (tacrolimus) was introduced in 1989, replacing cyclosporine,<sup>5</sup> and the 1-year survival further increased to approximately 80%.

## DEMOGRAPHICS AND EPIDEMIOLOGY

There has been a steady increase in the number liver transplants performed yearly in the United States since 1988 (1713 that year, increasing to 6291 in 2010). The vast majority of this increase is attributed to adult transplants. The total number of pediatric liver transplants in 1990 was 513. This increased to 589 in 2000 and has essentially remained unchanged 10 years later, with 560 in 2010. The increase from 1990 to 2000 is only a 10% to 11% increase, compared with the 169% increase in adult liver transplants (2177 in 1990 to 5875 in 2005, according to the United Network for Organ Sharing [UNOS] Scientific Registry 2011). However, the total number of adult liver transplants has plateaued since 2005, with 5731 transplants performed in 2010.

Indications for liver transplantation in children include the presence of an underlying primary liver pathology with acute or chronic liver failure caused by cholestatic liver disease, acute hepatic failure, metabolic disorders, cirrhosis, tumors, toxins, and other derangements (i.e., Budd-Chiari syndrome) (E-Table 29-1). The most common cause for liver transplantation in children is cholestatic liver disease secondary to biliary atresia, particularly in children less than 1 year of age, where it accounts for 50% or more of transplants.<sup>6</sup> Biliary atresia continues to be the most common overall cause for liver transplantation, and the most common cholestatic cause, but cholestatic liver disease secondary to total parenteral nutrition has become more prominent over the past 10 years and accounts for just over 4% of all pediatric liver transplants. After cholestatic liver disease, acute hepatic failure and metabolic disorders are the next most common causes for pediatric liver transplantation. In the past, the most common metabolic disorders, in decreasing frequency, were  $\alpha_1$ -antitrypsin deficiency, tyrosinemia, Wilson disease, oxalosis, and glycogen storage diseases. The three most common disorders that lead to liver transplantation have changed, with cystic fibrosis now the second most common metabolic indication for pediatric liver transplantation, according to the United Network for Organ Sharing/Organ Procurement and Transplantation Network (UNOS/OPTN.org).

The cause for acute or fulminant hepatic failure is not known in the majority of patients. Neonatal hepatitis is the primary cause for acute hepatic failure in children. Drugs and toxins are the second leading cause of acute hepatic failure and viral hepatitis is third. Acetaminophen is the most common cause of drug- or toxin-induced liver failure.<sup>7</sup>

There are not many absolute contraindications to pediatric liver transplantation. Children with neoplastic processes, such as hepatocellular carcinoma, and infectious processes, such as infection with human immunodeficiency virus (HIV), are transplanted. However, patients with acute infections from bacterial or fungal agents, metastatic neoplasm, or disease processes that are considered an immediate threat to life (severe cardiopulmonary disease, sepsis, or septic shock) are generally not transplanted.

Allocation of the available livers to the appropriate recipients has been a challenge. Initially liver transplant candidates were prioritized based on geographic location and medical condition, as defined by Child-Turcotte-Pugh (CTP) score. Patients were ranked as status 1, 2a, 2b, or 3. Status 1 patients received the highest priority and were defined by the presence of acute liver failure of less than 6 weeks or a failed liver transplant within 1 week. Status 2a, 2b, and 3 were defined by their CTP score and time on the wait list.<sup>8</sup> Efforts by the UNOS/OPTN Liver Disease Severity Scale (LDSS) committee to identify predictors

of mortality in patients with chronic liver disease resulted in the implementation of the model for end-stage liver disease (MELD) and the pediatric end-stage liver disease (PELD) severity score in 2002.<sup>9</sup> The PELD score incorporates variables for age, growth failure, serum albumin, bilirubin, and international normalized ratio (INR) (E-Table 29-2). In 2005, the cutoff for using the PELD score was revised to include only children 12 years of age or younger; the MELD score was extended downwards to include those as young as 12 years of age.<sup>10</sup> Serum creatinine is incorporated in the MELD score because it predicts mortality for adult patients waiting for liver transplantation. Although this value may predict mortality after liver transplantation in adults, it is not predictive in children.<sup>11</sup>

The allocation of deceased liver donors has changed with the new MELD/PELD policy. Before this policy, organs from donors younger than 18 years old were distributed only to those younger than 18 years old. With the new policy, the donor graft is first allocated to a status 1 child (less than 12 years of age) in the local region. If none is available, it is offered to the first status 1 adult in the region. If no status 1 adult is available, the liver is made available to children with more than 50% risk of mortality. Adults with mortality risk above 50% are next, and then all children are offered the graft over all other adult candidates. If there are no appropriate pediatric recipients in the region, the donor organ is offered to the national pool.<sup>12</sup> The introduction of the MELD/PELD score appears to have decreased the wait time for deceased donor liver grafts. Analysis of prescore and postscore MELD/PELD data indicates that the median time to transplant, defined as the number of days for half of the new registrants to receive organs, has significantly decreased from 981 days in 2002 to 361 days in 2007.<sup>10</sup>

Survival of deceased-donor organs is age dependent. Infants less than 1 year old have the lowest 3-month and 1-year survival, at 88% and 83%, respectively, when compared with other pediatric groups. If the infant recipient of a transplanted liver survives the first year, the survival for this age group increases. In fact the 5-year survival is the greatest for infants less than 1 year old, at 84%. The 10-year survival for infants less than 1 year old is 77%, for children 1 to 5 years old, 79%, and for children 6 to 11 years old, 81%.<sup>10</sup> However, outcomes other than survival, such as growth and cognitive function, should also be taken into consideration.<sup>13</sup>

## PATHOPHYSIOLOGY OF LIVER DISEASE

The liver is the only organ that can regenerate itself when damaged. The stigmata and multiorgan involvement from end-stage liver disease occurs because of loss of hepatocytes and the resulting fibrosis. The hepatic injury and loss of hepatocytes leads to decreased synthetic function. This cellular dysfunction results in coagulopathy, hypocholesterolemia, hypoalbuminemia, and encephalopathy. Attempts at regeneration result in fibrosis and destruction of the portal triad, with increased resistance to blood flow through the liver. Portal hypertension is the final consequence of this increased resistance. Much of the characteristic features of liver disease occur because of portal hypertension, specifically varices (esophageal, bowel), hemorrhoids, ascites, spontaneous bacterial peritonitis, splenomegaly with thrombocytopenia, and hepatic encephalopathy.

### Cardiac Manifestations

Cardiac disturbances occur in children with liver disease because of altered physiology, congenital heart defects, and toxic side

**E-TABLE 29-1** Primary Diagnosis of Liver Disease in Pediatric Patients, 1988 to 2011

Primary Diagnosis		Cirrhosis (Total)

 TPN, Total parenteral nutrition; tx, transplantation.

**E-TABLE 29-2** Pediatric End-Stage Liver Disease (PELD) Severity Score Determination

$$R = (0.436[\text{age}^*] - 0.687 \log[\text{albumin grams/dL}]) + 0.480 \log[\text{total bilirubin mg/dL}] + 1.857 \log[\text{INR}] + 0.667[\text{growth failure}^{\dagger}] - 10$$

INR, International normalized ratio; R, PELD severity score.

\*If younger than 1 year, use 1; if older than 1 year, use 0.

<sup>†</sup>If more than 2 standard deviations below the mean for age, use 1; if less than 2 standard deviations below the mean for age, use 0.

effects. A hyperdynamic circulation secondary to vasodilation characterizes the altered cardiac physiology from liver disease, with a compensatory increase in cardiac output (CO). Vasodilation is central to the hyperdynamic circulation that accompanies portal hypertension. It likely occurs because of the presence of vasoactive mediators. These mediators or gut-derived “humoral factors” (e.g., nitric oxide [NO], tumor necrosis factor  $\alpha$ , endocannabinoids) enter the systemic circulation through portosystemic collaterals and bypass hepatic detoxification.<sup>14</sup> Shunting also occurs at the level of the skin and the lungs. Mixed venous saturation increases in children with liver disease because of poor tissue oxygen extraction. Arterial-venous oxygen difference is reduced because of the combination of decreased oxygen consumption and hypoxia from arterial-venous shunting.

Cardiomyopathy associated with portal hypertension is well described in adults but is not well characterized in children with liver disease. However, children with liver disease can develop a cardiomyopathy for other reasons. Inborn errors of metabolism and other syndromes are associated with cardiomyopathies and cardiac anomalies. Some of the inborn errors include Wilson disease, oxalosis, glycogen storage disease type III, and Gaucher disease.<sup>15</sup> Tacrolimus and cyclosporine A have also been associated with hypertrophic cardiomyopathy in animal studies and in pediatric liver transplant recipients.<sup>16,17,18</sup> Echocardiographic assessment of cardiac function is generally well preserved in children receiving tacrolimus, but there may be evidence of subtle cardiovascular changes, which predispose a small percentage of children to develop hypertrophic cardiomyopathy.<sup>19</sup>

Other diseases that may lead to liver failure are associated with congenital heart disease. For example, children with Alagille disease may have pulmonary stenosis, coarctation, tetralogy of Fallot, atrial and ventricular septal defect.

QT prolongation has also been described in adults with alcoholic liver disease and may be associated with sudden cardiac death.<sup>20</sup> A decrease in  $K^+$  currents observed in rat cardiomyocytes with cirrhosis may provide a possible mechanism for the QT prolongation. Children with liver failure have also been shown to have an increase in QT interval (QTc greater than 450 msec in 18% of children with liver disease), possibly increasing the risk of ventricular arrhythmias, however, there is no evidence of an increased dispersion of repolarization (see Chapter 14). These changes appear to be transient and reversible after liver transplantation.<sup>21</sup> Nonselective  $\beta$ -adrenergic blockade has also been shown to reduce the QT prolongation, but it is unclear if this reduces the risk of arrhythmias or improves survival.<sup>22</sup> Although previous data suggested that prolonged QT did not predict decreased survival,<sup>23</sup> more recent evidence suggests that the presence of a prolonged QT was associated with an increased PELD score and portal hypertension. Children with chronic liver disease and prolonged QT may be at increased risk of mortality while waiting for a transplant.<sup>24</sup>

### Pulmonary Manifestations

The hallmarks of the pulmonary manifestations of liver disease are hypoxia and pulmonary hypertension. Hypoxia is secondary to hepatopulmonary syndrome (HPS) and ventilation/perfusion ( $\dot{V}/\dot{Q}$ ) mismatch from atelectasis caused by tense ascites, hepatosplenomegaly, and/or pleural effusions. HPS is characterized by hypoxia from intrapulmonary arteriovenous shunting and intrapulmonary vascular dilatation.<sup>25</sup> The diagnosis is predicated on either arterial hypoxia ( $\text{PaO}_2$  less than 70 mm Hg in room air) or an increased alveolar-arterial gradient of more than 20 mm Hg

in the setting of pulmonary vascular dilatation. Intrapulmonary vascular dilatation can best be demonstrated on echocardiography or lung perfusion scan with macroaggregated albumin.<sup>26</sup> HPS occurs in 15% to 20% of adults and in 0.5% to 20% of infants and children with cirrhosis<sup>27</sup> as young as 6 months of age. It appears to be more prevalent in children with biliary atresia and polysplenia syndrome.<sup>28,29</sup>

Treatment for hypoxia is long-term supplemental oxygen; definitive treatment is liver transplantation. In a case series of seven children with HPS who were successfully transplanted, all recovered postoperatively with their hypoxia resolving within an average of 24 weeks.<sup>30</sup>

Portopulmonary hypertension (PPH) is defined by the World Health Organization as pulmonary artery hypertension (pulmonary systolic pressure of 25 mm Hg or greater) in the setting of a normal pulmonary capillary wedge pressure and portal hypertension.<sup>31</sup> The incidence of PPH is 0.2% to 0.7% in adults with cirrhosis but increase to 3% to 9% in adults presenting for liver transplantation.<sup>32</sup> The incidence in children is unknown, with accounts limited to case reports and one case series. Signs and symptoms on presentation are new heart murmurs, dyspnea, and syncope. Echocardiography can successfully identify pulmonary hypertension in pediatric and adult patients with PPH<sup>33</sup>; the severity of PPH predicts mortality. In a retrospective review, mild PPH did not increase mortality; however, those children who underwent liver transplantation with moderate PPH (pulmonary artery pressure [PAP] is 35 to 45 mm Hg) had a 50% mortality rate and those with severe PPH (PAP greater than 50 mm Hg) had a 100% mortality rate.<sup>34</sup>

There are no definitive guidelines for the management of children with PPH. Early identification is essential, and this may be accomplished with echocardiography. If PPH appears likely, cardiac catheterization should be performed to confirm the diagnosis, measure pulmonary artery pressures, and assess the response to NO and epoprostenol. Children who respond to medical management may be candidates for liver transplantation.<sup>35</sup> Otherwise, severe PPH is generally a contraindication for liver transplantation because of the increased risk of mortality.

### Neurologic Manifestations

Hepatic encephalopathy (HE) is a significant neurologic complication that is classified as either acute (seen in fulminant hepatic failure) or chronic (seen in chronic cirrhosis or chronic portal hypertension). The classification of the severity of acute and chronic HE is similar and is shown in Table 29-1. The pathophysiology is not entirely known, but cerebral edema appears to

**TABLE 29-1** West Haven Staging Classification of the Severity of Acute and Chronic Hepatic Encephalopathy

Grade	Description
0	Detectable only by neuropsychological testing
1	Lack of awareness, euphoria, or anxiety; shortened attention span; impaired addition and subtraction
2	Lethargy, minimal disorientation to time, personality change, inappropriate behavior
3	Somnolence but responsive to verbal stimuli, confusion, gross disorientation, bizarre behavior
4	Comatose

be a feature of both acute and chronic HE. Cerebral edema is more severe in acute HE and can result in increased intracranial pressure. Ammonia is repeatedly implicated in the pathogenesis of HE and may participate in the process by causing astrocyte swelling and low-grade cerebral edema.<sup>36,37</sup> The two major sources of ammonia in humans are catabolism of endogenous protein and gastrointestinal absorption. Bacterial breakdown of nitrogen-containing products in the gut results in ammonia formation, which is then absorbed in the portal circulation. Factors that increase blood ammonia concentrations can exacerbate the signs and symptoms of HE. These typically include increased catabolism from infection, increased gut absorption from high-protein diets, constipation, and gastrointestinal bleeding. Other neurotoxins that have been implicated in the exacerbation of HE include endogenous production of benzodiazepines, hyponatremia, and inflammatory cytokines; these may all share the final common pathway of increasing cerebral edema.

Management of HE should begin with assessing the child's ability to manage their airway. Children with grade 3 (somnolence to semi-stupor, responsive to verbal stimuli but confused) and 4 (coma, unresponsive to verbal or noxious stimuli) HE may require tracheal intubation to protect the airway and to provide adequate oxygenation and ventilation. Otherwise, management typically focuses on reducing gastrointestinal production and absorption of ammonia. Lactulose is often prescribed to create an osmotic gastrointestinal diuresis and to acidify the lumen of the gut to trap ammonia and minimize absorption. Antibiotics (e.g., neomycin and metronidazole) kill the gastrointestinal bacteria that are involved in metabolizing nitrogen products to ammonia. Other medications include sodium benzoate, which combines in the liver with ammoniagenic amino acids, like glycine, to facilitate their excretion.<sup>38</sup> Ornithine aspartate may also provide a substrate to the liver for enhancing urea cycle and glutamine synthesis, and reduce ammonia levels. Flumazenil may reduce the symptoms of HE by inhibiting endogenous benzodiazepines and  $\gamma$ -aminobutyric acid, although 0.01 mg/kg in children with fulminant hepatic failure failed to correct the HE.<sup>38</sup>

Children with fulminant hepatic failure can have increased intracranial pressure (ICP), which is the major cause of mortality and may be a contraindication for liver transplantation. Intracranial hypertension occurs in 38% to 81% of adult patients with fulminant hepatic failure<sup>39</sup> and is often monitored in those with fulminant hepatic failure (grade 3 to 4 HE). The risk of intracranial hemorrhage secondary to coagulopathy can be reduced by replacing clotting factors and platelets, and by placing an epidural rather than a subdural monitor.<sup>40</sup> Management strategies for children with increased ICP should focus on maintaining cerebral perfusion pressure above 60 mm Hg, and ICP at less than 20 mm Hg. Management strategies often include tracheal intubation and ventilation with the head in midline position and slightly elevated to 30 degrees to facilitate venous drainage. Ventilation is adjusted to achieve a  $\text{PaCO}_2$  of 30 to 35 mm Hg with minimal positive end-expiratory pressure (PEEP). Medical management to reduce ICP includes administering barbiturates or propofol to minimize stimulation and to directly reduce ICP.<sup>41</sup> Mannitol can be administered if ICP remains increased. Hypothermia has also been described, and in a small trial with 14 patients with fulminant hepatic failure, ICP was reduced by maintaining core body temperature at 32° C to 33° C.<sup>42</sup> Orthotopic liver transplantation is the definitive treatment for children with acute or chronic HE.

## Hematologic Manifestations

There are several hematologic alterations associated with liver disease. Anemia is common because of a combination of gastrointestinal bleeding, poor nutrition, and decreased erythropoietin production from renal failure. Portal hypertension can result in splenomegaly, which causes platelet sequestration and thrombocytopenia. All of the coagulation factors (except factor VIII) are synthesized in the liver. As synthetic functions decline, coagulation factor production diminishes. The reduction in bile salt also decreases the absorption of fat-soluble vitamins (A, D, E, K) and contributes to the deficiency of factors II, VII, IX, and X. The result is an increase in prothrombin time (PT) and partial thromboplastin time (PTT). Children with acute or fulminant hepatic failure can present with a hematologic profile similar to disseminated intravascular coagulation.

## Renal Manifestations

Renal failure is common in children with acute and chronic liver disease and its cause is multifactorial. Renal failure can be classified as prerenal azotemia, acute tubular necrosis (ATN), or hepatorenal syndrome (HRS). Prerenal azotemia from hypovolemia is a common cause for renal failure and occurs secondary to diuretic therapy, gastrointestinal bleeding, splanchnic pooling, and sepsis. ATN occurs because of decreased central blood volume secondary to central splanchnic pooling, and decreased prostaglandin synthesis. HRS is characterized by renal failure in the setting of liver failure and portal hypertension. The incidence in adults with chronic liver disease is approximately 10% to 15%; in children the incidence is even less, at approximately 5%. The reduced incidence in children may reflect the lack of definitive criteria for diagnosis of HRS in children.<sup>43</sup> HRS occurs secondary to intense renal vasoconstriction from activation of the renin-angiotensin, arginine vasopressin, and sympathetic nervous systems. This activation is a homeostatic response to the profound splanchnic vasodilation that occurs with portal hypertension.<sup>44</sup> HRS presents similarly to prerenal azotemia (increased creatinine, decreased urine sodium [ $\text{U}_{\text{Na}}$  less than 10 mM,  $\text{Fe}_{\text{Na}}$  less than 1%]), but is differentiated from azotemia by its lack of response to a fluid challenge. HRS has been classified based on the rate of progression of renal failure into types 1 and 2: type 1, which has a worse prognosis, is characterized by a rapid progression of renal failure with a 100% increase in creatinine in less than 2 weeks. It usually occurs in patients with acute liver failure. In type 2, renal failure progresses over weeks to months, and usually occurs in patients with chronic liver disease. Regardless of the type, prognosis is poor in children with HRS, with a mortality of 80% to 95%.<sup>45</sup> The definitive treatment for HRS is liver transplantation, because the renal failure is reversible if the liver is replaced.<sup>46</sup>

The primary goal in the management of patients with liver disease and renal failure is to exclude treatable and reversible causes, such as nephrotoxins (NSAIDs), hypovolemia (diuretics, gastrointestinal bleeding), and sepsis. All nephrotoxins should be stopped and children should be given a fluid challenge, ideally with a colloid solution. If sepsis is suspected patients should be extensively cultured and antibiotics that are not nephrotoxic administered.

Pretransplant renal function predicts mortality in adult patients undergoing transjugular intrahepatic shunt and liver transplantation, and serum creatinine is used in the MELD score. Preexisting renal failure is also a major determinant of survival after liver transplantation in adults. Efforts to improve

renal function pretransplant may improve posttransplantation outcome.<sup>47</sup> At this time it is not clear that serum creatinine is a predictor of mortality in children with liver disease.<sup>48</sup> Before transplantation, type 1 HRS can be managed with vasoconstrictors (vasopressin analogs, norepinephrine), although there are limited data on their use in children. Critically ill children may require continuous renal replacement therapy (continuous venovenous hemofiltration or hemodiafiltration) as a bridge to transplantation.

### Metabolic Manifestations

The metabolic derangements seen in liver disease include glucose, ammonia, electrolyte, and acid-base disturbances. Electrolyte abnormalities include hyponatremia, hypo- and hyperkalemia, hypocalcemia, and hypomagnesemia. Hypoglycemia may occur in children with fulminant hepatic failure or abrupt discontinuation of total parenteral nutrition, but hyperglycemia is more common in the perioperative period. During the dissection and anhepatic phase there are several causes of hyperglycemia. Typically glucose concentrations will increase immediately after reperfusion. Serum glucose increases if there is an exogenous source of glucose or if there is altered glucose metabolism. Exogenous sources include glucose from blood products,<sup>49</sup> dextrose containing intravenous (IV) fluids, and damaged hepatocytes from the liver graft.<sup>50</sup> Glucose uptake is altered by methylprednisolone steroid-induced insulin resistance. Hepatic denervation likely results in alterations in insulin and glucose clearance during the postoperative period, and may explain the frequent occurrence of impaired glucose tolerance and diabetes in liver transplant recipients.<sup>51</sup>

Acid-base disturbances commonly occur during liver transplantation. Children with renal disease may have a preexisting metabolic acidosis from bicarbonate elimination. A metabolic acidosis is typically present during the dissection and anhepatic phase, but it is usually most pronounced immediately after reperfusion. Lactic acid and citrate (from blood products) are not metabolized during the anhepatic phase and contribute to the acidosis. Cross clamping of the inferior vena cava (IVC) and aorta alters blood flow to gut and lower extremity tissue beds and may also contribute to the lactic acidosis. Once the liver graft begins to function, the metabolism of lactate and citrate may lead to a metabolic alkalosis.<sup>49</sup>

### PREOPERATIVE EVALUATION

The preoperative evaluation begins with a history and physical examination to identify the primary cause of liver failure and to identify liver- and non-liver-related alterations in physiology that may affect the anesthetic and surgical plan. A complete review of the systems will identify most of the perioperative concerns (Table 29-2).

The primary cardiovascular concerns include acquired cardiomyopathies from liver disease and inborn errors of metabolism, congenital cardiac defects, and QT prolongation. Aside from a cardiovascular physical examination, the preoperative cardiac evaluation should include an echocardiogram and a 12-lead electrocardiogram.

The pulmonary concerns include hypoxia and PPH. Hypoxia can occur from V/Q mismatch caused by pleural effusions and ascites, and HPS. Oxygen saturation on room air and with oxygen will identify those who are hypoxic and whether they respond to oxygen. Children with significant intrapulmonary shunts from HPS will not increase their oxygen saturation significantly while

**TABLE 29-2** Preoperative Evaluation of Liver Transplant Candidates

#### History and Physical Examination

Cause for liver failure
Identifiable syndrome or metabolic disorder
Past medical history: medical problems not related to liver (e.g., asthma)
Past surgical history: portoenterostomy (Kasai), previous anesthetic concerns
Medications: diuretics, lactulose
Allergies
Family history of anesthesia-related problems
Immediate eating and drinking history

#### Cardiovascular

Echocardiography: to identify cardiomyopathy, pulmonary hypertension, and congenital cardiac defects
Electrocardiogram: to identify arrhythmias and QT prolongation

#### Pulmonary

Oxygen saturation (possible arterial blood gas): to assess hypoxia (HPS)
Radiography: to identify pleural effusions and central line position

#### Hematology

Complete blood count: to assess anemia, leukocytosis, and leukopenia (sepsis)
Prothrombin time and partial thromboplastin times
Platelet count

#### Renal

Blood urea nitrogen (BUN)
Creatinine (Cr)

#### Neurologic

Assessment of increased intracranial pressure in acute and/or fulminant hepatic failure
---

#### Electrolytes

Na <sup>+</sup> and K <sup>+</sup> : hyponatremia and hypokalemia secondary to diuretics
Calcium
Albumin
Magnesium
Glucose

HPS, Hepatopulmonary syndrome.

receiving oxygen. HPS can be diagnosed by demonstrating intrapulmonary vascular dilatation on echocardiography or lung perfusion scan with macroaggregated albumin.<sup>52</sup>

PPH can usually be identified on echocardiography (tricuspid regurgitation). Children suspected of having PPH may undergo a cardiac catheterization to define the severity of pulmonary hypertension and to assess the response to therapeutic agents (NO, epoprostenol). Children with severe pulmonary hypertension (PAP greater than 50 mm Hg) are at increased risk of perioperative mortality and liver transplantation is contraindicated.<sup>34</sup>

Anemia, deficiency of hepatic coagulation factors (decreased vitamin K absorption, smaller concentrations of clotting factors II, VII, IX, X), and thrombocytopenia are common and should

also be evaluated preoperatively. A PT and PTT should also be obtained before commencing surgery.

Renal failure is common and in adults predicts decreased survival in the period after transplantation.<sup>53</sup> Both a blood urea nitrogen and creatinine measurement should be obtained preoperatively.

Children should be evaluated for evidence of HE, particularly those with acute hepatic failure. Increased intracranial pressure is common and it is the most common cause of mortality. Children with advanced HE (grade 3 and 4) may already have had their airways intubated to protect them from regurgitation and control their PaCO<sub>2</sub>.

Baseline laboratory values should be obtained for liver function tests, sodium, potassium, calcium, magnesium, glucose, and albumin. Hyponatremia and hypokalemia are common with diuretic therapy. Children who have already received citrate-containing blood products may be hypocalcemic secondary to citrate induced chelation. Hypoglycemia occurs secondary to depleted glycogen stores in the failed liver and/or removal of chronic total parenteral nutrition.

An important issue that is rarely communicated to the ward team when the child is admitted for surgery, is that all preoperative IV access should be placed in the lower extremities. This ensures that none of the veins that the anesthesiologist will require intraoperatively (i.e., those originating in the upper extremities or neck) will be compromised preoperatively.

A key portion of the preoperative evaluation is the preparation of the child and family for the anticipated risks, benefits, and clinical course. Specifically, the child's airway will likely remain intubated and the child sedated to facilitate mechanical ventilation of the lungs in the immediate postoperative period. After surgery, the child may have significant facial and extremity edema. Likewise informing the family about the potential number and location of the intravascular catheters and their associated risks can be helpful in preparing them to see the child after surgery. Informed consent should also include a discussion about the use of blood products and risks associated with prolonged positioning (peripheral nerve injury, occipital alopecia).

## INTRAOPERATIVE CARE

Appropriate intraoperative care requires an understanding of the surgical and anesthetic issues. Several factors affect the child's physiology, including the underlying pathophysiology of liver disease, surgery, and response to anesthetics. A sound understanding of both surgical and anesthetic issues is needed to safely manage these children. In general, the surgical approach for liver transplantation in children is similar to that in adults. The most significant difference is the reduced size of the recipient. The obstacles imposed by the size of the child include a smaller blood volume, more challenging vascular access, size restriction of donor graft, venovenous bypass, and the incidence of surgical complications, such as hepatic artery thrombosis.

The initial anesthetic management begins with a thorough preoperative evaluation, as discussed previously. Children over the age of 1 year old will likely be anxious and may benefit from an anxiolytic like midazolam. Midazolam can be administered IV, orally, nasally, or rectally; children with HE should not receive midazolam because of the theoretic possibility of exacerbating the encephalopathy (see previous discussion).

Most children are considered to have a full stomach because of delayed gastric emptying from ascites, gastrointestinal bleeding, HE, and the nonelective nature of most transplants (i.e., a

rapid-sequence induction is required). The exception may be the child presenting for an "elective" transplant without any stigmata of portal hypertension (e.g., Crigler-Najjar syndrome). Induction agents should be tailored to meet the needs of the patient but etomidate (0.2 to 0.3 mg/kg), sodium thiopental (4 to 6 mg/kg), propofol (2 to 4 mg/kg), and ketamine (2 mg/kg) are suitable options. Appropriate neuromuscular blocking drugs for rapid-sequence induction include succinylcholine and high-dose rocuronium (1.2 mg/kg), because of their rapid onset. Children who are not at risk for aspiration can have an inhalation induction with sevoflurane and nitrous oxide. The use of nitrous oxide is not recommended after induction because it may increase the risk of bowel distension and expansion of gas emboli.

The trachea should be secured with a cuffed or uncuffed tracheal tube. If the tracheal tube is uncuffed there should not be a leak at less than 15 to 20 cm H<sub>2</sub>O. High inspiratory pressures may be required to achieve adequate ventilation in the intraoperative and postoperative periods because of atelectasis from pleural effusions and ascites, surgical retractors placed on the abdominal and chest wall, and a tight abdominal closure. Positive end-expiratory pressure should be used in all patients.

Anesthesia is typically maintained with an inhalational agent, an opioid, and a neuromuscular blocking drug. Isoflurane, sevoflurane or desflurane may be used because they are readily available, undergo minimal hepatic metabolism, and appear to have minimal adverse effects on the liver, although all three have been associated with isolated case reports of hepatotoxicity.<sup>54,55,56</sup> Propofol is also an option to maintain anesthesia during liver transplantation. It is relatively short-acting and even though the primary metabolic pathway is hepatic, there appears to be extrahepatic metabolism in the lung, kidney, and intestine.<sup>57,58</sup> However, when used for a prolonged period, the pharmacokinetics of propofol switch from those of a short-acting to those of a long-acting anesthetic, and the risk of propofol infusion syndrome becomes a substantive concern (see Chapter 6). Neuromuscular blockade can be maintained with a variety of agents. Rocuronium, vecuronium, pancuronium, atracurium, and cisatracurium have all been described. Pancuronium may have the added advantages of increased heart rate, long duration, and reduced cost. The disadvantage of pancuronium, rocuronium, and vecuronium is their partial hepatic metabolism, but this can be overcome with appropriate monitoring and dose adjustments. Dose requirements of continuous infusions of rocuronium, vecuronium, and pancuronium are reduced during the anhepatic phase of liver transplantation, but return to initial values after reperfusion.<sup>59</sup> There is no change in the dose requirements of atracurium during the anhepatic phase.<sup>60</sup> Atracurium or cisatracurium may be ideal in patients with combined hepatic and renal insufficiency, because they are cleared by nonspecific esterases in tissues, and erythrocytes and do not rely on hepatic or renal function.

The liver metabolizes all opioids, with the exception of remifentanyl, which is metabolized by plasma and tissue esterases. The metabolic pathway for most opioids is oxidation, although morphine undergoes glucuronidation.<sup>61</sup> There is evidence that the elimination half-life and clearance of alfentanil and fentanyl are not dramatically altered in patients with cholestatic and cirrhotic liver disease.<sup>62,63</sup> Fentanyl, sufentanil, alfentanil, and morphine have all been used during liver transplantation. Fentanyl is commonly selected and is usually administered as a bolus during induction (2 to 10 µg/kg) and maintained as an infusion throughout the anesthetic and the immediate postoperative period (2 to 5 µg/kg/hr).

Vascular access is important for resuscitation and monitoring. At least two peripheral upper extremity IV catheters should be placed, along with a central venous line. The central venous line is used to monitor trends in central venous pressure and measure superior vena cava oxygen saturation (a surrogate marker for venous oxygen saturation). Larger children tolerate rapid infusion catheters placed in the upper extremities. Blood loss can be significant, with estimates between 0.5 to 25 blood volumes (mean is approximately four blood volumes).<sup>49</sup> Fluid warmers and rapid infusion devices (e.g., Level 1 Rapid Infuser, SIMS Level One INC, Rockland, Mass.) need to be available to facilitate resuscitation if significant hemorrhage occurs (see Chapters 10 and 51). The Level 1 Rapid Infuser has been associated with massive air emboli, and all air must be removed from the infusion bags before using the device, or the device should be used with air-detection add-on modifications.<sup>64</sup> The Rapid Infusion System (RIS, Haemonetics, Braintree, Mass.) is no longer manufactured and has been replaced by the Belmont FMS (Belmont Instrument Corp., Billerica, Mass.). This device is not routinely used in small children (less than 30 kg) but may be indicated in larger children and adolescents (see Chapter 51). Choice of resuscitation fluids should be limited to 0.9% normal saline and Plasma-lyte. Lactated ringers is not recommended because the lactate will accumulate unmetabolized during the anhepatic stage. Many children with liver disease are hypoalbuminemic, and the use of 5% albumin is appropriate.

Standard monitoring should include electrocardiogram, pulse oximetry ( $\times 2$ ), noninvasive blood pressure, invasive arterial blood pressure, central venous pressure, and temperature. Other high-technology monitoring that is commonly employed in adult liver transplantation includes transesophageal echocardiography (TEE), continuous cardiac output (CCO) catheter, bispectral index (BIS), venovenous bypass (VVBP), and more than one arterial catheter. In children, there are limitations to the use of these monitors because of patient size. A United States-based utilization survey found that TEE, CCO, BIS, and VVBP are used in 0%, 7.7%, 15.4%, and 7.7% of pediatric transplant centers, respectively.<sup>65</sup>

Hematologic and electrolyte changes are common and measurements of arterial blood gases, sodium, potassium, calcium, magnesium, glucose, hemoglobin, platelets, and coagulation parameters (PT, PTT, fibrinogen, and D-dimers) need to be performed frequently throughout the procedure. Most centers use either portable devices or an operating room (OR) laboratory to obtain these data. Assessment of coagulation variables can be obtained with thromboelastography. However, only 28% of pediatric transplant centers used TEG routinely<sup>65</sup> (E-Fig. 29-1). Positioning is critical to prevent soft tissue and peripheral nerve injuries. All extremities should be padded and all cables and wires need to be wrapped to protect the skin. The head should be rotated and repositioned periodically to prevent pressure sores and alopecia. To minimize the risk of peripheral neuropathy, the upper extremities should not be abducted more than 90 degrees and the wrists should not be hyperextended for the arterial catheter.

### SURGICAL TECHNIQUE

The surgical approach can be divided into four stages; hepatectomy, anhepatic, reperfusion, and biliary reconstruction.

#### Hepatectomy (Stage 1)

The initial description of orthotopic liver transplantation is referred to as the “classic” technique. In the “classic” approach

**FIGURE 29-1** The classic approach for orthotopic liver transplantation. The suture lines are visible at the suprahepatic and infrahepatic anastomoses. (From Starzl TE, Iwatsuki S, VanTheil DH, et al. Evolution of liver transplantation. *Hepatology* 1982;2:614-36.)

the liver is dissected to its vascular supply and the supra- and infrahepatic IVC are clamped, along with the portal vein and hepatic artery. The liver is removed enbloc (Fig. 29-1). The disadvantage of this approach is that the IVC is cross clamped, thus reducing preload. The piggyback technique was described 1989 and is the preferred approach for pediatric transplants, because there is more flexibility with the organ size and it only requires partial clamping of the IVC.<sup>66</sup> The liver is dissected away from the IVC, the short hepatic veins, portal vein, and left, right, middle hepatic vein. The infrahepatic vena cava of the donor is oversewn and the suprahepatic vena cava is anastomosed to the native hepatic veins (Figs. 29-2 and 29-3). This only requires partial clamping of the IVC. A portacaval shunt can be established for children who do not tolerate clamping of the portal vein (see Fig. 29-3). Typically these are recipients who have not developed collateral flow secondary to portal hypertension (e.g., maple syrup urine disease).

There are several physiologic considerations that take place during the hepatic dissection that affect the anesthetic management. Hypotension is common and can occur for a variety of reasons. These include changes to the cardiovascular, hematologic, and metabolic systems. The most common cause of hypotension includes hypovolemia secondary to hemorrhage and third space volume losses. Resuscitation with citrated blood products can result in hypocalcemia and surgical manipulation can cause mechanical compression of the IVC or right ventricle. Bleeding occurs from fragile collaterals, adhesions from prior surgery (Kasai procedure), and coagulopathy.<sup>67</sup> Blood conservation during this portion of the surgery by maintaining low central venous pressure (decrease of 30% from baseline) has been described in adults. The reported benefit of a low central venous pressure is less bleeding, with subsequent decrease in allogeneic blood requirements and decreased morbidity. Some studies have suggested an overall reduction in 1-year mortality.<sup>68,69</sup> The technique is controversial and the potential risks include end-organ

**E-FIGURE 29-1** **A**, The reaction time  $r$  as measured by thromboelastography (TEG) denotes the time to onset of the start of coagulation and should be 6 to 8 minutes. It represents the rate of thromboplastin formation. Prolongation of this portion of TEG usually represents factor deficiency and is treated with the administration of fresh frozen plasma (FFP). The coagulation time ( $r + k$ ) is the period between the start of the TEG recording and the time to the generation of an amplitude of 20 mm. It is a measurement of the speed of solid clot formation. The clot formation rate is measured by the  $\alpha$  angle and normally is greater than 50 degrees. Abnormalities of the  $\alpha$  angle represent platelet function, fibrinogen, and the intrinsic pathway. The  $\alpha$ -angle abnormalities are usually corrected by cryoprecipitate administration. The maximum amplitude (MA) is most indicative of platelet function and normally measures between 50 and 70 mm. **B**, Abnormalities of coagulation noted before surgery. **A**: There is prolongation of the  $r$  time and a diminution of the  $\alpha$  angle, as well as the MA. **B**: Improved coagulation during stage 1 is noted, as there is administration of FFP and platelets as the surgery progresses. Note the improved MA and  $r$  time. There is also an improved  $\alpha$  angle. **C**: TEG representative of the continued coagulopathy seen during stage 2 of the surgery. Note the progressive diminution of the MA and the progressive tapering of the MA, which suggest possible fibrinolysis. **D**: A classic representation of fibrinolysis seen in stages 1 and 2. **E**: Fibrinolysis on graft reperfusion. Note that, in this case, the clot formed takes somewhat more time before dissolution occurs. **F**: Amicar-treated TEG, demonstrating dramatic improvement of the fibrinolytic stage. Note the improved MA and  $r$  time, and  $\alpha$  angle. **G**: The end TEG showing a normal coagulation profile, which is representative of normal liver function from the graft, as well as continued administration of coagulation factors. (From Scott V, Davis PJ. Autologous transfusion in orthotopic liver transplantation. In: Salem MR, editor. Blood conservation in the surgical patient. Baltimore: Williams & Wilkins; 1996, p. 340.)

**FIGURE 29-2** The piggyback technique preserves the inferior vena cava (IVC). This is the view of the liver graft after the recipient's hepatic confluence is anastomosed to the donor's IVC (the infrahepatic IVC of the donor is ligated). (From Tzakis A, Todo S, Starzl TE. Orthotopic liver transplantation with preservation of the inferior vena cava. *Ann Surg* 1989;210:649-52.)

injury, such as renal or graft failure.<sup>70</sup> This technique has not been described in the pediatric liver transplant population.

Hematologic abnormalities include anemia, thrombocytopenia, coagulation factor deficiency, and low fibrinogen. A progressive coagulopathy can develop during this stage. Metabolic derangements include hyperkalemia, hypocalcemia, hypomagnesemia, and acidosis from resuscitation with blood products.

### Anhepatic Stage (Stage 2)

The anhepatic phase begins once the hepatic veins, hepatic artery, and portal vein are cross clamped. The dissection of the recipient's liver is completed and the organ is removed. This phase ends when the hepatic and portal vein cross clamps are removed and the graft is reperused.

Cardiovascular changes that occur during this stage can result in hypotension. This occurs from the IVC cross-clamp, which causes a decrease in preload. Hemodynamically, there is a decrease in cardiac output, central venous pressure, and pulmonary artery pressure, with an increase in systemic vascular resistance.<sup>67</sup> Preload should be gently augmented to maintain mean arterial pressure (MAP) with the lowest filling pressures possible. Hypervolemia may cause hepatic congestion during reperfusion. Inotropic agents like dopamine or epinephrine may need to be used to maintain MAP. A portacaval shunt, if performed, may moderate some of these hemodynamic changes by preserving preload from the portal vein (if venovenous bypass is going to be used, it is initiated during this period). Unmetabolized citrate causes hypocalcemia and hypomagnesemia because it chelates both. Acidosis occurs from the unmetabolized citrate, lactate, and other acids. Bicarbonate may be administered if there is a significant metabolic acidosis (base deficit less than 5 mEq/L). Once the liver is on the surgical field warm ischemia time begins. The time to reperfusion should be brief, and steps should be in place for reperfusion. Before reperfusion, potassium should be in

**FIGURE 29-3** The native liver has been removed. There is a clamp across the right, middle, and left hepatic veins. The *black arrow* shows the portacaval shunt. The *white arrow* shows the hepatic artery. The *dashed white arrows* show the short hepatic veins. (From Kuo PC, Davis RD. *Comprehensive atlas of transplantation*. Philadelphia: Lippincott Williams & Wilkins; 2005, p. 132.)

the low-normal range and calcium and bicarbonate should be in the high-normal range. Hemoglobin should be maintained between 9 and 10 g/dL. If the potassium is greater than 5 mEq/L, steps need to be taken to reduce it. This may be achieved by increasing the serum pH with hyperventilation, and the administration of sodium bicarbonate (1 to 3 mEq/kg). Glucose and insulin can be administered to acutely reduce potassium (see Chapter 8). Potassium-wasting diuretics like furosemide (0.5 to 1 mg/kg) can also be used. Administering fresh blood or washed red blood cells will minimize the increase in potassium during transfusion therapy.  $\beta_2$ -Adrenoceptor agonists may decrease potassium and can be used. Calcium and epinephrine should be immediately available for reperfusion.

### Reperfusion (Stage 3)

The liver graft can be reperused once the hepatic and portal vein anastomosis are complete. Before reestablishing hepatic blood flow, the graft is flushed to remove the preservation solution to minimize the reperfusion syndrome. Many changes can occur acutely during the reperfusion period secondary to cardiovascular, hematologic, and metabolic derangements. Postreperfusion syndrome is characterized by a decrease in MAP of greater than 30%.<sup>71</sup> Several factors participate in this event, including myocardial dysfunction, arrhythmias, and bleeding. The myocardial dysfunction is thought to occur from release of NO and tumor necrosis factor  $\alpha$ .<sup>72</sup> Cardiovascular collapse can occur and the child may require epinephrine to correct the hemodynamic effects of reperfusion.<sup>71</sup> Hyperkalemia is a common event immediately after reperfusion and may cause ventricular arrhythmias. It should be treated with calcium chloride (10 to 30 mg/kg) initially to stabilize the cardiac membrane and then insulin and dextrose, hyperventilation, furosemide,  $\beta_2$ -adrenoceptor agonists, and sodium bicarbonate to decrease the serum potassium concentration (see previous section). The high potassium content of the preservation solution is the cause of the hyperkalemia. University

of Wisconsin (UW) solution, a very commonly used preservation solution contains large amounts of potassium (120 mmol/L). Histidine-tryptophan-ketoglutarate (HTK) solution was introduced in 1980 as a cardioplegic solution, and contains substantially less potassium (10 mmol/L) than the UW solution.<sup>73</sup> A recent study comparing the two found equal 1-month and 1-year graft survival with HTK and UW solutions. The viscosity is reduced with HTK and may introduce itself more easily into the vascular spaces in the donor liver.<sup>74</sup> Although hyperkalemia is the hallmark electrolyte disturbance in the immediate reperfusion period, hypokalemia is more common in children throughout the intraoperative period and may require correction.<sup>75</sup>

Fibrinolysis can occur after reperfusion, and in one study it occurred in 60% of children and 80% of adults.<sup>76</sup> This results from increased tissue plasminogen activator activity and decreased synthesis of fibrinolysis inhibitors. Heparin effect is produced by endogenous heparinoids from the graft, residual heparin from the preservation, and release of tissue plasminogen activator from endothelial cells of the revascularized graft. Aprotinin blunts this response by inhibiting kallikrein and plasmin, which led to the wide spread use of aprotinin. The beneficial effects of aprotinin to reduce blood loss in orthotopic liver transplant in adults and children had been considered inconclusive until the European Multicenter Study on the Use of Aprotinin in Liver Transplantation (EMSALT) study in 2000.<sup>77</sup> However, the benefits of aprotinin in pediatric patients are not as clear. A retrospective study in 18 pediatric transplant patients receiving a high or regular dose of aprotinin demonstrated a reduction of red cell and fresh frozen plasma transfusion by half, but it was not found to be statistically significant. There is concern that there may be an association between aprotinin and intraoperative thrombotic events (hepatic artery and portal vein thrombosis) in pediatric recipients of liver transplants. Children may be at increased risk for developing intraoperative thrombi or emboli. Children are hypercoagulable after liver transplantation because of a decrease in protein C and antithrombin III,<sup>78</sup> and they may be more likely to develop hepatic artery thrombosis.<sup>79,80,81</sup> Aprotinin has been removed from the market because of the increased risk of death in adult cardiac patients. Tranexamic acid, an alternative antifibrinolytic is being used in adults for liver transplants; a nonrandomized prospective study did not find a difference in transfusion requirements or thromboembolic events after changing from aprotinin to tranexamic acid.<sup>82</sup> Currently there are no pediatric data to support or refute the use of tranexamic acid or ε-aminocaproic acid.

#### Biliary and Hepatic Artery Reconstruction (Stage 4)

The final step is reestablishing hepatic artery blood flow and reconstructing the biliary system. In smaller children, the hepatic artery may require an anastomosis via a conduit to the infrarenal aorta. This requires temporary cross clamping of the aorta. Biliary reconstruction is established by directly connecting the graft and the recipient's common bile ducts or by connecting the common duct of the graft to a Roux-en-Y limb of the recipient's jejunum.

During biliary reconstruction, metabolic and hematologic alterations are addressed. As the liver graft begins to function, the citrate administered during the previous three phases is metabolized, and metabolic alkalosis may develop. The hemodynamic goals include maintaining a normal central venous pressure. If the central venous pressure is high (greater than 8 mm Hg), there is a concern that the liver graft can become congested and may not function normally. The risk of hepatic artery thrombosis

ranges from 0% to 25% and is greater in infants and children.<sup>80,81</sup> This risk increases if the PT and PPT are corrected. Also, the viscosity from a greater hematocrit may increase the risk of hepatic artery or portal vein thrombosis. The hematocrit does not need to be corrected to normal values. In fact, maintaining the hematocrit at 8 to 9 g/dL is safe and reasonable. Anticoagulation strategies with heparin, dextran, aspirin, and alprostadil may reduce the risk of hepatic artery thrombosis.

#### Split Liver Techniques and Living Donor Liver Transplants

Advances in surgical technique, tissue preservation, and immunosuppression have resulted in improved survival in children undergoing liver transplantation. The result is more children are awaiting liver transplantation, but the number of available organs has not increased significantly. Children are at a particular disadvantage because of size limitations. Two techniques have attempted to address these issues. The reduced liver technique does not increase the number of available grafts, and efforts were made to perform split liver techniques to make two grafts from one adult donor. The initial results were poor, with an increase in complications and mortality.<sup>83,84</sup> The technique has evolved, and today the graft is split while still in vivo (in the heart-still-beating donor), as compared to ex vivo (splitting performed after the graft is removed from the donor). This decreases cold ischemia time and facilitates hemostasis of the liver edge. The result is improved child and graft survival,<sup>85</sup> which has increased from 60% to 70% in the 1990's to 80% to 90% in 2003. In one series, 218 split-liver grafts were transplanted between 1995 and 2002. Overall child survival at 1 year was 81.7%, and overall graft survival was 75.8%. Surgical complications that caused a return to the OR were bleeding (9.2%), bowel perforation (8.3%), and biliary problems (7.5%); hepatic artery complications occurred in 6.7%.<sup>85</sup>

Living-donor liver transplantation was first described in 1989.<sup>86</sup> This approach has reduced mortality among children awaiting liver transplantation. The benefit of a living donor (especially if related), is improved posttransplant results because of better graft quality, smaller ischemic times, and better immune compatibility. In fact, these improved results have been observed in several institutions that perform this procedure.<sup>87</sup> In a recent study, the 1- and 5-year patient survivals were 94% and 92% respectively.<sup>88</sup> The left hepatic segment is removed for pediatric recipients, whereas the right hepatic lobe is removed for adult recipients. The regenerative capacity of the liver allows the donor to regenerate the liver without hepatic insufficiency. Despite the success of this technique for the recipients, there is considerable risk to the donor. Complications include exposure to blood products, peripheral nerve injuries, biliary leakage, abdominal wall defects, pleural effusions, pneumonia, pulmonary emboli, and death.<sup>88,89,90</sup> Other than death, these complications were without long-term sequelae, except for a peripheral nerve injury.<sup>88</sup>

#### Outcomes

The Studies of Pediatric Liver Transplantation (SPLIT) registry was initiated in 1995 and consists of 38 centers in the United States and Canada. These centers contributed 85% of the pediatric liver transplants in 2002. Transplants performed more recently had greater survival rates. In the past, age less than 1 year was considered an increased risk factor for mortality, but over the past 20 years there is little mortality difference between children less than 2 years of age and those greater than 2 years of age at transplant.<sup>91</sup>

Survival also depends on the preoperative MELD/PELD score. Patients stratified to status 1 had a significantly smaller 1-year survival rate when compared to other transplant recipients (76% vs. 87%). Adults with MELD scores greater than 35 demonstrated decreased 1-year patient and graft survival. There is a suggestion that pediatric patients with greater PELD scores have decreased 1-year patient and graft survival, but that association was not statistically significant. The overall 1-year survival remained excellent, at more than 85%<sup>92</sup> (E-Fig. 29-2).

### IMMEDIATE POSTOPERATIVE CARE

At the completion of surgery, the child is transported to the intensive care unit (ICU). All of the preoperative pathologies will continue into the postoperative period. Children with underlying cardiac, pulmonary, and renal dysfunction will be more difficult to manage.

Hemodynamically, patients after liver transplantation will continue to lose intravascular volume because of bleeding and third-space losses. These losses need to be replaced to maintain a normal central venous pressure and adequate urine output (0.5 to 1 mL/kg/hr). Replacement with a lactate free isotonic solution (0.9% normal saline or Plasmalyte) and albumin is appropriate. Particular attention should be focused on children with underlying ventricular dysfunction or PPH because they tolerate fluid overload poorly. In adults, evidence suggests that fluid overload was responsible for ICU readmission,<sup>93</sup> whereas hypovolemia could lead to renal insufficiency and increase the risk of hepatic artery thrombosis. Preexisting pulmonary hypertension will not dissipate immediately, and children that were previously on prostaglandins will need to continue these infusions in the OR and in the postoperative period. Systemic hypertension is common after liver transplantation and has been described in as many as one-third of children<sup>94</sup>; this is typically attributed to cyclosporine therapy.

Most children require tracheal intubation, mechanical ventilation, and sedation in the immediate postoperative period. This is particularly true for smaller pediatric patients who may have received a relatively large graft and in children with underlying lung disease (HPS). Ascites, pulmonary edema, and pleural effusions may prolong the period of mechanical ventilation.<sup>95</sup> Efforts to minimize atelectasis include positive-pressure ventilation with PEEP. Diuretics may be required on the second or third postoperative day to treat edema and effusions. There is speculation that prolonged mechanical ventilation may have a negative effect on the hemodynamics of transplant patients and may contribute to overall morbidity and mortality.<sup>96</sup> High levels of PEEP may play a role in this morbidity. Some have advocated for early extubation to decrease the incidence of pulmonary complications and to facilitate discharge from the ICU.<sup>97</sup>

Renal failure secondary to HRS usually resolves after successful liver transplantation. The goal in the immediate postoperative period is to maintain normovolemia and to avoid nephrotoxic agents. These include aminoglycoside antibiotics and immunosuppressant agents like cyclosporine and tacrolimus. The immunosuppressant agents may need to be delayed until renal function improves.

Neurologic complications after liver transplantation are common. In adults, 10% to 40% develop these complications.<sup>98</sup> Comparable pediatric data are lacking. In adults, neurologic complications manifest as encephalopathy, seizures, or coma. The causes of encephalopathy and coma include drugs (immunosuppressive agents like tacrolimus and OKT3), infection (meningitis

and brain abscess), strokes (bleeding), and hyponatremia with central pontine myelinolysis (CPM). The most common cause of seizures is an adverse drug reaction associated with immunosuppressant agents.<sup>99</sup> Hyponatremia, which can contribute to neurologic complications, should be corrected slowly to prevent CPM. Correcting the hyponatremia no faster than 0.5 mEq/L/hr is considered safe. If the correction proceeds faster than recommended, then evidence from animal models indicates that dexamethasone administered within 6 hours of the correction may minimize the risk of CPM.<sup>100</sup>

Surgical complications after transplantation include vascular complications, acute rejection, and infections; frequent monitoring for their occurrence is important to ensure prompt treatment. Vascular complications include hepatic artery and portal vein thrombosis, bleeding, and bowel perforation.<sup>94</sup> Hepatic artery thrombosis is identified with frequent hepatic Doppler flow imaging. Children may be anticoagulated with aspirin, heparin, dextran, and alprostadil to reduce the risk of thrombosis.<sup>101</sup> Infections are common and contribute to significant morbidity. The primary source for infections appears to be central lines, percutaneous catheter drainage, and mechanical ventilation. Acute rejection should be suspected in children with fever and elevated liver enzymes. The diagnosis is made by histologic examination.<sup>94</sup>

Rejection is an immune response, and efforts to understand and control this immune response lie at the heart of transplant medicine. Initial efforts to control the response involved suppressing the recipient's immune system. There has been a move from immunosuppression to immunotolerance. Immunotolerance describes the concept of immune cells from both the recipient and the donor coexisting without attacking each other.<sup>102</sup> The goal of managing immunosuppression medication is to get to this state of tolerance. In this state of immunotolerance, minimal immunosuppression can be used. The benefits of decreasing immunosuppression include the reduced risk of infection, hypercholesterolemia, malignancy, hypertension, and diabetes mellitus. Protocols to induce tolerance include exposing patients to lymphoid-depleting agents (antilymphoid antibodies), like anti-thymocyte globulin, before liver engraftment, to reduce the anti-donor response to a more controllable or "deletable" range and allow maintenance therapy (e.g., tacrolimus) to begin with one agent. Other agents are added only when there is evidence of rejection.<sup>103</sup> The immunosuppressant agents currently used include calcineurin inhibitors (CNIs) like tacrolimus and cyclosporine, and they provide the mainstay of therapy. Other options include azathioprine or mycophenolate mofetil, for children who cannot tolerate the CNIs because of toxicity. Adverse effects of the CNIs include hypertension, tremor, and renal failure. Other agents being used include monoclonal antibodies against interleukin-2 (IL-2).<sup>104</sup>

### LONG-TERM ISSUES

Recipients of liver transplants require repeated anesthetics for a variety of reasons (central line placement, wound irrigation, dental rehabilitation, bowel obstruction, cholangiogram, biliary dilation, esophagogastroduodenoscopy). A primary concern in the posttransplant child is the adverse effects of immunosuppressant agents. Most organ systems become involved, and a thorough review of systems is important.

The cardiovascular effects of immunosuppressant agents includes hypertension from cyclosporine and cardiomyopathy (rare) from tacrolimus.<sup>105,106</sup> Renal insufficiency can occur

**E-FIGURE 29-2** Kaplan-Meier plots of patient survival for pediatric recipients receiving deceased-donor liver transplants, stratified by calculated PELD score. *M*, MELD score; *P*, PELD score. (From Freeman RB, Harper A, Edwards EB. Excellent liver transplant survival rates under the MELD/PELD system. *Transplant Proc* 2005;37:585-8.)

secondary to cyclosporine, diuretics, or hypertension. Baseline blood urea nitrogen and creatinine should be obtained preoperatively in children with a history of renal insufficiency, and medications that are renally cleared (morphine, rocuronium, vecuronium) should be adjusted or avoided. Hyperkalemia may accompany renal failure and should be evaluated before induction of anesthesia.

Pediatric recipients of a liver transplant can have multiple hematologic abnormalities. Azathioprine can cause anemia, leukopenia, and thrombocytopenia. Gastrointestinal bleeding from corticosteroid-induced ulcers may also cause occult anemia. Children receiving azathioprine should have a complete blood count before surgery, particularly if the procedure may involve blood loss.

The endocrine effects of chronic steroid exposure include diabetes, growth retardation, and adrenal insufficiency. Children receiving insulin for diabetes need intraoperative blood glucose monitoring and dextrose-containing IV fluids if they are hypoglycemic or are at risk of developing hypoglycemia. Children receiving chronic steroids need stress-dose steroids during the perioperative period (see Chapter 25).

Most recipients of a liver transplant have been exposed to multiple procedures and may benefit from an anxiolytic preoperatively.<sup>107</sup> Midazolam is safe, provided there is no evidence of residual HE. Anesthesia can be induced with an inhalational technique, provided the liver graft is functioning normally and nothing-by-mouth (NPO) guidelines have been followed. Children who are hospitalized, septic, bleeding, encephalopathic, or rejecting the graft should have an IV induction and their airways should be secured with an endotracheal tube. Isoflurane, sevoflurane, and desflurane are suitable for maintenance of anesthesia.

## Kidney Transplantation

### DEMOGRAPHICS AND EPIDEMIOLOGY

Renal transplantation improves development, quality of life, and survival<sup>108,109</sup> in children with chronic renal failure. The OPTN maintains the national transplant registry in the United States; the OPTN data as of 2011 shows 826 children under the age of 18 on the active waiting list; this represents fewer than 1% of the 89,169 patients in the US waiting for a kidney.<sup>110</sup> Characterization of such a small patient population is challenging. The North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS) group has obtained the voluntary participation of all centers in the United States and Canada performing renal transplants on more than four children per year. Since the advent of the NAPRTCS in 1987, it has registered 11,603 pediatric renal transplants in 10,632 recipients.<sup>111</sup> This represents a capture rate of approximately 68% of the 16,000 kidney transplants that have been performed in the United States in children younger than 18 years of age<sup>110</sup> (E-Table 29-3). The inclusion into the NAPRTCS of pediatric patients requiring dialysis began in 1992, and the inclusion of children in chronic renal failure (creatinine clearance of 75 mL/min/1.73 m<sup>2</sup> or less) began in 1994. Currently, there are 16,874 children in the NAPRTCS registry based on the above indications (E-Table 29-4).

### PATHOPHYSIOLOGY: IMPLICATIONS OF THE PATIENT IN RENAL FAILURE

The kidneys perform a number of vital functions; both their dysfunction and the current methods of mechanical renal-replacement therapy have systemic implications. Because renal

**FIGURE 29-4** Patient survival while on dialysis. (Exhibit 1.9 from The North American Pediatric Renal Trials and Collaborative Studies 2011 Annual Dialysis Report. Available at <https://web.emmes.com/study/ped/annlrept/annlrept.html> [accessed June 17, 2011].)

dysfunction creates profound disturbances in normal homeostasis, morbidity and mortality is increased in children with renal failure, especially the very young (Fig. 29-4).

Disturbances in growth and development occur with renal failure, and depend on both the age of onset and the severity of the disease.<sup>112</sup> Infants, in particular, are vulnerable to growth retardation caused by renal failure. Appropriate management of nutrition, with<sup>113</sup> or without<sup>114</sup> the provision of renal replacement therapy, is necessary to ameliorate this effect. Renal transplantation may provide for some “catch-up” growth, although this is limited to younger children; the child’s final height is a function of the height at the time of transplant, graft function, and the immunosuppression regimen.<sup>111,114,115</sup> Growth hormone therapy can be used for children, both pretransplant and post-transplant, to manage height deficits. However, when therapy is initiated before severe growth retardation has occurred, growth hormone therapy is more effective.<sup>114,116,117,118</sup> A possible complication of growth hormone replacement in transplant recipients has been scoliosis.<sup>119</sup>

In addition to the effects on growth, renal failure also effects intellectual and behavioral development. Children requiring renal-replacement therapy from infancy are particularly vulnerable. Nutritional invasive enteral support and renal replacement therapy, along with early transplantation, can lead to near-normal cognitive function.<sup>120</sup> However, these children may have more problems with hyperactivity and conduct disorder. In addition, if these children are suffering from other comorbid conditions, they are very likely to have diminished IQ.<sup>121</sup> In older children and adults with end-stage renal disease since childhood, age at diagnosis and increased duration of dialysis are risks for decreased mental capacity. Renal transplantation status did not appear to be protective from the risks of decreased mental capacity.<sup>122,123</sup>

Chronic renal failure is associated with cardiovascular changes. Between 20% and 33%<sup>116,124</sup> of deaths in children on dialysis are cardiac in nature. Approximately 25% to 33%<sup>125,108</sup> of deaths in children and young adults with end-stage renal disease whose disease began in childhood are from cardiac causes. The incidence of coronary artery calcifications and carotid intimal-medial thickening, two surrogate measures of coronary artery disease, are increased in dialysis-dependent children<sup>126</sup> and in young adults with childhood-onset chronic renal failure.<sup>127</sup> Hyperhomocysteinemia, associated with cardiovascular disease in adults, is

CKD, Chronic kidney disease.

common in children with chronic renal failure,<sup>128</sup> as is dyslipidemia.<sup>129</sup> Hypertension is frequent, and is a risk factor for deterioration of renal function.<sup>130,131</sup> Left ventricular hypertrophy (LVH) is prevalent, both in children with chronic renal failure and in children on dialysis.<sup>132-134</sup> LVH may be associated with diastolic dysfunction.<sup>135</sup> Both LVH<sup>134</sup> and diastolic dysfunction<sup>135</sup> were noted to be more severe in children requiring dialysis.

In transplanted children, cardiac deaths constitute 15% of the causes of death.<sup>104</sup> Renal transplantation does decrease the risk of cardiac death, compared to that of children in chronic renal failure or dialysis-dependent children.<sup>108,125</sup> However, transplanted children have a persistence of pretransplant risk factors. LVH is still found in 50% to 75% of transplant recipients.<sup>136,137</sup> Risk factors for LVH in the posttransplant patient include a history of dialysis, anemia, and hypertension.<sup>136</sup> LVH can occur in renal transplant patients with normal 24-hour ambulatory blood pressure measurements.<sup>137</sup> In addition to LVH, 10 of 73 posttransplant patients in one study<sup>136</sup> demonstrated left ventricular dilation with systolic dysfunction. The incidence of coronary artery calcification in young adults who were transplanted as children is greater than in control patients,<sup>127,138</sup> and may be associated with carotid intimal-medial thickening.<sup>127</sup> Hyperhomocysteinemia is present in 63% to 77%<sup>138,139</sup> of transplanted children, and its presence is associated with poor graft function.<sup>139</sup> Folate supplementation may normalize homocysteine levels.<sup>140</sup> Even with good graft function following transplantation, dyslipidemia persists and is generally related to immunosuppression medications.<sup>129</sup> The incidence of diabetes requiring insulin treatment is 2.6%. Tacrolimus use and African American race are the two major risk factors for insulin requiring diabetes.<sup>141</sup>

Anemia is common both before and after transplantation. Anemia is caused by a decrease in erythropoietin production and iron deficiency. In posttransplant patients, CNIs, especially tacrolimus, are additional risk factors for anemia.<sup>142</sup> In pediatric patients requiring dialysis for the first time, anemia was associated with a greater risk of death and prolonged hospitalization.<sup>109</sup> Treatment of anemia has been shown to retard the progression of renal disease in adults.<sup>143</sup> In children with chronic renal failure, a hematocrit less than 33% is a risk factor for progression to end-stage renal disease.<sup>112</sup> Anemia may be associated with LVH in children<sup>132-136</sup> and in adult patients with chronic renal disease; erythropoietin has been shown to improve LVH.<sup>144</sup>

## PREOPERATIVE EVALUATION

Immediately before transplantation, the child should be stable, and fluid or electrolyte imbalances should be corrected. It is important to assess the urine output (anuric, polyuric) so that appropriate intraoperative fluid replacement can be administered before unclamping the blood vessels of the donor organ. Active infection is a contraindication for transplantation. Any concurrent systemic disorders should be optimized. Finally, the NPO status of the child should be ascertained; many who present for cadaveric transplantation will have a full stomach.

## SURGICAL TECHNIQUE

The surgical techniques used in the pediatric recipient differ from those used in the adult and depend on the child's size and underlying preexisting abnormalities, as well as the approach to the transplant (intraoperative or extraperitoneal). The extraperitoneal approach may be more technically difficult in smaller children. Removal of native tissue, either concurrently or (ideally)

previously, occurred in approximately 22% of children registered in the NAPRTCS database.<sup>111</sup> Preservation of urine-producing native kidneys may be desirable to prevent fluid overload during dialysis, especially for small children.<sup>145</sup>

Native nephrectomy may be required for polycystic kidney disease, uncontrollable hypertension, urinary tract infection, or nephrotic syndrome.<sup>145-148</sup> Removal of polycystic kidneys may be necessary for space reasons, especially in small children. Children with severe vesicoureteral reflux and intractable urinary tract infections may also require native nephrectomy. Nephrectomy for severe nephrosis may be necessary to resolve associated hypoalbuminemia, malnutrition, and hypercoagulability. Ideally, native nephrectomy is performed before transplant.<sup>147-149</sup> Native nephrectomy performed at the time of transplant increases operative time and cadaveric graft ischemic time,<sup>140</sup> and has been shown to be a risk factor for ATN in the grafted organ.<sup>111</sup>

## Children Weighing More Than 20 kg

In larger children (more than 20 kg), the surgical approach is similar to that in the adult transplant patient; the kidney is placed in the iliac fossa, and the vascular anastomoses are to the common iliac vein and artery.<sup>146,147</sup> In larger children, the external iliac vessels may be used.<sup>147</sup> An extraperitoneal approach has the advantage of increased ease of future graft biopsy and ability to resume peritoneal dialysis in case of delayed graft failure.<sup>145</sup>

## Children Weighing Less Than 20 kg

If renal transplantation in smaller children were restricted to size-compatible organs, then the surgical approach would be similar to that of the larger patient. However, a 1992 NAPRTCS report noted an increased loss of cadaveric grafts from pediatric donors. These pediatric donor organs had a greater rate of graft thrombosis and primary nonfunction, as well as a greater risk for acute rejection.<sup>150,151</sup> Consequently, the use of pediatric donors has declined and living donors increased (Fig. 29-5). More importantly, the improvement in graft survival (Figs. 29-6 and 29-7) and patient survival (Fig. 29-8) with a living donor, although present across age-groups, is markedly greater in these young children.<sup>111</sup>

For these reasons, the surgical technique for renal transplantation in the infant and small child has been modified to accommodate the adult-sized kidney. The use of a size-discrepant organ precludes the traditional approach. As Starzl et al<sup>152</sup> describe: "the adult organ almost completely fills a child's right paravertebral gutter, extending from the undersurface of the liver to the pelvis." Typically, a midline incision from pubis to xiphoid is used and the cecum and right colon are mobilized.<sup>146,149,152,153</sup> An alternate approach used by some centers, is a right lower quadrant incision, dissecting extraperitoneally;<sup>147,154</sup> this may have the advantage of quicker return of bowel function. Depending on the size of the recipient's vessels, the donor organ anastomoses may be made to the common iliac artery and vein, or directly to the aorta and vena cava.<sup>146,147,149,153</sup>

In addition to difficulties in surgical technique, adult organs in pediatric recipients present physiologic challenges. The adult-sized organ sequesters a disproportionate amount of the infant's blood volume and cardiac output.<sup>145,146,155</sup> In one study<sup>156</sup> that involved nine infant recipients of adult-sized kidneys, pretransplant, early posttransplant, and late posttransplant blood flows were determined in both the infant's aorta and the adult graft. Pretransplant graft flow was approximately 618 mL/min, whereas 8 to 12 days posttransplant, graft flow had decreased to

**FIGURE 29-5** Patient registrations, transplants, and selected characteristics. (Exhibit 1.1 from The North American Pediatric Renal Trials and Collaborative Studies 2010 Annual Transplant Report. Available at <https://web.emmes.com/study/ped/annlrept/annlrept.html> [accessed June 17, 2011].)

**FIGURE 29-6** Living-donor graft survival by recipient age. (Exhibit 5.4 from The North American Pediatric Renal Trials and Collaborative Studies 2010 Annual Transplant Report. Available at <https://web.emmes.com/study/ped/annlrept/annlrept.html> [accessed June 17, 2011].)

385 mL/min, despite aortic blood flow increasing from 331 mL/min to 761 mL/min. A further decrease was observed at 4 to 6 months, with aortic blood flow at 665 mL/min and graft flow at 296 mL/min. At 4 months the graft size had decreased by 26%. Even with excellent conditions, optimal hydration, and a doubling of aortic blood-flow, these adult grafts are still underperfused, both during transplant and in the late posttransplant period. In addition, the transplanted kidney is vulnerable to further reductions of flow resulting from gastrointestinal illness, poor oral intake, or hypotension during nontransplantation surgery.<sup>151</sup> This may explain why early graft loss in these smaller children is either primary nonfunction or thrombosis (E-Fig. 29-3).<sup>157</sup>

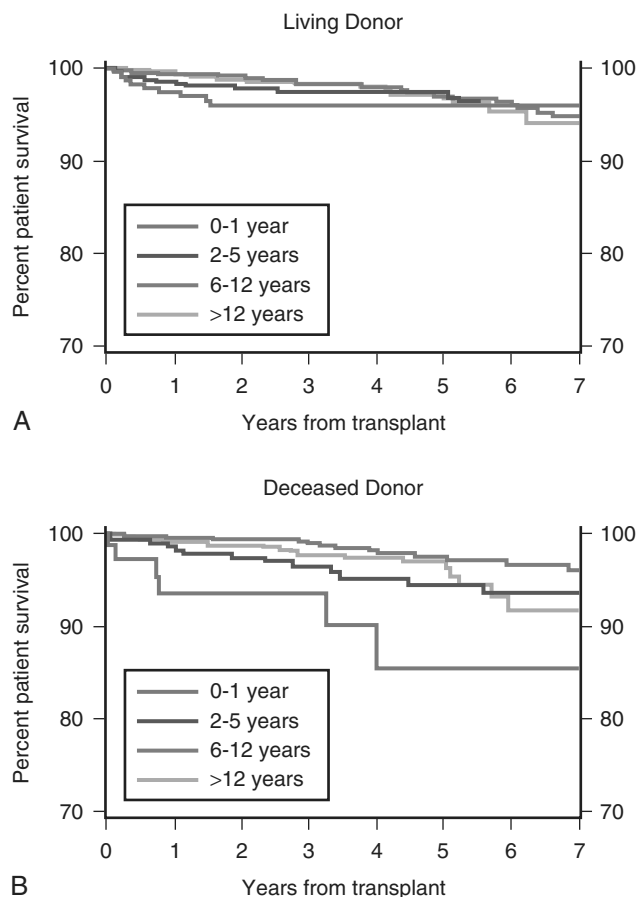

## ANESTHETIC APPROACH

### Periinduction

A living-donor renal transplantation is an elective procedure, whose only time constraints involve coordination with the donor harvest team, whereas in a cadaveric transplant, any delay could potentially increase donor organ cold-ischemic time. As such, most recipients of living-donor kidneys will arrive in the OR with an IV, empty stomach, completed blood work, and any immunosuppressant induction treatment underway. Conversely, recipients of cadaveric kidneys likely have a full stomach, have pending blood work, and may have immunosuppressant induction medications ordered but not yet given. An acceptable electrolyte panel, assurance that any cross-matching is under way, and confirmation with the treatment team regarding the type of immunosuppressant induction (and premedicant) planned is necessary. In particular, it is important to confirm that any

**E-FIGURE 29-3** Causes of graft loss—relationship with recipient age. (From Hwang AH, Cho YW, Cicciarella J, et al. Risk factors for short- and long-term survival of primary cadaveric renal allografts in pediatric recipients: a UNOS analysis. *Transplantation* 2005;80:466-70.)

**FIGURE 29-8** Patient survival by age at transplant when grafts were received from living (A) and deceased (B) donors; transplant era 1996 to 2006. (Exhibit 7.6 from The North American Pediatric Renal Trials and Collaborative Studies 2010 Annual Transplant Report. Available at <https://web.emmes.com/study/ped/annlrept/annlrept.html> [accessed June 17, 2011].)

immunosuppressant induction drug and its premedicant (if any) is ordered and will be immediately available when the child arrives in the OR.

### Immunosuppressant Induction Therapy

Children may receive immunotherapy perioperatively (Fig. 29-9) to assist the development of immunotolerance<sup>158</sup> of the implanted graft, and potentially to delay the administration of the nephrotoxic CNIs.<sup>145,146</sup> Antilymphocyte antibodies include alemtuzumab (Campath), equine antilymphocyte globulin (Atgam), and polyclonal rabbit antithymocyte globulin (Thymoglobulin), and the infusion of these agents cause a cytokine response. This cytokine response can include fever, chills, rigors, and malaise that should be pretreated with acetaminophen, corticosteroids, and diphenhydramine.<sup>158,159</sup> Anti-IL-2 antibodies include basiliximab (Simulect) and daclizumab (Zenapax), and these drugs do not cause a cytokine response. Adverse effects from anti-IL-2 antibodies are comparable to those from a placebo, save for an acute hypersensitivity reaction that can occur with basiliximab.<sup>158</sup>

Depending on the child, premedication may be administered to facilitate separation from the family. The cytokine effects of the antilymphocyte induction drugs can be unpleasant, and can erode the coping mechanisms of any age child. In children with a suspected full stomach, a rapid-sequence induction should be performed. Succinylcholine may be used in the absence of contraindications, such as hyperkalemia. In children with an empty stomach, an inhalational, IV, or combination technique may be used. Drug choices should avoid those drugs primarily metabolized or excreted by the kidney. One should not assume immediate resumption of renal function by the new graft. Because renal failure affects both protein-binding and volume of distribution, anesthetic agents and adjuncts should be titrated to effect. Preferential use should be made of drugs that undergo organ-independent elimination (cisatracurium, remifentanyl), or do not rely exclusively on the

**FIGURE 29-9** Induction antibody use by year of transplant. (Exhibit 3.2 from The North American Pediatric Renal Trials and Collaborative Studies 2010 Annual Transplant Report. Available at <https://web.emmes.com/study/ped/annlrept/annlrept.html> [accessed June 17, 2011].) ATG/ALG, Polyclonal antibodies antithymocyte globulins and antilymphocyte globulins.

kidney for metabolism (propofol), or whose renally excreted metabolites are inactive (midazolam, fentanyl). Regarding drugs with renally excreted metabolites that are active (morphine), these agents should be used cautiously and titrated to effect. Drugs with renally excreted metabolites that are toxic (i.e., meperidine) should be avoided.

### Monitors and Vascular Access

Standard monitors, including core temperature, should be used. The need for vascular access should reflect third-spacing requirements, and the potential for brisk blood loss inherent in a long intraabdominal procedure in which the surgeon will be directly accessing large vessels. Urine output may not reflect intravascular volume status secondary to native renal dysfunction, the ureter not yet anastomosed with the bladder, or polyuria in the reperfused graft.<sup>145,146</sup> Smaller children will have the most severe fluid shifts and will be the most vulnerable to graft hypoperfusion. Therefore central venous and arterial catheters to monitor intraoperative and postoperative pressures are extremely useful.<sup>145,145,155,160</sup> In the larger child, for whom assessment and maintenance of intravascular volume is more reliable, a central venous catheter may not be necessary in the presence of adequate peripheral access.<sup>153</sup>

### Maintenance and Reperfusion

The anesthetic management plan should take into account hemodynamic conditions necessary for adequate perfusion of the donor organ. Combined general-regional techniques have been used, but have been associated with larger intraoperative fluid requirements and the need for IV opioid supplementation in half the children.<sup>160</sup> A hypnotic agent supplemented with an opioid to minimize negative inotropy is appropriate, and avoiding nitrous oxide in a long intraabdominal case is prudent. Sevoflurane has been associated with the production of inorganic fluoride and compound A (see Chapter 6). Although no negative outcome data exist for the use of this agent in renal transplant recipients, case numbers are not sufficient to demonstrate its safety in this population.

Optimal hemodynamic conditions for reperfusion are more important when a large size discrepancy exists between the native organ and the graft. The extreme of this situation would be in the infant receiving an adult graft. In children, recommendations for central venous pressure range from 8 to 12 mm Hg to 16 to 20 mm Hg,<sup>146,154,155</sup> with most centers in the middle.<sup>145,147,149</sup> Some authors suggest a systolic blood pressure above 120 mm Hg,<sup>146</sup> and MAP above 65 to 70 mm Hg.<sup>145,146</sup> In the smaller child, blood sequestration in the graft will constitute a significant portion of the patient's total blood volume,<sup>145,146,155</sup> and the anastomosis will likely require the clamping, and subsequent unclamping, of the aorta. Both preload supplementation with blood, crystalloid, and colloid, and possible dopamine infusion to optimize cardiac output may be necessary.<sup>145,146</sup> Furosemide and/or mannitol may be given at the completion of the anastomoses to promote diuresis, and sodium bicarbonate may be given after aortic unclamping to attenuate subsequent acidosis.<sup>145-148</sup> Avoidance of blood products is desirable, as children with more than five lifetime transfusions are at increased risk of ATN.<sup>111</sup> Although there are data regarding prevention of anemia in the chronic management of the renal transplant patient, there does not appear to be an optimal hematocrit in the immediate postoperative period. Blood therapy must therefore be specific for each child.

### IMMEDIATE POSTOPERATIVE MANAGEMENT

In the immediate postoperative period, maintenance of the child's blood volume remains important. In small children, the volume resuscitation required to adequately perfuse the graft may preclude early extubation.<sup>147,154,155,160</sup> Maintenance of an adequate blood volume continues into the postoperative period, where usually copious urine output is replaced mL for mL.<sup>145-148,154,155</sup> Prevention of graft hypoperfusion and subsequent ATN potentially prevents acute rejection,<sup>151</sup> as ATN in the early postoperative period is a major risk factor for graft loss.<sup>111,130</sup> Maintenance of the circulating blood volume continues to be important even in the late postoperative period. One study<sup>161</sup> noted improved glomerular filtration rates at 6 months in their transplant recipients after starting an aggressive 2500 mL/m<sup>2</sup>/day fluid regimen (via nasogastric or gastrostomy tube) for 6 months; this difference persisted into the 12-month period.

### LONG-TERM ISSUES

Much has been accomplished in preservation of graft function for kidney transplant children. Unfortunately, cardiovascular morbidity, infection, and malignancy are the major long-term concerns. Almost half of renal transplant recipients die with a functioning graft.<sup>111</sup>

#### Infection

Increased success in immunotolerance for transplant recipients, unfortunately, can result in an increase in opportunistic infections from exogenous pathogens. After the first 5 months posttransplantation, infection surpasses acute rejection as the cause of hospitalization.<sup>111</sup> In particular, fungal infection is a significant risk for graft loss.<sup>162</sup> Deaths from infection eclipse cardiovascular causes of death for transplant recipients. Infection accounts for 28.4% of deaths in the NAPRTCS database.<sup>111</sup> Epstein-Barr virus (EBV) related adenotonsillar hypertrophy is common in the transplant population, occurring in 11 of 16 children in one series.<sup>163</sup> Risk factors for EBV-related adenotonsillar hypertrophy include young age and seronegativity at time of transplant.<sup>164</sup> Posttransplant lymphoproliferative disorder (PTLD), a result of EBV infection, is common and occurs earlier in the renal transplant population.<sup>165</sup>

#### Malignancy

Malignancy accounts for between 11.3% and 14% of the deaths after transplant in children.<sup>111,108</sup> A case report<sup>166</sup> describes the graft loss of two living-donor related kidney grafts to renal cell carcinoma 9 and 11 years posttransplant; neither donor developed cancer in their remaining kidney. In one series of 282 pediatric kidney recipients with cancer, PTLD and skin cancer were the most common cancers, 31% each, followed by cancers of the perineum, 7%, and Kaposi sarcoma, 5%; PTLD and Kaposi sarcoma were more likely to manifest in childhood.<sup>167</sup>

### SUMMARY

Anesthetic management of the child for renal transplant may be complicated by a number of factors. Impaired renal function may be present pre- and posttransplant. Comorbidities as a result of impaired renal function are numerous, and may require altered anesthetic management. Although the renal transplant patient is not normal, the continued function of the transplanted kidney allows for near normal function, growth, and development. Therefore the ultimate goal of management is preservation of both patient and graft.

## Cardiac Transplantation

Cardiac transplantation, as a viable treatment strategy in infants and children with congenital and acquired heart disease, has matured considerably since Kantrowitz performed the first heart transplant in a 16-day-old infant in 1967.<sup>168</sup> As the indications for pediatric cardiac transplantation continue to evolve and expand, donor organ availability is the major limiting factor.<sup>169</sup> The advances in immunosuppression, coupled with a better understanding of rejection, have resulted in improved graft and child survival, fewer adverse effects, and an improved quality of life.

However, rejection, infection, and posttransplant neoplasia continue to remain the major causes of death.

### DEMOGRAPHICS AND EPIDEMIOLOGY

Cardiac transplantation has become a valuable therapeutic option for a broad range of pediatric cardiac abnormalities. Approximately 20% of the pediatric recipients are younger than 1 year of age (Fig. 29-10).<sup>169</sup> The primary indication for cardiac transplantation in infants younger than 1 year of age is a severe structural congenital cardiac defect (Fig. 29-11).<sup>169</sup> Dilated, hypertrophic, or restrictive cardiomyopathies are less frequent

NOTE: This figure includes only the heart transplants that are reported to the ISHLT Transplant Registry. As such, this should not be construed as evidence that the number of hearts transplanted worldwide has increased and/or decreased in recent years.

indications in infants. However, in children 1 to 17 years of age, cardiomyopathies account for at least half of all indications for transplantation.<sup>169</sup> Unresectable cardiac tumors, severe life-threatening arrhythmias, and other diseases, such as Kawasaki syndrome, are uncommon indications in all age-groups (Figs. 29-12 and 29-13).<sup>170</sup>

### PATHOPHYSIOLOGY OF THE DISEASE

An understanding of the basic cardiac anatomy and pathophysiology in recipients presenting for cardiac transplantation is the key to safe perioperative management. Many recipients have

underlying lesions that allow alterations in the balance between systemic and pulmonary blood flow. Changes that accompany normal anesthetic management can radically alter this balance and thereby result in the recipient's deterioration. Other recipients have marginal cardiac output secondary to their underlying myopathies, or structural defects that hinder normal myocardial function.

### Congenital Heart Disease

This group of children includes those with complex lesions for which no option for palliation exists, children with end-stage

**FIGURE 29-12** Diagnosis in pediatric heart transplant recipients (1 to 10 years of age). ReTX, Retransplantation. (From Kirk R, Edwards LB, Kucheryavaya AY, et al. heart failure after surgical repair of congenital heart defects, children with failed palliation for single-ventricle physiology (Fontan type), and neonates with hypoplastic left heart syndrome (HLHS). There are children who have undergone surgical palliation with successful early results who later in life present with dilated cardiomyopathies secondary to long-standing valvular regurgitation, ventricular outflow tract obstruction, or dysrhythmias. Although the right ventricle has been shown to be capable of adapting to work as the “systemic” ventricle in cases of HLHS or in children who have undergone an “atrial type” switch operation for transposition of the great vessels, with time, these systemic right ventricles fail and develop both systolic and diastolic dysfunction. Thus in these children, the only therapeutic option left is transplantation.

### Dilated Cardiomyopathy

The etiology of dilated cardiomyopathy is often unknown or complex but includes viral myocarditis and drug-induced, ischemic, metabolic (disorders of fatty acid, amino acid, glycogen and mucopolysaccharide metabolism), genetic, or mitochondrial disorders.<sup>171</sup> The primary disorder in dilated cardiomyopathy is an abnormality of systolic function. Congestive heart failure is the most common presentation. Predictors of poor outcome include a family history of cardiomyopathy, syncope, ventricular arrhythmia, left ventricular end-diastolic pressure greater than 25 mm Hg, and left ventricular ejection fraction less than 30%.

### Restrictive Cardiomyopathy

Restrictive cardiomyopathies are uncommon disorders, with generally poor prognoses, that are associated with infiltration of the myocardium, such as glycogen storage disease, amyloidosis, mucopolysaccharidosis, hemochromatosis, and sarcoidosis. The infiltration results in diastolic dysfunction and diminished stroke output. Endocardial fibroelastosis also causes a restrictive cardiomyopathy and an increased pulmonary vascular resistance (PVR).<sup>172,173</sup> The increased PVR is secondary to an increased left ventricular end-diastolic pressure with associated increases in PAP.

### Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy is a concentric thickening of the left ventricular wall that can lead to both a fixed and a dynamic obstruction to left ventricular outflow (see Chapter 14). A number of sarcomeric genotypes have been described for this lesion. Many children with hypertrophic cardiomyopathy first present as infants. Their clinical course depends on the presence or absence of outflow tract obstruction. If obstruction is present, more than 25% of infants will present with failure to thrive and feeding intolerance as manifestations of congestive heart failure. A large septal muscular prominence can lead to mitral regurgitation secondary to abnormal systolic anterior motion of the mitral valve leaflets. The major consequence of this diagnosis is sudden death. Risk factors for sudden death include a family history of sudden death, marked concentric left ventricular wall thickness, age at presentation, and a reduced fractional shortening Z score.<sup>174</sup>

### Other Conditions

Although rare, some children require cardiac transplantation for unresectable cardiac tumors or sequelae of other diseases, such as Kawasaki disease. The pathophysiology of these lesions varies with the disease, but the end result is similar: systolic dysfunction, diastolic dysfunction, or both.

Contraindications to pediatric cardiac transplantation include multiple severe congenital anomalies, marked prematurity (before 36 weeks), low birth weight (less than 2 kg), ectopia cordis, diffuse pulmonary artery hypoplasia, pulmonary venous hypoplasia, active malignancy, active infection, severe metabolic disease, irreversible noncardiac end-organ damage, and a fixed pulmonary vascular resistance index (PVRI) greater than or equal to 6 Wood units, or a fixed transpulmonary pressure gradient greater than or equal to 15 mm Hg (1.9 kPa).<sup>175,176</sup> The increase in PVR is usually assessed during cardiac catheterization. These contraindications are considered by some to be relative, rather than absolute contraindications to cardiac transplantation. Additional potential contraindications include severe psychosocial problems that may impede proper postoperative care, the lack of reliable caretakers, and an unstable family structure; these are critical factors in the decision to offer transplantation as a treatment option.

### DONOR SELECTION

Donor selection for pediatric heart transplantation is often complicated by difficult social settings associated with the death of the donor. In addition, the usual criteria for selection of adult donors may not correlate well with myocardial pathologic findings in infants and children, thereby potentially limiting the availability of donor organs for infants and children.<sup>177</sup> There have been reports of neonatal transplants crossing the ABO barrier.<sup>178,179,180</sup> Donor-to-recipient weight ratios up to 3.0 have been used successfully. In a comparison with more equally matched donor-to-recipient weight ratios, children who received hearts from oversized donors had no differences in ICU ventilator days, fractional shortening as assessed by echocardiography, ability to close the chest, or duration of inotropic support.<sup>181</sup> In contrast to the use of oversized donor organs, undersized donor organs were associated with an increased rate of donor organ failure. Recipient PVR is a major determinant for appropriate donor selection, and larger donor hearts should be considered for those with increased PVR to permit the right ventricle to compensate for the increased afterload.<sup>182</sup> Myocardial preservation of the donor organ is aimed at minimizing the ischemia time. Ischemic times of 6 hours were thought to be ideal, but pediatric allograft ischemic times may be extended to 8 hours with little adverse consequence.<sup>183,184</sup>

### PREOPERATIVE EVALUATION

A comprehensive, multidisciplinary evaluation of a potential cardiac allograft recipient is required to determine the recipient's suitability for transplantation. This evaluation includes an assessment of the child's underlying cardiopulmonary, hepatic, renal, neurologic, infectious disease, and immune system status, as well as socioeconomic and psychosocial function (Table 29-3).

Assessment of cardiopulmonary function usually begins with a thorough history, with attention to exercise tolerance, oxygen requirements, and need for diuretics and inotropic support. Examination of the electrocardiogram, chest radiographs, echocardiograms, and Holter monitors may be helpful in the discovery of pleural or pericardial effusions, conduction disturbances, cardiac function, and arrhythmias. Radionuclide angiography may be useful in defining systemic ventricular dysfunction in children with complex cardiac morphology. The pretransplant assessment ultimately includes cardiac catheterization with angiography. The anatomy and hemodynamics of the recipient must be carefully delineated, because this influences anesthetic

In: Allen HD, Gutgesell HP, Clark EB, et al., editors. *Moss and Adams' heart disease in infants, children, and adolescents including the fetus and young adult* 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2001, p. 295-407.

INR, International normalized ratio; PPD, purified protein derivative.

management, surgical donor harvesting, and recipient transplant technique. For instance, in children with unrepaired HLHS, the donor harvest team has to conserve a large segment of donor aorta to facilitate reconstruction of the recipient aorta. The anesthetic management of this child before bypass must account for the possibility of pulmonary overcirculation. Determination of the PVRI, transpulmonary gradient (TPG), and reactivity of the pulmonary vascular bed to pharmacologic manipulation is crucial to the assessment of suitability for cardiac transplant.

$$\text{PVRI (units/m}^2\text{)} = (\text{PAP [mm Hg]} - \text{PAWP [mm Hg]}) / \text{CI (L/min/m}^2\text{)}$$

$$\text{TPG (mm Hg)} = \text{PAP (mm Hg)} - \text{PAWP (mm Hg)}$$

where PAP is the mean pulmonary artery pressure, PAWP is the mean pulmonary artery wedge pressure, and CI is the cardiac index.

A PVRI greater than 6 Wood units/m<sup>2</sup> or a TPG in excess of 15 mm Hg can lead to acute right ventricular graft failure, although the upper limit of PVR associated with successful cardiac transplantation has not been established in children. An endomyocardial biopsy can identify acute myocarditis and myocardial infiltrates. Pulmonary function studies may be useful in older children with chronic lung disease.

Laboratory evaluation should include serum electrolytes, complete blood cell count with differential, coagulation profile, viral titers for possible latent viral infections, such as cytomegalovirus (CMV) and EBV, and metabolic or genetic work-ups. Donor matching is based on ABO typing, although successful transplantation of ABO-incompatible hearts in infants has increased the potential donor pool for infants in critical need.<sup>185,186</sup> ABO-incompatible hearts are possible because of the immaturity of the infant immune system and the lack of production of ABO antibodies during the first 3 to 6 months of life. The use of triple-volume exchange transfusions also minimizes the potential reaction to maternally transmitted, preformed ABO antibodies. The recipient's blood is also screened for antibodies against sera of random blood donors and, if reactive, a serum crossmatch with the donor may be performed. Panel reactive antibodies are preformed circulating human leukocyte antigen (HLA) alloantibodies that, in high titers, are associated with diminished graft survival.<sup>187,188,189</sup> These antibodies arise from the use of homologous blood products, and blood products should be avoided if at all possible in the pretransplant period. Treatments to reduce panel-reactive antibodies may include IV immunoglobulin, cyclophosphamide, and plasmapheresis.<sup>190</sup> Although HLA compatibility may improve graft survival, HLA matching is not routinely performed, owing to time constraints and limited availability of donor organs.

The mean time from listing for transplant to the actual surgery is about 3 months, but varies with the child's age, blood group, and list status. UNOS has developed allocation procedures that give priority to the most urgently ill children. Status 1 children have a projected life expectancy of less than 6 months, and status 2 children have a projected life expectancy of more than 6 months. Status 1 children generally require mechanical or pharmacologic support to sustain life, and most require support in ICUs. These children are further subdivided into 1A and 1B, where 1A is reserved for those with a projected life expectancy of less than 1 month. Physicians of status 1A children must recertify every 7 to 14 days if their patients do not require mechanical support for acute hemodynamic decompensation, and even those who require mechanical support are only guaranteed 30 days until physician recertification becomes necessary. Approximately 20% of children with cardiomyopathy and 30% of those with end-stage congenital heart disease die while waiting for a donor heart.<sup>191-193</sup> Medical stabilization frequently includes the use of diuretics, inotropic agents, arrhythmia therapy, oxygen or subatmospheric oxygen, and mechanical ventilation, if warranted. Studies of  $\beta$ -adrenergic blockade therapy (carvedilol) have shown promise in children with dilated cardiomyopathy and chronic heart failure.<sup>194,195</sup> Those with severe chamber

enlargement, arrhythmias, and low cardiac output may require systemic anticoagulation to prevent thrombus formation and systemic embolization. Implantable defibrillators have been effective in children large enough for these devices, and biventricular pacing has shown promise as well.<sup>196,197</sup>

Children with end-stage myocardial failure will require mechanical circulatory support as a bridge to transplantation (see Chapter 19). Extracorporeal membrane oxygenation (ECMO) has been used for up to 1200 hours as a bridge to cardiac transplantation.<sup>198</sup>

Newer ventricular assist devices show more promise and applicability to a broad range of children for a much more prolonged period of support.<sup>199-202</sup> Renal failure that requires dialysis reduces survival.<sup>203</sup> Sepsis, neurologic injury, and bleeding are also serious complications of mechanical circulatory support.

Congenital heart disease is the primary indication for cardiac transplantation in infants younger than 1 year of age, and many of these recipients will have HLHS. The patency of the ductus arteriosus must be maintained with prostaglandin E<sub>1</sub>, initially as a continuous infusion, and perhaps by stenting the ductus in the catheterization laboratory later, if a suitable donor organ is not found. Alteration of flow across the atrial septal defect can be addressed as well by the interventional cardiologist (see Chapter 20). If the balance between systemic and pulmonary blood flow cannot be managed medically, pulmonary artery banding may be necessary to reduce pulmonary overcirculation while waiting for a donor organ.

## SURGICAL TECHNIQUE

The original orthotopic technique devised by Lower and Shumway in adults was popular for many years in children in whom the anatomy was straightforward.<sup>204</sup> This technique avoided individual systemic and pulmonary venous anastomoses by leaving a large cuff of right and left atrial recipient tissue behind and anastomosing the donor right and left atria to these cuffs. The resulting atrial chambers were a combination of donor and recipient atria that contracted asynchronously. Because the atrial contribution to cardiac output may be augmented with total cardiac transplantation, most centers have converted to the “bicaval” technique with a modification to use the standard left atrial anastomosis.<sup>205-208</sup> This technique improves sinus node function, causes less tricuspid regurgitation, and improves exercise tolerance.<sup>209,210</sup>

Cardiac transplantation in children with congenital heart disease may require surgery of greater complexity, involving reconstruction of the great vessels or alterations in venous anastomoses. It is important that the donor harvesting team understand the recipient’s anatomy and the potential harvest needs that may require large portions of aorta, pulmonary arteries, and venae cavae. In children with HLHS who require aortic arch reconstruction, deep hypothermic circulatory arrest may be necessary.<sup>211-213</sup>

The recipient is placed on cardiopulmonary bypass (CPB) after median sternotomy with aortic and bicaval cannulation. Cannulation may be modified, depending on the cardiac anatomy encountered. The aorta is cross clamped, and both the aorta and the pulmonary artery are divided at the level of their semilunar valves. The superior and inferior vena cavae are transected, preserving a cuff of atrial tissue on each to facilitate the anastomoses. The interatrial groove is prepared, an encircling left atriotomy is performed, and the recipient heart is removed from the field. The donor organ is prepared and brought to the field.

The left atrial anastomosis is completed first; and while iced saline is bathing the interior and exterior of the heart, the aortic anastomosis is completed. A vent is left in the left ventricular cavity for decompression and evacuation of air as the caval anastomoses are completed while the child is rewarming. The cross clamp is removed, and the donor heart is reperfused while the pulmonary arterial anastomosis is completed. Ventilation is resumed, and the child is liberated from CPB after return of cardiac function is documented by transesophageal echocardiography. Epicardial pacing wires are placed, mediastinal drainage tubes are positioned, and the chest is closed.

## INTRAOPERATIVE PROBLEMS AND MANAGEMENT

Some children listed for cardiac transplantation may be hemodynamically stable and living at home. Preoperative fasting may be an issue in these children. The anesthesiologist must carefully assess the relative risks of a full stomach compared with the potential complications associated with an unexpected difficult airway in a child undergoing a rapid-sequence induction. Several hours may lapse between the call to mobilize the team and the actual surgery, but therapy to modify gastric pH and volume, and the application of cricoid pressure may be warranted. It is equally likely that the pediatric recipient is hospitalized and requires a host of treatments designed to promote hemodynamic stability while a donor organ is sought. These children have minimal cardiovascular reserve. Anesthetic agents, positive-pressure ventilation, and surgical stress frequently result in hemodynamic instability. Anesthetic preparation should include the immediate availability of a variety of medications for the perioperative manipulation of myocardial function and hemodynamics. Vasoactive drugs and inotropic agents, such as epinephrine, phenylephrine, dopamine, dobutamine, isoproterenol, milrinone, nitroprusside, and nitroglycerin, should be readily available. For children with underlying congenital heart disease, the anesthesiologist needs to understand the child’s underlying pathophysiology. The anesthetic management before CPB is similar to that for nontransplant cardiac surgery. For children with end-stage myocardial dysfunction, the sympathetic nervous system is chronically activated, with downregulation of the cardiac  $\beta_1$ -adrenoceptors and an impaired response to  $\beta$ -adrenoceptor agonists.<sup>214</sup> Reduced renal perfusion stimulates the renin-angiotensin system, leading to increases in vasoconstriction, venoconstriction, and increased intravascular volume. These compensatory changes further aggravate the congestive heart failure by increasing preload and afterload. A dysfunctional, dilated myocardium is very sensitive to changes in preload, afterload, heart rate, and contractility. Both systolic and diastolic myocardial function is impaired, and an increased mean atrial pressure is needed to ensure adequate ventricular filling volume. Increasing heart rate results in a decreased diastolic filling time and, therefore, a diminution in stroke volume as a result of the poor systolic and diastolic ventricular function, atrial pressure increase, and atrial enlargement. There is a loss of preload reserve. Cardiac output then becomes more heart rate dependent, and a decrease in heart rate results in a decreased cardiac output. Furthermore, small increases in afterload result in an increased end-systolic volume, decreased stroke output, and a further decrease in cardiac output. Dysrhythmias are poorly tolerated in these children.

Coordination of the arrival of the child to the OR with the donor team ensures the briefest possible ischemic time for the donor organ. Premedication is best administered under monitored conditions. If the child was receiving supplemental oxygen,

it should be continued during the preinduction period. Before induction, monitoring devices, such as a precordial stethoscope, electrocardiogram, noninvasive blood pressure cuff, and pulse oximeter, are applied. Meticulous airway management is critical, because hypoxemia and hypercarbia may alter PVR and further depress cardiac output. A wide variety of anesthetic agents have been used, depending on the nature of the cardiac disease and the risk of pulmonary aspiration. After induction, invasive monitoring does not differ from that used during routine pediatric cardiac open-heart surgery. Some centers avoid right internal jugular vein cannulation because that vessel may be repeatedly accessed for posttransplant endomyocardial biopsy. TEE is useful to assess graft function, mechanical issues, and pulmonary hypertension. In children, TEE has been shown to be a more sensitive monitor for changes in cardiac function than hemodynamic changes.<sup>215,216</sup> Many experienced centers do not use pulmonary artery catheters routinely because the value of the information gained does not warrant the additional risk. In children who have undergone multiple cardiac operations, the potential risks of reoperation should be addressed and should include the need for adequate-sized vascular catheters, the availability of blood products in the OR, the preparation for alternate cannulation sites, and the use of antifibrinolytics. The use of ultrafiltration during CPB may be beneficial by removing free water, hemoconcentrating the red blood cells and coagulation factors, and modulating the inflammatory response.<sup>217-221</sup>

Anesthesia is generally maintained with opioids, benzodiazepines, isoflurane, and a nondepolarizing muscle relaxant. In children with congenital heart disease, this anesthetic technique preserves cardiac output better than some inhalational agents, provided the heart rate is maintained.<sup>222</sup> In preparation for termination of CPB, it is critical that the hemodynamics are optimized. A stable cardiac rhythm and acceptable heart rate are desirable. Chronotropic support, using IV therapy with  $\beta$ -adrenergic agents, such as isoproterenol and epinephrine, or the use of epicardial pacing, may be needed to maintain an appropriate heart rate between 120 and 150 beats per minute. The denervated transplanted heart does not respond in the normal fashion to hypotension. Medications with indirect cardiac effects, such as atropine, glycopyrrolate, or ephedrine, will likewise be ineffective. Direct-acting medications, such as dopamine, dobutamine, epinephrine, or isoproterenol, are required if inotropic or chronotropic support is needed. Some children benefit from vasodilator infusions to improve left ventricular stroke volume and cardiac output.<sup>223</sup> The use of inotropic agents to separate from CPB and provide early postoperative stability is common. The choice of agents is based largely on the perceived balances between pulmonary and systemic vascular resistance, the patient's underlying myocardial function, blood pressure, and cardiac output. Ventilation should be managed to ensure mild respiratory alkalosis and adequate oxygenation. Factors that potentially increase PVR, such as hypothermia, acidosis, hypercarbia, hypoxemia, increased adrenergic tone secondary to light anesthesia, and polycythemia, should be eliminated. Children with increased PAP before bypass show a greater response to ventilatory changes than those without increased PAP. In addition, children with congenital heart disease and associated pulmonary hypertension may develop severe pulmonary hypertension in response to hypoxemia.<sup>224-226</sup> The narrow range of afterload that the donor right ventricle is capable of handling is critical; if managing the pulmonary hypertension with conservative methods is unsuccessful, more aggressive pharmacotherapy is

warranted. The use of prostaglandin, prostacyclin, nitroglycerin, high-dose milrinone, calcium-channel blockers, sildenafil, and inhaled NO have all been effective in treating pulmonary hypertension in children (see Chapter 16).<sup>227-239</sup> In extreme cases, mechanical assist devices or ECMO have been used (see Chapter 19).<sup>240,241</sup>

Dysrhythmias may be common in the postbypass period, and, depending on the technique of implantation, there may be two independent P waves on the electrocardiogram, one from the recipient sinoatrial node and the other from the donor sinoatrial node. It is only the donor sinoatrial node that transmits impulses to the atrioventricular node and thus to the ventricle. The most common dysrhythmias are junctional rhythms, underscoring the utility of direct-acting  $\beta$ -adrenoceptor agonists and epicardial atrioventricular sequential pacing. This denervated state results in the loss of the baroreceptor reflex, forcing cardiac output to become primarily dependent on venous return and circulating catecholamines, and thus unable to respond acutely to changes in the circulating blood volume and blood pressure.<sup>242-243</sup>

After separation from CPB, hemodynamic stabilization, and control of surgical bleeding, protamine sulfate is administered slowly to reverse anticoagulation. Risk factors for hypotension in children after protamine administration following bypass include female sex, greater protamine doses, and smaller heparin doses.<sup>244</sup> Transfusion of blood products is determined by a balance of the need against the associated risks of administration. There may be significant acid-base and electrolyte disturbances associated with large-volume transfusions. These disturbances may be decreased by washing the cells before transfusion.<sup>245,246</sup> Donor blood should be screened for CMV and, ideally, CMV-negative recipients should receive blood that has screened negative for CMV.<sup>247</sup> Leukocyte reduction by filtration may be associated with a diminished risk of exposure to CMV through transfusion.<sup>248,249</sup> Another concern associated with transfusion in cardiac transplant recipients is the risk of transfusion-associated graft-versus-host disease (TAGVHD). This results from active T lymphocytes in the transfused blood of a recipient who is unable to reject them, such as a neonate, those undergoing chemotherapy, and the otherwise immunocompromised child.<sup>250,251</sup> To limit the risk of TAGVHD in cardiac transplant recipients, some centers routinely irradiate cellular blood products with  $\gamma$ -radiation before administration. At recommended doses,  $\gamma$ -radiation has an insignificant effect on platelet, red cell, or granulocyte function, but it may increase the free potassium concentrations (see Chapter 10).<sup>252,247</sup>

Transport of the child from the OR proceeds as in any other open-heart procedure. In selected recipients with excellent allograft function and hemodynamics, extubation of the trachea is possible in the OR or within a few hours of arrival in the ICU. It is important that these children are comfortable, but otherwise ventilating adequately to prevent atelectasis, hypoxemia, or hypercarbia that may increase PAP and thus strain the donor right ventricle. Newer agents, such as dexmedetomidine, may facilitate early extubation in these children.<sup>253</sup> Other children may require sedation and mechanical ventilation as a result of hemodynamic instability or because of delayed sternal closure, particularly if a large donor-to-recipient size mismatch is present.

## IMMEDIATE POSTOPERATIVE MANAGEMENT

Early postoperative management consists primarily in maintaining hemodynamic stability. Infusions and volume needs are adjusted to maintain an optimal balance of preload, afterload, cardiac output, and peripheral perfusion. Attention should be

directed toward maintaining normal acid-base and electrolyte balance. In some children, pulmonary hypertension remains a serious concern, and management of sedation, ventilation, inotropic infusions, and pulmonary vasodilator administration is required to optimize right ventricular function. Ventilation modes may need to be adjusted to reduce the mean intrathoracic (airway) pressure. Renal dysfunction continues to be a major source of morbidity and mortality after cardiac transplantation. Decreased perioperative renal function can occur in as many as 20% of children after cardiac transplantation.<sup>254,255</sup> A peritoneal dialysis catheter, placed at the time of cardiac transplant, can be used to reduce ascites and improve ventilatory mechanics in those with right-sided heart dysfunction, and in the treatment of renal insufficiency. Arrhythmias in the postoperative period may herald rejection.

Immunosuppression begins with corticosteroids administered before removal of the aortic cross clamp, and continues into the postoperative period. Immunosuppression induction continues postoperatively, with infusions of antibodies to reduce early rejection and to diminish dose requirements of corticosteroids and calcineurins. T-cell-depleting antibodies include polyclonal rabbit antithymocyte globulin (Thymoglobulin), equine antithymocyte globulin (Atgam), and monoclonal muromonab-CD3 (OKT3). IL-2 blockers (basiliximab and daclizumab) may also be used for induction. Maintenance therapy is guided largely by institutional experience and the recipient's clinical profile. The goal of maintenance therapy is to prevent acute and chronic rejection, while minimizing the adverse effects of immunosuppression. All maintenance regimens involve a CNI along with antiproliferative agents, or sirolimus. Corticosteroids may also be used, although most centers limit or avoid their long-term use. CNIs include cyclosporine and tacrolimus. Antiproliferative agents include azathioprine and mycophenolate mofetil (Cell-Sept). Sirolimus (rapamycin) is a macrolide antibiotic that acts synergistically with the CNIs and can be used to reduce the dose of cyclosporine or tacrolimus. Sirolimus may also inhibit the process of coronary arteriopathy.<sup>256</sup>

First-line therapy for acute rejection is high-dose corticosteroids. Other agents, including monoclonal and polyclonal anti-T-lymphocyte antibodies, are reserved for refractory or recurrent severe acute rejection, or rejection with severe hemodynamic compromise. Recurrent moderate rejection is usually controlled with modulation of the maintenance-therapy dosing.<sup>257</sup>

In spite of the remarkable improvements in immunosuppression and patient selection, acute and chronic rejection remain the major cause of death after pediatric cardiac transplantation (E-Tables 29-5 and 29-6).<sup>258,259</sup> Monitoring and diagnosis of allograft rejection remain a challenge. Some studies suggest that transplant before 1 year of age offers protection from episodes of acute rejection, and significantly greater freedom from rejection and time to first rejection.<sup>260</sup> Rejection surveillance in children includes three levels of detection. The clinical assessment includes nursing and parental accounts of changes in the child's activity and appetite, nausea, emesis, malaise, resting heart rate 15 to 20 beats per minute above normal, and presence of ectopia. Echocardiography has become very important in the postoperative follow-up, especially in neonates. These studies are performed frequently, especially in the first months after the transplant. Acute changes in left ventricular end-diastolic dimension, posterior wall thickness, and shortening fraction are potential signs of acute rejection.<sup>261</sup> Endomyocardial biopsy remains the standard in the diagnosis

of acute cardiac allograft rejection. It provides tissue for both precise documentation of the presence or absence of rejection, and allows more accurate titration of immunosuppression, to avoid the adverse effects of increased use of immunosuppression based on clinical and noninvasive examinations only. Biopsy specimens are also analyzed for signs of humoral and vascular rejection. The biopsy specimen is examined for evidence of lymphocytic accumulations in the graft interstitium and perivascular tissue, and in severe forms of cellular rejection, myocardial necrosis and polymorphonuclear cell infiltrates. Over time, it is also possible to develop chronic rejection, which is primarily a vasculopathy that involves vascular inflammation, with binding of IgG and/or IgM and complement. This produces a diffuse and concentric stenosis affecting the mid and distal coronary arteries and is often asymptomatic. Although annual coronary angiography is recommended, accelerated graft arteriosclerosis is underestimated angiographically.

New techniques are being developed to identify early evidence of rejection. Serum vascular endothelial growth factor may be a marker for cellular rejection.<sup>262</sup> Vascular endothelial growth factor is an established angiogenesis factor and is expressed in allografts undergoing rejection, but its function in the rejection process has not been defined. The possibility also exists for the detection of graft rejection by the examination of the characteristic gene expression patterns in peripheral blood mononuclear cells of heart transplant recipients.<sup>263</sup>

## LONG-TERM OUTCOME AND QUALITY OF LIFE

Over 500 pediatric heart transplants are performed annually, giving a total of more than 6000 worldwide since 1982. Approximately 50% of the recipients do not require hospitalization in the first year after transplantation and, by 3 years, more than 70% are free from hospitalization. One year after transplant, 93% of survivors are without functional limitations. This increases to 95% by 5 years after transplant (E-Figs. 29-4 and 29-5; Table 29-4). The prevalence of posttransplant morbidities for 5-year transplant survivors is as follows: hypertension (61%), hyperlipidemia (21%), coronary vasculopathy (11%), renal dysfunction (9%), and diabetes mellitus (5%) (Table 29-5). At one center, 13% of pediatric cardiac recipients returned to the ORs for noncardiac procedures.<sup>264</sup> Preoperative evaluation requires an understanding of the unique features associated with the transplanted heart, such as its denervation, risk of vasculopathy (coronary artery disease), and arrhythmias. The interaction of the immunosuppressive regimens with anesthetic agents and their association with hypertension and renal dysfunction are additional considerations. Medication and monitoring choice should be tailored to the individual needs of the child to minimize anesthetic morbidity. Most medically stable cardiac transplant patients can undergo routine noncardiac surgical procedures in a similar fashion to children who haven't received transplants (see Chapter 21). It is important to remember that reflex mechanisms are impaired in the denervated heart, and changes as a result of light anesthesia, hypovolemia, or contractility will be delayed until circulating catecholamines can influence the cardiac  $\beta$ -adrenoceptors directly.<sup>265,266</sup> As cardiac-transplant children live longer, the risks of coronary vasculopathy increase, with coronary ischemia becoming a major concern. Therefore attention to the maintenance of coronary perfusion is paramount. As in all immunocompromised patients, these children are vulnerable to infection, and strict adherence to aseptic and sterile technique is mandatory.

## Pediatric Heart-Lung and Lung Transplantation

### DEMOGRAPHICS AND EPIDEMIOLOGY

Pediatric heart-lung and lung transplants, unavailable just a generation ago, are now relatively commonplace at a number of pediatric specialty hospitals. There are 35 to 40 centers that perform pediatric lung transplants, and roughly 10 centers perform heart-lung transplants. The first successful pediatric heart-lung transplant was performed at the Children's Hospital of Pittsburgh in 1985. Pediatric lung transplantation followed in Toronto in 1986, recalling the success of adult lung transplantation in the early 1980's.

In 1962 the first adult lung transplant recipient survived for eighteen days after transplantation. It was not until the early 1980s that advances in surgical technique and immunosuppressive therapy ushered in the modern era of lung transplantation. Subsequently, heart-lung and lung transplantation have become a well-accepted treatment for both adults and children with end-stage cardiopulmonary and pulmonary disease. There have been over 1500 pediatric lung transplants since the first pediatric lung transplantation in 1986, with an additional 550 heart-lung transplants.<sup>267</sup> The management of the heart-lung transplant patient enjoys many similarities with that of the lung transplant patient, including a sharing of many of the underlying disease processes. Nonetheless, the number of heart-lung transplants continues to decrease yearly, from a high of seventeen in the late 1990's. Only 4 centers reported performing a pediatric heart-lung transplant in 2008.<sup>268</sup> Although this decrease in transplants may be related to a decrease in suitable donor availability, it is more likely a result of an increasing awareness that even longstanding right ventricular dysfunction in the face of significant pulmonary hypertension exhibits reversibility post-lung transplant. Therefore heart-lung transplants are less necessary than previously thought.

Children with end-stage pulmonary and cardiopulmonary disease who receive heart-lung transplant or lung transplants, frequently undergo a variety of interventions both pre- and post-transplant. These ill children require special considerations in all phases of their anesthetic care.

The number of children listed on all transplant waiting lists continually outstrips the donor supply. Donor identification and management are more selective for heart-lung and lung transplant candidates than isolated heart transplants. One example of this increased selectivity is that the thoracic capacity of the donor should not be greater than that of the recipients. If it is larger the transplanted lungs will be at an increased risk of post-operative atelectasis and infections.<sup>269</sup> Donor supply remains the largest obstacle in transplantation. As many as one-third of all children listed on the waiting list die before receiving lung transplantation.<sup>270-271</sup> The average waiting time for cadaveric lungs is 20 months for adolescents and 6 to 12 months for children less than 2 years old. As experience in pediatric lung transplantation increases, it is likely that accepted indications for transplantation will increase as well. In that eventuality, time spent on the waiting list is likely to grow, given that there is no indication the donor pool is increasing.

A variety of strategies have been undertaken to increase the size of the donor pool. Television, radio, and print advertisements have been provided to the public. Everyone has the opportunity to declare themselves a potential donor when obtaining a drivers license in the United States. Some states go further. Pennsylvania has laws requiring nurses to ask the patient's family members whether they will consent for donation in the event of the patient's death.

Some countries have a longstanding reluctance to donate organs. These barriers to transplantation can come down by increasing education. More often it takes a dramatic event to engender change. Nicholas Green, a 7-year-old American boy, was vacationing in Italy in 1999 when he was shot in the head by a random act of violence and subsequently declared brain dead. His parents elected to donate his organs. Seven Italian citizens received his organs. In the wake of the publicity of the shooting and subsequent organ donation, signed organ donation cards in Italy quadrupled, and actual donations tripled. Donors' families may also gain some solace from donation. Green's father stated: "There is some consolation with the process. It puts something on the other side of the balance. It will never bring my son back, but it can help somewhat with the grief."<sup>272</sup> However, in other

countries, such as Japan, organ donation rate is much less than in North America. In part, this is because of cultural concerns and fears that patients might be declared brain-dead just for their organs and, in part, because Japanese culture expects reciprocal gift giving rather than selfless altruism of organ donation, as is more common in Western cultures. Despite the 1997 inculcation of "brain-death" criteria in Japan, it was not until July 17, 2010, that the revised Organ Transplant Act permitted children less than 15 years of age to donate organs.

### **PATHOPHYSIOLOGY OF THE DISEASE**

The indication for heart-lung and lung transplantation is severe end-stage pulmonary disease, for which there is no other medical treatment, and a life expectancy less than 18 months. The listing criteria for the prospective transplant patient additionally includes consideration of the functional status of the child, the child's hemodynamic parameters, and the natural history of the underlying disease. For example, children with pulmonary hypertension may progress to end-stage pulmonary disease rapidly. Most pediatric lung transplant patients are 11 to 17 years old, with a smaller subset of children less than 2 years old.<sup>273</sup> The most common underlying disease in elder pediatric lung transplantation patients is cystic fibrosis, accounting for nearly half of all pediatric lung transplants. Of children with cystic fibrosis who do not receive transplants, 95% will eventually succumb because of pulmonary issues. Factors associated with why less than 50% of cystic fibrosis patients survive include an FEV<sub>1</sub> (forced expiratory volume in 1 second) of less than 30%, a predicted PaO<sub>2</sub> less than 55 mm Hg or a PaCO<sub>2</sub> greater than 50 mm Hg.<sup>274</sup> Pulmonary vascular disease accounts for nearly one-fourth of the remaining transplantations. Infants who require transplantation, most often have a variety of relatively rare diseases, such as surfactant B deficiency, primary alveolar proteinosis, or pulmonary vascular disease.<sup>275</sup> These infants are often severely ill at the time of their transplantation. Their tracheas are frequently intubated and they receive mechanical assistance for oxygenation and ventilation, or even require ECMO. Independent risks for mortality after lung transplant include repeat transplant, mechanical ventilation at time of transplant,<sup>276</sup> and congenital heart disease.<sup>277,278</sup> Although at one time it was thought that prior thoracic surgery was a contraindication for lung transplantation, as experience has grown, this is no longer considered a contraindication.<sup>279</sup> In fact, a significant number of children who receive lung transplant have had prior thoracic surgery for congenital heart disease. Furthermore, prior lung transplantation is not a contraindication for subsequent lung transplantation.<sup>280</sup> Today the primary contraindications for lung transplantation are (1) active malignant disease within the prior 2 years, which may be unmasked by the immunosuppressive therapy required in transplantation, (2) significant active infectious processes (including HIV and hepatitis B and C), (3) significant coexisting cardiac disease, (4) hepatic or renal disease (although these children may be candidates for multiple organ transplants), (5) collagen vascular disease, (6) major irreversible neurologic injury, and (7) patient or family history of poor medical compliance or severe psychiatric illness that would preclude the child from effective posttransplant care. Relative contraindications include (1) significant musculoskeletal disease, (2) invasive ventilation, (3) colonization with atypical mycobacterium or fungi, (4) poor nutritional status (body mass index at either extreme), and (5) inability to reduce dependency on corticosteroids. A lung allocation score is calculated for each patient on the waiting list aged twelve years or older.<sup>281</sup> Variables

considered in calculating the individual child's score include age, underlying illness, forced vital capacity, functional status, and need for supplemental oxygen.<sup>282</sup> The UNOS also includes ABO compatibility and distance between the donor and the recipient in its considerations for organ allocation.

UNOS adopted a new allocation system for children younger than 12 years old in 2010. There are now two distinct priority levels, with the most ill children given a priority 1 ranking. Priority 1 candidates will have respiratory failure with the need or presence of continuous mechanical ventilation, fraction of inspired oxygen (FiO<sub>2</sub>) greater than 0.5 to maintain arterial oxygen saturation levels of more than 90%, an arterial or capillary PCO<sub>2</sub> of more than 50 mm Hg or a venous PCO<sub>2</sub> of more than 56 mm Hg and/or significant pulmonary hypertension despite medical therapy. Children not meeting the above conditions are listed as priority 2. Donor lungs are first allocated to the priority 1 candidate longest on the waiting list who matches the donor's size and blood type. If there is no suitable priority 1 candidate, the lungs are then offered to the priority 2 candidate with the most waiting time.

The care of the donor is critical. The donor must first meet criteria for brain death. Additionally, the donor should have been intubated less than 5 days to decrease the risk of lung injury, particularly ventilator-associated pneumonia. The donor should have no active infection. In particular, tracheal secretions must be void of infection. The donor should have either a PaO<sub>2</sub> greater than 300 mm Hg at an FiO<sub>2</sub> 1.0, or greater than 100 mm Hg at an FiO<sub>2</sub> of 0.4, with an inflation pressure less than 30 cm H<sub>2</sub>O, with tidal volumes of 15 mL/kg, and a PEEP of 4 cm H<sub>2</sub>O. For lung donation, the donor is kept euvoletic to slightly hypovolemic, with central venous pressures in the range of 8 to 10 mm Hg. On occasion this places the physicians desiring to use the donor kidneys at odds with those desiring to use the heart and lungs. In such situations, the goal is to meet the desires of all, within reason, so that as many of the potential organs may be used as possible. When lungs are harvested, they are perfused with a preservative solution and prostaglandins, which reduces the incidence of graft failures. The lungs are inflated and the trachea is stapled closed to maintain an inflated position. The organs are then transported to the recipient at a temperature of 4° C. Ischemic times of less than 8 hours are desired; less than 3 to 4 hours is ideal.

Another avenue being explored to increase the availability of organs suitable for lung transplantation is the nonheartbeating donor (NHBD).<sup>283</sup> Kidneys,<sup>284</sup> livers,<sup>285</sup> and other tissues have been used successfully from NHBDs. NHBDs may prove to be an as yet untapped resource and facilitate an expansion of pediatric lung transplantation. A system has been developed in Madrid that allows out-of-hospital emergency services personnel and transplant teams to initiate a protocol to harvest organs from NHBDs. They reported success in two children who were discharged to home after receiving lung transplants from NHBDs.<sup>286</sup> NHBDs are typically younger than traditional donors.

An additional resource of lung donation is the living related-donor with transplantation of adult lobes into the child.<sup>287,288</sup> Living related transplants overcome some of the difficulties inherent in attempting to predict the clinical course of the underlying disease, by being able to electively schedule the transplant. However, the inherent size mismatch limits the use of this technique to children 5 years and older. Typically, the left lower lobe is harvested from one donor while the right lower lobe is

harvested from another donor. The harvest technique is similar to that of a lobectomy; however, the technique requires an appropriate length of bronchus and adequate vascular pedicles. Morbidity in the donor is significant.<sup>289</sup>

### PREOPERATIVE EVALUATION

Children listed for lung transplantation undergo an extensive work up. Commonly included are chest radiographs, pulmonary function tests, arterial blood gas, complete metabolic panel, electrocardiogram, and echocardiogram. If the child has pulmonary hypertension and/or associated cardiac defects, they also require a cardiac catheterization. The catheterization will define the patient's anatomy and allow measurement of pulmonary vascular resistance.

When the decision is made to proceed with transplantation, the donor is notified. A short ischemic time (the time from when the donor lungs are explanted to when they are implanted into the recipient) is desired. Prolonged ischemic times have been implicated in increasing the risk of bronchiolitis obliterans (BO), a major source of morbidity in the posttransplant period. In light of this desire to proceed expeditiously, the anesthesiologist commonly has limited time to collate all the data and perform their preoperative evaluation. The cautious use of premedication may be beneficial. Commonly used anxiolytics include midazolam and ketamine, with consideration of a relatively new agent, dexmedetomidine, an  $\alpha_1$ -adrenoceptor agonist sedative with minimal depression of respiratory drive.

### SURGICAL TECHNIQUE

Children most commonly receive bilateral lung transplants with CPB.<sup>290,291</sup> To facilitate this, most pediatric lung transplantations are performed via a bilateral anterolateral transsternal "clamshell" incision. Before institution of CPB, as much dissection as possible is carried out. The anastomosis itself is made with two bronchial anastomoses rather than one tracheal anastomosis. Tracheal anastomoses have been found to produce less satisfactory results than bilateral bronchial reanastomosis and have largely fallen out of favor. Bilateral bronchial anastomosis has been found to produce better results, without the concern of tracheal stenosis. Traditionally each bronchus is anastomosed with an end-to-end anastomosis. The most popular technique now is the telescoping anastomosis, in which the larger bronchus is telescoped several centimeters over the smaller bronchus portion, with peribronchial tissue being wrapped around the anastomosis to ensure blood supply, because bronchial blood supply is not reestablished. If the end-to-end anastomosis technique is used, this traditional method may include an omental wrap around the suture line. Once the bronchus is anastomosed, the pulmonary artery is anastomosed. The donor lung includes an atrial cuff, which is sutured directly to the left atrium of the recipient. Use of the donor atrial cuff avoids the complication of pulmonary vein stenosis. Although donor lungs are selected to be a size match, occasionally the lungs are too large for the recipient and can not be used en toto without predisposing to significant areas of atelectasis. If deemed too large, volume reduction may be undertaken to remove areas prone to atelectasis.<sup>292,293</sup>

Single lung transplants are infrequently performed in children and are specifically avoided in cystic fibrosis patients, to avoid damage from the remaining diseased lung. If single lung transplantation is performed for the non-cystic fibrosis patient, the side chosen to transplant is the most diseased side, preserving the best lung to remain in situ. Additionally, if emphysema changes

are present, the most emphysematous lung is removed to decrease the risk of compression of the donor lung. Single lung transplants are most often performed without CPB. Single lung ventilation is procured and a thoracotomy is performed, exposing the bronchus and vessels. A test occlusion by the surgeon of the pulmonary artery to the proposed explant lung is then performed to evaluate the ability of the child to withstand the procedure without CPB. Presuming the child tolerates the test clamp, the surgery proceeds with the removal of the native diseased lung. The donor lung is anastomosed by first connecting the pulmonary vein atrial flap to the native left atrium, followed by anastomosing the pulmonary artery. As in the technique for sequential bilateral lung transplants previously described, the smaller of the two bronchial ends is telescoped into the other, with an overlap of one cartilage ring. The lung is then gently inflated. Air within the lung vasculature is vented via the pulmonary artery or the atrial cuff, with the left atrium partially occluded. Once de-airing is accomplished, ventilation and perfusion of the donor lung are both established.

### INTRAOPERATIVE PROBLEMS AND MANAGEMENT

Children arriving for lung and heart-lung transplant are often critically ill. Cystic fibrosis patients are often quite compromised when they arrive for transplant, frequently unable to comfortably lie down because of excess secretions. Children with pulmonary fibrosis or end-stage chronic obstructive pulmonary disease may be marginally hypoxic and hypercarbic at baseline, with elevated pulmonary artery pressures and right heart dysfunction. If premedication is necessary, caution must be exercised to not decrease respiratory drive to any significant degree, which would possibly precipitate worsening hypoxemia, hypercarbia, and right heart failure.

Pretransplant, children commonly have a "full stomach" because of the often short interval between their notification of impending transplant and the timing of the transplant itself. In such circumstances, a rapid sequence or modified rapid sequence induction may be considered. However, if possible, the best route is likely one of a more gentle induction. The choice of induction agents is broad and must take into account comorbid illnesses, such as significant right heart dysfunction or other congenital anomalies, in addition to the end-stage pulmonary disease. A one-size-fits-all anesthetic technique is not appropriate for heart-lung and lung transplantations. Once standard monitors have been applied, propofol, sodium thiopental, etomidate, or even volatile anesthetics may be considered as primary induction agents, either alone or in combination with narcotics or benzodiazepines. Much of the peritransplant anesthetic considerations focus on the optimization of pulmonary vascular resistance. Elevations in pulmonary vascular resistance may cause acute right ventricular failure, with reduced cardiac output. Right sided pressures can increase enough to cause significant right-to-left shunting through intracardiac lesions, and result in desaturation. Heart-lung transplants are generally reserved for those children with the worst pulmonary hypertension and right heart dysfunction. Ketamine does not appear to significantly alter pulmonary vascular resistance in infants<sup>294</sup> and may be considered as a first-choice drug.<sup>295,296,297</sup> Given the desire to rapidly intubate and control the airway, a relatively rapid-onset neuromuscular blocking agent, such as rocuronium, is most commonly used. Initial ventilator settings must take into account the underlying disease process. For example, fibrotic lungs may be better served by smaller tidal volumes with a faster rate, allowing a decreased peak

inspiratory pressure while preserving minute ventilation. On the other hand, severe obstructive disease may best be served by a slower pattern, with an expiratory time long enough that it does not induce dynamic hyperinflation (auto-PEEP). PEEP may be beneficial to improve oxygenation and ventilation, and decrease atelectasis. Nonetheless, both dynamic hyperinflation and PEEP, by increasing intrathoracic pressure, may decrease venous return and cause hemodynamic compromise, particularly in relatively hypovolemic children. Should hemodynamic collapse occur with the institution of ventilation in a child with severe obstructive lung disease, dynamic hyperinflation should be immediately considered among the possible etiologies. Rapid treatment is provided by just disconnecting the child from the ventilator circuit and allowing the child to exhale. When ventilation is reinstituted, care must be taken to allow for adequate expiratory time.

Anesthetic maintenance is most commonly with a balanced anesthetic, typically opioid-based and supplemented with volatile anesthesia to ensure amnesia. Volatile anesthetic based techniques are less common because of their cardiovascular depression and vasodilation. Furthermore, volatile anesthetics blunt hypoxic pulmonary vasoconstriction, and may make it more difficult to maintain adequate oxygenation should off CPB lung transplantation be desired. Nitrous oxide is avoided because of its propensity to increase pulmonary vascular resistance<sup>298,299,300</sup> and its property of expanding small air bubbles, which may be present in the microcirculation of the transplanted lung on reimplantation. Consideration may also be given to regional anesthesia techniques. Because of concerns regarding the use of CPB for these procedures and its attendant need for systemic heparinization, epidural thoracic catheters used for postoperative pain control are generally placed postoperatively, when the child's coagulation profile has normalized.

The anesthesiologist is also likely responsible for the administration of the preoperative antibiotics and immunosuppressive medications required for lung transplantation. Many transplant centers include the use of immunosuppressive induction therapy. More than half of all recipients are now receiving either IL-2 receptor antagonists or cytolytic medications. There is no clear-cut consensus on this point; however, some centers believe it best to avoid this treatment because of the profound immunosuppression and the risk for perioperative infections.

The vast majority of pediatric lung transplants are performed with the assistance of CPB. This contrasts to the non-CPB technique most commonly employed in adults. There are several reasons for the evolution of this distinction. Cystic fibrosis patients have a significant risk of cross contamination of the donor lung during a bilateral sequential lung transplant. This risk of damage is minimized by the simultaneous removal of both lungs. Furthermore, children with pulmonary hypertension are frequently too unstable to tolerate single-lung ventilation. An additional difficulty is that many children are too small to accommodate a double-lumen tube and single-lung ventilation may be difficult. CPB alleviates these issues and allows the surgeon a quiet field with good exposure and predictable hemodynamics, thus speeding the time for anastomosis and decreasing the overall ischemic time.

If the child does undergo either single-lung transplant or sequential bilateral lung transplant without CPB, continual vigilance and reassessment of the patient's condition is required. These are extremely ill children undergoing dramatic perturbations to their homeostasis. Single-lung ventilation often precipitates hypoxemia and hypercarbia. The combination of the

increased afterload on the right heart by the clamping of the pulmonary artery, along with hypercarbia and hypoxemia-induced pulmonary hypertension on the other lung, may precipitate right heart failure. Attempts to diminish pulmonary hypertension may be undertaken with pulmonary vascular dilators and inotropes, such as milrinone, prostaglandins, or NO, along with maintaining an adequate right-sided filling pressure. Nonetheless, continued right heart failure may necessitate CPB. If the child can tolerate clamping of the pulmonary artery, it is typical that the gas exchange improves as the shunting through the nonventilated lung is stopped and the perfusion-ventilation mismatch is diminished.

Bilateral sequential lung transplants performed on CPB do not offer these problems. Nonetheless, CPB does not come without cost. Gas exchange may worsen as a result of reperfusion injury and pulmonary edema, with the concomitant decrease in lung compliance. Inflammatory mediators are liberated and the complement cascade is initiated, perhaps contributing to reperfusion injury in the transplanted lungs. The systemic heparinization required for CPB further increases the risk for perioperative bleeding and the need for transfusion of blood products. Packed red blood cells, platelets, and clotting factors are typically required. Some of these needs may be mitigated with the addition of fibrinolytics.

When the procedure is performed with CPB, there is no need to perform single-lung ventilation, so airway management of the child is accomplished with a single lumen endotracheal tube after the patient has been anesthetized. Cuffed endotracheal tubes are typically chosen for the ability to provide a better tracheal fit and allow for the potential ventilation of the lungs with relatively high pressures, both pretransplant and posttransplant, with less concern about excessive air leak. In the rare circumstances that the operation of pediatric lung transplantation is performed without CPB, single-lung ventilation will be required. Double-lumen tubes may be used in older children. If a double-lumen tube is used, it is exchanged for a single lumen endotracheal tube at the conclusion of the operation, unless there is a desire to continue with differential lung ventilation or there is a concern about contralateral lung contamination. In small children either a bronchial blocker or selective intubation of a single bronchus may be considered. These options, however, preclude the ability to suction the nonventilated lung. Once the child has been intubated, additional invasive monitoring is placed, typically an arterial catheter and a central venous catheter, along with two large-bore IV catheters. Some centers will place a pulmonary artery catheter, in addition to or in place of the percutaneous central venous line. Occasionally, the surgeon will place a right atrial catheter. If a pulmonary artery catheter is placed, it must be withdrawn into the main pulmonary artery before pneumonectomy. A transesophageal echocardiography (TEE) probe is then placed to assist in evaluation of residual cardiac abnormalities and cardiac performance, particularly right ventricular performance, both pretransplant and posttransplant, while weaning from CPB.<sup>301</sup>

Perioperative bleeding is common, both in the OR after coming off CPB and in the immediate postoperative period. Extensive pulmonary-to-systemic collaterals, coagulopathies resulting from hepatic dysfunction, and significant adhesions from prior surgeries or cystic fibrosis may make the surgical dissection difficult and precipitate blood loss. Fibrinolytics have been demonstrated to reduce bleeding in children with prior thoracic surgery.<sup>302</sup>

During CPB the patient is typically cooled to 32° C. Cystic fibrosis patients are uniformly colonized with bacteria, and after the native lungs are removed, their tracheal stump is irrigated with antibiotic solution to reduce contamination of the transplanted lungs. Despite best efforts, occasionally these children develop sepsis or a syndrome similar to septic shock caused by liberation of bacteria and toxic mediators during the removal of the native lungs. Such children require intensive therapy and often do poorly.

Following the first lung being implanted, a small amount of blood is allowed to eject into the pulmonary artery while the second lung is being anastomosed, reducing ischemic time for the first lung. After the second lung is implanted, the lungs are ventilated to remove all areas of atelectasis. Posttransplant ventilation strategy limits tidal volumes to maintain peak inspiratory pressures less than 35 cm H<sub>2</sub>O and PEEP in the range of 5 to 10 cm H<sub>2</sub>O. It is typical to augment myocardial performance with inotropic support before termination of CPB. Occasionally, a combination of inotropes, dilators, or pressors may be required. Some centers routinely use NO and/or prostaglandin E<sub>1</sub> (PGE<sub>1</sub>) to reduce pulmonary vascular resistance, whereas others reserve their use only to treat problematic pulmonary hypertension. Fiberoptic bronchoscopy may be performed to assess the bronchial anastomotic sites, either in the OR, or within the first 24 hours postoperatively, along with a lung perfusion scan.

In the heart-lung transplant patient, weaning from CPB is analogous to that for the cardiac transplant patient, described elsewhere in this chapter. There remains the need to support the denervated heart with adequate fluids and inotropy. Maintaining adequate fluid status in these children may require a bit more effort because of increased bleeding when compared to heart transplant patients. Bleeding is further exacerbated in these children as a result of bronchial circulation and extensive collaterals, which have often developed. Blood products are uniformly required in these children.

The onset of acute graft dysfunction may present with persistent hypoxemia after weaning from CPB. Although this may be attributable to relatively reversible causes, such as inadequate ventilation, atelectasis, or right ventricular dysfunction with right-to-left shunting, a more ominous problem may be reperfusion injury. Free radicals and inflammatory mediators are readily produced by the lung during both the ischemic time and during reperfusion. Reperfusion injury is correlated with greater ischemic times. Reperfusion injury presents as hypoxemia in the face of adequate ventilation and no other clear etiology of the hypoxemia. Pink frothy secretions noted in the endotracheal tube often indicate reperfusion injury. PGE<sub>1</sub> may reduce reperfusion injury risk and symptoms. Although some routinely start PGE<sub>1</sub> infusion at 0.025 µg/kg/min, even before returning circulation to the first anastomosed lung, and continue this treatment for the first 24 to 48 postoperative hours, prevention of prolonged ischemic times is the best treatment. Ventilation strategy aims at maintaining adequate oxygenation and ventilation with adequate PEEP and the lowest peak inspiratory pressures possible. FIO<sub>2</sub> is aimed to keep PaO<sub>2</sub> less than 120 mm Hg to avoid oxygen toxicity. NO, a potent smooth muscle relaxant, is gaining favor for use in this setting as well. Although it has not been shown that prophylactic NO prevents reperfusion injury, NO in the dose range of 20 to 60 parts per million has been demonstrated to be effective in children with elevated pulmonary artery and right heart pressures coupled with hypoxemia.<sup>303,304</sup> Another option may be inhaled prostacyclin, which

had been demonstrated to be safe and useful in the treatment of pulmonary hypertension and reperfusion injury.<sup>305</sup> Nonetheless, on occasion, all these measures remain inadequate. In this event, ECMO should be instituted to allow the donor lungs to recover.<sup>306</sup>

### IMMEDIATE POSTOPERATIVE MANAGEMENT

The immediate postoperative care of the patient is individualized based on the child's age, pretransplantation diagnosis and pretransplantation comorbidities. Older children with cystic fibrosis usually require mechanical ventilation for several days. Their time-to-discharge from the critical care unit averages less than 1 week.<sup>307</sup> After extubation, these children may still require some supplemental oxygen for exercise therapy. Infants and children without cystic fibrosis, typically more acutely ill pretransplant, require an average of more than 3 weeks of mechanical ventilation and average nearly 2 months of critical care stay.<sup>308</sup> These younger transplantation patients are smaller in size, have an increased incidence of airway complications, and may suffer from associated congenital cardiac defects. Children with significant pretransplantation pulmonary hypertension often manifest significant hemodynamic instability postoperatively. In anticipation of this, these children are kept intubated, sedated, and frequently paralyzed for the first 2 postoperative days.

Posttransplantation patients require aggressive chest physiotherapy to avoid lung congestion that could lead to infection and respiratory failure. The child's cough reflex is absent and mucociliary transport is disrupted across the bronchial suture line. Frequent endotracheal suctioning is mandatory. Therapeutic bronchoscopy for pulmonary toilet may also be required. In addition to the risk for infections resulting from pulmonary considerations, the surgical sites, catheters, and drains also add to the risk of infection. Prophylactic antibiotics are given perioperatively, including antivirals and antifungals, particularly if underlying fungal infection or viral infection (such as cytomegalovirus)<sup>309</sup> are present in either the donor or recipient.

Postoperative pain control is critical to ensure effective pulmonary toilet. It is most readily obtained with judicious use of opioids. Patient-controlled analgesia may be considered in those children deemed able to use such a device. Regional anesthesia may also be used, but because of the systemic heparinization on CPB, many are reluctant to place a catheter prebypass. If regional anesthesia is desired, a thoracic epidural or paravertebral catheters may be placed postoperatively when the coagulation status of the child has normalized. Dexmedetomidine may also be used as adjunct pain management. Dexmedetomidine is an α<sub>2</sub>-adrenoceptor agonist, offering an arousable sedation with minimal effect on respiratory drive. Dexmedetomidine has been demonstrated to decrease opioid use by one-half in postoperative children, and may additionally decrease the incidence of opioid tolerance.

### LONG-TERM ISSUES

Because of the large endothelial surface in the lungs and the resulting large number of immunologically active cells that predispose to major histocompatibility class antigens, and an extreme lymphocyte-directed host response, immunosuppressive drugs are used in greater doses in lung transplant and heart-lung transplant patients than in other organ transplant patients. Induction immunosuppression is used in more than half of the heart-lung and lung transplant centers.<sup>310</sup> Most transplant centers use a continuing multiple-drug immunosuppressive regimen.<sup>311</sup>

Bearing in mind the adverse effect profiles and efficacy of immunosuppression, the International Pediatric Lung Transplant Collaborative has recommended that tacrolimus, mycophenolate mofetil, and prednisone form the mainstay of immunosuppressive therapy. The most widely used regimens rely on a CNI, coupled with a cell cycle inhibitor, and a corticosteroid. The most commonly used CNIs are cyclosporine and tacrolimus. Both work similarly, and both have clinically important side-effect profiles. Neither one appears to offer a significant benefit over the other in preventing BO from occurring. The major adverse effects of tacrolimus include hyperglycemia, alopecia, possibly worsening renal function, and possibly increased risk of PTLD. Cyclosporine's major adverse effects include hypercholesterolemia, hirsutism, gingival hyperplasia, and hypertension. Cyclosporine may prolong the neuromuscular blockade of atracurium and vecuronium.<sup>312</sup> Cyclosporine blood concentrations must be monitored closely, particularly in patients with cystic fibrosis who are prone to variable absorption. Elevated concentrations of cyclosporine have been implicated in central nervous system adverse effects, such as seizures, headaches, and even strokes.<sup>313,314</sup> Steroids are included in nearly all lung transplant programs. Over time the steroid dose is weaned to prevent complications, such as hyperglycemia and osteoporosis, yet at 1 year and 5 years posttransplant, nearly all lung transplant patients remain on a dose of prednisone. Cell cycle inhibitors are used in addition to the CNIs and corticosteroids. Mycophenolate use is increasing, but there has not been a clearly demonstrated benefit over azathioprine. Azathioprine may prolong neuromuscular blockade of succinylcholine.<sup>315</sup> Sirolimus acts by blocking IL-2-induced T-cell proliferation. Its role as a primary medication is limited by its hindrance of wound healing, potentially contributing to a dehiscence. It may be used as rescue therapy for children with BO who have mature suture lines.

More than one-third of children on chronic immunosuppression develop hypertension during the first posttransplant year. By 5 years that number is nearly three-quarters of all survivors. Additionally, a significant number of these children, particularly those receiving tacrolimus, develop chronic renal insufficiency with decreasing creatinine clearance. Occasionally, renal insufficiency progresses such that the child requires dialysis and renal transplantation.

A variety of perioperative complications may occur.<sup>316</sup> Posttransplant airway complications may be devastating. Although life-threatening bronchial dehiscence is uncommon, bronchial stenosis and tracheomalacia remain problematic.<sup>317,318</sup> Bronchial stenosis is thought to be related to relative ischemia at the anastomotic site, recurrent infections, and possibly high-dose corticosteroids. Initial treatment of stenosis is balloon dilation; however, up to half of the children with bronchial stenosis will require placement of bronchial stents. In younger children, dynamic obstruction may be a complication that makes extubation difficult. This dynamic airway obstruction usually is self limited, improves over time, and does not require intervention.

Posttransplantation, patients are followed closely for signs of rejection, infection, and/or BO. Pulmonary function tests are followed and the results examined for change. The choice of anesthetic agents and techniques for these patients after transplantation must be individualized, accounting for comorbidities, such as right heart dysfunction, decreased ability to handle secretions, and airway involvement affecting bronchial suture lines. Flexible fiberoptic bronchoscopies with bronchoalveolar lavage and transbronchial biopsies are the most common indications

for anesthesia in children after transplantation.<sup>319</sup> Bronchoscopies are performed at regular intervals, typically every 3 months, to evaluate even very early pathologic changes. Flexible fiberoptic bronchoscopies are most frequently performed under general anesthesia in children. A supraglottic airway (SGA) is the preferred manner of airway management. The SGA lumen is significantly larger than that of an endotracheal tube and allows the bronchoscopist to use a larger fiberoptic bronchoscope, facilitating improved view, improved suctioning, easier bronchoalveolar lavage, along with enhancing the ability to obtain adequate transbronchial biopsies.<sup>320</sup> Acute rejection is common in the first several weeks to months posttransplantation. Although acute rejection is often asymptomatic, fever and dyspnea may be present. Radiographic findings may include infiltrates and pleural effusions. Pulmonary function tests may demonstrate a decreased FEV<sub>1</sub> and decreased forced vital capacity. Diagnosis is confirmed by bronchoscopy, bronchoalveolar lavage and transtracheal biopsy. Acute rejection is graded on a scale of A0 to A4. Grade A2 and above are treated with increased immunosuppression. The major manifestation of chronic rejection, BO,<sup>321</sup> remains the bane of the lung transplantologists, occurring in nearly 50% of all post-lung transplant patients within 5 years of transplant. BO is the leading cause of death after the first posttransplant year. BO presents as progressive deterioration of exercise tolerance, and deterioration in airflow. BO is characterized by fibrosis of small airways and thickening of blood vessels. BO is diagnosed by a decrease in FEV<sub>1</sub>, compared to the immediately previous FEV<sub>1</sub>. Known risk factors for BO include prolonged ischemic time of the donor lung, more than two rejection episodes, and age greater than 3 years.<sup>322</sup> Unfortunately, there is no consistently reliable treatment for BO. A variety of immunosuppressive medications have been used with variable results. The primary treatment for BO is immunosuppressive prevention of acute rejection and prompt CMV treatment. In severe instances of BO, retransplantation is the only treatment option.

Posttransplant vascular complications are uncommon, but when they do occur are most commonly a result of mechanical obstruction of blood flow secondary to redundant tissue in either the pulmonary artery or at the cuff of the atrial tissue, impeding venous return. Vascular complications may be difficult to distinguish from reperfusion injury, presenting with elevated right sided and pulmonary artery pressures, with pink frothy secretions in the endotracheal tube. Pulmonary arterial or venous stenosis may be diagnosed in the OR, or at bedside in the critical care unit, with a TEE. If there are still questions regarding the diagnosis, cardiac catheterization may be required. Depending on the findings, the children may be treated with a stent placed during cardiac catheterization, or they may require reoperation to alleviate the stenosis. Furthermore, transplanted lungs do not have lymphatics anastomosed. Therefore there is a loss of lymphatic drainage in the transplanted lungs. This loss of lymphatic drainage increases the risk for pulmonary edema in the postoperative period. Increased parenchymal water and increased vascular filling further serve to decrease the compliance of the posttransplant lungs.<sup>323</sup>

Posttransplantation donor lungs are denervated. Although this produces minimal effect on airway reflexes, mucociliary transport, and bronchial reactivity,<sup>324</sup> the larger effect is the loss of stimuli to the respiratory drive center, with a loss of coordination of the respiratory accessory muscles. This lack of coordination may be visually apparent. Additionally, in the early posttransplantation period, children often demonstrate episodes

of bradycardia. A later effect is a tendency toward an elevated sympathetic tone and an increased heart rate.<sup>325</sup>

Phrenic, recurrent laryngeal, and vagus nerve injuries are common after lung transplant.<sup>326</sup> Although phrenic nerve injury is typically transient, the resulting diaphragmatic paralysis may result in prolonged need for mechanical ventilation or even consideration of placement of a diaphragmatic pacer. Recurrent laryngeal nerve injury may occur in up to 10% of pediatric lung transplants. The left recurrent laryngeal nerve is most often involved, resulting in a left vocal cord paralysis, from which most patients will recover.<sup>326</sup>

Gastroesophageal reflux disease (GERD) is a considerable problem for post-lung transplant patients. A significant number of children with GERD require a Nissen fundoplication. Laparoscopic Nissen fundoplication may be the preferred technique.<sup>327</sup> GERD and gastroparesis may be precipitated by vagal nerve injury. Not only do recurrent-aspiration pneumonias contribute to the transplanted lung's failure, but the delayed gastric emptying results in unreliable absorption of the child's immunosuppressive drugs.

Children with cystic fibrosis, in particular, have a high incidence of intestinal obstruction after lung transplantation. These children may require gastrostomy, jejunostomy, or other procedures for ileus. As many as one in ten children with cystic fibrosis also have intestinal obstruction after lung transplantation.<sup>328</sup>

Post-lung transplant graft rejections are common. Older children average 10 times more episodes of rejection than infants,<sup>329,330</sup> likely because of the infants more immature immune system. The signs and symptoms of rejection are nonspecific. Any diminished clinical measure is generally aggressively investigated to rule out rejection. If rejection is confirmed, aggressive treatment with immunosuppressive therapy is instituted.

CMV is one of the most common infections in children, posttransplantation. CMV infections may present with mild symptoms, but they may progress to pneumonitis, gastrointestinal symptoms, or even a sepsis syndrome with multiorgan failure. CMV has been associated with both acute cellular rejection and chronic rejection.<sup>331</sup> Antiviral medications have decreased the severity of this infection. Prophylactic treatment is often considered if either the donor or the recipient are CMV positive.

Patients with cystic fibrosis remain at a greater risk for infection postoperatively. *Pseudomonas aeruginosa* or fungal organisms may be noted. Aggressive antibiotic therapy is warranted. Additionally, a number of malignancies have been reported in post-lung transplant patients at greater rates than their age-matched counterparts, and may be attributed to immunosuppressive therapy. PTLD has a greater incidence in lung and heart lung transplant patients than in other solid organ transplants, perhaps owing to the greater level of immunosuppression required in these children. Even in this group of children, the cystic fibrosis subgroup of transplant patients has an even greater incidence of PTLD. PTLD includes a group of tumors, ranging from B-cell hyperplasia to immunoblastic lymphoma. Mortality has been reported to be as much or greater than 60% for those afflicted, with a number of the deaths attributed to graft failure resulting from the treatment of PTLD (by the need to decrease immunosuppressive therapy). As many as 25% of cystic fibrosis patients may suffer from PTLD. PTLD is, in most cases, associated with EBV infection, either as a reactivation of the virus with immunosuppression, or with new infection acquired from the donor lung. EBV occurs uncommonly in children who are seropositive

for EBV pretransplantation. In those seronegative, EBV-associated disease occurs in one in five children. The diagnosis of PTLD is made by the symptoms, evidence of lymphoproliferation on biopsy, and EBV DNA or RNA in the biopsied tissue. PTLD presents with a variety of nonspecific symptoms, including a mononucleosis-type syndrome. The most common symptoms include elevated temperature, lymphadenopathy, and gastrointestinal symptoms. Most PTLD occurs in the first year posttransplantation. EBV infection results in both a humoral and cellular immune reaction in children. In immunodeficient children, the normal immune responses are blunted at best. The natural regulation by T cells and natural killer cells is impaired. Natural killer cells' function is impaired for several months posttransplantation. The immunosuppression required to prevent graft rejection impairs T-cell immunity and allows for unchecked proliferation of EBV-infected B cells.

The treatment of PTLD is reduction or withdrawal of immunosuppressive therapy,<sup>332</sup> which may double survival rates.<sup>333</sup> Unfortunately, reduction or withdrawal of immunosuppressive therapy places these children at risk for graft failure. Additional treatments that have been demonstrated to be effective include localized excision of the lesion, antiviral therapy,<sup>334</sup> monoclonal antibodies,<sup>335</sup> interferon,<sup>336,337</sup> immunoglobulin, and cytotoxic T lymphocytes.<sup>338</sup> Chemotherapy does not appear to offer an advantage and may worsen survival.<sup>339</sup> One method to follow the efficacy of treatment is to measure EBV titers weekly. Declining viral load is indicative of response to treatment, whereas persistently high or increasing titers indicate continuing or progressing disease. Continuing surveillance includes serial physical examinations and radiographic studies. Reintroduction of immunosuppression may precipitate recurrence. Recurrence rates for PTLD average 10%.

Dysrhythmias may also occur post-lung transplant, but are relatively uncommon and typically do not require treatment. Atrial dysrhythmias associated with extensive left atrial suture lines were among the first dysrhythmias to be described.<sup>340,341</sup> However, the types of dysrhythmias after lung transplant surgery include junctional escape rhythm, nonsustained ventricular tachycardia, accelerated junctional rhythm, sinus bradycardia, nonsustained supraventricular tachycardia, ectopic atrial tachycardia, and second degree heart block. The incidence of the dysrhythmias is low, less than 5%, without apparent sustained supraventricular tachycardia, atrial flutter, atrial fibrillation, or complete heart block. Treatment is not commonly required in these children.<sup>342</sup>

Chronic kidney disease is a major comorbidity in pediatric lung transplant recipients.<sup>343,344</sup> More than one-third of children have a degree of renal dysfunction within 7 years posttransplantation. Renal dysfunction is associated with increased mortality.

Children who have received a lung transplant fall behind their contemporaries in height and weight (typically between the fifth and tenth percentile for age) with the overall growth rate only two-thirds of the predicted value. It appears, based on pulmonary function tests, radiographic studies, and histologic examination, that the transplanted lung's grow in the recipient is appropriate for the recipient's height and weight. Functional reserve capacity,<sup>345</sup> airway size,<sup>346</sup> and absolute number of alveoli increase as height and weight grow, in a manner comparable to their normal counterparts. Furthermore, recipients of mature lobar lungs from living related-donors are also noted to grow. Transplanted mature lung lobes expand and fill the entire chest. In these mature lung lobes, however, although the airways appear to grow in size, the

alveoli appear to become distended rather than increasing in absolute number. Pediatric post-lung transplant survival after the first year has remained the same for the past 20 years.<sup>347</sup> Just over half of the transplant patients will survive 5 years. This follows overall 1-year and 3-year survival rates of three-quarters and two-thirds of the children, respectively.<sup>310</sup> Children with idiopathic pulmonary hypertension do slightly better, with 1- and 5-year survival rates of 95% and 61%, respectively, but still have a median survival posttransplantation of 5.8 years.<sup>348</sup>

The early death rate in infants is substantive, at 25%. Children with significant pretransplantation pulmonary hypertension and those who undergo retransplantation also have a greater than average death rate. More than half of the early (first month) deaths in all ages are a result of primary graft failure. The main culprits in later deaths are infections, BO, and malignancies. The leading cause of death from 1 month through 1 year of age is non-CMV infections. The leading cause of death in 1- to 3-year-olds is BO, followed by non-CMV infections. After 3 years of age, BO is the leading cause of death, accounting for nearly half of all deaths. The majority of malignancies are from posttransplant lymphoproliferative disease. In those children who do survive, more than 75% have minimal limitation on activity at 1, 3, and 5 years posttransplantation.

**ANESTHESIA FOR ORTHOPEDIC AND SPINAL SURGERY** provides a multitude of challenges. Children often present with concomitant diseases that affect cardiovascular and respiratory function. The ability to maintain a clear airway during anesthesia is not straightforward for some children, such as those with arthrogryposis multiplex congenita.<sup>1</sup> Operating times can be protracted. Significant blood loss can occur that requires strategies for blood product management and transfusion reduction (see Chapter 10). Major trauma causing orthopedic injuries invariably involves other organ systems that may adversely interact with or compromise anesthesia management (see Chapter 38). The risks of aspiration of gastric contents into the lungs and the requisite fasting times,

after even minor trauma involving an isolated forearm fracture, continue to be debated. Fat embolus is uncommon in children with long-bone fractures but should be considered in any child with hypoxia and altered consciousness in the perioperative period.<sup>2</sup> Tumor surgery may be complicated by chemotherapy, altered drug disposition, or bone grafting considerations akin to those for plastic and reconstructive surgery (see Chapter 33) and complex postoperative pain management may be required (e.g., phantom pain, reflex sympathetic dystrophy) (see Chapter 44).

Children with chronic illnesses present repeatedly for surgical or diagnostic procedures. A single bad experience can blight attitudes about anesthesia for a long time. Positioning children on

the operating table involves care, especially for those with limb deformities and contractures (Video 30-1). Padding, pillows, and special frames are required to protect against damage from inadvertent pressure ischemia while achieving the best posture for surgery. Plaster application, particularly around the hip, should allow for bowel and bladder function, avoid skin breakdown due to pressure or friction, and allow access to epidural catheters. Postoperative management of casts on peripheral limbs must account for the possibility of compartment syndromes attributable to restrictive casts or compartment pathology. Major plexus blocks may mask pressure effects under plaster casts or compartment syndrome, but epidural blocks using low-dose amide anesthetics are ineffective against the discomfort of pressure.<sup>3,4</sup> Intraoperative temperature regulation may be affected by tourniquet application or disease (e.g., osteogenesis imperfecta, arthrogryposis multiplex congenita). The use of radiology is common during orthopedic surgery, and precautions against excessive radiation exposure should not be neglected by the anesthesiologist.

Regional anesthesia (see Chapter 41) reduces anesthesia requirements intraoperatively and provides analgesia postoperatively. The use of ultrasound techniques to locate neural tissue improves success and reduces local anesthetic doses (see Chapter 42).<sup>5,6</sup> This has heralded increasing use of peripheral nerve blockade rather than central blockade for unilateral lower limb surgery. Acetaminophen (paracetamol) and nonsteroidal antiinflammatory drugs (NSAIDs) are the most common analgesics prescribed for moderate pain. Regular administration of acetaminophen and NSAIDs decreases the amount of systemic opioids administered,<sup>7</sup> but NSAIDs decrease osteogenic activity and may increase the incidence of nonunion after spinal fusion.<sup>8,9</sup> Intravenous acetaminophen improves the early effectiveness of this drug before the child is able to tolerate oral intake, but this formulation is not available in all countries.<sup>10</sup> Long-term pain associated with limb-lengthening techniques (e.g., Ilizarov frame) may require oral opioids after hospital discharge.

## Scoliosis Surgery

Children presenting for scoliosis surgery represent a spectrum, ranging from uncomplicated adolescents to severely compromised patients with neuromuscular disease, respiratory failure, and cardiac problems. The age range at presentation varies from infancy to young adulthood. Anesthesia techniques for scoliosis surgery vary with individual patient requirements.<sup>11,12</sup> Approaches aimed at minimizing blood loss and transfusion requirements have progressed from extremes of hypotension and hemodilution to a more balanced approach involving moderate degrees of both, use of antifibrinolytic agents, predonation programs, and intraoperative cell salvage. The impact of anesthetic agents on complex physiologic signals has become increasingly important as more sophisticated measurements of neural transmission using somatosensory evoked potentials (SSEPs) and motor evoked potentials (MEPs) have become the standard of care.

### TERMINOLOGY, HISTORY, AND SURGICAL DEVELOPMENT

Early Hindu literature (3500 to 1800 BC) describes Lord Krishna curing a woman whose back was “deformed in three places.”<sup>13</sup> The terms scoliosis (i.e., crooked), kyphosis (i.e., humpbacked), and lordosis (i.e., bent backward) originated with the Greek physician Galen. *Scoliosis* is a lateral deviation of the normal vertical line of the spine, which is greater than 10 degrees when measured by radiographs. Scoliosis consists of a lateral curvature of the

spine with rotation of the vertebrae within the curve. *Lordosis* refers to an anterior angulation of the spine in the sagittal plane, and *kyphosis* refers to a posterior angulation of the spine as evaluated on a side view of the spine. Curves may be simple or complex, flexible or rigid, and structural or nonstructural. Primary curves are the earliest to appear and occur most frequently in the thoracic and lumbar regions. Secondary (or compensatory) curves can develop above or below the primary curve and evolve to maintain normal body alignment. Various combinations of curve types have different pathophysiologic consequences.

The magnitude of the scoliosis curve is most commonly measured using the Cobb method.<sup>14</sup> Measurement is made from an anteroposterior radiograph and requires accurate identification of the upper and lower end vertebrae involved with the curve. These vertebrae tilt most severely toward the concavity of the curve. The Cobb method of angle measurement is shown in Figure 30-1.

Hippocrates (circa 400 BC) developed treatments that relied primarily on manipulation and traction, using an elaborate traction table called a *scammum*.<sup>15</sup> Nonsurgical treatments for spinal deformities persisted until 1839, when a surgical treatment in the form of a subcutaneous tenotomy and myotomy was described by a French surgeon, Jules Guerin.<sup>16</sup>

Posterior spinal fusion was first described by Russell Hibbs for tuberculous spinal deformity in 1911.<sup>17</sup> The original spinal instrumentation system was the Harrington rod system.<sup>18</sup> Modification of this technique that allowed segmental fixation of the rods and early mobilization followed.<sup>19</sup> These systems treated the lateral curve but did not allow for correction of the axial rotation. Subsequent developments allowed both corrections by cantilever maneuvers using Cotrel-Dubousset instrumentation.<sup>20</sup>

Pedicle screws rather than hooks were the next advance. They were initially used as a distal anchor for lumbar curves and were found to enhance correction and stabilization, even when used with hooks for the more proximal curves (i.e., hybrid constructs).<sup>21</sup> Pedicle screw instrumentation techniques for total curve correction are a recent development that offer better curve

**FIGURE 30-1** Diagram of an anteroposterior spinal radiograph shows the Cobb method of scoliosis curve measurement.

correction than hook techniques<sup>22</sup> and the hybrid pedicle screw and hook technique.<sup>23</sup>

### CLASSIFICATION

Classification of scoliosis deformities is imperfect because the systems used are clinically rather than etiologically based. Most classifications are surgically based and used for surgical decision making. Curves can be described on the basis of age at onset, associated pathology, and anatomic configurations of the curve, such as single, double, or triple curves; amount of pelvic tilt;

curve flexibility; and three-dimensional analysis of the curve.<sup>24</sup> A classification that could indicate the risk of an adverse outcome of anesthesia, particularly respiratory failure, would be of clinical benefit. Children younger than 5 years of age with early-onset scoliosis or with independent cardiac or pulmonary disease appear to be at increased risk for respiratory failure, whereas those with idiopathic scoliosis in whom the curve develops at adolescence appear to have minimal risk.<sup>25</sup> A classification adapted from that proposed by the Scoliosis Research Society in 1973 remains relevant for anesthesiologists (Table 30-1).<sup>26</sup>

**TABLE 30-1** Classification of Scoliosis with Associated Key Anesthetic Risk Factors

Classification	Issues Associated with Scoliosis Surgery	Increased K <sup>+</sup> with Succinylcholine	Expected High Blood Loss	Respiratory Complications and Ventilatory Support
<b>Idiopathic</b>				
Infantile <3 years	Repeat operations, small size		✓	✓
Juvenile 3-9 years				
Adolescent 9-18 years	Regarded as cosmetic by patient; perfect result expected			
<b>Congenital</b>				
Bony abnormalities	Acute angle deformity; high risk of spinal cord injury, genitourinary malformations			
Neural tube defects				
Meningomyelocele, spina bifida, syringomyelia	Latex allergy, pressure sores, hydrocephalus, Arnold-Chiari and Chiari malformations (avoid neck extension)			
<b>Neuromuscular</b>				
<i>Neuropathic</i>				
Upper motor neuron				
Cerebral palsy, cerebral hypoxia	Upper airway obstruction, recurrent pneumonia, postoperative pain management		✓✓	✓✓
Lower motor neuron				
Poliomyelitis				
<i>Myopathic</i>				
Progressive				
Duchenne muscular dystrophy	Cardiomyopathy, mitral valve prolapse, conduction abnormalities	✓	✓✓	✓✓
Spinal muscular atrophy	Electrocardiographic abnormalities	✓	✓	✓
Facioscapulohumeral muscular dystrophy	Hypertrophic cardiomyopathy, cardiac failure	✓		
Other				
Freidrich ataxia		✓		
<b>Neurofibromatosis</b>	Hypertension, other neurofibromas			
<b>Mesenchymal</b>				
Marfan syndrome	Mitral and aortic regurgitation			
Mucopolysaccharidoses (e.g., Morquio syndrome)	Atlantoaxial subluxation, difficult intubation			
Arthrogryposis	Difficult intubation, severe contractures		✓	
Osteogenesis imperfecta	Small size			
<b>Trauma</b>				
<b>Tumor</b>				

Modified from Goldstein LA, Waugh TR. Classification and terminology of scoliosis. Clin Orthop Relat Res 1973;93:10-22.

✓, Anesthetic risk is likely; ✓✓, anesthetic risk is very likely.

The Lenke classification system, developed in 2001 for idiopathic scoliosis, provides a means to categorize curves and guide surgical treatment.<sup>27</sup> It is increasingly used by the surgeons as an integral part of their decision making.<sup>28</sup> Major and structural minor curves included in the instrumentation and fusion are excluded. The system has three components: curve type, a lumbar spine modifier, and a sagittal thoracic modifier. The resulting six curve types have specific radiographic characteristics that differentiate structural and nonstructural curves as proximal thoracic, main thoracic, and thoracolumbar/lumbar regions such that the number, curve type, and main structural curves are related as follows:

Type 1, main thoracic: single; main thoracic structural curve

Type 2, double thoracic: double; proximal, and main thoracic structural curves

Type 3, double major: double; main thoracic (major curve) and thoracolumbar/lumbar structural curves

Type 4, triple major: triple; all three structural curves

Type 5, thoracolumbar/lumbar: single; thoracolumbar/lumbar structural curve

Type 6, thoracolumbar/lumbar main thoracic: double; thoracolumbar/lumbar (major curve) and main thoracic structural curves

In types 1 through 4, the main thoracic curve is the major curve, and in types 5 and 6, the thoracolumbar/lumbar curve is the major curve.

#### **PATHOPHYSIOLOGY AND NATURAL HISTORY**

Vertebral rotation and rib cage deformity usually accompany any lateral curvature. With progression of the curve, the vertebral bodies in the area of the primary curve rotate the convex aspect of the curve and the spinous process to the concave side. This vertebral rotation can be determined by measurement of the position of the pedicles from the midline (i.e., Moe method).<sup>29</sup> The vertebral bodies and the discs develop a wedge-shaped appearance, with the apex of the wedge toward the concave side. On the convex side of the curve, the ribs are pushed posteriorly, which narrows the thoracic cavity and causes the characteristic hump. On the concave side, the same rotation forces the ribs laterally, with consequent crowding toward their lateral margins (Fig. 30-2). These changes result in an increasingly restrictive lung defect. Exactly when this becomes a problem depends on the child's accompanying pathology. The thoracic and lumbar regions are the most common sites of the primary curve. In children in whom the primary curve is in the lumbar region, the rotation of the vertebral bodies and spinous processes should be taken into consideration when spinal or epidural insertion is attempted because the spinal canal is relatively displaced toward the convex aspect of the curve.

The physical distortion in the thorax results in restriction of lung volumes and function. Ventilation depends on the mobility of the thoracic cage, the volume of each hemithorax, and the muscle power and elastic forces required to move the thorax. Children with idiopathic scoliosis with a mild decrease in vital capacity also have reduced forced expired volume at 1 second (FEV<sub>1</sub>), gas transfer factor, and maximal static expiratory airway pressures (PE<sub>max</sub>) (see Fig. 11-4). The predominant deformity of lateral flexion and vertebral rotation results in the lung on the concave side being able to achieve a near-normal end-expiratory position but not end-inspiratory position, whereas the lung on the convex side achieves a normal end-inspiratory position but

**FIGURE 30-2** Characteristic distortion of the vertebra and ribs in thoracic scoliosis. (Modified from Kleim HA. Scoliosis. Ciba foundation symposium, Vol. 1. Summit, N.J.: Ciba; 1978, p. 609; Gregory GA, editor. Anesthesia for orthopaedic surgery. In: Paediatric anesthesia. 3rd ed. Edinburgh: Churchill Livingstone; 1994.)

cannot reach a normal end-expiratory position. The concave side contributes less than normal at total lung capacity, resulting in a decrease in PE<sub>max</sub>. Similarly, because the convex side does not reach a normal end-expiratory position, the intercostal muscles and hemidiaphragm will be less efficient, resulting in a reduced maximum static inspiratory airway pressure (PI<sub>max</sub>), although this reduction may not be quite so marked.<sup>30</sup> The main effect of scoliosis on respiratory function is mechanical, and the anatomic changes in the chest wall cause impaired movement and reduced compliance. Potential long-term respiratory problems when these defects are left untreated include hypoxemia, hypercarbia, recurrent lung infections, and pulmonary hypertension.

#### **Congenital, Infantile, and Juvenile Scoliosis**

Congenital spinal anomalies are caused by failures of formation and segmentation that result in scoliosis and kyphosis. The hemivertebra, caused by failure of formation, is the most common anomaly. Fully segmented hemivertebrae contribute to progressive deformity during periods of rapid spinal growth (e.g., first 5 years of life). The most severe deformities are seen in the thoracolumbar spine. Congenital spinal anomalies may be associated with malformations of the ribs, chest wall, and hemifacial microsomia.<sup>31</sup> Children with congenital scoliosis have a 25% chance of urologic abnormalities and 10% chance of a cardiac abnormality. Bracing or casting techniques are not effective for this form of scoliosis. Surgical options for these patients include fusion in situ, convex hemiepiphysiodesis, hemivertebra excision, growing rods, and vertical expandable prosthetic titanium rib (VEPTR) treatment.<sup>32</sup> Although short-term correction is easily achievable,

a short thoracic or even thoracic insufficiency syndrome can result.<sup>33</sup> Approximately one half of the children who have extensive thoracic fusions and those whose fusions involve the proximal thoracic spine develop restrictive pulmonary disease ( $FEV_1 < 50\%$ ).<sup>34</sup> Expansion thoracoplasty and stabilization using a VEPTR may be used.<sup>35</sup>

Infantile and juvenile scoliosis are part of the spectrum of idiopathic scoliosis but are considered here because they manifest and require treatment at an early age. Infantile scoliosis accounts for less than 1% of idiopathic scoliosis and is defined as scoliosis appearing between birth and 3 years of age.<sup>32</sup> It usually occurs in the thoracic spine, and the curve is convex to the left. Bracing and serial casting techniques are used for infantile scoliosis. Improvement and resolution in some cases have been achieved at 9-year follow-up.<sup>36</sup>

Treatment of infantile scoliosis may begin as early as 4 to 5 months of age or as soon as the diagnosis of scoliosis has been made. Body casting appears useful in selected children, such as those with smaller, flexible spinal curves, but curve progression and the need for secondary treatments affect a significant proportion of these children.<sup>37</sup> Bracing is considered when the curve reaches 30 degrees.<sup>32</sup> Success has also been reported for more severe curves (60 degrees) when casting was started before 20 months.<sup>38</sup> After induction of anesthesia, the child is positioned on the frame (first described by Cottrell and Morel), securing the pelvis to the caudal end of the frame and tethering the head by a chin strap to the rostral end. The spine is mildly distracted, but the main maneuver derotates the spine through the ribs (Fig. 30-3, *A*). General anesthesia with tracheal intubation is required to facilitate positioning the child, stretching the spine, and molding the body cast. Hemoglobin desaturation frequently occurs when the cast is molded to correct the spinal deformity. An oral airway is also needed to prevent compression of the tracheal tube after the chin strap is applied and tightened. After the cast has hardened, it is cut back and trimmed to maintain the correction to the spine while facilitating breathing, gastrointestinal function, and day-to-day living (see Fig. 30-3, *B*). Halo traction may be used to stretch and improve the curves. Pin infections occur in almost half of the children.<sup>39</sup>

Juvenile idiopathic scoliosis comprises 10% to 15% of idiopathic scoliosis and is defined as scoliosis that is first diagnosed between the ages of 4 and 10 years. Approximately 20% of these children and those with infantile scoliosis with a curve greater than 20% have an underlying spinal condition, particularly Arnold-Chiari malformation and syringomyelia.<sup>40</sup> Although bracing is used to manage these curves, almost all children in this group with curves greater than 30% require surgical intervention.<sup>41</sup>

Growing rods may be used for congenital, infantile, or juvenile scoliosis to maintain the correction obtained at initial surgery while allowing spinal growth to continue. Several procedures are required before a definitive fusion.<sup>42</sup> All the systems (i.e., growing rods and VEPTR) have a moderate complication rate (i.e., rod breakage and hook displacement). VEPTR systems are being used to correct large-magnitude curves in this group of children when conservative treatment is inadequate.<sup>43</sup>

### Idiopathic Scoliosis

Although adolescent idiopathic scoliosis is relatively common, severe morbidity is seen only in children with early-onset (infantile or juvenile) idiopathic scoliosis.<sup>44</sup> Respiratory deterioration alone is seldom the reason for surgery in those who develop

**FIGURE 30-3** *A*, Nonoperative correction of scoliosis in infants and toddlers may be achieved with repeated casting. *B*, Cutting and trimming of the cast allows correction of the spine while facilitating daily living.

scoliosis after the age of 5 years.<sup>25</sup> This is explained by the fact that the respiratory alveoli are mature by this age.<sup>45,46</sup>

Scoliosis evolves during growth spurts. The earlier the age of onset and the more immature the bone growth at the time the process begins, the more severe the outcome. The relentless progression of infantile-onset idiopathic scoliosis with rapidly deteriorating curves and lung function is often not amenable to surgery. Treatment involving spinal instrumentation and anterior epiphysiodesis does not prevent the reappearance of the deformity or the decrease in pulmonary function.<sup>47</sup>

Pulmonary impairment correlates directly with the magnitude of the thoracic curve. Severity of the scoliosis is the most accurate predictor of impaired lung function.<sup>48</sup> The morphology of the thoracic curve, the number of vertebrae in the major curve, and the rigidity of the curve also are associated with deteriorating pulmonary function.<sup>49</sup> Conventional wisdom has held that there is minimal impact on the vital capacity until the curve exceeds 60 degrees, with clinically relevant decreases in respiratory function occurring only after the thoracic scoliosis has progressed

**FIGURE 30-4 A,** The bar graph demonstrates increasing pulmonary impairment with increasing curve severity as measured by degrees. **B,** Pulmonary impairment increases with increasing length of the thoracic curve. (From Newton PO, Faro FD, Gollogly S, et al. Results of preoperative pulmonary function testing of adolescents with idiopathic scoliosis. A study of six hundred and thirty-one patients. *J Bone Joint Surg Am* 2005;87:1937-46.)

beyond 100 degrees.<sup>34</sup> However, it has been shown that children with adolescent idiopathic scoliosis may have pulmonary impairment that is disproportionate to the severity of the scoliosis and that it occurs well before the curve reaches 100 degrees. Forced vital capacity (FVC) may decrease below the normal threshold (<80% of predicted) after the magnitude of the thoracic curve exceeds 70 degrees; FEV<sub>1</sub> decreases to less than the normal threshold after the main thoracic curve exceeds 60 degrees.<sup>35</sup> Twenty percent of children with a thoracic curve of 50 to 70 degrees have moderate or severe pulmonary impairment (i.e., less than 65% of predicted) (Fig. 30-4, A).<sup>50</sup> Those with thoracic hypokyphosis are more likely to have moderate or severe pulmonary impairment; complex curves have a greater prevalence of moderate or severe pulmonary impairment, and the number of vertebrae in the thoracic curve is the most significant predictor of impaired respiratory function (see Fig. 30-4, B).<sup>51</sup> These data indicate that children with a structural cephalad thoracic curve, a major thoracic curve spanning eight or more vertebral levels, or thoracic hypokyphosis are at increased risk for moderate to severe pulmonary impairment.

### Neuromuscular Scoliosis

Children with neuromuscular scoliosis have the burden of deteriorating muscle function in addition to mechanical distortion. Crowding of the ribs on the concave side of the curve limits chest wall expansion, and the sitting posture restricts diaphragmatic excursion. This inevitably leads to more rapid deterioration in the curve and respiratory function. These children also have the potential for rapid and unpredictable deterioration of the curve.<sup>36</sup> It is important to consider the natural history of the specific neuromuscular disease when trying to balance the risks of surgery against conservative management.

Children with Duchenne muscular dystrophy (DMD) suffer from progressive muscular weakness and increasing disability until death occurs, usually by the beginning of the third decade.<sup>52</sup> These children tend to become wheelchair bound by 8 to 10 years of age because of increasing motor muscle weakness. Scoliosis then progresses with an acute deterioration during the growth spurt between the ages of 13 and 15 years, such that it becomes difficult or impossible to sit unaided. After the lumbar curve exceeds 35 degrees, further progression becomes inevitable.<sup>53</sup> A

normal cough requires an inspiratory effort of more than 60% of total lung capacity and effective glottic closure to produce an effective peak flow (more than 160 L/min in adults). Forced expiratory flows are typically reduced proportionally to the decrease in lung volume. As muscle weakness progresses, patients hypoventilate, initially at night. If nocturnal ventilatory support is not provided at this stage, diurnal hypercapnia will result.<sup>54</sup>

There have been two significant changes in the overall management of children with DMD: the use of steroids and the earlier use of nocturnal noninvasive positive-pressure ventilation (NPPV). Steroid treatment in the early phase of the disease appears to slow disease progression for a few years; treatment with prednisone can stabilize strength and function for 6 months to 2 years.<sup>55,56</sup> This may delay the presentation of children for corrective surgery. Earlier adoption of nocturnal NPPV for nocturnal hypoventilation improves survival and quality of life. Clinically unsuspected nocturnal hypoventilation occurs in about 15% of patients with DMD and can be predicted by moderate impairment according to pulmonary function tests (FVC <70% and FEV<sub>1</sub> <65% of predicted) and scoliosis. Those with nocturnal hypoventilation have increased gas trapping, decline of muscle strength, and worse perception of health status despite NPPV.<sup>57</sup>

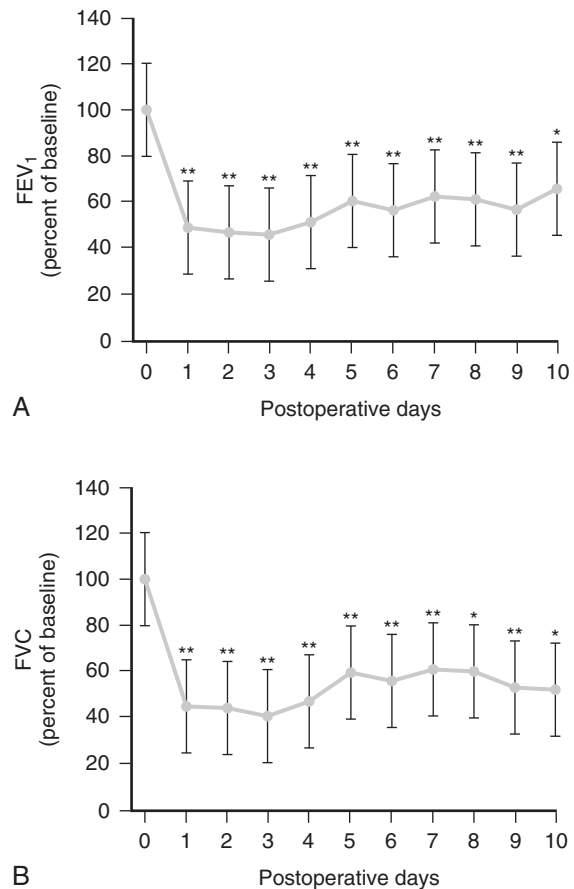

A 2007 multidisciplinary consensus statement on the “Respiratory and Related Management of Patients with Duchenne Muscular Dystrophy undergoing Anesthesia or Sedation” provided recommendations to standardize the approach to these patients<sup>58</sup> and others with flaccid neuromuscular diseases undergoing anesthesia; the most important of these are as follows: An FVC less than 50% of predicted indicates an increase in postoperative respiratory complications, and an FVC less than 30% suggests a further increase in that risk. Respiratory function tests should be part of the preoperative evaluation whenever possible and should include FVC, maximal inspiratory pressure, maximal expiratory pressure, peak cough flow, SpO<sub>2</sub> on room air, and PaCO<sub>2</sub> if the SpO<sub>2</sub> value is less than 95%. Consider preoperative training and postoperative use of NPPV if FVC is less than 50% of predicted, and strongly consider NPPV if FVC is less than 30%. Consider preoperative training and postoperative use of manual and mechanically assisted cough in those with impaired cough. In older children, this can be predicted by a peak cough flow less than 270 L/min or maximal expiratory pressure less than 60 cm H<sub>2</sub>O. Strongly consider planning to extubate the trachea directly to NPPV when the FVC is less than 30%.

Dilated cardiomyopathy occurs in up to 90% of DMD individuals older than 18 years of age. The severity of the physical disability in boys with DMD in their late teens often masks the clinical symptoms of cardiac failure. Cardiomyopathy has been considered responsible for death of up to 20% of individuals with DMD, but this proportion may increase in the future for individuals in whom NPPV prevents respiratory-related mortality.<sup>56</sup> (See also Chapter 22.)

## Risk Minimization and Improving Outcome from Surgical Intervention

### RESPIRATORY FUNCTION AND COMPLICATIONS IN THE EARLY POSTOPERATIVE PERIOD

Decreases in lung volumes and flow rates similar to thoracic and upper abdominal surgery occur after scoliosis surgery. The FVC and FEV<sub>1</sub> decrease with a nadir at 3 days and are about 60% of

**FIGURE 30-5** **A**, Changes in forced expiratory volume in 1 second (FEV<sub>1</sub>) during the 10 days after scoliosis surgery. **B**, Changes in forced vital capacity (FVC) during the 10 days after scoliosis surgery. (From Yuan N, Fraire JA, Margetis MM, et al. The effect of scoliosis surgery on lung function in the immediate postoperative period. *Spine* 2005;30:2182-5.)

preoperative values 7 to 10 days after surgery (Fig. 30-5). It is not until 1 to 2 months after surgery that pulmonary function test results again approach baseline values. The magnitude of this decrease is not affected by the type of surgery performed or whether the scoliosis has an idiopathic or neuromuscular cause.<sup>59</sup>

Children with neuromuscular disease are more likely to require prolonged mechanical ventilation after spinal surgery because of more severe preoperative respiratory impairment.<sup>60</sup> The marked decrease in vital capacity and peak flows is undoubtedly related to the risk of postoperative complications, but determining when it is no longer safe to anesthetize those with a restrictive lung defect remains an imperfect science.

Equipment is available to assist the postoperative management of children with impaired respiratory function. The routine use of NPPV and cough augmentation therapy should be planned if the preoperative FVC is less than 30%. Cough augmentation can be provided manually by hyperinflation and forced expiration, alone or together, and by mechanical insufflation-exsufflation (MIE) therapy.<sup>61</sup> The effectiveness of MIE may be limited in children with a weak or enlarged tongue if it blocks exsufflation flow.

Less extensive surgery with the newer pedicles screw systems decreases the need for pelvic fixation to correct pelvic obliquity.

The procedures require less extensive surgery and shorter operating times, which may benefit children with impaired respiratory function.<sup>62-65</sup>

Respiratory complications after surgery for idiopathic scoliosis are relatively uncommon. In contrast, respiratory complications after surgery in children with nonidiopathic scoliosis is reported to be fivefold greater.<sup>66</sup> The risk increases as the degree of curvature increases and the respiratory function decreases.<sup>67</sup> Anterior spinal procedures are associated with a greater incidence of complications than posterior spinal fusion, such that some consider this to be the main risk factor for postoperative respiratory complications.<sup>67</sup> Modern pedicle screw systems may decrease the need for anterior procedures, thereby decreasing the complication rate.<sup>68</sup>

Atelectasis, infiltrates, hemothoraces, pneumothoraces, pleural effusions, and prolonged intubation have the greatest incidence, whereas pneumonia, pulmonary edema, and upper airway obstruction occur less frequently. These problems are more common when the scoliosis is associated with mental retardation and developmental delay. The greatest complication rate occurs for those with cerebral palsy and flaccid neuromuscular scoliosis.<sup>66-69</sup> Although respiratory complications increase as the severity of scoliosis and the degree of respiratory impairment increase, reported complication rates vary considerably. Studies of children with neuromuscular scoliosis suggest an overall respiratory complication rate of 15% to 30%<sup>69-73</sup> and minimal mortality. In one of these studies, which identified three groups by respiratory impairment (FVC <30%, FVC = 30% to 50%, FVC >50%), an overall complication rate of 31% occurred independent of the degree of respiratory impairment,<sup>69</sup> perhaps reflecting improvement with modern management techniques (Table 30-2).

Children with cerebral palsy have additional problems associated with their lack of muscular control (e.g., swallowing incoordination, excessive salivation, gastroesophageal reflux) and sometimes have developmental delay that contribute to a postoperative complication rate of 30%.<sup>70,71,74</sup> Nonambulatory patients and those with curves greater than 60 degrees are at increased risk for major complications, with nonambulatory patients almost four times more likely to have a major complication.<sup>74</sup> Gastrointestinal dysmotility in cerebral palsy patients can be exacerbated after scoliosis surgery and cause persistent vomiting and bloating.<sup>75</sup> Pancreatitis may occur in up to 30% of cerebral palsy patients after surgery, with a greater incidence among those with documented gastroesophageal reflux and reactive airway disease.<sup>76</sup>

## LONG-TERM CHANGES

### Idiopathic Scoliosis

Improvements in pulmonary function are not impressive after correction of idiopathic scoliosis. Early studies suggested that spinal fusion stabilized the respiratory dysfunction that existed preoperatively, but failed to offer any improvement.<sup>77</sup>

Improvements may be possible in certain subgroups of patients with some surgical techniques, but it takes months to years for pulmonary function to improve. Children with a preoperative curve less than 90 degrees undergoing a posterior procedure only had a greater than 10% increase in vital capacity, maximum voluntary ventilation, and maximum respiratory mid-flow rate after 2 years; this improvement did not occur in those who underwent anterior surgery.<sup>78</sup> Harrington rod instrumentation in children with idiopathic scoliosis resulted in only a small improvement in vital capacity.<sup>79</sup>

The newer instrumentation systems, such as the Cotrel-Dubousset instrumentation that allows segmental realignment and approximation, result in further improvements in pulmonary volumes.<sup>80</sup> Pulmonary function returns to preoperative values within 3 months after the posterior approach using the newer instrumentation systems, with additional improvements occurring and being sustained for 2 years.<sup>81</sup> Pedicle screws provide greater curve correction in adolescent idiopathic scoliosis, with a trend toward improved pulmonary function after 2 years compared with other instrumentation techniques.<sup>23</sup> A 10-year follow-up analysis demonstrated an absolute increase in the FVC (3.25 versus 3.66 L) and FEV<sub>1</sub> (2.77 versus 3.10 L) but no changes in percent of predicted values in children who underwent a posterior fusion and instrumentation only. In the same analysis, those with chest wall disruption experienced no change in FVC and FEV<sub>1</sub> over 10 years, but the assessment demonstrated a significant decrease in percent of predicted FVC (85% versus 79%), and FEV<sub>1</sub> values (80% versus 76%).<sup>82</sup>

Chest cage disruption (i.e., thoracoplasty or anterior thoracotomy) is associated with reduced pulmonary function at 3 months and a 10% to 20% decrease in total lung capacity and FVC. These values do not return to baseline until 1 to 2 years after surgery. Improvements in lung function with this approach are seldom seen.<sup>44,45</sup> Video-assisted thoracoscopic surgery (VATS) for anterior release and instrumentation appears to result in less pulmonary morbidity and a smaller decrease in pulmonary function at 3 months. One year after surgery, values for children treated thoracoscopically had returned to baseline, but this did not occur for those undergoing open thoracotomy (Fig. 30-6).<sup>83,84</sup> Two- and 5-year follow-up evaluations of those undergoing VATS showed no significant changes with regard to the correction of the major Cobb angle (56% ± 11% and 52% ± 14%, respectively) or average total lung capacity as a percent of the predicted value (95% ± 14% and 91% ± 10%) over the study period.<sup>85</sup>

Changing surgical techniques may challenge these findings in the future because some surgeons think that anterior fusions with modern systems offer short-term benefits of reduced blood loss and transfusion and long-term benefits due to shorter fusions, better maintenance of thoracic kyphosis, and improved spontaneous lumbar curve correction. A 2-year postoperative study concluded that VATS for thoracic curves and open procedures

**TABLE 30-2** Incidence of Pulmonary Complications

Forced Vital Capacity	Total Number of Patients	Patients with Pulmonary Complications	Pneumonia	Atelectasis	Pneumothorax	Ventilator Care (>3 days)
<30%	18	6	3	0	1	2
30-50%	18	7	3	1	0	4
>50%	38	10	2	1	0	7

**FIGURE 30-6** Changes in percent of forced vital capacity (FVC) for thoracoscopic versus open anterior instrumentation during the first year after surgery. (From Faro FD, Marks MC, Newton PO, Blanke K, Lenke LG. Perioperative changes in pulmonary function after anterior scoliosis instrumentation: thoracoscopic versus open approaches. *Spine* 2005;30:1058-63.)

for thoracolumbar curves resulted in minimal to no permanent pulmonary impairment 6 months after the procedure compared with posterior spinal fusion, despite a short-term decrease observed after VATS.<sup>86</sup>

### Neuromuscular Scoliosis

Improvements in the scoliosis angle and the degree of pelvic obliquity are achieved after spinal instrumentation in children with neuromuscular disease. Significant improvement can usually be shown in the ability to sit unaided, particularly if children are unable to do so beforehand.<sup>87,91</sup> Some investigators have reported an increase in the quality of life perceived by the child or caregiver.<sup>89,91</sup>

There is little evidence for any improvement in respiratory function in this group of children. There may be a period of delay or even stabilization of the inevitable deterioration of respiratory function.<sup>52,88,92</sup> Other investigators have shown no difference in respiratory function after 5 years compared with patients managed conservatively<sup>90,93</sup> or an early loss in vital capacity after surgery with a progressive decrease of 25% over 4 years, with 66% of patients requiring mechanical respiratory assistance by that time.<sup>89</sup> A Cochrane review was unable to find any data evaluating the effectiveness of scoliosis surgery in patients with DMD and even suggested, "Patients should also be informed about the uncertainty of benefits on long-term survival and respiratory function after scoliosis surgery."<sup>94</sup>

Some retrospective analyses, however, deserve consideration. A review of the long-term survival of children with DMD after spinal surgery and nocturnal ventilation demonstrated that those having spinal surgery and ventilation had a median survival of 30 years, whereas those receiving nocturnal ventilation only survived to 22.2 years. This result occurred despite a decrease in mean vital capacity from 1.4 to 1.13 L in the first postoperative year.<sup>95</sup> Posterior spinal fusion for scoliosis in DMD was associated with a significant slowing in the rate of decrease in respiratory function; the rate of 4% per year before surgery decreased to 1.75% per year (over 8 years) after surgery.<sup>96</sup> In a study of 14 children with DMD and an FVC of less than 30%, the mean rate of decrease in percent of FVC after surgery was 3.6% per year. Most children and parents thought scoliosis surgery improved their function, sitting balance, and quality of life and gave it high satisfaction scores.<sup>97</sup>

Less outcome information is available for children with cerebral palsy. Surgery is perceived as having a positive impact on patients' quality of life, overall function, and ease of care by parents and other caregivers,<sup>98</sup> despite the high complication rates described earlier. A 3-year follow-up after a pedicle screw construct for scoliosis, which reduced the mean Cobb angle to 31%, demonstrated improved functional ability in 42% of children. Most children had improved sitting balance and nursing care requirements. A 32% complication rate occurred; most were pulmonary in origin but ultimately reversible. There were two perioperative deaths and one transient neurologic deficit due to screw impingement among 56 patients.<sup>68</sup>

Less morbidity has been claimed for the same-day (one-stage) surgery compared with the two-staged approach in children with neuromuscular disease requiring anterior and posterior spinal surgery.<sup>99,100</sup> However, it seems reasonable to avoid anterior thoracotomy in neuromuscular patients in view of the poor respiratory function after chest cage disruption.<sup>81,83</sup> Currently, pedicle screw systems in children with neuromuscular scoliosis produce outcomes similar to those of earlier systems but with quicker operating times and less blood loss.<sup>63</sup>

## Spinal Cord Injury during Surgery

### ETIOLOGY

Spinal cord injury can occur by four main mechanisms: direct contusion of the cord during surgical exposure; contusion by hooks, wires, or pedicle screws; distraction by rods or halo traction; and reduction in spinal cord blood flow.<sup>101</sup> Epidural hematoma should be included in the differential diagnosis of deficits occurring postoperatively. The areas of the spinal cord most vulnerable to ischemic injury are the motor pathways, which are supplied by a single anterior spinal artery. This is fed in a segmental manner by the radicular arteries that arise from the vertebral, cervical, intercostals, lumbar, and ilio-lumbar arteries. The largest radicular artery is the artery of Adamkiewicz, which arises between T8 and L4. A watershed area between T4 and T9 is prone to ischemia because the blood supply in this region of the cord is poorest.<sup>102</sup> Paraplegia is the most feared neurologic complication, but partial spinal cord injury resulting in areas of localized weakness and numbness as well as bladder and bowel disturbances also have been reported.

The increasing use of pedicle screws in spinal surgery raises the possibility of increased risk to individual nerve roots. A systematic review of pedicle screw complications that involved a total of 4570 pedicle screws in 1666 patients reported an overall 4% malposition rate that increased to 16% in studies that systematically examined their patients postoperatively.<sup>103</sup> Eleven patients required revision surgery for the malpositioned screws, and there was one temporary neurologic complication (i.e., epidural hematoma). No vascular injuries were reported, although six cases of aortic abutment were described.

### RISK OF SPINAL CORD INJURY AND SPINAL CORD MONITORING

Combined surveys undertaken by the Scoliosis Research Society and the European Society for Deformities of the Spine investigating idiopathic scoliosis suggested an incidence of neurologic impairment of 0.72% in 1975.<sup>104</sup> At the end of the last millennium, that incidence had decreased to less than half (0.3%), and all were partial cord lesions.<sup>101</sup> Patients with curves greater than 100 degrees, congenital scoliosis, kyphosis, and

postirradiation deformity appear to be at greatest risk for complications. The use of pedicle screws may have increased the immediate neurologic complication rate. Nine neural complications were reported among 1301 patients, for an incidence of 0.69% in 2007. Three thecal penetrations occurred, two as a result of pedicle screws, all without sequelae. There were two nerve root injuries and four spinal cord injuries, all of which resolved within 3 months.<sup>105</sup>

A retrospective review of 19,360 cases of pediatric scoliosis showed significantly different overall complication rates among idiopathic (6.3%), congenital (10.6%), and neuromuscular (17.9%) scoliosis. Neurologic deficits had a different distribution, with the greatest rate among congenital cases (2%), and lower rates with neuromuscular (1.1%) and idiopathic scoliosis (0.8%).<sup>106</sup> Mortality rates of 0.3% were observed for neuromuscular and congenital scoliosis, with an idiopathic scoliosis rate of 0.02%. Rates of new neurologic deficits were greater with anterior screw-only constructs (2%) or wire constructs (1.7%) than with pedicle screw constructs (0.7%).

Spinal cord function is monitored to ensure that the complication rate is as small as possible. The Scoliosis Research Society issued a position statement concluding that neurophysiologic monitoring can assist in the early detection of complications and can possibly prevent postoperative morbidity in patients undergoing operations on the spine. For any monitoring technique to be effective, it needs to have a sensitivity and specificity that allows true changes to be recognized with a very low occurrence of false-negative and false-positive results. The test or technique must also produce its results in a time frame that allows the problem to be reversed or prevented. Recognition of the limitation of individual techniques has seen the development of increasingly sophisticated monitoring systems to identify and minimize this risk. Older tests, such as the wake-up test and ankle clonus test, have largely been superceded by monitoring of SSEPs, MEPs, and triggered electromyographic techniques (EMGs). The importance of using a multimodal approach is increasingly recognized and is well addressed in the literature.<sup>107-110</sup> The capabilities and limitations of the various techniques are summarized in E-Table 30-1.

## METHODS OF MONITORING SPINAL CORD FUNCTION

### Wake-up Test

The wake-up test measures gross motor function of the upper and lower extremities. It has been used widely since it was first described.<sup>111</sup> The test consists of decreasing the depth of anesthesia almost to the point of wakefulness and asking the patient to respond to verbal commands. Failure to move the feet and toes while being able to squeeze a hand suggests a problem with the spinal cord. The test requires limiting or reversing muscle relaxation and reducing the depth of anesthesia sufficiently to enable the patient to follow commands. When the test was initially described, 3 of 124 patients had a positive result (i.e., no movement) and were saved from paraplegia.<sup>111</sup> A major concern is that the test is conducted after maximal spinal correction, which may occur after any neurologic insult has occurred; however, removal or modification of the spinal instrumentation within 3 hours of the onset of the neurologic deficit has been reported to prevent the risk of permanent neurologic sequelae.<sup>112</sup> The wake-up test is unlikely to detect isolated nerve root injury or sensory changes. It is limited to neurologically normal patients with an appropriate developmental age who can follow instructions.

With the clinical application of SSEP and MEP monitoring (Fig. 30-7) well established and in the absence of intraoperative changes, there is no justification to perform the wake-up test.<sup>113</sup> Nonetheless, some surgeons still regard the wake-up test to be the gold standard, and it may be used to confirm changes demonstrated by SSEP or MEP monitoring.<sup>114</sup> Risks include lack of nerve root and sensory information, accidental extubation, dislodgement of the instrumentation, intraoperative recall with subsequent psychological trauma, air embolism, and cardiac ischemia. If a wake-up test is planned, it is prudent to fill the wound with saline to reduce the risk of an air embolism.

### Ankle Clonus Test

The ankle clonus test uses the clonus that occurs just before consciousness is regained during wakening from anesthesia. Rhythmic muscle contractions are thought to result from spinal reflexes returning while the higher neurologic centers remain inhibited by anesthesia, and the oscillations demonstrate an intact spinal cord. Inability to demonstrate clonus suggests spinal cord injury.<sup>115</sup> Like the wake-up test, it is a post hoc test rather than real-time monitoring. However, in a review of more than 1000 patients undergoing spinal procedures in which six postoperative neurologic deficits occurred, this test identified all the deficits but produced three false-positive findings, giving a sensitivity of 100% and a specificity of 99.7%. In comparison, the wake-up test produced false-negative results for four of the five patients who developed deficits.<sup>115</sup>

### Somatosensory Evoked Potentials

SSEPs involve stimulating a peripheral nerve and measuring the response to that stimulation using scalp electrodes (i.e., cortical SSEPs).<sup>116,117</sup> Alternatively, the response can be measured subcortically near the spinal cord by electrodes placed in the epidural space, interspinous ligament, or spinous processes of the vertebrae.<sup>118</sup> An intranasally placed pharyngeal electrode can act as a surrogate for these. The advantage of the subcortical evoked potential is that the responses are more stable, reproducible, and resistant to the effects of anesthesia.

The signal produced with SSEP monitoring travels from the peripheral nerve through the nerve root and up the ipsilateral dorsal column. The impulses then cross over at the level of the brainstem and progress rostrally through the thalamus to the primary sensory cortex. The rationale for using SSEP to monitor motor deficits is based on the fact that the sensory tracts are in proximity to the motor tracts of the spinal cord. Injury to the motor tracts indirectly affects the sensory tracts and causes changes in the SSEP. When spinal cord function is significantly impaired, there is usually an increase in latency and a decrease in amplitude in the SSEP, with eventual loss of signal. A 10% increase in latency of the first cortical peak (P1) or 50% decreases in the peak-to-peak amplitude (P1N1) constitute an indication for intervention.<sup>119,120</sup> Although SSEP signals primarily monitor transmission through the sensory dorsal columns, they are effective,<sup>120</sup> and SSEP monitoring is associated with a 50% decrease in the incidence of neurologic deficits.

It is unusual for motor tract injury to occur when SSEPs remain unchanged, but false-positive and false-negative results have been reported.<sup>120,121</sup> Seventy percent of the postoperative complications were detected by the monitor, but 30% (false negatives) were not detected. Pedicle screw misplacement leading to radiculopathy may not be detected by SSEP monitoring.<sup>122</sup> Several case reports of paraparesis also attest to the limitations of

**E-TABLE 30-1** Intraoperative Electrophysiologic Monitoring in Spinal Surgery

Modality	Anatomy	Not Addressed	Anesthetic Concerns	Temporality	Risks
Wake-up test	Gross motor function	Nerve roots, sensation	Only short-acting, reversible agents should be employed	1 point, difficult to repeat	Self-extubations, missed focal deficit, delayed warning
SSEP	Ascending pathways; dorsal column proprioception and vibration	Focal motor pathway injury, nerve roots	Muscle relaxants helpful, volatile anesthetics inhibit, balanced by <50%; no dose-related barbiturate inhibition	3-5 minutes summation	Missed focal motor and nerve root injury; delay in warning during summation
tcMEP	Anterior spinal gray matter of descending pathways; 4%-5% of motor neuron pool in corticospinal tract	Sensation, complex motor movement	TIVA best, limited muscle relaxant (CMAP)	1 point, easily repeated	Concern for patient movement
nMEP	Whole cord with significant antidromic column component	Nerve roots, possibly no true motor data	Inhaled anesthetics acceptable however no muscle relaxant if CMAP recording	1 point, easily repeated	Possible lack of true motor data
sEMG	Nerve root: assessment in selected myotomes	Sensation, anterior descending motor pathways	No muscle relaxants, inhalational anesthetic okay	Continuous	
tEMG	Nerve root: stimulator (pedicle screw) to end muscle	Sensation, anterior descending motor pathways	No muscle relaxants, inhalational anesthetic okay	1 point, easily repeated	Concern about patient movement

Modified from Malhotra NR, Shaffrey CI. Intraoperative electrophysiological monitoring in spine surgery. *Spine* 2010;35:2167-79.

CMAP, Compound motor action potential; nMEP, neurogenic (spinal cord) motor evoked potentials; sEMG, spontaneous electromyography; SSEP, somatosensory evoked potentials; tcMEP, transcranial motor evoked potentials; tEMG, triggered electromyography; TIVA, total intravenous anesthesia.

**FIGURE 30-7** Comparison of pathways involved in somatosensory evoked potential (SSEP) and motor evoked potential (MEP) monitoring. (Modified from de Haan P, Kalkman CJ. Spinal cord monitoring: somatosensory- and motor-evoked potentials. *Anesthesiol Clin North Am* 2001;19:923-45.)

SSEP monitoring. These problems are caused by injury occurring outside the monitored domain of SSEP rather than a failure of this modality. These concerns encouraged development of methods to monitor the motor tracts of the spinal cord. SSEP monitoring is possible in patients with cerebral palsy, whereas MEPs may not be.<sup>123</sup>

### Motor Evoked Potentials

The motor pathways can be activated by transcranial stimulation of the motor cortex or by spinal cord stimulation. Transcranial stimulation is achieved using electrical or magnetic stimulation applied to the scalp. Electrical stimulators are most commonly used in spinal surgery and operate by applying high-voltage pulses to the scalp using corkscrew, needle, or surface electrodes. The stimulation pulses can be applied as single stimuli or brief pulse trains with intervals between the pulse trains. Multiple stimuli result in a stronger signal with less variability due to temporal summation of the excitatory postsynaptic potential.<sup>124</sup> Epilepsy and proconvulsant medicines are considered relative contraindications to MEP monitoring because of concerns about brain injury from prolonged seizure activity due to the electrical current required for stimulation.<sup>125,126</sup> Not surprisingly, MEPs may be difficult to record and interpret in patients with cerebral palsy and should not be attempted if the child has seizures.

MEP monitoring may be a problem in younger children, particularly those younger than 6 or 7 years of age.<sup>125,127</sup> Use of a spatial summation technique in addition to temporal summation increased the success rate from 78% to 98% over all ages. Using this technique along with ketamine anesthesia in children younger than 6 years of age, reliable MEPs were documented in 98% (111 of 113) of children older than 6 years of age and in 86% (18 of 21) in children younger than 6 years of age.<sup>127</sup> There is also evidence that younger children require a greater stimulating voltage and pulse train frequency for MEP monitoring, probably because of immaturity of the central nervous system, specifically the descending corticospinal tracts.<sup>128</sup>

Spinal cord stimulation is achieved electrically and can be applied using electrodes placed outside or inside the spinal cord rostral to the area of interest. Single stimuli rather than brief pulse trains typically are used for spinal cord stimulation.<sup>129</sup> This approach is not commonly used in scoliosis surgery.

Responses can be recorded anywhere distal to the area of interest. They have included the lower lumbar epidural space (i.e., epidural MEP), peripheral nerve (i.e., neurogenic MEP), and peripheral muscles using compound muscle action potential (CMAP) (see Fig. 30-7).<sup>130</sup> Each recording site has its limitations regarding the accuracy of the information displayed and the susceptibility to anesthetic drug interference. Epidural MEPs are

the least affected by neuromuscular blocking drugs (NMBDs), but they only monitor conduction in the corticospinal tract and provide no information about the anterior horn gray matter.<sup>131</sup> They have a much slower response to acute spinal cord ischemia when compared with myogenic responses (i.e., CMAPs).<sup>132</sup> Neurogenic MEPs are also resistant to anesthetic interference but appear not to accurately measure motor conduction. Most of the spinally elicited peripheral nerve responses seen with neurogenic MEPs occur through the dorsal columns in a retrograde fashion and are sensory rather than motor.<sup>133</sup> Anterior spinal cord injury has been demonstrated with normal neurogenic MEPs.<sup>134</sup> CMAPs after transcranial stimulation are thought to be exclusively generated by motor tract conduction, and unlike epidural MEPs, they include the ischemia-sensitive anterior horn alpha motor neurons.<sup>130</sup> These responses are very sensitive to anesthetic agents. The responses obtained with CMAPs after spinal cord stimulation also appear to contain signals that include transmission through the dorsal columns and may represent a mixed response.<sup>135</sup>

One outstanding problem with MEP monitoring is deciding when and how much change in the signal is significant and indicative of spinal cord ischemia. Some centers use the same criteria they have adopted for SSEP monitoring, whereas others require a greater degree of change, such as a 75% decrease in amplitude.<sup>136</sup> An amplitude decrease of 80% at one of six sites using transcranial myogenic MEP monitoring was demonstrated to have a sensitivity of 1.0 and a specificity of 0.91 when used as the sole monitor during spinal surgery.<sup>137</sup> A 65% decrease in amplitude identified all postoperative motor deficits (SSEP changes identified only 43%) in children with idiopathic scoliosis.<sup>138</sup> An alternative technique of measuring MEP has been described in which a minimum threshold for producing a response is established, and a significant increase in that threshold is used to signal a problem.<sup>139</sup> Supportive data for this technique are lacking.

The dorsal columns may be injured without involvement of the motor tract.<sup>140</sup> Occasionally, adverse changes in SSEPs occur without changes in MEPs.<sup>129,141</sup> Because of these reports, MEP monitoring should be used in addition to SSEP monitoring rather than as a replacement.<sup>107-110,142</sup>

### Triggered Electromyographic Techniques

The increasing use of pedicle screws allows greater curve and rotational correction than earlier techniques but has an additional risk of direct nerve root trauma. Triggered EMGs using a monopolar needle or bipolar handheld stimulator have been described, with a threshold stimulation level of more than 8 mA considered to be normal, 5 to 8 mA to be critical, and less than 5 mA to be pathologic, indicating that there was not enough distance between the screws and the neural tissue.<sup>142</sup> This technique requires monitoring rectus abdominis or intercostal muscles when used for thoracic curves.<sup>143,144</sup>

## Preoperative Assessment and Postoperative Planning

### RESPIRATORY ASSESSMENT AND PLANNING FOR POSTOPERATIVE VENTILATORY SUPPORT

The preoperative pulmonary assessment should identify patients at increased risk for postoperative respiratory compromise. Patients with idiopathic scoliosis tend to have less decrease in pulmonary function with correspondingly reduced complication

rates, so most studies have focused on nonidiopathic patients.<sup>66</sup> The rate of postoperative pulmonary complications correlates broadly with the decrease in vital capacity.<sup>60,145,146</sup> Vital capacity less than 30% to 35% of predicted values indicates marginal respiratory reserve and a level at which complications and a need for postoperative respiratory support are likely. Many patients with these low vital capacities are unable to cough effectively, rendering them prone to postoperative atelectasis, pneumonia, and respiratory failure.

Studies involving a mixed population with a vital capacity less than 40% (but few with neuromuscular disorders) suggest that although short-term and middle-term pulmonary complications occur, these patients can be successfully managed to achieve discharge to home, although some require prolonged postoperative ventilation.<sup>147,148</sup> Modest numbers of patients with a vital capacity of less than 25% of the predicted value are described in these studies and do not appear to have greater complication rates than those with greater vital capacity values. Anterior or combined approaches increase the likelihood of respiratory complications, particularly due to pleural effusion.<sup>147,148</sup>

Children with neuromuscular scoliosis are likely to need postoperative ventilation that is often prolonged.<sup>60,146</sup> These patients may also have abnormalities in the central control of breathing and impaired airway defense mechanisms. Impaired coordination of laryngeal and pharyngeal muscles may result in impaired swallowing and inadequate cough with increased risk of aspiration. Initial work suggested that as the vital capacity decreased to less than 35% of predicted, most patients would need a short period of postoperative ventilation.<sup>84</sup> The earlier use of nocturnal NPPV and use of NPPV in the postoperative period may alter our perception of risk by decreasing the impact or severity of postoperative respiratory complications while allowing children with increasingly severe respiratory impairment to be considered for surgery. Scoliosis surgery can be successfully undertaken in patients with a vital capacity of less than 35% of predicted, often with no more than 24 hours of planned ventilation followed by a period of noninvasive ventilation (e.g., bi-level positive airway pressure [BiPAP]).<sup>60,69,149,150</sup> In one study ( $n = 30$ ), the overall complication rate was similar whether the FVC was more than or less than 30%, and the average hospital stay was approximately 3 weeks (see Table 30-2). Tracheostomy was required in two children, and the overall pulmonary complication rate was 30%.<sup>150</sup> Similar results are reported by others.<sup>69</sup> It seems reasonable to anticipate using noninvasive ventilator support for several days after spine stabilization surgery in children with a vital capacity of less than 25% of predicted values. Children with a mean FVC of 20% of predicted have been successfully managed with a brief period of postoperative ventilation and transitioned to BiPAP within 48 hours.<sup>151</sup>

Whether a child should be denied surgery requires consideration of individual patient factors. The successful management of children with a vital capacity of 15% to 20% of predicted has been described, although the numbers were small.<sup>147-150</sup> Although the risk of an unsuccessful outcome can increase at this level, individual circumstances may justify the risk.

### CARDIOVASCULAR ASSESSMENT

Muscle disorders may affect the myocardium and the skeletal system. Children with DMD develop a cardiomyopathy that may be difficult to evaluate because the child is wheelchair bound. Sinus tachycardia is an early manifestation, and in terms of frequency and severity, cardiac function declines

from early adolescence.<sup>152</sup> More than 90% of adolescents with DMD have subclinical or clinical cardiac involvement.<sup>153</sup> Echocardiography is an essential part of the preoperative evaluation of any wheelchair-bound patient presenting for scoliosis surgery. (See also Chapter 14.)

### POSTOPERATIVE PAIN MANAGEMENT

Scoliosis surgery is associated with severe pain that lasts for at least 3 days.<sup>154</sup> Effective analgesia minimizes postoperative respiratory complications by allowing deep breathing, chest physiotherapy, early ambulation, and rehabilitation. Postoperative pain may be managed with systemic or epidural analgesics. A multimodal approach is likely to be most effective.

#### Intraoperative Intrathecal and Intravenous Opioids

Intraoperative intrathecal morphine (2 to 5 µg/kg) has provided potent analgesia during the first 24 hours after spinal fusion in children.<sup>155,156</sup> Intrathecal morphine also decreases the amount of remifentanyl required intraoperatively, contributing to less pain on cessation of remifentanyl.<sup>157,158</sup> However, perioperative administration of intravenous morphine, when using remifentanyl as part of the anesthesia technique, does not result in any measurable benefit.<sup>159</sup>

Methadone (0.2 mg/kg) decreases pain scores and opioid requirements for 36 hours in children undergoing surgery, but it seems to have been ignored in modern practice.<sup>160</sup> This drug is used in adult spinal surgery, but reports of its use in children are few.<sup>161</sup>

#### Nonsteroidal Antiinflammatory Drugs

NSAIDs, but not acetaminophen, impair fracture healing in animal models.<sup>162</sup> Cyclooxygenase-2 (COX-2) activity plays an important role in bone healing, and the use of NSAIDs decreases osteogenic activity that may increase the incidence of nonunion after spinal fusion.<sup>8,9</sup> The effect on osteogenic activity is dose dependent and reversible.<sup>163</sup> Similar effects have not been demonstrated in humans. Nonetheless, based on animal evidence, NSAIDs should be used with caution and in consultation with the surgeon during the first 3 to 5 days after scoliosis surgery.<sup>164</sup>

#### Systemic Analgesics

Morphine remains the mainstay of systemic analgesic regimens. Morphine infusions of 20 to 40 µg/kg/hr are required during the first 48 hours after surgery. Achieving a balance of effective analgesia while avoiding sedation can be difficult in children with neurodevelopmental delay. Regular evaluation of these children is important if complications are to be avoided. Patient-controlled analgesia (PCA) is appropriate for children older than 6 to 7 years of age. It can be used with a typical bolus dose of 20 µg/kg and a lockout interval of 5 to 10 minutes. The use of a background morphine infusion may be effective in some patients, although its inclusion is controversial.<sup>165,166</sup> Our preference is to use a nighttime background infusion at 5 to 10 µg/kg/hr but to use PCA alone during the day (see Chapter 43). Nurse- and parent-controlled analgesia are effective if the child is too young or unable to use PCA.<sup>167</sup> Intrathecal morphine plus PCA appears to offer the optimal combination of effective analgesia and minimal adverse effects in idiopathic scoliosis patients compared with PCA morphine alone or epidural morphine.<sup>168</sup>

Low-dose ketamine infusion (0.05 to 0.2 mg/kg/hr) has been used as an adjunct to morphine infusions or PCA, although its role is debated.<sup>169-174</sup> Ketamine may be initiated intraoperatively

(initial infusion of 5 µg/kg/min, decreasing to 2 µg/kg/min at the end of surgery) as part of the anesthetic technique to minimize the hyperalgesia reported after high-dose remifentanyl infusions.<sup>175,176</sup> The literature continues to be confused with conflicting reports showing no effect<sup>177</sup> or a modest decrease in pain scores and morphine consumption.<sup>178</sup> Ketamine added to morphine PCA has produced mixed results, with no clear beneficial effect in orthopedic surgery, despite such evidence being apparent for thoracic surgery.<sup>179</sup> If added to PCA, the optimal combination of morphine: ketamine is a 1:1 ratio.<sup>172</sup> Despite scoliosis causing severe pain, it is probably best to reserve the use of ketamine for those with significant preoperative pain or morphine-resistant pain.

Gabapentin and pregabalin provide some benefit with an opioid-sparing effect,<sup>180</sup> although postoperative nausea and vomiting benefits are limited.<sup>181</sup> Gabapentin (15 mg/kg followed by 5 mg/kg three times daily for 3 days) reduced morphine consumption by about 30% over the study period but without any improvement in morphine's adverse effects. Improved pain relief was observed only until the morning after surgery.<sup>182</sup>

#### Epidural Analgesia

Continuous epidural analgesia using single- and double-catheter techniques may provide effective analgesia after spinal surgery. The single-catheter technique using bupivacaine-fentanyl and sited at T6-7 for patients undergoing a mean 12-level scoliosis surgery resulted in analgesia similar to that of PCA but with more postoperative nausea and vomiting and pruritus. Bowel sounds returned earlier in the epidural group, but liquid intake and hospitalization were similar.<sup>183</sup> Similar results were reported with a bupivacaine-morphine combination in patients undergoing 10-level spinal fusions. Full diet and discharge from hospital were achieved one-half day earlier with the epidural technique than with PCA.<sup>184</sup> A retrospective review of more than 600 patients treated with an epidural or PCA for analgesia after scoliosis surgery, in which the average number of segments fused was 8.5, confirmed the effectiveness of epidural analgesia.<sup>185</sup> In that study, a bupivacaine-hydromorphone epidural combination was used, and although pain management was effective, more complications occurred in the epidural group. Respiratory depression and transient neurologic changes were the most common complications observed. Thirteen percent of patients with an epidural catheter required discontinuation of the epidural, most commonly for inadequate pain relief.<sup>185</sup> Effective analgesia and a large incidence of postoperative nausea and vomiting and pruritus have been features of studies that combined bupivacaine and morphine.<sup>186,187</sup>

Patient-controlled epidural analgesia (PCEA) has been successfully used in children older than 5 years of age for orthopedic surgery and thoracotomies.<sup>188</sup> In scoliosis surgery, PCEA with bupivacaine and hydromorphone compared with PCA resulted in a slightly improved pain score but a 37% failure rate.<sup>189</sup> PCEA with a single- or double-catheter technique, depending on the number of spinal segments involved, and using a bupivacaine, fentanyl, and clonidine solution has been successful and is associated with a relatively small incidence of complications.<sup>190</sup>

Improved pain control and bowel function with decreased adverse effects may be possible by using a double-epidural technique using moderate amounts of fentanyl and clonidine with local anesthetics.<sup>191</sup> Double-epidural techniques comprise an upper catheter positioned in the upper to middle thoracic segments and a lower catheter at the upper to middle lumbar

level.<sup>192,193</sup> This modality resulted in improved pain control compared with morphine infusion and had fewer gastrointestinal adverse effects.

## Anesthetic and Intraoperative Management

### POSITIONING AND RELATED ISSUES

The patient must be positioned so that extreme pressure points are avoided, the limb positions are adjusted to prevent nerve injury, and the abdomen is free to minimize venous congestion. This is usually achieved by the use of the Relton-Hall frame or a variant.<sup>194</sup> The frame comprises four well-padded supports arranged into V-shaped pairs, with the upper pads supporting the thoracic cage and the lower pair supporting the anterolateral aspects of the pelvic girdle at the anterior iliac crests. The arms must not be abducted or extended greater than 90 degrees from their natural position. The weight of the arms is evenly distributed across the forearm to avoid pressure on the ulnar nerve at the elbow. The range of motion of the shoulders should be assessed preoperatively for optimal positioning during anesthesia. This can present quite a challenge in children with severe deformities, and creative positioning may be required. In some centers, the nipples are covered with Tegaderm (3M, St. Paul, Minn.) and positioned free of direct pressure. It is also essential that the head is maintained in a neutral position and that pressure is evenly distributed between the forehead and face, avoiding direct pressure on the eyeballs. Care must be taken to avoid any direct pressure on the knees, and the patient's weight should be distributed throughout the lower limb (Fig. 30-8). Reston self-adhering foam (3M, St. Paul, Minn.) may be used to pad the pelvic brim and knees.

Not all spinal tables and frames affect cardiac function in the same way. There is some evidence that the Jackson spine table or longitudinal bolsters have minimal effects on cardiac function, whereas Wilson, Siemens, and Andrews frames may negatively impact cardiac function.<sup>195</sup>

Postoperative visual loss is an uncommon, unpredictable, and devastating complication associated with spinal surgery in the prone position. It may occur in up to 0.2% of cases, and although most of the reports involve adult patients, older children are not immune.<sup>196,197</sup> The most common cause is ischemic optic neuropathy, but the cause remains obscure. Prolonged operating

time (>6 hours) and increased or uncontrolled blood loss are features of most of the reports.<sup>198-201</sup> The phenomenon is unrelated to pressure on the globe and usually occurs without evidence of any other ischemia-related complications.<sup>201</sup> There is nothing to support controlled hypotension or hemodilution as contributory factors despite occasional expert opinion to the contrary.<sup>198,201,202</sup>

### TEMPERATURE REGULATION

The long preparation time and exposure of an undraped patient on the spinal frame render them susceptible to hypothermia. Hypothermia is associated with hemodynamic instability and increased blood loss.<sup>203</sup> A threefold increase in surgical wound infection occurs with a 2° C decrease in core temperature.<sup>204</sup> Efforts should be made to increase the ambient temperature in the operating room while the patient is prepared for surgery. Subsequent hypothermia can be minimized if the room temperature is maintained at 24° C during this period rather than at 18° to 21° C, as is often encountered during surgery.<sup>205</sup> After the patient has cooled during preparation and positioning, it may take several hours before the core temperature begins to return toward normal. Even with forced air warming systems, it is often difficult to restore normothermia because only a small amount of the patient's body is exposed to these devices. It may be possible to position a warming blanket underneath the frame so that warming from below and above occurs (see Fig. 30-8 and Video 30-1).

### PATIENT MONITORING

Patient monitoring needs to be tailored to the individual case, but at a minimum, arterial oxygen saturation, end-tidal carbon dioxide (CO<sub>2</sub>), electrocardiographic (ECG) patterns, core temperature, and urine output should be recorded. In most cases, invasive arterial and central venous pressures are monitored because of large blood losses, fluid shifts, and the risk of cardiovascular instability. Direct pressure by the surgeon during dissection or curve correction may compromise cardiac function or filling. Central venous pressure is an accurate and valid measurement in the prone position, providing the zero is adjusted for the patient's position on the spinal frame. Patients with a significant kyphotic component are at increased risk for venous air embolism and should be monitored for this possibility. Depth of anesthesia monitoring should be considered, particularly when MEP monitoring limits the concentrations of anesthetic drugs. Care should be taken when positioning the head because pressure on the forehead by the sensor while the patient is in the prone position for many hours may cause erythema, localized swelling, and tissue necrosis. Contact dermatitis from the adhesive has also been reported.<sup>206</sup> Mixed venous oxygen tension trends may be helpful for children with myocardial compromise. Transesophageal echocardiography can be useful for determining ventricular filling and function when hemodynamic compromise is identified or suspected preoperatively.

### MINIMIZING BLOOD LOSS AND DECREASING TRANSFUSION REQUIREMENTS

Scoliosis surgery involves exposure of a large wound over a considerable period. Positioning the patient with the abdomen free to avoid venous compression is important to control and minimize blood loss. Increased intraabdominal pressure attributable to positioning can double intraoperative blood loss.<sup>207</sup>

Posterior spinal fusion procedures tend to lose more blood than anterior procedures. This loss probably corresponds to the

**FIGURE 30-8** Positioning on the Orthopedic Systems Incorporated (OSI) Jackson frame, showing protected pressure points and an underframe forced-air warming blanket.

greater number of vertebral levels fused with the posterior approach. Blood loss increases as the number of vertebrae included in the fusion increases. The estimated blood loss (EBL) is approximately 750 to 1500 mL in patients with idiopathic scoliosis, or 60 to 150 mL per vertebral segment fused. The blood loss of 1300 to 2200 mL (100 to 190 mL per vertebral segment) is significantly greater in patients with cerebral palsy. Children with DMD experience the largest EBL—2500 to 4000 mL (200 to 280 mL per vertebral level).<sup>208</sup>

Children with neuromuscular scoliosis demonstrate a prolonged prothrombin time and a decrease in factor VII activity intraoperatively, suggesting that consumption of clotting factors and dilution of clotting factors enhance the blood loss.<sup>209</sup> It has been postulated that children with DMD lack dystrophin in all muscle types and that the poor vascular smooth muscle vasoconstrictor response may be a factor in the increased blood loss.<sup>210</sup> Hypothermia exacerbates blood loss by decreasing platelet function, decreasing coagulation factor activity, and slowing vasoconstriction.<sup>203</sup>

Adverse reactions to blood appear to be more common in children than adults, with human error as the most common cause.<sup>211</sup> Several techniques have been used to decrease blood loss and minimize exposure to blood products.

### Hypotensive Techniques

Controlled hypotension has been used to minimize blood loss during scoliosis surgery since it was first described more than 30 years ago. A greater than 50% decrease in blood loss with a decreased need for blood replacement and a reduced operating time was demonstrated in early studies. Ganglion-blocking agents (i.e., pentolinium and trimethaphan) have been superseded by  $\beta$ -blockers, direct arterial vasodilators, calcium channel blockers, and  $\alpha_2$ -agonists. It remains uncertain whether reduced blood loss results from lowered blood pressure<sup>212</sup> or lower cardiac output.<sup>213</sup> A target mean arterial pressure (MAP) of 50 to 65 mm Hg has been recommended. Although this appears to be safe, concerns that the margin of safety for cerebral and spinal cord ischemia is reduced by controlled hypotension apply to operations of prolonged duration, and there is the potential for periods of hypovolemic hypotension in addition to drug-induced (controlled) hypotension.<sup>214,215</sup> The incidence of these feared complications is fortunately very small with or without hypotension. Renal function appears well preserved even when hypotensive anesthesia is used during scoliosis surgery.<sup>216,217</sup> Because of these concerns and the concomitant use of hemodilution, less extreme degrees of hypotension are usually employed. Robust data supporting the beneficial effects of controlled hypotension in scoliosis surgery is minimal, although clear benefits have been demonstrated for orthognathic and orthopedic surgery.<sup>218,219</sup>

In modern practice, moderate hypotension with good control of the heart rate can often be achieved without the use of specific vasoactive drugs by using a remifentanyl infusion titrated to the desired blood pressure.<sup>220</sup> Although not considered a hypotensive agent, intrathecal morphine decreases blood loss and may facilitate blood pressure control, particularly with a remifentanyl infusion. At an analgesic dose of 5  $\mu$ g/kg, a decrease in EBL from 41 to 14 mL/kg occurred.<sup>156</sup> Using this technique, blood pressure control can frequently be achieved without any additional agents. We have found that using an anesthetic combination of less than 1 minimal alveolar concentration (MAC) of inhalational agent plus remifentanyl with clonidine (2  $\mu$ g/kg)<sup>221</sup> provides controlled hypotension in most patients without the need for additional

agents. Dexmedetomidine may be used as part of a technique for controlling blood pressure.<sup>222,223</sup>

Short-acting calcium channel blockers have been used for controlled hypotension for scoliosis surgery, and although they are effective, experience is limited. Nicardipine is associated with less blood loss at the same MAP compared with sodium nitroprusside, although a slower return to baseline blood pressure (27 versus 7 minutes) is seen.<sup>224,225</sup> Clevidipine has been used without evidence of clear benefit, but it may be associated with an increase in heart rate.<sup>226</sup> If a hypotensive technique is to be used, invasive arterial monitoring is essential, and central venous pressure catheters are useful for the safe conduct of anesthesia (see Chapter 10).

### Hemodilution

Decreasing the hemoglobin concentration by removing red cells and replacing the volume with a combination of crystalloid and colloid means that for a given volume loss, there is less red cell loss (see Chapter 10). The decreased metabolic rate during anesthesia suggests that oxygen delivery can be maintained with a reduced hemoglobin concentration if normovolemia is maintained.

It has been estimated that more than 2 to 3 units of blood must be removed during hemodilution to significantly reduce transfusion requirements. Hemodilution modeling in adult patients has suggested that as many as 5 units of blood must be removed before there is a decrease in transfusion requirements.<sup>227</sup> Deciding on the degree of hemodilution and establishing a threshold for transfusion may be difficult. In scoliosis surgery, reduction to an initial hematocrit of 30% has been effective for reducing and minimizing transfusion requirements.<sup>228</sup> Some posit that only modest benefits are gained from the technique.<sup>229</sup> Hypotensive anesthesia, hemodilution, and a cell saver used as part of a “bloodless surgery” program with erythropoietin and supplemental iron resulted in an average EBL of 855 mL (blood returned by the cell saver averaged 341 mL), with an average drop in hemoglobin after surgery of 3.1 g/dL.<sup>230</sup>

Tachycardia and hemodynamic instability are common at hemoglobin concentrations less than 7 g/dL. Myocardial ischemia becomes a risk as the hemoglobin concentration decreases below 5 g/dL.<sup>231</sup> At this level of anemia, cyanosis cannot develop because 5 g/dL of desaturated hemoglobin are required for cyanosis to be detected. Extreme hemodilution techniques such as these are reserved for patients who oppose blood transfusion. One report detailed patients who had hemodilution during scoliosis surgery that produced a hemoglobin concentration of 3 g/dL in the absence of preexisting cardiac disease.<sup>232</sup> Cardiac output increased by more than 30%, with only a modest increase in heart rate and decrease in blood pressure.<sup>232</sup> Although no cerebral sequelae were reported, *this degree of extreme hemodilution is not recommended.*

### Autologous Predonation

Preoperative strategies, including predonation of blood and preoperative red cell augmentation, may be used alone or in addition to intraoperative techniques to minimize exposure to blood (see Chapter 10). In idiopathic scoliosis surgery, preautologous blood donation plus intraoperative red cell salvage and controlled hypotension resulted in an average EBL of 1055 mL, avoided transfusion, and the hematocrit only decreased by 10% (35.6 to 32.4) at discharge.<sup>233</sup> The advantages of preoperative erythropoietin in addition to preautologous blood donation

include a greater preoperative hemoglobin concentration and fewer donated units. Its effect on blood use depends on the total blood loss.<sup>234,235</sup> In children with neuromuscular scoliosis, erythropoietin alone did not affect the amount of blood transfused, although the preoperative and discharge hematocrits were greater in treated patients.<sup>236</sup>

### Antifibrinolytic Agents

The use of synthetic antifibrinolytic agents to decrease perioperative blood loss after scoliosis surgery has produced mixed results. To be most effective, an effective plasma concentration of the antifibrinolytics should be established before skin incision.  $\epsilon$ -Aminocaproic acid (Amicar) decreases the EBL by 25% during the perioperative period,<sup>237</sup> mainly attributable to decreasing the postoperative suction drainage.<sup>238</sup> In contrast, an initial dose of tranexamic acid (10 mg/kg) followed by an infusion of 1 mg/kg/hr failed to significantly decrease blood loss in a small sample.<sup>239</sup> High-dose tranexamic acid (100 mg/kg loading dose, followed by an infusion of 10 mg/kg/hr) did decrease blood loss by 40% but did not affect transfusion requirements. Post hoc analysis in patients with secondary (neuromuscular) scoliosis showed significant reduction in blood loss and transfusion requirements.<sup>240</sup> The correct dose of tranexamic acid remains elusive, but it may be one half of the high dose reported previously.<sup>241</sup>

A meta-analysis of aprotinin, tranexamic acid, and  $\epsilon$ -aminocaproic acid on blood loss and use of blood products in children undergoing scoliosis surgery showed that all antifibrinolytic drugs decreased the amount of blood transfused and that aprotinin, tranexamic acid, and  $\epsilon$ -aminocaproic acid were equally effective.<sup>242</sup> A similar meta-analysis of major pediatric surgery showed that in the scoliosis studies, aprotinin and tranexamic acid reduced blood loss compared with placebo (385 mL, 95% confidence interval [CI] 42 to 727 mL, versus 682 mL, 95% CI 214 to 1149 mL).<sup>243</sup> In all operations, both drugs also decreased red cell transfusion. Demonstration that tranexamic acid is as effective as aprotinin is fortunate, because aprotinin has been withdrawn in many countries after reports of increased morbidity and mortality in adults after cardiac surgery.<sup>244</sup> However, after a review of the evidence, aprotinin has been reintroduced in Canada, citing off-label use of the drug as the cause of complications. Studies are being conducted in the United States. Use of  $\epsilon$ -aminocaproic acid reduces mean intraoperative blood loss (1125 mL versus 2194 mL), total perioperative blood loss (1805 mL versus 3055 mL), and transfusion requirements (660 mL versus 1548 mL) compared with placebo.<sup>245</sup> Reduced blood loss has significant cost savings from decreased operating room time and blood products use.<sup>246</sup> Desmopressin is ineffective in decreasing blood loss associated with spinal surgery. Initial beneficial results with desmopressin<sup>247</sup> have not been reproduced in patients with idiopathic scoliosis<sup>248,249</sup> or in those with neuromuscular scoliosis.<sup>250,251</sup>

### Intraoperative Salvage of Shed Blood

Decisions concerning the use of intraoperative salvage of shed blood (e.g., cell saver) depend on the anticipated blood loss, size of the patient, and use of other methods to minimize blood transfusion, such as predonation and hemodilution (see Chapter 10). It is important to have some idea of the blood loss associated with idiopathic scoliosis in your institution when deciding to use cell saver techniques. For example, the cell saver was found to be beneficial in less than 5% of adolescents with idiopathic scoliosis involved with an autologous predonation program or

modest intraoperative hemodilution in one institution.<sup>228</sup> At another institution, however, allogeneic transfusion rates were reduced from 55% to 18% when the cell saver was used. The allogeneic transfusion relative risk was 2.04 for patients undergoing surgery lasting more than 6 hours and 5.87 for patients not receiving cell saver blood.<sup>252</sup>

Pediatric systems are available with small spinning bowls (55 to 75 mL). These systems benefit children with smaller body weights and greater than anticipated blood loss such as patients with neuromuscular scoliosis undergoing extensive spinal fusion.<sup>253,254</sup> Among children undergoing anterior instrumentation for thoracolumbar curves, cell saver use decreased the number requiring allogeneic blood transfusion from 39.4% to 6.7% and with similar mean postoperative hemoglobin values (10.2 versus 9.6 g/dL).<sup>255</sup>

### MANAGING BLOOD LOSS

Autologous blood before donation requires an organized schedule of donation with or without the administration of erythropoietin.<sup>256,257</sup> This may be the safest and most effective method of avoiding or minimizing the use of allogeneic blood products in this group of patients.<sup>258</sup> A predonation program was effective in minimizing blood exposure in idiopathic adolescents undergoing surgical correction for their scoliosis. A mean of 3.7 units of blood was donated by each patient before surgery, and 97% of adolescents avoided the use of allogeneic blood during and after surgery.<sup>256</sup>

Measurement of blood loss during scoliosis surgery is difficult. Accuracy is lost as measurements embrace blood suctioned from the operative field that includes irrigation fluid, weighing or estimating blood collected on swabs and sponges, approximations of blood on drapes and gowns, and estimations of evaporation from the wound.

The decision about when to administer blood component therapy (i.e., non-red cell blood components) is often based on clinical judgment. Dilutional thrombocytopenia is expected only after several blood volumes have been lost and depends on the preoperative platelet count (see Chapter 10). Platelet concentrations should be measured after loss of one blood volume and at periodic intervals after this. Dilution of coagulation factors may also lead to surgical bleeding when only packed red blood cells are used to replace blood loss. Prolongation of prothrombin time and activated partial thromboplastin time may occur when the blood loss exceeds one blood volume, and they should be checked for at this time. These coagulation tests are not usually associated with increased bleeding until values are greater than 1.5 times mean control values, at which time increased surgical bleeding can be effectively treated with fresh frozen plasma.<sup>259</sup> Platelet counts after one blood volume loss, whether associated with normal or abnormal clotting, were within the normal range.<sup>259</sup> Blood component therapy should probably be based on abnormal clotting test results, uncontrolled bleeding, or the absence of normal clotting in the surgical field. It is preferable to intervene with blood component therapy before uncontrolled bleeding develops. If pooled blood in a dependent part of the operative field fails to show evidence of clotting, it is time to transfuse with blood components starting with fresh frozen plasma and administering platelets only if this approach is not effective.<sup>259</sup>

Massive transfusion protocols, in which predefined ratios of red blood cells, plasma factors, and platelets (usually in a 1:1:1 ratio) are administered early in the resuscitation phase of massive trauma, are being increasingly used in all situations of

uncontrolled blood loss.<sup>260,261</sup> Evidence that these protocols decrease morbidity and mortality in the trauma setting has resulted in their implementation in surgery, in which significant and uncontrolled bleeding may be expected.<sup>262,263</sup> This approach results in proportionally greater administration of factors and platelets than with conventional approaches to severe hemorrhage, but it is associated with increased survival.<sup>264</sup>

The thromboelastogram is also useful in refining blood product administration if multiple blood volumes are required for resuscitation.<sup>262,264</sup> Scoliosis surgery in patients with neuromuscular scoliosis or cerebral palsy, particularly in those with severe complex curves in whom pelvic stabilization and iliac crest grafts are considered, fulfill these criteria. In this group of patients, early administration of blood and factors using a massive transfusion protocol may be beneficial.<sup>265</sup>

Recombinant factor VIIa may be a useful therapy for patients with a dilutional coagulopathy who are unresponsive to blood component replacement therapy. Successful use with doses as small as 20 µg/kg, has been described in spinal surgery.<sup>266-269</sup>

### EFFECTS OF ANESTHETICS ON SOMATOSENSORY EVOKED AND MOTOR EVOKED POTENTIALS

Anesthetic agents act by directly inhibiting synaptic pathways or by indirectly changing the balance of inhibitory and excitatory influences.<sup>270,271</sup> The greater the number of synapses and the more complex the neuronal pathway being monitored, the greater the potential impact of anesthetic agents on the evoked potentials. Most anesthetic agents depress the amplitude and increase the latency of SSEPs and MEPs. For this reason, cortical SSEPs are more sensitive than spinal cord or brainstem measured SSEPs. MEPs are susceptible to anesthetic agents at three sites: the motor cortex, the anterior horn cell, and the neuromuscular junction. Consequently, transcranial stimulation with peripheral muscle detection (using CMAPs) is most susceptible to anesthetic interference. Although inhalational anesthetics and most intravenous anesthetics markedly depress SSEPs and MEPs, ketamine and etomidate appear to enhance the amplitudes of both, possibly by attenuating inhibition.<sup>271</sup>

#### Inhalational Anesthetics

Inhalational anesthetics cause dose-dependant depression of the SSEP and myogenic MEP. At equipotent concentrations, the MEP is affected to a greater degree than the SSEP. This means that while inhalation agents can be used during SSEP monitoring, they often need to be administered in subanesthetic doses during MEP monitoring. Adequate cortical SSEPs and subcortical SSEPs can be measured with up to 1 MAC of isoflurane, sevoflurane, and desflurane, although some increase in latency and decrease in amplitude may be detected.<sup>272,273</sup> It is important to maintain constant end-tidal concentrations throughout anesthesia after baseline measurements have been established. Concentrations of these anesthetics that allow adequate monitoring are significantly less than was possible with halothane.<sup>274</sup>

Myogenic MEPs (i.e., CMAPs) are recordable only at low concentrations of inhalational anesthetics. The exact concentration depends on the system being used and is greatly influenced by the number of pulses in the stimulus. Single-pulse transcranial stimuli may be inhibited by end-tidal concentrations as small as 0.2 MAC and abolished by end-tidal concentrations as small as 0.5 MAC.<sup>275-277</sup> This suppression can be partially overcome by using greater intensity stimuli with multipulse stimulation of up to 6 pulses per stimulus. An increasing number of patients lose

recordable myogenic MEPs, even when multipulse stimuli are used, as the concentration of inhalational anesthetic exceeds 0.5 MAC. At end-tidal concentrations in excess of 0.75% isoflurane, monitoring conditions become unacceptable.<sup>278-282</sup> Stimulus intensity and pulse train frequency probably are factors in determining successful myogenic MEPs with inhalational anesthetics. Using direct stimulation of the cortex during craniotomy, CMAP was easily recordable at 1 MAC of isoflurane and sevoflurane.<sup>283</sup> Similar results have been demonstrated with sevoflurane using transcranial stimulation.<sup>284</sup> Information regarding desflurane is limited, and although it causes a dose-dependent depression, myogenic MEPs have been successfully recorded at 0.5 MAC.<sup>282,285</sup> Using a multipulse stimulation technique, intraoperative recording of MEPs was equally successful during desflurane or propofol anesthesia.<sup>286</sup> In contrast to its effects on SSEPs, halothane depresses myogenic MEPs to a lesser extent than the newer inhalational anesthetics.<sup>284</sup>

#### Nitrous Oxide

Nitrous oxide reduces the amplitude of the cortical SSEP, but comparisons with other inhalational anesthetics are limited. Nitrous oxide (0.5 MAC) depresses SSEPs to a greater extent than isoflurane at a similar MAC.<sup>287</sup> Similarly, 66% nitrous oxide depressed SSEPs to a greater extent than propofol (6 mg/kg/hr; 100 µg/kg/min).<sup>288</sup> Nitrous oxide depresses myogenic MEPs.<sup>273</sup> The effect relative to other inhalational anesthetics is difficult to determine. Nitrous oxide appears to affect CMAP amplitude to a lesser extent than isoflurane.<sup>289</sup> Multipulse stimulus techniques can partially reverse nitrous oxide-induced depression of amplitude. Compared with a propofol infusion designed to maintain a target concentration of 3 µg/mL, 50% nitrous oxide decreases CMAPs with single or paired stimuli to a lesser extent.<sup>290</sup> When 60% nitrous was added to low-dose propofol infusion at a target concentration of 1 µg/mL, adequate CMAPs were obtained using multipulse transcranial stimulation.<sup>291</sup> Conversely, the addition of nitrous oxide to a variety of different total intravenous techniques significantly depressed the CMAP such that some were not recordable.<sup>292</sup> With the widespread availability of remifentanyl and the variable but mostly negative effects of nitrous oxide on SSEP and MEP signals, it seems that nitrous oxide is best avoided when spinal cord monitoring is used.

#### Propofol

Propofol decreases the amplitude of the cortical SSEP, but adequate signals can be recorded, even in the presence of nitrous oxide, at doses used for anesthesia (6 mg/kg/hr; 100 µg/kg/min).<sup>293</sup> Propofol better preserves cortical SSEP amplitude and provides a deeper level of hypnosis as measured by processed electroencephalographic values than combinations of low-dose isoflurane and nitrous oxide or low-dose isoflurane or sevoflurane alone.<sup>294-296</sup>

Propofol depresses the amplitude of myogenic MEPs. In addition to its cortical effect, it suppresses activation of the alpha motor neuron at the level of the spinal gray matter.<sup>297,298</sup> Low-dose propofol infusions have become popular as part of the anesthetic technique used with MEP monitoring due to the rapid improvement of signals when the drug is terminated and because multipulse stimulation techniques can improve the response amplitude.<sup>279,299</sup> Propofol, even in combination with nitrous oxide, depresses multipulse transcranial CMAPs less than isoflurane.<sup>279</sup> Propofol (5 mg/kg/hr; 83 µg/kg/min) combined with 66% nitrous oxide produced satisfactory CMAP recordings in 75% of patients when a four-pulse stimulation sequence was

used. In contrast, no recordings were possible with 1 MAC of isoflurane.<sup>280</sup> The infusion rates or target concentrations that allow acceptable myogenic MEP recordings vary considerably and reflect different adjuvants (e.g., opioids, ketamine, nitrous oxide), degrees of neuromuscular blockade, and transcranial pulse rates. Propofol at a target of 4 µg/mL or at an infusion rate of 6 mg/kg/hr (100 µg/kg/min) produces acceptable signals with multipulse stimuli.<sup>299-301</sup>

### **α<sub>2</sub>-Adrenoreceptor Agonists: Clonidine and Dexmedetomidine**

The cerebral effects of the α<sub>2</sub>-agonists appear to act mainly at the locus ceruleus, rather than by the more generalized inhibition of synaptic pathways, as in the case of general anesthetics.<sup>302</sup> Clonidine at doses of 2 to 5 µg/kg given intravenously had minimal effects on cortical SSEPs when added to isoflurane.<sup>303-305</sup> In view of its lack of effect on SSEPs and its anesthetic-sparing properties with inhalational agents and propofol,<sup>305-307</sup> it seems reasonable to consider clonidine at a dose of 2 to 4 µg/kg as part of an anesthetic technique. Dexmedetomidine has similar beneficial properties on SSEPs.<sup>308,309</sup>

There are no published studies on the effects of clonidine on MEPs, but a few publications have examined dexmedetomidine and MEPs with variable results.<sup>310-313</sup> The effects of dexmedetomidine, like other anesthetic agents, produce a dose-dependent depression of MEPs, and the ability to interpret these signals may depend on the depth of anesthesia, which suggests that depth of anesthesia monitoring should be used when recording MEPs to maintain a plane of anesthesia that is adequate to prevent recall but still enable good MEP signals to be recorded.

We have observed similar effects with clonidine as an adjunct to desflurane anesthesia. A temporary decrease in MEPs sometimes occurs if clonidine is administered too rapidly, but signals are improved if the bispectral index (BIS) is maintained at 50 to 60.

### **Opioids**

Alfentanil, fentanyl, sufentanil, and remifentanyl minimally depress SSEP and MEP signals.<sup>314,315</sup> Dose-dependent depression of the CMAP does occur at doses of opioids that far exceed those used in clinical anesthesia.<sup>316,317</sup> Comparison of alfentanil, fentanyl, and sufentanil at doses sufficient to suppress noxious stimuli suggested that sufentanil exerted the least effect.<sup>316</sup> A similar study that included remifentanyl showed that this drug had the least depressive effects, with CMAPs measurable at infusion rates of 0.6 µg/kg/min.<sup>317</sup> It is likely that greater doses can be used if clinically indicated.

### **Ketamine and Etomidate**

Ketamine enhances the cortical SSEP amplitude and has a minimal effect on subcortical and peripheral SSEP responses.<sup>318</sup> It also produces minimal effects on the myogenic MEP responses as a bolus of 0.5 mg/kg<sup>319</sup> or when used in moderate doses (1 to 4 mg/kg/hr; 17 to 83 µg/kg/min) as a supplement to a nitrous oxide-opioid anesthesia.<sup>319,320</sup> Experimental evidence suggests S(+)-ketamine modulates the CMAP by a peripheral mechanism at or distal to the spinal alpha motor neuron.<sup>321</sup> Ketamine (4 µg/kg/min) has been successfully used with MEP monitoring during propofol-remifentanyl anesthesia for scoliosis correction.<sup>127,322</sup>

Etomidate, although capable of inducing general anesthesia, behaves more like ketamine in its effect on evoked potentials. It improves the quality of SSEPs and enhances the amplitude of

MEPs.<sup>323</sup> It produces minimal changes in MEPs compared with barbiturates or propofol.<sup>297</sup> Etomidate infusions (10 to 35 µg/kg/min) produce adequate MEP monitoring signals.<sup>319,324</sup> Concerns regarding adrenocortical depression with etomidate infusions remain and limit its widespread use.<sup>325</sup> Bolus doses of etomidate, however, can transiently depress MEPs.<sup>319</sup>

### **Midazolam**

Intravenous midazolam (0.2 mg/kg) decreases the SSEP amplitude by 60%.<sup>326</sup> This does not occur with subcortical SSEPs, for which a slight increase in latency but no change in amplitude has been demonstrated.<sup>327</sup> Although midazolam (0.5 mg/kg) caused marked depression of MEPs in monkeys that persisted during awakening,<sup>328</sup> this finding does not hold true in human studies. MEP amplitude was unaffected by a midazolam-ketamine infusion technique compared with propofol-ketamine or propofol-alfentanil techniques.<sup>292</sup> Midazolam did not suppress myogenic MEPs, even at doses sufficient to produce anesthesia.<sup>317</sup> Effects were similar to those with etomidate.<sup>317</sup>

### **Neuromuscular Blockade**

NMBDs exert little or no effect on the SSEP. They prevent or limit recording of CMAPs during myogenic MEP recording because of their effects on the neuromuscular junction. Partial neuromuscular blockade, however, is commonly used during MEP monitoring because it improves conditions for surgery by providing adequate muscle relaxation when retraction of the tissues is required and limits any patient movement during the stimulus generation. Partial muscle relaxation may also reduce noise caused by spontaneous muscle movement. Constant neuromuscular blockade must be maintained during the procedure. Many centers avoid neuromuscular blockade after intubation, the initial incision, and muscle dissection.

Two methods have been used to assess the degree of neuromuscular blockade for MEP monitoring. One is measurement of the amplitude of the CMAP produced by single supramaximal stimulation (T1) before an NMBD is administered. When T1 is maintained between 20% and 50% of the baseline level, reproducible CMAP responses can be obtained with a degree of muscular blockade that allows surgery.<sup>324,329</sup> The other technique is adjustment of the neuromuscular blockade based on the train-of-four responses. Comparison of the fourth twitch (T4) with that of first twitch (T1) suggests acceptable CMAP monitoring is possible when two of the four twitches remain.<sup>329-331</sup> Neuromuscular blockade should be evaluated in the specific muscle groups that are used for electrophysiologic monitoring because different muscle groups have different sensitivities to the NMBDs. Patients with preoperative neuromuscular dysfunction tend to demonstrate greater effect after partial neuromuscular blockade than those with normal preoperative motor function. It is appropriate to avoid neuromuscular blockade in most of these patients.<sup>324</sup>

### **CHOOSING ANESTHETIC DRUGS AND TECHNIQUES**

The choice of anesthesia depends on the patient's pathology and the type of electrophysiologic monitoring for the operation. A marked increase in the use of MEPs and advances in MEP techniques have occurred since the previous edition of this text. CMAPs appear to provide the most useful data for minimizing the risk of spinal cord injury.

The key to success is to use a technique that allows a stable concentration of the hypnotic component of anesthesia. There

is probably no difference between the inhalational anesthetics (<1 MAC) and propofol (<6 mg/kg/hr; 100 µg/kg/min). Concentrations of the inhalational anesthetics approaching 1 MAC are now compatible with multipulse MEP monitoring systems that did not appear possible several years ago. Short-acting medications offer greater flexibility if the monitored signals deteriorate. The use of a remifentanyl infusion allows a rapidly titratable analgesic component with minimal effect on spinal cord monitoring. Clonidine or dexmedetomidine may be used to decrease the concentration of hypnotic drugs during SSEP monitoring and MEP monitoring, but the depth of anesthesia should be also be monitored.

Ketamine as the main component of anesthesia may improve MEP monitoring because it better preserves the MEP signals and allows reduced doses of other hypnotic agents to be used, but low-dose ketamine used as an adjunct to a conventional anesthetic does not. If processed electroencephalographic monitoring is used to determine anesthetic depth, the addition of ketamine may confound the reading by increasing it.<sup>332,333</sup> This occurs despite a deepening level of hypnosis.<sup>332</sup> An NMBD improves the SSEP monitoring and may be used in conjunction with MEP monitoring within the confines described earlier. However, even in patients with idiopathic scoliosis, adequate operating conditions after the initial muscle dissection can be produced in the absence of neuromuscular blockade. In the absence of muscle relaxation, muscle contractions, including those of the masseter muscles, occur during stimulation. In this situation, it is prudent to insert a bite block to prevent obstructing the tracheal tube or to intubate the patient nasally.

## Tourniquets

### INDICATIONS AND DESIGN

The tourniquet was used by the Romans to control bleeding during amputation.<sup>334</sup> The arterial tourniquet is used during orthopedic procedures to reduce blood loss and provide good operating conditions, for intravenous regional blockade and sympathectomy, and for isolated limb perfusion in the management of localized malignancy.<sup>335</sup>

The word *tourniquet* is derived from the French verb *tourner*, meaning “to turn,” referring to the twisting or screwing action applied to the constricting bandage to tighten it. In 1873, von Esmarch introduced the use of a flat rubber bandage wrapped repeatedly around a limb.<sup>334</sup> Although this rubber bandage is still used to render a limb bloodless, the pneumatic tourniquet, introduced by Cushing in 1904, has replaced the rubber bandage to maintain ischemia. Compressed nitrogen or air is used for inflation. The target pressure is preset, and compensatory feedback mechanisms maintain that pressure during inflation. Curved and wider tourniquet cuffs, which are designed to fit conical limbs, are associated with lower arterial occlusion pressures than standard cuffs.<sup>336</sup> A soft dressing applied to the limb before tourniquet application helps to prevent wrinkles and blisters that may occur when the skin is pinched.<sup>337</sup> Adequate exsanguination can also be achieved by elevation of the arm at 90 degrees or the leg at 45 degrees for 5 minutes.<sup>338,339</sup>

### PHYSIOLOGY

#### Ischemia

Ischemia leads to tissue hypoxia and acidosis. The severity and consequences of the associated changes (e.g., increased capillary permeability, coagulation alteration, cell membrane sodium

pump activity) depend on the tissue type, duration of ischemia, and collateral circulation. Muscle is more susceptible to ischemic damage than nerves. Histologic changes are more pronounced in muscle beneath the tourniquet compared with muscle distal to the tourniquet.

#### Reperfusion

Reperfusion removes toxic metabolites and restores energy supplies. There is a sudden release of lactic acid, creatinine phosphokinase (i.e., creatine kinase), potassium (peak increase of 0.32 mEq/L), and CO<sub>2</sub> (peak increase of 0.8 to 18 mm Hg) when the cuff is deflated suddenly. Metabolic changes increase after longer periods of ischemia but return to baseline within 30 minutes. Muscle damage may release myoglobin, which can collect in the collecting tubules of the kidney, precipitating renal failure.

Systemic effects after deflation of the tourniquet include a shift of blood volume back into the limb with a transient decrease in blood pressure that is exacerbated by a postischemic reactive hyperemia in the limb. CO<sub>2</sub> release transiently increases the minute volume. The rapid increase in CO<sub>2</sub> is also associated with a transient (8 to 10 minutes) increase in cerebral blood volume that may affect patients with raised intracranial pressure.<sup>335</sup>

Increased microvascular permeability of muscle and nerve tissue occurs with tourniquet release after 2 to 4 hours of ischemia. Interstitial and intracellular edema and capillary occlusion due to endothelial edema and leukocyte aggregation may take months to resolve.

#### Ischemic Conditioning

Short periods of ischemia followed by reperfusion render muscle more resistant to subsequent ischemia. Ischemic preconditioning improves skeletal muscle force, contractility, and performance and decreases fatigue of skeletal muscle. This preconditioning may enable prolongation of orthopedic and reconstructive procedures.<sup>340</sup>

### COMPLICATIONS

#### Local Complications

##### Muscle Damage

Histologic changes in the muscle beneath the tourniquet occur after 2 hours of tourniquet time (at 200 mm Hg [26.7 kPa]), but similar changes can occur in the distal ischemic muscle after 4 hours of tourniquet use. Direct pressure and mechanical deformation contribute to increased severity of muscle damage under the cuff.<sup>335</sup> These changes include an increase in the number of inflammatory cells in the perivascular space, focal fiber necrosis, and signs of hyaline degeneration.

The combination of muscle ischemia, edema, and microvascular congestion contributes to posttourniquet syndrome: edema, stiffness, pallor, weakness without paralysis, and subjective numbness of the extremity without objective anesthesia. The common use of postoperative casts may conceal the true incidence of this syndrome. Recovery usually occurs over 7 days.<sup>341</sup>

##### Nerve Damage

The cause of nerve injuries after tourniquet use probably is direct compression under the cuff rather than ischemia. Shear forces that are maximal at the upper and lower edges of the tourniquet cause the most damage. These forces are greater with the Esmarch bandage than with the pneumatic tourniquet. The incidence of

nerve injuries is greater in the upper limb (1 case per 11,000 patients) than in the lower limb (1 case per 250,000 patients); the radial nerve is the most vulnerable nerve in the upper extremity, and the sciatic nerve is the most vulnerable in the lower extremity.<sup>342</sup>

### **Vascular Damage**

Arterial injury is uncommon in children. It is an injury of adults with atheromatous vessels, and the tourniquet should be avoided in patients with absent distal pulses, poor capillary return, a calcified femoropopliteal system, or a history of vascular surgery on the involved limb.<sup>343</sup>

### **Skin Safety**

Pressure necrosis and friction burns may occur with poorly applied tourniquets, and some form of skin protection should be used routinely.<sup>344</sup> Chemical burns may result from antiseptic skin preparations that seep beneath the tourniquet and are then retained and compressed against the skin.

### **Tourniquet Pain**

The tourniquet causes a vague, dull ache that becomes intolerable after approximately 30 minutes.<sup>345</sup> This pain is associated with an increase in heart rate and blood pressure that is not ameliorated by general anesthesia and neuraxial blockade.<sup>345</sup> The pain is transmitted by unmyelinated C fibers, which are normally inhibited by fast pain impulses transmitted by myelinated A-delta fibers, but in this case, mechanical compression reduces transmission through the larger A-delta fibers.<sup>346</sup>

### **Systemic Complications**

#### **Temperature Regulation**

The combination of decreased heat loss from the ischemic limb and reduced heat transfer from the central to ischemic peripheral compartment increases core body temperature.<sup>347,348</sup> Bilateral tourniquets increase the temperature more than use of a unilateral tourniquet.<sup>348</sup> Children who require intraoperative tourniquets should not be aggressively warmed during surgery.<sup>348</sup> Redistribution of body heat and the efflux of hypothermic venous blood from the ischemic area into the systemic circulation after deflation of the tourniquet decreases the core body temperature, which may switch off thermoregulatory vasodilation and decrease the skin-surface temperature.<sup>349</sup>

#### **Deep Vein Thrombosis and Emboli**

The incidence of emboli after release of the tourniquet in children is unclear. The tourniquet appears to have no influence on deep vein thrombosis, but release of the tourniquet may be associated with an increased risk of embolism in adults. Some clinicians have suggested that heparin be used during total joint arthroplasty in adults to prevent emboli formation,<sup>350</sup> although this practice is not routine in children. Some surgeons use such therapy in adolescents.

#### **Sickle Cell Disease**

Hypoxia, acidosis, and circulatory stasis contribute to the sickling of sickle cells in susceptible individuals. However, several institutions routinely use tourniquets in children with sickle cell disease while maintaining acid-base status and oxygenation throughout the procedure.<sup>351,352</sup> Each case must be assessed individually for the balance between the advantages of a bloodless field and the risks of precipitating sickling crises (see Chapter 9).

### **Drug Effects**

Antibiotics given after the tourniquet is inflated do not produce effective concentrations in the blood and tissue of the ischemic limb. Inflation of the tourniquet should be delayed at least 5 minutes after administration of the antibiotics.<sup>353,354</sup> Medications administered before inflation of the tourniquet may be sequestered in the ischemic limb and then re-released into the systemic circulation when the tourniquet is deflated. The antibiotic effect depends on the amount of antibiotic sequestered, the tissue binding, and the concentration-response relationship for the antibiotic, although the impact is minimal for most medications used in anesthesia. Volume of distribution may be reduced if the drug is administered after tourniquet inflation, but the plasma clearance remains unaffected.

### **RECOMMENDED CUFF PRESSURES**

Tourniquets usually should remain inflated for less than 2 hours, and most clinicians suggest a maximal time of 1.5 to 2 hours. Techniques such as hourly release of the tourniquet for 10 minutes, cooling of the affected limb, and alternating dual cuffs may reduce the risk of injury.<sup>355</sup> Nerve and muscle injuries that occur beneath the tourniquet cuff are related to the pneumatic pressure. Consequently, the lowest possible pressure that maintains ischemic conditions should be sought. Hypotensive anesthetic techniques have been used in adults to reduce the need for high cuff inflation pressures,<sup>356</sup> but there seems to be little need for this in children. Lieberman and colleagues suggested that pediatric occlusion pressures should be measured by Doppler and the tourniquet pressure set at 50 mm Hg above this value.<sup>357</sup> Maximum mean pressures recommended for the upper and lower extremities are  $173.4 \pm 11.6$  mm Hg (range, 155 to 190 mm Hg) and  $176.7 \pm 28.7$  mm Hg (range, 140 to 250 mm Hg), respectively.<sup>357</sup> Wider cuffs exert less force per unit area and reduce the risk of local sequelae. Recommendations for adults suggest that the cuff should exceed the circumference of the extremity by 7 to 15 cm. This is difficult to achieve in infants, in whom the proximal limb length is proportionally shorter than in adults and the wide cuffs impinge on the surgical field.

## **Acute Bone and Joint Infections**

The mainstay of management for osteomyelitis and septic arthritis are antibiotics and surgical drainage. The incidence of these infections is increasing, particularly in immunocompromised children with human immunodeficiency virus (HIV) infection. Tuberculosis remains a scourge in many developing countries. Mortality rates for hospital-acquired staphylococcal disease in compromised children<sup>358</sup> and community-acquired disease in healthy children<sup>359,360</sup> range from 8% to 47% for those presenting with severe sepsis.<sup>361</sup> *Mycobacterium* and *Staphylococcus* species resistant to conventional antibiotics increase morbidity and mortality rates.

### **PATHOPHYSIOLOGY**

*Staphylococcus aureus* is the most common pathogen. Osteomyelitis develops after bacteremia and occurs mostly in prepubertal children. Normal bone is highly resistant to infection, but *S. aureus* adheres to bone by expressing receptors for components of bone matrix, and the expression of collagen-binding adhesin permits the attachment to cartilage.<sup>362</sup> After the microorganisms adhere to bone, they express phenotypic resistance to antimicrobial treatment.<sup>362</sup>

The metaphyseal region around the growth plate is the predominant area of infection. Sluggish blood flow in the metaphysis predisposes children to bacterial infection, and endothelial gaps in developing vessels allow bacteria to escape into the metaphysis. Subsequent abscesses may decompress into the joint or subperiosteally. Infection may involve adjacent tissue planes, and hematogenous spread causes multiple pathologic processes beyond the primary site of infection.

Septic arthritis is more common in neonates because transphyseal vessels link the metaphysis and epiphysis. Growth plate and epiphyseal destruction may occur in this age group. Articular cartilage damage is attributable to the release of proteolytic enzymes by the pathogen and activated neutrophils.

### CLINICAL PRESENTATION

Most children with staphylococcal disease present with musculoskeletal symptoms and fever, but those with disseminated disease may be critically ill (4% to 10%) with severe sepsis and lung disease.<sup>359,360</sup> There is often a history of trauma.<sup>359,360</sup> It can be difficult to diagnose extracutaneous foci. One report found that 50% of extracutaneous foci of staphylococcal infection were not detected on hospital admission, and one third of these lesions were observed for the first time at autopsy.<sup>358</sup> An absolute polymorphonuclear cell count of greater than 10,000/mm<sup>3</sup> or an absolute band-form count of greater than 500/mm<sup>3</sup>, or both, correlates with the presence of one or more inadequately treated sites of staphylococcal infection.<sup>358</sup> Tuberculosis is the great mimic and must always be suspected in endemic areas.

Diagnosis is confirmed by blood, bone, or joint aspirate culture. Radiologic procedures (e.g., plain radiographs, computed tomography, magnetic resonance imaging, radionuclide scans) are often required to identify foci, and the anesthesiologist is often requested to provide sedation.

### TREATMENT OPTIONS

Antibiotic therapy is the mainstay of treatment. Initial antibiotic choice is dictated by age and by local pathogen and sensitivity profiles. Antibiotic treatment should be extended to cover gram-negative enterococci in neonates and *Streptococcus* in older children. *Haemophilus influenzae* remains a pathogen in unvaccinated regions. Surgical decompression of acute osteomyelitis that is responding poorly to antimicrobial therapy may release intramedullary or subperiosteal pus and lead to clinical improvement. Pus within fascial planes also requires release. Venous thrombosis attributable to pus in soft tissue planes around major joints was associated with a high mortality rate in one series.<sup>359</sup> Determining and eradicating the primary focus improves the mortality and reduces recurrence rates.<sup>363</sup> An aggressive search for foci and surgical drainage of infective foci is required.

Highly active antiretroviral therapy (HAART) has positively altered the mortality rates for HIV-infected children. However, acute bone and joint infections still occur,<sup>364</sup> and these drugs can cause significant morbidity due to changes in fat distribution, lipid profiles, glucose concentrations, homeostasis, and bone turnover.<sup>365</sup> Infarction may replace infection as the major cause of morbidity and mortality from HIV.<sup>365</sup> It is uncertain whether HAART should be continued during acute osteomyelitis. Worsening cell-mediated immune function may occur during tuberculosis treatment if HAART is continued.<sup>366</sup> The combination of HIV infection and tuberculosis can be lethal in children, and antituberculosis treatment is continued for 12 to 18 months.

### ANESTHESIA CONSIDERATIONS

Anesthesiology services are commonly required for sedation during diagnostic investigation, anesthesia for surgical exploration and release of pus or fixation of pathologic fractures, management of pulmonary complications (e.g., intercostal chest drain insertion, pleurodesis), central venous cannulation for long-term antibiotic treatment, and analgesic modalities.

Children with disseminated staphylococcal disease may be critically ill with multisystem disease and require fluid volume augmentation, inotrope support, positive-pressure ventilation, extracorporeal renal support, and coagulation factor replacement. Others may appear clinically stable before induction of anesthesia; the assessment of hypovolemia in children is subject to moderate to poor interrater agreement.<sup>367</sup> Intravenous access and rehydration are required before beginning anesthesia to avoid a precipitous blood pressure drop immediately after induction. Bacteremic showering during manipulation and drainage of pus causes further decompensation. Excessive bleeding due to altered coagulation status should also be anticipated.

The presence of a septic arthritis in the shoulder or neck may cause cervical ligamentous laxity predisposing to C1-2 subluxation during intubation.<sup>368</sup> Pneumatoceles from staphylococcal pneumonia can rupture during positive-pressure ventilation. A spontaneous breathing mode, however, may be difficult to achieve because of laryngospasm, breath holding, increased secretions, and bronchospasm. The use of NMBDs and positive-pressure ventilation in these patients with a low threshold for introducing inotropes to support the cardiovascular system is an easier option. Vigilance is required for acute pneumothorax.

Myocarditis, pericarditis, and pericardial effusions compromise myocardial function. A 12% prevalence of infective endocarditis among children with hospital-acquired *Staphylococcus aureus* bacteremia has been reported.<sup>369</sup> This prevalence of infective endocarditis was frequently associated with congenital heart disease and the necessity for multiple blood cultures.<sup>369</sup> The incidence of infective endocarditis among children with community-acquired disease without preexisting cardiac abnormalities was low,<sup>359</sup> suggesting that echocardiography could be reserved for children with preexisting cardiac disease, those with suspicious clinical findings, those whose temperature fails to stabilize, or those who have prolonged bacteremia without an obvious source of infection.

### PAIN MANAGEMENT

Morphine and acetaminophen are the analgesics commonly used for postoperative pain management. The use of tramadol in children is increasing as our understanding of the pharmacokinetics of this medication increases.<sup>370,371</sup> The low incidence of respiratory depression and constipation, fewer controls on use, and similar frequency of nausea and vomiting (10% to 40%) compared with opioids make tramadol an attractive alternative.<sup>372-374</sup> NSAIDs are relatively contraindicated in the presence of coagulation disorders, altered renal function, and COX-2-mediated osteogenesis.

The performance of regional blockade in children with acute bone or joint infection is controversial. There are no studies addressing the risk/benefit ratios of regional techniques in this population. It seems reasonable to use these techniques only after 24 hours of appropriate antibiotic therapy in afebrile children who show no signs of a coagulopathy.

## Common Syndromes

Children with some specific conditions present repeatedly for orthopedic procedures. It is worthwhile maintaining a database that details their anesthetic management. There should be 24-hour access to standard texts or electronic information concerning anesthesia and uncommon pediatric diseases.

### CEREBRAL PALSY

#### Clinical Features

*Cerebral palsy* is an umbrella term that describes a group of non-progressive, but often changing motor impairment syndromes caused by lesions or anomalies in the brain that occur during the early stages of its development.<sup>375</sup> It is the leading cause of motor disability during childhood, with a prevalence of approximately 2 cases per 1000 live births in developed countries.<sup>376</sup>

Disorders include cognitive impairment, sensory loss (i.e., vision and hearing), seizures, and communication and behavioral disturbances. Systemic disorders resulting from cerebral palsy affect the gastrointestinal, respiratory, urinary tract, and orthopedic systems. Cerebral palsy is divided into three broad categories: spastic (70%), dyskinetic (10%), and ataxic (10%). Children with spastic cerebral palsy commonly present for orthopedic procedures because of contractures at major peripheral joints.<sup>377,378</sup> Functional improvement after surgery in children with spastic diplegia and spastic hemiplegia is better than in those suffering spastic quadriplegia.<sup>377</sup>

#### Orthopedic Considerations

Orthopedic manipulations form only part of the treatments designed to improve performance or improve the ease of care. Management, including orthopedic surgery, physical and occupational therapy, recreational therapy, orthotics, and assistive devices, improve functional outcomes. Medical modalities such as intramuscular injections of botulinum toxin and intrathecal administration of baclofen by means of an implanted pump may also be of benefit.<sup>379</sup> Selective dorsal rhizotomy has been used to control spasticity.<sup>380,381</sup>

The indications for and timing of surgical interventions vary. Gait analysis increases the age of the patient at the first orthopedic surgical procedure, and botulinum toxin type A treatment delays and reduces the frequency of surgical procedures on the lower extremities.<sup>382,383</sup> Bone and soft tissue surgical procedures are designed to lengthen or weaken spastic muscles to give opposing muscles a chance to attain muscle balance.

#### Anesthetic Considerations

Children with cerebral palsy who present for orthopedic surgery often have previous experience of operating rooms. They should be handled with sensitivity because communication disorders and sensory deficits may mask mildly impaired or normal intellect. They may be accompanied by a parent or caregiver or be premedicated for induction of anesthesia or in the recovery room. If there is a communication problem, the parent or caregiver should be present before and after anesthesia.<sup>377,384</sup>

Medical conditions (e.g., seizure control, respiratory function, gastroesophageal reflux) should be optimized preoperatively. Contracture deformities, spinal deformities, decubitus ulceration, and skin infection must be considered when positioning the child for anesthesia and surgery. Poor nutritional status affects postoperative wound healing and the risk of infection. Concurrent medications may influence anesthesia; cisapride for

gastroesophageal reflux is associated with prolonged QT interval, sodium valproate can cause platelet dysfunction and affect drug metabolism, and anticonvulsant use increases resistance to NMBDs.<sup>385</sup> A history of latex allergy should be sought because of exposure to latex allergens from an early age.<sup>386</sup>

Intravenous access may be difficult. Drooling, a decreased ability to swallow secretions, and gastroesophageal reflux may dissuade some against an inhalational induction, but there is no evidence that rapid-sequence induction is safer. Succinylcholine may be used because it does not cause hyperkalemia in these children, whose muscles have never become denervated. Non-communicative or nonverbal children with cerebral palsy require less propofol to obtain the same BIS values (i.e., 35 to 45) than do otherwise healthy children.<sup>387</sup> The minimum alveolar concentration of halothane is 20% less in children with cerebral palsy, whether they took anticonvulsant drugs or not (MAC of 0.62 and 0.71, respectively).<sup>388</sup>

Intraoperative hypothermia is common in children with disordered temperature regulation due to hypothalamic dysfunction, reduced muscle bulk, and fat deposits. Thermal homeostasis should be managed aggressively from the moment the child enters the operating room.

Extensive plaster casting is an important component of bone and soft tissue surgical procedures. These casts may conceal blood loss, and limb swelling within the cast may contribute to compartment syndromes. Plaster jackets and hip spicas have been associated with mesenteric occlusion and acute gastric dilatation.

Pain and spasm are regular features postoperatively. Epidural analgesia is particularly valuable when major orthopedic procedures are performed. Occasionally, two epidurals at different spinal sites may be required for multilevel surgery. Systemic benzodiazepines, baclofen, dantrolene, and clonidine have been used to reduce muscle spasms. Selective dorsal rhizotomy is associated with severe pain, muscle spasms, and dysesthesia. Epidural and intrathecal forms of morphine have been used to control this pain. Intravenous morphine and midazolam also have been successfully used.<sup>389</sup> Oral benzodiazepines may be required to reduce the incidence and severity of muscle spasms but should be used with caution if combined with opioid analgesia.

Pain assessment is difficult in these children, but several scoring systems are available.<sup>390,391</sup> (See also Chapter 43.) The opinions of parents and caregivers are extremely valuable in the assessment of pain and discrimination from other factors such as irritability on anesthetic emergence, poor positioning, a full bladder, or nausea.

### SPINA BIFIDA

Spina bifida is characterized by developmental abnormalities of the vertebrae and spinal cord that may be associated with changes in the cerebrum, brainstem, and peripheral nerves. The failure of fusion of the vertebral arches is commonly known as *spina bifida*. *Spina bifida occulta* refers to spina bifida that occurs when skin and soft tissues cover the defect. *Spina bifida aperta* is used to describe lesions that communicate with the outside as a meningocele or a myelomeningocele (incidence of 1 case per 1000 live births). The myelomeningocele sac contains nerve roots that do not function below the level of the lesion.

#### Clinical Features

Nerve root dysfunction results in muscle paralysis and a neurogenic bowel and bladder. Eighty percent of children develop

hydrocephalus because of aqueductal stenosis (Arnold-Chiari [type II] malformation). Skeletal abnormalities such as clubfoot and congenital dislocation of the hip are common. Scoliosis may result from congenital vertebral abnormalities or, more commonly, abnormal neuromuscular control. Epilepsy and learning disorders can also occur, but most children have normal intelligence.

### Orthopedic Considerations

Denervation causes muscle imbalance that results in abnormalities at the hip, knee, and foot. The aims of surgery are to reduce flexor posture at the hip and knee and plantigrade feet. Children with clubfeet, hip subluxation, or scoliosis commonly present for orthopedic correction.

### Anesthetic Considerations

The potential for infection of the central nervous system dictates closure of the sac within the first few days of life. Subsequent surgical procedures and urinary catheterizations set the stage for a sensitivity to latex.<sup>392</sup> Primary prophylaxis (i.e., avoiding all latex materials and using a latex-free operating room) is recommended for prevention of latex allergy and anaphylaxis.<sup>393</sup>

Preoperative assessment should include motor and sensory deficits, respiratory and renal function, and functioning of a ventriculoperitoneal shunt. Positioning on the operating table may require additional pillows for support of limbs with contractures. As a result of hypesthesia in the lower extremities, intravenous cannulae can be inserted painlessly. However, venous access is usually poor in the lower extremities because of limited use. The risk of endobronchial intubation is increased because of a short trachea (36% of patients).<sup>394</sup> Kyphoscoliosis may distort tracheal anatomy. Renal dysfunction may dictate NMED choice and avoidance of NSAIDs. Succinylcholine may be used because it does not cause hyperkalemia in these children.<sup>395</sup> A reduced hypercapnic ventilation response means that these children should be closely observed in the recovery period.

### OSTEOGENESIS IMPERFECTA

Osteogenesis imperfecta (OI) is thought to have afflicted Ivar the Boneless (Ivar Ragnarsson), a Viking chieftain who led a successful invasion of the East Anglia region of England in 865 AD. Because he “had legs as soft as cartilage,” he was unable to walk and had to be carried on a shield. Ivar’s name is also associated with an early form of thoracoplasty. When King Ælla of Northumbria was captured, Ivar subjected him to the horrific “Blood Eagle” ordeal. His ribs were torn out and folded back to form the shape of an eagle’s wings, and his lungs were removed.

### Clinical Features

OI is a genetically determined disorder of connective tissue that is characterized by bone fragility. The disease state encompasses a phenotypically and genotypically heterogeneous group of inherited disorders that result from mutations in the genes that code for type I collagen.<sup>396</sup> The disorder manifests in tissues in which the principal matrix protein is type I collagen—mainly bone, dentin, sclerae, and ligaments. Musculoskeletal manifestations vary in severity along a continuum ranging from perinatal lethal forms with crumpled bones to moderate forms with deformity and propensity for fracture to clinically silent forms with subtle osteopenia and no deformity.<sup>396</sup>

Classification (types I through IV) is based on the timing of fractures or on multiple clinical, genetic, and radiologic

features. Type I is the most common (1 case per 30,000 live births), and type I and type IV have autosomal dominant inheritance patterns. These children have the classic triad of blue sclera, multiple fractures, and conductive hearing loss in adolescence. Bowing of the lower limbs, genu valgum, flat feet, and scoliosis develop with age. Type IV is characterized by osteoporosis, leading to bone fragility without many of the other features of type I. Types II and III are more severe forms of OI and have autosomal recessive inheritance patterns. Molecular genetic studies have identified more than 150 mutations of the *COL1A1* and *COL1A2* genes, which encode for type I procollagen.<sup>396</sup>

### Orthopedic Considerations

The goals of treatment of OI are to maximize function, minimize deformity and disability, maintain comfort, achieve relative independence in activities of daily living, and enhance social integration. Physiotherapy, rehabilitation, and orthopedic surgery are the mainstays of treatment for moderate and severe forms of OI. Medical treatment with the antiresorptive bisphosphonates (e.g., pamidronate) can decrease pain, lower the fracture incidence, and improve mobility. Initial investigations have demonstrated an acceptable safety profile for pamidronate. Long-term follow-up data are lacking and will be necessary for the development of responsible therapeutic guidelines.<sup>397</sup> Medical therapies other than bisphosphonates, such as growth hormone and parathyroid hormone, have only minor roles. Gene-based therapy remains in the early stages of preclinical research.<sup>398,399</sup>

Operative intervention is indicated for recurrent fractures or deformity that impairs function.<sup>396</sup> Fractures in mild to moderately severe cases of OI type I are treated using the same methods as for patients without OI. Deformed bones that are fracturing are realigned, frequently followed by providing external or internal support. In selecting various modes of treatment, it is important to consider the natural history of the particular type of OI and to set realistic goals.<sup>400-404</sup>

### Anesthetic Considerations

In common with other children suffering chronic disabilities, children with OI are veterans of the operating room. Chronic pain from frequent fractures complicates handling. Deafness may hinder communication. Preoperative assessment centers on the chest wall deformity because it determines the severity of restrictive lung disease and subsequent cardiovascular compromise. Neck mobility, mouth opening, and dentition should also be assessed.

There is a risk of further fractures with positioning, tourniquet application, airway handling, and use of a blood pressure cuff. Invasive pressure monitoring may be less traumatic than a blood pressure cuff for some patients. If noninvasive blood pressure monitoring is used, less frequent monitoring of the blood pressure is recommended if possible. A laryngeal mask airway may avoid pressure from facemasks. An individual history may help determine the risk/benefit ratio for each child. Succinylcholine has the potential to cause fasciculation-induced fractures.

Abnormal temperature homeostasis may result in intraoperative hyperthermia that may be severe and accompanied by tachycardia and metabolic acidosis. This response is different from that of malignant hyperthermia in that there is an absence of respiratory acidosis and muscle rigidity.<sup>405</sup> Surface cooling is usually effective in restoring thermal homeostasis.

## DUCHENNE MUSCULAR DYSTROPHY

### Clinical Features

DMD is the most common of the progressive muscular dystrophies. It is an X-linked recessive disorder with an incidence of 3 cases per 10,000 births (see Chapter 22). The *DMD* gene (located at Xp21.2) codes for a large sarcolemmal membrane protein, dystrophin, which is associated muscle cell membrane integrity and signal transduction. Dystrophin is missing or non-functional in DMD patients. Both sexes can carry the *DMD* mutation, but girls rarely exhibit signs of the disease.

Children usually present before school age with a waddling gait and later develop a lumbar lordosis and difficulty climbing stairs. Children use their arms to assist standing up (i.e., Gowers sign) due to proximal weakness of the hip girdle. Distal muscles, such as the calves, appear hypertrophied. The disease process is progressive, with increasing muscle weakness occurring with age. These boys often become wheelchair bound by 10 to 11 years of age. Respiratory weakness, often exacerbated by scoliosis and by difficulty swallowing secretions due to pharyngeal involvement, can progress to a terminal pneumonia in late teenage years.<sup>406</sup> By late adolescence, most children with DMD have cardiac disease, whether it is an abnormal electrocardiogram, arrhythmias, or a cardiomyopathy. Death from cardiorespiratory failure usually occurs before age 30, although respiratory support is extending life expectancy.

DMD is not a static disease. In early childhood, skeletal muscle is constantly catabolized and becomes unstable. The use of membrane-destabilizing medications such as succinylcholine and potent inhalational anesthetics (halothane in particular) in these young children can result in hyperkalemia, rhabdomyolysis, and cardiac arrest. However, after the children reach adolescence, the bulk of the skeletal muscle catabolism has arrested, and membrane-destabilizing medications are left with no substrate. Succinylcholine and potent inhalational anesthetics may be used without sequelae in adolescents with DMD who were undergoing scoliosis surgery and instrumentation. In contrast, the cardiac and smooth muscle consequences of DMD are minor and insignificant in childhood but become life-threatening during adolescence and adulthood. The anesthesiologist must appreciate the developmental nature of DMD and recognize the risks that may be associated with the use of succinylcholine and inhalational anesthetics in this group of children.

DMD can affect cardiac, smooth, and skeletal muscle. Right ventricular function may be compromised by nocturnal oxygen desaturation and sleep apnea contributing to pulmonary hypertension. Sinus tachycardia and arrhythmias may occur at an early age, but clinically apparent cardiomyopathy usually does not develop before 10 years of age. One third of children have some degree of intellectual impairment.

DMD should be suspected in male preschool children with delayed walking ability, and measurement of high serum creatinine phosphokinase concentrations provides a screening tool. Steroids are increasingly used for the management of DMD because they appear to increase muscle mass by decreasing protein breakdown.<sup>407</sup>

Becker muscular dystrophy (BMD) is a milder form of DMD with an onset at puberty or later in adolescence. Clinical expression varies, but even adolescents presenting with mild or subclinical weakness can develop cardiomyopathy with age progression. Death from cardiac or respiratory failure does not usually occur until the fourth or fifth decade. Because of improvements in

respiratory care, dilated cardiomyopathy has become the major cause of death.<sup>408</sup>

BMD is an autosomal recessive myopathy that also results from mutations of dystrophin caused by a deletion of the exons 11 to 13 in the *DMD* gene (located at Xp21.2).<sup>409</sup> Dystrophin exerts its effect at the voltage-gated chloride channel 1 (CLCN1). Genetic analysis is an essential step in confirming the diagnosis. Additional EMG procedures may be of diagnostic value even when muscle biopsy may reveal no evidence of dystrophy.

Of importance to anesthesiologists, two thirds of patients with mild or subclinical BMD have evidence of right ventricular dilation, and one third have evidence of left ventricular dysfunction.<sup>410</sup> A thorough cardiac evaluation (similar to that for DMD) is recommended before scoliosis surgery.<sup>408</sup> Hyperthermia and heart failure, mimicking malignant hyperthermia and hyperkalemia with rhabdomyolysis after inhalational agents, have been reported in patients with BMD.<sup>411,412</sup> Despite these reports, the relationship between BMD and malignant hyperthermia remains unclear.

### Orthopedic Considerations

Orthopedic surgery is indicated to improve or maintain ambulation and standing. Early treatment of contractures of the hips and the lower limbs prevents severe contractures and delays the progression of scoliosis.<sup>413</sup> Techniques designed to improve deformities and permit early postoperative mobilization include subcutaneous release of contracted tendons and percutaneous removal of cancellous bone with corrective manipulation of the feet. Maintenance of upright posture extends the ability of patients to attend to the tasks of daily living.<sup>414</sup> Spinal deformities attributable to muscle imbalance or a collapsing spine are corrected to improve or maintain sitting posture. Spinal fusion may also decrease the rate of deterioration of respiratory function, although this has been questioned.<sup>415</sup>

### Anesthetic Considerations

Respiratory and cardiovascular compromise dominates preoperative assessment. Deformities and contractures of limb joints hinder vascular access, regional anesthetic techniques, and positioning on the operating table. Hypertrophy of the tongue may cause difficulty during intubation. Gastric motility is delayed, and gastric emptying times are prolonged.<sup>416</sup> Tracheobronchial tree compression has been described in a child positioned prone for spinal instrumentation.<sup>417</sup> These children tend to have greater blood loss during surgery. The precise cause remains unclear, but it may be because fat and connective tissue have replaced muscle or because of abnormalities in the blood vessels.<sup>210</sup>

Nondepolarizing NMBS have a slow onset and prolonged duration of action.<sup>418-420</sup> All NMBS should be monitored with a peripheral nerve stimulator.<sup>421</sup> *Succinylcholine is contraindicated in these children because of the risk of hyperkalemia, muscle rigidity, rhabdomyolysis, myoglobinuria, arrhythmias, and cardiac arrest.* There is no clear link between DMD and malignant hyperthermia.<sup>422,423</sup> The predominant candidate gene (*RYR1*) for malignant hyperthermia is located on the long arm of chromosome 19, whereas the *DMD* gene is located on the short arm of the X chromosome.<sup>424</sup> Although volatile anesthetic agents continue to be used in young children with DMD, rhabdomyolysis and hyperkalemia have been reported in the recovery room after halothane, isoflurane, desflurane, and sevoflurane anesthesia.<sup>425-429</sup> Potent inhalational anesthetics are best avoided in young children with DMD;

instead, alternative anesthetics that do not trigger rhabdomyolysis and hyperkalemia, such as propofol, ketamine, opioids, and benzodiazepines, are preferred.<sup>430</sup>

Regional techniques such as epidurals may be technically more difficult due to kyphoscoliosis and obesity. The use of ultrasound-guided peripheral nerve blockade can improve the quality and reduce complications of neuronal blockade.<sup>6</sup> Opioids are not contraindicated in the postoperative period but should be used with caution in children with respiratory compromise. Tramadol is an effective alternative. Noninvasive ventilation support using BiPAP or continuous positive airway pressure is sometimes required after major surgery or in those already receiving this treatment overnight.

## ARTHROGRYPOSIS MULTIPLEX CONGENITA

### Clinical Features

Arthrogryposis multiplex congenita is a spectrum syndrome of multiple, persistent limb contractures often accompanied by associated anomalies, including cleft palate, genitourinary defects, gastroschisis, and cardiac defects.<sup>431</sup> The incidence is 1 case per 3000 births. Joint contractures are present at birth and are a result of immobility in utero, commonly related to a neurogenic abnormality or myopathy.<sup>432</sup> These children have been likened to a "thin, wooden doll," because muscles connected to affected joints are atrophic and replaced by fibrous tissue and fat.<sup>433</sup> The temporomandibular joint may also be involved, causing restricted jaw opening and micrognathia. Scoliosis commonly develops. Restrictive lung disease, rib cage deformities, and pulmonary hypoplasia predispose to recurrent chest infections.

### Orthopedic Considerations

The aim of surgery is to improve function. Most operations involve the soft tissues, tendons, and osteotomies of the lower limbs and hips.<sup>434</sup> Upper limb surgery is less common. Extension contracture of the elbow joint makes it impossible to reach the mouth or to perform hygienic necessities. Improvement in passive elbow flexion by capsulotomy or in active flexion by triceps transfer can increase independence and personal hygiene. When both arms are involved, consideration may be given to maintaining one arm in flexion for reaching the head and mouth passively or even actively and one arm in extension for basic hygiene cares.<sup>435</sup>

### Anesthetic Considerations

Arthrogryposis multiplex congenita is commonly associated with other syndromes that may complicate anesthesia.<sup>431,436</sup> Venous cannulation is difficult because veins tend to be small and fragile. The concavity of joints is difficult to access. Care must be taken in positioning the patient on the operating table and protecting skin overlying bony joints to prevent pathologic fractures.

These children should be evaluated for a difficult airway because of temporomandibular joint limitation and micrognathia.<sup>437-439</sup> Fusion or underdevelopment of the first and second cervical vertebrae may further complicate laryngoscopy and tracheal intubation with a severe reduction in neck mobility. Tracheal intubation may become progressively more difficult with age. During infancy, however, evaluating mouth opening may be difficult; it may be necessary to insert a tongue blade into the mouth to determine whether the mandible can be distracted from the maxilla.

Succinylcholine has been used without incident in these children, although teleologically, the use of a depolarizing muscle relaxant in the presence of anterior horn cell disease is contentious. The response to nondepolarizing NMBDs should be monitored.

Hyperthermia and persistent tachycardia have been reported during general anesthesia.<sup>431,440-442</sup> These signs occur irrespective of the anesthetic agent and are not associated with malignant hyperthermia. In this case, hyperthermia responds to simple cooling techniques.

Pulmonary dysfunction and an increased sensitivity to opioids dictate suitable monitoring postoperatively. Regional techniques may be difficult in the presence of contractures, but if successful, they offer intraoperative and postoperative analgesia.<sup>433</sup> Success can be improved by using ultrasound-guided techniques.

## Airway Trauma

**OTORHINOLARYNGOLOGIC PROCEDURES REPRESENT A** large segment of elective pediatric surgery. Anesthetic management of these children is provided by both pediatric and general anesthesiologists, frequently working in anesthesia care teams, most commonly in ambulatory surgery centers and office practices.<sup>1</sup> Additionally, anesthesiologists are often consulted to help manage potentially life-threatening pediatric otolaryngologic emergencies. These include airway obstruction suffering from croup, foreign body aspiration, airway trauma and acute epiglottitis.<sup>2</sup> In both the elective and emergent scenarios, it is essential to understand the pathophysiology, and to discuss the anesthetic plan in advance of the procedure with the surgeon, who will frequently be sharing the airway with the anesthesiologist. This ensures safe anesthetic management and ideal conditions for both children and surgeons.

## Anesthesia for Otologic Procedures

### MYRINGOTOMY AND VENTILATING TUBE INSERTION

Chronic serous otitis media is common in young children. If untreated or poorly managed, it can lead to hearing loss and formation of cholesteatoma. When conservative medical management fails, surgical drainage of accumulated fluid in the middle ear is indicated. Myringotomy creates an opening in the tympanic membrane through which fluid can drain. If performed alone, when the incision heals, the drainage path is occluded. Therefore myringotomy is frequently accompanied by placement of a ventilation tube. A small plastic tube (a variation of the grommet or the T-tube) inserted in the tympanic membrane serves as a stent for the ostium, facilitating continuous drainage from the middle ear until the tubes are naturally extruded in 6 months to a year, or surgically removed at an appropriate time.

Children with cleft palate have a high frequency of middle ear disease compared with the noncleft population, because of associated abnormalities of the cartilage and muscles surrounding

the eustachian tubes. Surgical drainage and ventilation tube insertion is a standard treatment for chronic otitis media in these children. This is usually performed at the time of the surgical repair of the cleft.

Most young children require general anesthesia for tympanotomy tube placement, although an occasional older child may tolerate topical anesthesia. This may be accomplished by iontophoresis or instillation of lidocaine-prilocaine cream (EMLA cream), which remains in the ear canal for an hour and is then suctioned out before the procedure.

Myringotomy with tube insertion is a very brief operation, usually performed as ambulatory surgery using a potent inhalational agent (e.g., sevoflurane), oxygen, and nitrous oxide administered by facemask with spontaneous respirations. An oropharyngeal airway may assist in maintaining a patent airway when the head is laterally rotated and reduces head movement (which is amplified through the microscope). Gentle manual assistance of ventilation can also help reduce head movement. Occasionally, a laryngeal mask airway (LMA) may be used in children in whom the procedure is expected to be prolonged (e.g., children with narrow ear canals) or those with a difficult airway. Most children can be managed safely without intravenous (IV) access,<sup>3</sup> but it is reasonable to have an IV setup ready. Some children with severe underlying medical or surgical conditions will require IV access, despite the anticipated brief duration of the minor procedure. Although premedication is often omitted because their duration of action exceeds that of the procedure, an anxious child may still benefit from a sedative premedication.

In some instances, it is desirable to remove a retained tympanotomy tube. This can be easily accomplished in the surgeon's office without anesthesia. Some stiff-flanged grommet tubes require general anesthesia for removal. If the incision does not heal spontaneously, a paper patch or fat graft may have to be placed to stimulate healing of the tympanic membrane. The anesthetic would be the same as that for the tube placement,

except that nitrous oxide is best avoided to minimize the chance of graft dislodgment (see later discussion).

Discomfort after myringotomy and tube insertion is usually managed by the administration of acetaminophen, either via the oral route preoperatively or the rectal route intraoperatively. The recommended dose of acetaminophen to achieve therapeutic blood levels is 10 to 20 mg/kg when administered via the oral route, and 30 to 40 mg/kg when administered via the rectal route.<sup>4-7</sup> Oral acetaminophen is very rapidly absorbed, achieving therapeutic blood levels in minutes, whereas rectal acetaminophen is slowly absorbed, with a time to onset of action of 60 to 90 minutes, and a time to peak effect of 1 to 3 hours.<sup>8-11</sup> Consequently, the oral route is preferred for this procedure.

Preschool-aged children who receive sevoflurane without an analgesic for myringotomy and tube insertion may exhibit emergence delirium and postoperative agitation (see Chapter 4). Although pain may be partially responsible for these responses, their etiologies are not completely understood. Because the procedure is so brief and IV access is not usually established, intranasal fentanyl, 1 to 2 µg/kg, has been shown to provide analgesia and to reduce the frequency of emergence agitation.<sup>12,13</sup> The only significant side effect is a 12% incidence of vomiting when oral fluids are administered in the early postoperative period.<sup>5</sup> Other medications, including IV ketorolac (1 mg/kg), or intranasal butorphanol (25 µg/kg), and intranasal dexmedetomidine (1 to 2 µg/kg), have been shown to reduce the pain after myringotomy and tube insertion.<sup>14-16</sup> However larger doses of dexmedetomidine (2 µg/kg) significantly prolong the duration of stay in the post-anesthesia care unit (PACU). Some practitioners prefer to use more soluble anesthetics, such as isoflurane, for anesthesia maintenance to reduce the incidence of agitation after myringotomy and tube insertion, although there is limited evidence to support this practice.

Children with chronic otitis frequently have persistent rhinorrhea and suffer recurrent upper respiratory tract infection (URI) (see Chapter 11). Eradication of middle ear congestion and improved fluid drainage often resolves the concomitant symptoms. The frequency of perioperative complications in children with mild URIs is similar to that in children who are asymptomatic. In general, morbidity is not increased in children who present for minor surgery with acute uncomplicated mild URIs, provided tracheal intubation can be avoided.<sup>17,18</sup> Canceling this surgery because of rhinorrhea or recurrent mild respiratory symptoms is not usually justifiable. It is, however, recommended that children with respiratory symptoms have their oxygen saturation measured before induction of general anesthesia, and that supplemental oxygen is administered postoperatively to those whose oxygen-saturation readings are less than 93%.<sup>19</sup>

### MIDDLE EAR AND MASTOID SURGERY

Tympanoplasty and mastoidectomy are two of the most common major ear operations performed in children. General anesthesia usually consists of an inhalational anesthetic and IV opioids. Surgical identification and preservation of the facial nerve are necessary because of its proximity to the surgical field. To ensure the facial nerve can be identified using electrical stimulation, neuromuscular blockade is usually avoided. If a muscle relaxant must be used, a small dose should be given to facilitate tracheal intubation; if a muscle relaxant is used for maintenance, suppression of the twitch response should not exceed 70%.

To gain access to the surgical site, the child's head is placed on a headrest, which may be positioned below the operating

table. In addition, extreme degrees of lateral rotation may be required to visualize the middle ear anatomy. The anesthesiologist and surgeon must be especially vigilant to ensure that nerves, muscles, and bony structures are not injured as a result of this unusual positioning; the sternocleidomastoid muscles generally limit the safe degree of lateral head rotation. Left or right tilting (airplaning) of the operating room (OR) table minimizes the need for extreme lateral head rotation as in the case of children with Down syndrome. The laxity of the ligaments of the cervical spine, as well as immaturity of the odontoid process in these children predisposes them to C1-C2 subluxation. Of children with Down syndrome or achondroplasia, 15% to 31% have atlantoaxial instability.<sup>20-23</sup> Anteroposterior positioning requires the utmost care to avoid injury. Positioning of the OR table to allow access to the respective middle ear and accommodate all the extra surgical equipment can also pose a challenge. Depending on the room configuration, the table may be rotated 90 degrees or even 180 degrees away from the anesthesia machine, necessitating the use of extra-long breathing circuits (Fig. 31-1). As a result of the limited access to the airway, very careful attention must be paid to securing the tracheal tube. Draping must allow immediate access to the airway should that be required.

Bleeding must be kept to a minimum during surgery on the small structures of the middle ear. Relative hypotension (i.e., mean arterial pressure 10% to 25% less than baseline) may help to reduce bleeding. Concentrated epinephrine solution, 1:8000, is frequently applied to the tympanic membrane to induce vasoconstriction of the blood vessels. Close attention should be paid to the dose of epinephrine used to avoid arrhythmias and wide swings in blood pressure. The maximum dosage of topical epinephrine is 10 µg/kg, which may be repeated after 30 minutes.

**FIGURE 31-1** An operating room table turned 180 degrees may limit access to the child during ear surgery. ESU is the electrosurgical unit.

The middle ear and sinuses are air-filled, nondistensible cavities. An increase in the volume of gas within these cavities increases the pressure within the cavities. Nitrous oxide diffuses along a concentration gradient into air-filled middle ear spaces more rapidly than nitrogen moves out because nitrous oxide is 34 times more soluble in blood than nitrogen. The middle ear is vented through the opening of the eustachian tube. Normal passive venting of the eustachian tube occurs at 20 to 30 cm H<sub>2</sub>O pressure. Nitrous oxide increases the pressures within the middle ear such that they exceed the ability of the eustachian tube to vent the middle ear within 5 minutes, leading to pressure buildup.<sup>24</sup> If the function of the eustachian tube is compromised during the surgical procedure, then pressure in the middle ear can increase further. Venting the middle ear occurs intermittently, and leads to constant fluctuations in middle ear pressure that cause movement of the tympanic membrane.<sup>25</sup> During procedures in which the tympanic membrane is replaced or a perforation is patched, nitrous oxide should be discontinued or, if this is not possible, limited to a maximum of 50% of the concentration before the application of the tympanic membrane graft to reduce the potential for pressure-related displacement.<sup>26</sup> The omission of nitrous oxide does not significantly increase the requirements (minimal alveolar concentration) for the less-soluble inhaled anesthetics, desflurane, or sevoflurane in children.<sup>27</sup> After nitrous oxide is discontinued, it is quickly reabsorbed, creating a void in the middle ear, with resulting negative pressure. This negative pressure may result in serous otitis, disarticulation of the ossicles in the middle ear (especially the stapes), and hearing impairment, which may last up to 6 weeks postoperatively. The use of nitrous oxide may increase the incidence of postoperative nausea and vomiting (PONV), as a direct result of negative middle ear pressure during recovery. The negative pressure created by the reabsorption of nitrous oxide stimulates the vestibular system by producing traction on the round window. Although all children are at risk for PONV, older children and adolescents, in particular, seem to be at greatest risk.<sup>28</sup> Prophylactic administration of antiemetics (e.g., dexamethasone and ondansetron) is usually warranted. Local infiltration of the great auricular nerve can provide pain relief equivalent to that of opioids and may reduce the incidence of opioid-induced vomiting (see Chapter 41).<sup>29</sup>

A smooth, quiet emergence is desirable. Deep tracheal extubation can be accomplished if the child breathes spontaneously during the last 15 to 20 minutes of surgery, the concentration of inhalational anesthetic is greater than 1.3 times the minimal alveolar concentration, and opioids are titrated to produce regular slow respirations. Gentle suctioning of the oropharynx and possibly the use of IV lidocaine (1 to 1.5 mg/kg) in children older than 1 year of age can minimize or even prevent coughing after the tracheal tube is removed.

### COCHLEAR IMPLANTS

In recent years, the indications for cochlear implants have broadened and continue to evolve. With the application of universal neonatal hearing screening programs, a large pool of hearing-impaired infants has been identified. The benefits of early intervention with cochlear implants are being explored. Younger children with severe to profound hearing loss markedly improve their auditory, speech, and language skills after cochlear implants, and more of these children can be mainstreamed with their age-appropriate hearing peers when they receive an implant early in life. Experience has shown that cochlear implant surgery is safe

in infants older than 6 months of age, provided that special attention is paid to the physiologic and anatomic differences present in this age-group. Surgery requires meticulous care with hemostasis, soft tissue dissection, and bone drilling because bleeding from bone can be difficult to control and can complicate the surgical outcome. Availability of skilled postoperative nursing and a pediatric intensive care unit (ICU) is also essential.<sup>30</sup> Postoperative fitting of the externally worn speech processor is very important for successful use of the cochlear implant. However, this fitting process can be difficult, particularly in infants and young children, because of limited communication capabilities. Stapedius reflex thresholds obtained intraoperatively have been used for postoperative speech processor fitting, although the influence of anesthetics on the threshold values must be taken into account. More reliable threshold values can be obtained by adjusting the dosage of hypnotics to achieve a lighter level of hypnosis during stapedius reflex measurement.<sup>31</sup> In most children, increasing the concentration of inhalational anesthetics increases the stapedius reflex threshold. As always, appropriate communication with the surgeon will help ensure a successful outcome.

### Anesthesia for Rhinologic Procedures

Chronic sinusitis in children can be caused by antibiotic-resistant bacteria and is usually treated with broad-spectrum antibiotics. In some children with obstructive adenoid pads, adenoidectomy will improve the signs and symptoms of sinusitis. Functional endoscopic sinus surgery using sharp biting instruments and/or a microdebrider has become the primary method of surgical therapy for chronic sinusitis.<sup>32</sup> Current techniques aim to leave the mucosa intact to prevent scarring in the frontal recess. Although sometimes controversial, there is no evidence at present that functional endoscopic sinus surgery affects facial growth in children. Of interest to the anesthesiologist is that many children who require functional endoscopic sinus surgery have coexisting medical problems, such as asthma and cystic fibrosis. These conditions must be optimized before surgery (see Chapter 11).

Anesthetic management usually requires tracheal intubation to secure the airway; the use of an oral preformed tracheal tube (e.g., the Ring-Adair-Elwyn [RAE] tube) allows secure fixation to the mandible and unobstructed access to the maxilla and sinuses. The use of a cuffed tracheal tube is particularly advantageous to eliminate a gas leak that could fog up the endoscopic instruments. A throat pack is frequently inserted to absorb blood in the oropharynx and limit the gas escaping around an uncuffed endotracheal tube (ETT). It is critically important that the pack is removed before tracheal extubation. Occasionally, an LMA may be used to facilitate a quick "second look."

Because bleeding is inevitable with this surgery and can interfere with the surgical exposure, packing the nasal cavity with a vasoconstricting solution is frequently done before surgery commences. The most commonly used topical vasoconstrictors include oxymetazoline 0.025% to 0.05%, phenylephrine 0.25% to 1%, and cocaine 4% to 10%. It is important for the anesthesiologist to be aware of the type and dose of the vasoconstrictor used and that no more than the maximum effective dose is applied. Application of topical phenylephrine or other potent vasoconstrictors to mucous membranes or open surgical sites can cause severe hypertension, reflex bradycardia, and even cardiac arrest.<sup>33</sup> Hypertension that is induced by topically applied vasoconstrictors often resolves spontaneously and may not require

aggressive treatment. The use of  $\beta$ -adrenergic blockers or calcium-channel blockers to control blood pressure in these circumstances can depress cardiac output, leading to pulmonary edema and cardiac arrest.<sup>33</sup> It is recommended that the initial topical dose of phenylephrine should not exceed 20  $\mu\text{g}/\text{kg}$  in children.<sup>33</sup>

Corticosteroids, such as IV dexamethasone (0.25 to 0.5 mg/kg), are usually administered to reduce swelling and scarring. Frequently, the surgeon will want to leave an absorbable stenting material, such as MeroGel (Medtronic ENT, Jacksonville, Fla.), at the end of surgery. Unfortunately, this will interfere with nasal breathing and may increase the incidence of emergence agitation. An anesthetic technique that ensures adequate analgesia and rapid return of consciousness at the end of surgery is therefore desirable. One of us (RSH) has found that a combination of desflurane, fentanyl, and low-dose propofol works well in this regard. A unilateral or bilateral infraorbital nerve block can also be performed via the intraoral or extraoral route to provide analgesia (see Chapter 41).<sup>34</sup> One further concern is the need to avoid nonsteroidal antiinflammatory drugs (NSAIDs) in children with asthma and sinusitis secondary to nasal polyps (Samter triad).<sup>35</sup>

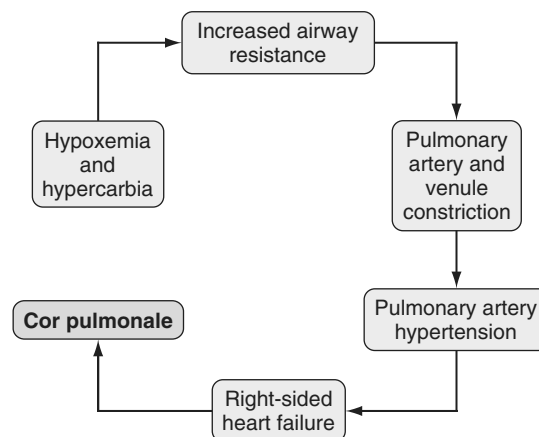

## Adenotonsillectomy

Adenotonsillectomy is one of the oldest and most commonly performed pediatric surgical procedures worldwide. More selective indications, however, have reduced the annual caseload.<sup>36,37</sup>

Chronic or recurrent tonsillitis and obstructive adenotonsillar hyperplasia are the major indications for surgical removal, although other indications do exist (Table 31-1).<sup>38,39</sup> Surgical treatment is required when tonsillitis recurs despite adequate medical therapy, or when it is associated with peritonsillar abscess or acute airway obstruction. Halitosis, persistent pharyngitis, and cervical adenitis may accompany chronic tonsillitis. Tonsillar hyperplasia may lead to chronic airway obstruction, resulting in sleep apnea,  $\text{CO}_2$  retention, intermittent nocturnal hypoxemia, cor pulmonale, failure to thrive, swallowing disorders, and speech abnormalities (Fig. 31-2). Many of these adverse effects are reversible with surgical excision of the tonsils. Certain children with cardiac lesions may be at risk for endocarditis caused by recurrent streptococcal bacteremia secondary to infected tonsils and will require prophylactic antibiotics (see Chapter 14).

Adenoidectomy is usually performed in conjunction with tonsillectomy although, in some situations it is performed as the sole surgical procedure. Indications for adenoidectomy alone include chronic or recurrent purulent adenoiditis (despite adequate medical therapy), recurrent otitis media with effusion secondary to adenoidal hyperplasia, and chronic sinusitis. Advanced degrees of adenoidal hyperplasia may lead to nasopharyngeal obstruction, obligate mouth breathing, poor feeding resulting in failure to thrive, speech disorders, and sleep disturbances. Longstanding nasal obstruction can result in orofacial abnormalities with a narrowing of the upper airway and dental abnormalities, which may be avoided by removal of hypertrophied adenoid tissue.

Surgical techniques for adenotonsillectomy include guillotine and snare techniques, cold and hot knife dissection, suction, radiofrequency ablation, and unipolar and bipolar electrocautery techniques. A major advantage of the electrocautery dissection technique is a reduction in the incidence of intraoperative blood loss, as well as postoperative hemorrhage; a major disadvantage is greater pain and poor oral intake postoperatively.<sup>40-44</sup>

**FIGURE 31-2** Children with chronic tonsillar hypertrophy may have long-standing hypoxemia and hypercarbia, which can lead to cor pulmonale.

**TABLE 31-1** Indications for Adenotonsillectomy

Tonsillar/adenoidal
Benign
Malignant

The mortality associated with adenotonsillectomy is estimated at 1 per 16,000 to 1 per 35,000 procedures.<sup>45,46</sup> Hospital-based reviews of anesthetic mortality continue to list adenotonsillectomy as a surgical procedure associated with perioperative cardiac arrest and death.<sup>47,48</sup> Bleeding, burns, and airway fires account for over one third of malpractice claims associated with this procedure.<sup>49</sup>

Surgical complications after adenotonsillectomy are rare but include uvular amputation, uvular edema, velopharyngeal insufficiency, and nasopharyngeal stenosis. Atlantoaxial subluxation manifesting as neck pain and torticollis, mandibular subluxation and condylar fracture, cervical adenitis, and cervical osteomyelitis have also been reported.<sup>46,50</sup>

Throat pain, otalgia, emesis, poor oral intake, and dehydration are common morbidities. Respiratory morbidity after adenotonsillectomy in the otherwise healthy child affects less than 1%,<sup>51-53</sup> but has assumed a greater importance since obstructive breathing has replaced infection and halitosis as the most common indication for adenotonsillectomy.

Age has a major influence on postadenotonsillectomy complications. Secondary postadenotonsillectomy hemorrhage is

more common in children older than the age of 10 years.<sup>54,55</sup> Young age is a risk factor for both poor oral intake and respiratory complications. The majority of children younger than age 3 years experience airway problems after adenotonsillectomy for obstructive breathing.<sup>56,57</sup>

### PREOPERATIVE EVALUATION

The general health of the child and the indications for surgery must be reviewed. URIs are frequent in these children and can interfere with the timing of adenotonsillectomy because the risk of respiratory morbidity and hemorrhage is increased.<sup>46,51,58,59</sup> A history of bleeding tendencies requires investigation. Medications that interfere with coagulation include aspirin, NSAIDs, and valproic acid. Discontinuation of these drugs preoperatively is sometimes problematic, and preoperative consultation with neurology, cardiology, and hematology specialists may be indicated.

A careful cardiorespiratory history and physical examination is essential. Children with chronic tonsillar hypertrophy may have long-standing hypoxemia and hypercarbia, which can lead to cor pulmonale (see Fig. 31-2). The oropharynx should be evaluated and the tonsillar size classified (Fig. 31-3).<sup>60</sup> In some centers, a complete blood cell count is required before adenotonsillectomy. There is no evidence that routinely performed preoperative coagulation studies are beneficial unless they are indicated by history.<sup>61,62</sup> The indications for the procedure should be clearly delineated. If the indication is for obstructed breathing, then further evaluation for symptoms of possible obstructive sleep apnea (OSA) is indicated. Parents should be asked if the child

snores loudly, if the snoring can be heard through a closed door, if there are gasps or pauses in respirations, if there is daytime somnolence, night terrors, nocturnal enuresis, attention deficit disorder, or poor school performance. A positive response to any of these questions is suggestive of OSA, in particular when combined with obesity (weight greater than the 95th percentile).<sup>63-67</sup>

### Special Considerations for the Child with OSA

*The single most important task during the preoperative evaluation of the child for adenotonsillectomy is to distinguish the child with OSA from the child with obstructive breathing, because the former is at greater risk for developing severe perioperative respiratory complications, possibly including death, after adenotonsillectomy.*<sup>68-71b</sup>

OSA is the most severe form of sleep-disordered breathing. Sleep-disordered breathing ranges from normal respirations to primary snoring, upper airway resistance syndrome (UARS), obstructive hypopnea, and OSA. At the most extreme form of sleep-disordered breathing, OSA, clinical signs of partial or complete upper airway obstruction (UAO) must be present during sleep, as well as some degree of hypercarbia and/or hypoxemia.<sup>72</sup> Although it is important to recognize the significance of OSA in children who are scheduled for adenotonsillectomy, children who do not meet the criteria for OSA but who have less severe forms of sleep-disordered breathing, such as UARS or obstructive hypopnea, may also be at increased risk for morbidity after surgery. Guidelines for the perioperative management of these children continue to be developed.<sup>71a,73,74</sup>

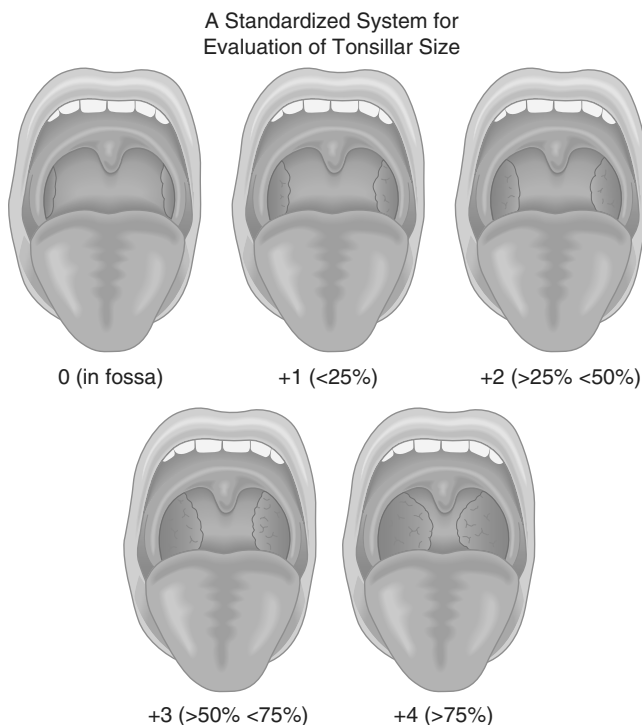

A high index of suspicion is required to identify the child with OSA on clinical criteria, although clinical criteria do not distinguish primary snoring from OSA in children.<sup>75</sup> There is a greater incidence of OSA in Asian and African American populations.<sup>76,77</sup> In addition, African American children desaturate more profoundly during sleep-related obstructive airway events than do Caucasian and Hispanic children<sup>78</sup>; the reason for this difference is unclear.

Anatomic features, including increased nasal resistance, may underlie the pathogenesis of OSA; common medical conditions and syndromes that predispose to the development of OSA are listed in Table 31-2. Infants suffering acute life-threatening events have a greater incidence of OSA in childhood and adolescence.<sup>79-81</sup>

The obstructive events that characterize OSA result in recurrent episodes of hypoxia, hypercarbia, and sleep disruption, a trilogy that has been linked to the development of medical sequelae that accompany severe OSA. Because adenotonsillectomy is very often the initial treatment for the majority of children, these children may present with a spectrum of disease affecting multiple organ systems. Failure to thrive is common. Cardiovascular abnormalities, including ventricular dysfunction, a depressed ventricular ejection fraction, right ventricular hypertrophy, and pulmonary hypertension, may be present.<sup>82-85</sup> Repeat infections affecting the lower respiratory tract have been linked to chronic aspiration.<sup>86</sup>

The severity of OSA is assessed by the frequency and severity of the obstructive respiratory events during sleep; both vary with sleep stage and occur most often during rapid eye movement (REM) sleep. The frequency and severity of obstructive events worsen after midnight, a finding that may reflect the greater proportion of REM sleep in the latter part of the night and fatigue of the upper airway musculature.<sup>87-89</sup>

Apneas are classified as central, obstructive, and mixed. Central apnea occurs when there is no apparent respiratory effort. Obstructive apnea is associated with apparent, often vigorous,

**FIGURE 31-3** Classifying tonsil size may be helpful in evaluating the degree of airway obstruction. Children classified as +3 or greater (i.e., having more than 50% of the pharyngeal area occupied by hypertrophied tonsils) are at an increased risk of developing airway obstruction during anesthetic induction. (Modified from Brodsky L. Modern assessment of tonsils and adenoids. *Pediatr Clin North Am* 1989;36:1551-69; illustration by Jon S. Krasner.)

inspiratory efforts that are ineffective because lack of upper airway patency. A mixed obstructive apnea is diagnosed when both central and obstructive apnea occur without interruption by effective respirations. The presence of sleep-disordered breathing is documented by polysomnography and is quantitated by the frequency of obstructive events and by oxygen-desaturation indices. The polysomnogram simultaneously records the electroencephalogram, electromyogram, electrocardiogram, pulse oximetry, airflow, and thoracic and abdominal movement during sleep. A recent consensus paper on the criteria for diagnosing OSA in children has been developed.<sup>71a,84</sup> A common definition of obstructive apnea in children is an obstructive effort that includes more than two obstructive breaths, regardless of the duration of the apnea.<sup>87</sup> An obstructive apnea index of 1 is the cutoff for normality in children.<sup>90</sup> *Hypopnea* is defined as a reduction in airflow of more than 50%.<sup>87</sup> The apnea hypopnea index (AHI) is the summation of the number of obstructive apnea and hypopnea events and is analogous to the respiratory disturbance index (RDI). A common definition of desaturation is a 4% decrease in oxygen saturation from baseline. The saturation nadir is the minimum oxygen saturation recorded during the sleep study. A saturation nadir of 92% is the minimum normal saturation in children.<sup>90,91</sup>

The severity of OSA predicts the nature of perioperative respiratory complications (Table 31-3). An RDI of greater than 20 events per hour is associated with breath holding during induction, whereas an RDI greater than 30 is associated with laryngospasm and desaturation during emergence.<sup>92</sup> Ten obstructive events per hour during a screening polysomnogram is the threshold for severe postoperative respiratory complications.<sup>69</sup> An oxygen-saturation nadir less than 80% is associated with a greater incidence of respiratory morbidity after adenotonsillectomy, compared with a saturation nadir greater than 80%.<sup>68,71</sup>

**TABLE 31-3** Clinical Diagnostic Criteria for Pediatric Obstructive Sleep Apnea Syndrome

1. Predisposing physical characteristics
  - a. Body mass index greater than 95th percentile for age and gender
  - b. Craniofacial abnormalities affecting the airway
  - c. Anatomic nasal obstruction
  - d. Tonsils nearly touching or touching in the midline
2. History of apparent airway obstruction during sleep (*two or more of the following*)
  - a. Loud snoring (loud enough to be heard through a closed door)
  - b. Frequent snoring
  - c. Observed pauses in breathing during sleep
  - d. Frequent arousals from sleep
  - e. Intermittent vocalization during sleep
  - f. Parental report of restless sleep, difficulty breathing, or struggling respiratory efforts during sleep
  - g. Nocturnal enuresis
3. Somnolence (*one or more of the following*)
  - a. Parent or teacher comments that the child appears sleepy during the day, is easily distracted, is overly aggressive, or has difficulty concentrating
  - b. Child often is difficult to arouse at the usual awakening time

*Note:* If signs and symptoms in at least two categories are present, there is a significant probability of moderate obstructive sleep apnea (OSA). If severe abnormalities are present, children should be treated as having severe OSA. Modified from Table 1 in Gross JB, Bachenberg KL, Benumof JL, et al. Practice guidelines for the perioperative management of patients with obstructive sleep apnea: a report by the American Society of Anesthesiologists Task Force on Perioperative Management of patients with obstructive sleep apnea. *Anesthesiology* 2006;104:1081-93.

The RDI and AHI correlate inversely with the oxygen-saturation nadir,<sup>93,94</sup> making simplified testing with continuous pulse oximetry a meaningful metric. The McGill oximetry score has been shown to correlate with the risk of respiratory complications after adenotonsillectomy in children (Fig. 31-4). Of children with a McGill oximetry score of 4, 24% experienced major postoperative respiratory complications.<sup>94</sup>

Children with severe OSA may require additional preoperative testing before adenotonsillectomy. A capillary blood gas sample drawn in the morning can be evaluated for an increased concentration of bicarbonate, suggestive of CO<sub>2</sub> retention during sleep. When indicated, a preoperative electrocardiogram or echocardiogram may provide evidence of right ventricular hypertrophy and/or pulmonary hypertension. A chest radiograph may suggest lower airway disease or cardiomegaly.

Consultations to plan the perioperative care of children with severe OSA are important. Young children with profound oxygen desaturation during sleep and CO<sub>2</sub> retention may require admission to the pediatric ICU for optimization before and/or after adenotonsillectomy.<sup>36,94</sup> Urgent adenotonsillectomy for severe OSA is associated with significant respiratory morbidity after surgery.<sup>70,95</sup> On occasion, adenotonsillar hypertrophy may progress to compromise the upper airway during wakefulness. In some instances the anesthetic considerations for the obstructed and difficult airways may overlap.

## ANESTHETIC MANAGEMENT AND POSTOPERATIVE CONSIDERATIONS

The anesthetic goals for adenotonsillectomy are (1) to provide a smooth, atraumatic induction; (2) to provide the surgeon with optimal operating conditions; (3) to establish IV access for

**FIGURE 31-4** Representative figures for McGill oximetry scores 1 to 4 (top to bottom). McGill oximetry scores 2 to 4 are abnormal in that they all show at least three clusters of desaturation. The severity of the saturation nadir determines the score such that McGill oximetry scores 2, 3, and 4 correspond to saturation nadirs of less than 90%, less than 85%, and less than 80%, respectively. (From Nixon GM, Kermack AS, Davis GM, et al. Planning adenotonsillectomy in children with obstructive sleep apnea: the role of overnight oximetry. *Pediatrics* 2004;113:e19-25.)

volume expansion and medications as indicated; and (4) to provide rapid emergence so that the child is awake and able to protect the recently instrumented airway. The need for a premedication is determined during the preanesthetic evaluation. *Children with symptoms of sleep-disordered breathing who require premedication should be closely observed*, although the desaturation is transient and infrequent (1.5% of cases) after oral midazolam premedication.<sup>96</sup> *Monitoring with pulse oximetry after premedication may be indicated for select children with severe OSA and confounding variables.*<sup>96</sup> *Premedication with short-acting drugs and/or those that can be antagonized is advised (see further).*

The anesthetic techniques for adenotonsillectomy are varied and include the choice of an inhalational or IV technique, the choice of an ETT or LMA, and the choice of spontaneous or

controlled ventilation. Of the currently available inhalational agents, sevoflurane provides a smooth induction of anesthesia, and desflurane (for those whose airway is secured with an ETT) used for maintenance provides a rapid emergence and recovery.<sup>97,98</sup> The rapid return of airway reflexes is particularly important when the dose of opioids must be titrated after extubation.

Children who are scheduled for adenotonsillectomy have a high incidence of airway reactivity and laryngospasm. This will influence the choice of airway management. Placement of an oral RAE or standard uncuffed ETT with a leak at 20 cm H<sub>2</sub>O (the leak increases with neck extension and insertion of the mouth gag) is generally sufficient to prevent soiling of the trachea during the surgery, yet reduces the incidence of postextubation croup. Cuffed ETTs have become increasingly used in

children of all age-groups.<sup>99</sup> A cuffed tube prevents an air leak and the consequent bubbling of gases through the oropharyngeal secretions and blood that can interfere with surgery. It also minimizes pollution by anesthetic gases and decreases the risk of an airway fire when electrocautery is used.

Blood and secretions may be present in the oropharynx at the conclusion of surgery and should be carefully suctioned before emergence from anesthesia. Emptying the stomach with an orogastric tube, a maneuver frequently performed by the surgeon under direct vision after completion of surgery, does not reduce the incidence of PONV, although the study was underpowered to detect a difference.<sup>100</sup>

It is preferable to wait until the child is fully awake and able to clear blood and secretions from the oropharynx before removing the ETT. A common practice is to position the child in the lateral position (known as the “tonsil” or “recovery” position) with the head slightly down at the time of extubation to permit blood and secretions to pool in the dependent cheek and drain out of the mouth rather than accumulate at the laryngeal inlet. Intact airway and pharyngeal reflexes are of utmost importance in preventing aspiration, laryngospasm, and airway obstruction.<sup>101</sup> The child should remain in the tonsil position postoperatively, while being carefully observed and monitored during transport to the recovery room.

The use of the LMA for adenotonsillectomy was described in 1990, but it was not until the widespread availability of a model with a flexible spiral, metallic reinforced shaft that it was widely used (E-Fig. 31-1).<sup>102,103</sup> The wide, rigid tube of the original model did not fit under the mouth gag and was easily compressed or dislodged during full mouth opening. The newer, flexible model has a soft, reinforced shaft, which easily fits under the mouth gag without becoming dislodged or compressed. Adequate surgical access can be achieved and the airway is reasonably well protected from exposure to blood during the surgery.<sup>104,105</sup> Early advantages cited for the LMA over the ETT include a decrease in the incidence of postoperative stridor and laryngospasm, and an increase in immediate postoperative oxygen saturation,<sup>106</sup> although recent evidence disputes any difference in the frequency of laryngospasm.<sup>107</sup> Insertion of the LMA, however, may be difficult in the presence of tonsillar enlargement, and careful placement to avoid kinking of the LMA is essential.<sup>108</sup> Although it has been recommended that the LMA be used only in spontaneously breathing children and that positive-pressure ventilation be avoided, gentle assisted ventilation is both safe and effective if peak inspiratory pressure is limited to 20 cm H<sub>2</sub>O or less. If there is any leak of gases around the LMA then the potential for an airway fire must be considered and appropriate precautions taken if electrocautery is used.

## Analgesic Management

Surgical technique has a major impact on the analgesic requirements after adenotonsillectomy because electrocautery techniques are generally associated with greater pain, presumably owing to increased thermal injury,<sup>40,41,109</sup> although this is debated.<sup>110</sup> Opioids have been the mainstay of perioperative analgesia. However, because opioids increase the incidence of emesis<sup>111</sup> and respiratory morbidity, the use of opioid-sparing adjuncts has been advocated, including dexamethasone, acetaminophen, NSAIDs, and ketamine.

A single intraoperative dose of dexamethasone reduces post-adenotonsillectomy pain and edema when electrocautery has been used. Large doses are traditionally used, especially in children with OSA. Dexamethasone (1 mg/kg) administration is associated with reduced parental- and physician-rated pain scores after adenotonsillectomy (Table 31-4).<sup>41</sup> The minimum morphine-sparing dose for dexamethasone is reported to be 0.5 mg/kg.<sup>112</sup> For dexamethasone doses between 0.0625 mg/kg and 1.0 mg/kg, the frequency of postoperative vomiting, pain scores, and times to first liquid and first analgesics were similar.<sup>113</sup> A similar absence of a dose response for dexamethasone between 0.050 and 0.15 mg/kg for vomiting after tonsillectomy was reported in another study.<sup>114</sup> Single doses of dexamethasone have not been associated with aseptic necrosis of the hip or infections, but have been responsible for several cases of acute tumor lysis syndrome, including one death.<sup>115-117</sup> One study suggested an increased risk of bleeding after tonsillectomy in children who received dexamethasone up to 0.5 mg/kg (maximum 20 mg).<sup>118</sup> These findings have been refuted by a recent meta-analysis and several studies.<sup>119-122a</sup>

The routine use of NSAIDs for adenotonsillectomy remains controversial because of the potential for postadenotonsillectomy hemorrhage. A meta-analysis of seven randomized controlled trials (505 children) on the effects of NSAIDs on bleeding risk after tonsillectomy reported the number needed to harm, in terms of reoperation for hemostasis, to be 29.<sup>123</sup> NSAIDs were associated with a greater risk of both postoperative bleeding that required treatment and reoperation for hemostasis. The Cochrane Collaboration assessed the effect of NSAIDs on bleeding after pediatric tonsillectomy in 13 trials (955 children) and found no increase in bleeding that required reoperation for hemostasis.<sup>124</sup> An audit of more than 4800 pediatric tonsillectomies in which the NSAIDs diclofenac and ibuprofen were routinely used, reported a primary hemorrhage rate of 0.9%.<sup>55</sup> Because the effects of ketorolac on platelet function are reversible, the effect is dependent on the presence of ketorolac within the body.<sup>125</sup> Thus, unlike the effect of aspirin, this effect is short-lived. However, we recommend administering NSAIDs only after consulting with

**TABLE 31-4** Effect of Single Intraoperative Dose of Dexamethasone on Postoperative Pain in Pediatric Tonsillectomy or Adenotonsillectomy: A Comparison of Randomized, Double-Blind Studies

Source	No. of Children	Dexamethasone Dose	Electrocautery Technique	Effect on Pain
Catlin and Grimes <sup>292</sup>	25	8 mg/m <sup>2</sup>	No	No difference
Ohlms et al. <sup>293</sup>	69	0.5 mg/kg	No	No difference

**E-FIGURE 31-1** Laryngeal mask airway made for ear, nose, and throat surgery.

the surgeon and, if in agreement, administering them after hemostasis is achieved.<sup>126</sup> Acetaminophen is commonly used as a component of multimodal analgesic approach in these children.<sup>127</sup> IV formulations of acetaminophen are now available in many countries, offering the theoretical advantage of greater predictability than the oral and rectal routes. However, recent studies suggest that the duration of analgesia after 15 mg/kg of acetaminophen given IV is less than that after 40 mg/kg given rectally.<sup>128</sup> Furthermore, although introduced only 7 years ago, two reports of 10-fold overdoses of IV acetaminophen with near-catastrophic outcomes in infants should alert clinicians to the very serious risk of dosage errors with this medication.<sup>129</sup>

An IV infusion of dexmedetomidine 2 µg/kg over 10 minutes followed by 0.7 µg/kg/hr combined with an inhalation agent can provide satisfactory intraoperative conditions for adenotonsillectomy without adverse hemodynamic effects. In children with OSA syndrome, postoperative opioid requirements are significantly reduced and the incidence and severity of severe emergence agitation is reduced, with few children desaturating.<sup>130</sup> After larger doses of dexmedetomidine (2 and 4 µg/kg), the opioid-free interval increases and the postoperative opioid requirements decrease. However, duration of stay in the PACU is prolonged.<sup>131</sup>

Infiltration of local anesthetics into the tonsillar fossa during tonsillectomy is sometimes reported to decrease postoperative pain, but the pain relief is transient (E-Fig. 31-2).<sup>132</sup> In addition, life-threatening complications have been reported after local anesthetic infiltration in the tonsillar fossa, including intracranial hemorrhage, bulbar paralysis, deep cervical abscess, cervical osteomyelitis, medullopontine infarct, and cardiac arrest. The risks associated with injection of local anesthesia in the tonsillar fossa may outweigh its potential benefits, particularly in inexperienced hands.<sup>133,134</sup>

### Postoperative Nausea and Vomiting

Emesis and poor oral intake are common comorbid conditions after adenotonsillectomy. Opioids increase the incidence of PONV, with two thirds of treated children experiencing PONV.<sup>37,55,135</sup> The incidence of PONV increases with morphine dose.<sup>111,136</sup> Propofol infusions,<sup>136a,136b</sup> ondansetron and dexamethasone are widely used to reduce the incidence of emesis after adenotonsillectomy. Postdischarge vomiting continues for days in some children. One study has shown that at-home use of oral ondansetron disintegrating tablets may prevent emesis during the first 3 days after adenotonsillectomy.<sup>137</sup> A single intraoperative dose of dexamethasone reduces the incidence of emesis during the first 24 hours after adenotonsillectomy.<sup>138</sup> The number of children needed to treat was only four, which means that the use of dexamethasone in four children undergoing adenotonsillectomy results in one less child experiencing PONV. In addition, children who received dexamethasone were more likely than those receiving placebo to advance to a soft diet on postoperative day 1, with a number needed to treat of five. Given the antiemetic and possible morphine-sparing advantages of a single dose of dexamethasone, and its low cost and safety profile, the evidence suggests that routine use of dexamethasone reduces morbidity after adenotonsillectomy in children.<sup>41,138</sup> Although the literature supports the effectiveness of a single dose of dexamethasone, the smallest effective dose remains somewhat unclear. One study suggested an IV dose of 0.15 mg/kg,<sup>139</sup> whereas another reported no difference in postoperative vomiting, pain scores, time to first liquid, and time to first analgesics between doses of

0.0625 and 1.0 mg/kg (Fig. 31-5).<sup>113</sup> Acupuncture, acupressure, as well as therapeutic suggestion, have also been used with variable results.<sup>140-142</sup>

### Special Considerations for Children with OSA

Children with OSA who require premedication should be closely observed, because transient oxygen desaturation has been reported in 1.5% of children with OSA who received 0.5 mg/kg oral midazolam.<sup>96</sup>

### Induction of Anesthesia

Compared with children undergoing adenotonsillectomy for chronic tonsillitis, those whose indication was OSA experienced more respiratory complications during induction of anesthesia.<sup>92</sup> The vulnerability of the upper airway musculature described for halothane<sup>143</sup> has subsequently been reported for most anesthetic agents, resulting in a graded reduction in airway caliber with increasing anesthetic concentration.<sup>144-148</sup> Airway obstruction occurs in the upper two thirds of the pharyngeal airway, and the smallest pharyngeal dimension is in the area of overlap between the adenoids and tonsils.<sup>147</sup> During induction of anesthesia, early pharyngeal airway obstruction may require a jaw thrust maneuver, insertion of an oral or nasopharyngeal airway, and the application of continuous positive airway pressure (CPAP). Propofol-associated loss in airway caliber is reversed with the application of CPAP.<sup>148</sup> CPAP acts as a pneumatic splint to increase the caliber of the pharyngeal airway (Fig. 31-6).<sup>149</sup> Of equal importance, CPAP increases longitudinal tension on the pharyngeal airway, thereby decreasing the collapsibility of the upper airway (see Fig. 12-10), and increases lung volumes.<sup>150,151</sup> Small increments in CPAP between 5 and 10 cm H<sub>2</sub>O increase the dimension of the pharyngeal airway dramatically (Fig. 31-7).<sup>152,153</sup> The closing pressure of the pharynx increases with OSA severity, such that greater levels of CPAP are required in children with severe OSA compared with those with mild OSA. It is prudent to consider securing IV access before induction of anesthesia in children with severe OSA, to expedite administration of muscle relaxants or IV agents should pharyngeal obstruction or laryngospasm occur during induction. The small oropharynx and adenotonsillar hypertrophy associated with severe OSA may increase the difficulty in properly inserting an LMA.

### Analgesic Management in Children with OSA

Severe OSA is characterized by recurrent episodes of transient hypoxia and hypercarbia during sleep. In animal models, exposure to intermittent hypoxia during development affects the opioid system, increasing the density of µ-opioid receptors in the respiratory-related areas of the brainstem. The cellular mechanism whereby this increased density is achieved has yet to be elucidated, but it may represent an adaptive response to the effects of recurrent intermittent hypoxia that allows µ-receptor-mediated opioid respiratory effects to predominate.<sup>154-157</sup>

For children with severe OSA, the severity of the nocturnal oxygen desaturation correlates with the sensitivity to exogenously administered opioids (Fig. 31-8).<sup>158-160</sup> The morphine dose required to achieve a uniform analgesic endpoint in children with OSA who exhibited a low preoperative oxygen-saturation nadir during sleep (less than 85%) (Fig. 31-9) was less than in those whose preoperative saturation nadir was greater.<sup>159</sup> Young age was also associated with an increased sensitivity to opioids. *An unforeseen risk of perioperative opioid use in children with severe OSA is that smaller-than-expected doses of opioids may produce exaggerated*

**E-FIGURE 31-2** Tonsillar infiltration.

**FIGURE 31-5** No dose-escalation response to dexamethasone to prevent vomiting in children undergoing tonsillectomy. Time-to-event analysis for first vomiting episode was performed; tick marks indicate time of censoring for patients who did not have complete follow-up ( $N = 13$ ). No significant difference was found between dose levels,  $P = 0.28$  (Cox Proportional Hazard Likelihood Ratio Test). (Redrawn with permission from Kim MS, Coté CJ, Cristoloveanu C, et al. There is no dose-escalation response to dexamethasone (0.0625-1.0 mg/kg) in pediatric tonsillectomy or adenotonsillectomy patients for preventing vomiting, reducing pain, shortening time to first liquid intake, or the incidence of voice change. *Anesth Analg* 2007;104:1052-8.)

**FIGURE 31-6** When a child has upper airway obstruction caused by laryngospasm (A) or mechanical obstruction (B), application of approximately 10 cm  $H_2O$  of positive end-expiratory pressure (PEEP) during spontaneous breathing often relieves obstruction. PEEP helps to hold the vocal cords apart (A) and the airway open (broken lines in B). (From Coté CJ. *Pediatric anesthesia*. In Miller RD, editor. *Miller's anesthesia*. 8th ed. New York: Churchill Livingstone; 2012. In press.)

**FIGURE 31-7** The relationship between airway pressure and the cross-sectional area of the pharynx. Maximal airway dimension is achieved between 15 and 20 cm H<sub>2</sub>O. At reduced airway pressures, around 5 cm H<sub>2</sub>O, small increments in airway pressure make a large difference in airway caliber. (From Isono S, Tanaka A, Nishino T. Dynamic interaction between the tongue and soft palate during obstructive apnea in anesthetized patients with sleep-disordered breathing. *J Appl Physiol* 2003;95:2257-64.)

**FIGURE 31-8** Relationship between morphine requirement, age, and the preoperative arterial oxygen-saturation nadir in 46 children who were otherwise well. The lengths of the stems supporting the 46 dots are proportional to the morphine dose. The stems in the foreground are shorter than those in the background, indicating a significant correlation between the three variables. SaO<sub>2</sub>, Arterial oxygen saturation. (From Brown KA, Laferrière A, Moss IR. Recurrent hypoxemia in young children with obstructive sleep apnea is associated with reduced opioid requirements for analgesia. *Anesthesiology* 2004;100:806-10.)

**respiratory depression.** Of children with severe OSA who were anesthetized with halothane, 46% experienced apnea after a uniform dose of fentanyl, compared with 4% of controls.<sup>161</sup> This increased sensitivity to the respiratory depressant effects of fentanyl in children with OSA is supported by the exaggerated respiratory depression to subsequent administration of a uniform dose of fentanyl in rat pups exposed to intermittent hypoxia.<sup>162</sup> Hence, allowing spontaneous respirations during maintenance of anesthesia enables an assessment of the response to small challenges of opioid analgesics. In this manner, the anesthesiologist can assess the sensitivity of the child with OSA to opioids.

**FIGURE 31-9** The total analgesic dose of morphine required to achieve a uniform analgesic endpoint in children with obstructive sleep apnea (OSA). Children were grouped by severity of OSA into those who had a preoperative oxygen saturation nadir of <85% or ≥85%. The asterisks indicate post hoc differences between groups,  $p < 0.05$ . (From Brown KA, Laferrière A, Lakheeram I, Moss IR. Recurrent hypoxemia in children is associated with increased analgesic sensitivity to opiates. *Anesthesiology* 2006;105:665-9.)

Controlling respiration precludes such an evaluation. Sleep fragmentation blunts the arousal response to acute airway occlusion during sleep.<sup>163,164</sup> In addition, exposure to intermittent hypoxia during development is associated with an increase in the arousal latency to hypoxia.<sup>165-167</sup> Morphine acting at the level of the basal forebrain blunts arousal.<sup>168</sup> If the increased sensitivity to both the analgesic and respiratory effects of exogenously administered opioids reported in children with OSA extends to arousal mechanisms, the use of opioids in children with severe OSA may further impair arousal mechanisms. Guidelines for the perioperative management of OSA assign a greater risk score if opioids are used for postoperative analgesic regimens in children with OSA.<sup>91</sup> Although these guidelines suggest that the use of low-potency oral opioid analgesia carries a reduced perioperative risk, the use of codeine, a “low-risk” oral opioid commonly used in the ambulatory setting, may also be problematic in children with OSA. Codeine is metabolized by the cytochrome P450 debrisoquine 4-hydroxylase (CYP2D6) to its active analgesic metabolites. The CYP2D6 gene displays polymorphism, including gene duplication (ultra-rapid metabolizers) and inactive genes. Gene duplication may lead to ultra-rapid metabolism, which for prodrugs, such as codeine, might yield a 50% greater fraction of morphine and its glucuronides compared with extensive metabolizers.<sup>169</sup> Respiratory arrest after codeine has been reported in both adults and children who demonstrate ultra-rapid metabolism of codeine.<sup>170-171a</sup> Whereas the ultra-rapid metabolizing genotype is present in 3% of Caucasians, it is present in 10% to 30% of Arabian and Northeast African populations. In contrast, almost 10% of children lack CYP2D6, rendering codeine an ineffective analgesic. Given the broad variability in codeine metabolism and our lack of knowledge of which polymorphism is carried by each child, the use of codeine and the dose prescribed for children with OSA must be very carefully considered or an alternate opioid selected.

### Neural Blockade

Blockade of neural input to the upper airway dilator musculature in children with OSA is also problematic. Serious life-threatening complications, including severe UAO and pulmonary edema, have been reported after local anesthetics have been infiltrated in the tonsillar fossa to prevent pain after adenotonsillectomy. The pharynx in children with OSA is not only smaller in size,<sup>147,172</sup> but also more collapsible, even during wakefulness, compared with those children who do not have OSA.<sup>173-175</sup> Topical anesthesia applied to the mucosa of the pharynx of children with OSA reduces the caliber of the pharynx compared with control subjects.<sup>176</sup>

### Extubation Strategy and Management of the Postoperative Period in Children with OSA

Extubation of the trachea is usually performed when the child is fully awake. Techniques that involve minimal stimulation of the airway have been suggested.<sup>101</sup> Although a minority of children receive muscle relaxants for adenotonsillectomy, residual neuromuscular blockade in the recovery room will selectively depress the function of the upper airway dilators relative to the diaphragm, promoting collapse of the pharyngeal airway.<sup>177</sup> Full antagonism of neuromuscular blockade is strongly recommended before extubating the tracheas of children with OSA.<sup>91</sup> Antagonism of neuromuscular blockade with atropine and neostigmine after tonsillectomy has been associated with less PONV than antagonism with glycopyrrolate and neostigmine.<sup>178</sup>

Several other factors may increase the risk of respiratory difficulties after adenotonsillectomy in children with OSA. Otherwise healthy children with severe OSA, whose adenotonsillectomy is performed in the morning, are less likely than those whose surgery is performed in the afternoon to desaturate when managed in a PACU setting.<sup>179</sup> In addition, meticulous attention to the position of the head and neck is required during recovery from anesthesia, because hypercarbia and a loss of lung volume (functional lung capacity) both promote collapse of the pharyngeal airway.<sup>151,180,181</sup> Extension of the cervical spine, the sniffing position, the lateral recovery position, and mouth opening with anterior advancement of the mandible all increase the dimension of the pharynx<sup>182-186</sup> and reduce the risk of UAO.

Two drugs, atropine and naloxone, have the potential to augment the function of the upper airway. Atropine administered after induction of anesthesia decreased the risk of postadenotonsillectomy respiratory complications.<sup>70</sup> Of possible relevance is the report that muscarinic blockade of the hypoglossal nucleus in the rat model enhances activity of the genioglossus muscle.<sup>181</sup> Agonists of opioid  $\mu$ -receptors have been shown to depress activity in the pharyngeal dilator muscles, including the genioglossus muscle.<sup>155,187-189</sup> Given the increased sensitivity to both analgesic and respiratory effects of exogenously administered opioids in children with severe OSA, a similar sensitivity may also apply to the respiratory-related activity of the pharyngeal musculature. Small doses of naloxone may alleviate UAO after adenotonsillectomy if exogenous opioids have been administered.

The severity of OSA is a predictor of the outcome after adenotonsillectomy.<sup>190</sup> A preoperative RDI above 19 may predict an RDI in excess of 5 in long-term follow-up.<sup>75,93</sup> Children with OSA continue to demonstrate obstructive apnea and desaturation during sleep on the first night after adenotonsillectomy, with the frequency of the obstructive events and the severity of desaturation usually greater in those children with severe OSA (Fig. 31-10).<sup>191,192</sup> Thus despite removal of the hypertrophied

tonsils and adenoids, children with OSA continue to experience symptoms on the first postoperative night. This underscores the need to admit these children to a hospital for continuous overnight monitoring postoperatively, rather than discharge them home. Long-term follow-up studies more than 6 months after tonsillectomy in children with OSA show that symptoms completely resolve in those with mild OSA (AHI less than 10) but are persistent in 35% of those with severe OSA (AHI greater than 20).<sup>190</sup> Furthermore, recent epidemiologic evidence suggests that residual sleep-disordered breathing is more likely to be present after adenotonsillectomy in older children (more than 7 years of age) and obese children. It has also been suggested that obese children with large tonsils and OSA also show evidence of systemic inflammatory disease that persists after the tonsillectomy.<sup>190,193</sup>

Measures to support airway patency in the postoperative period have included insertion of nasal airways, administration of noninvasive ventilatory support (e.g., CPAP), reintubation, ventilation, and the administration of bronchodilators, racemic epinephrine, and heliox. Bilevel positive airway pressure and/or CPAP may be useful in children with preexisting neurologic disorders.<sup>194</sup> However, nasal secretions may be copious after adenotonsillectomy, limiting the efficacy of noninvasive ventilatory support. Children with complex medical diseases, who are critically dependent on the function of upper airway musculature, may benefit from delayed extubation. Acute relief of chronic UAO favors the exudation of intravascular fluid into the pulmonary interstitium and noncardiogenic pulmonary edema, which may present preoperatively, intraoperatively, and postoperatively. Supportive measures include the administration of oxygen, endotracheal intubation, mechanical ventilation with positive end-expiratory pressure, and administration of furosemide.<sup>195-197</sup>

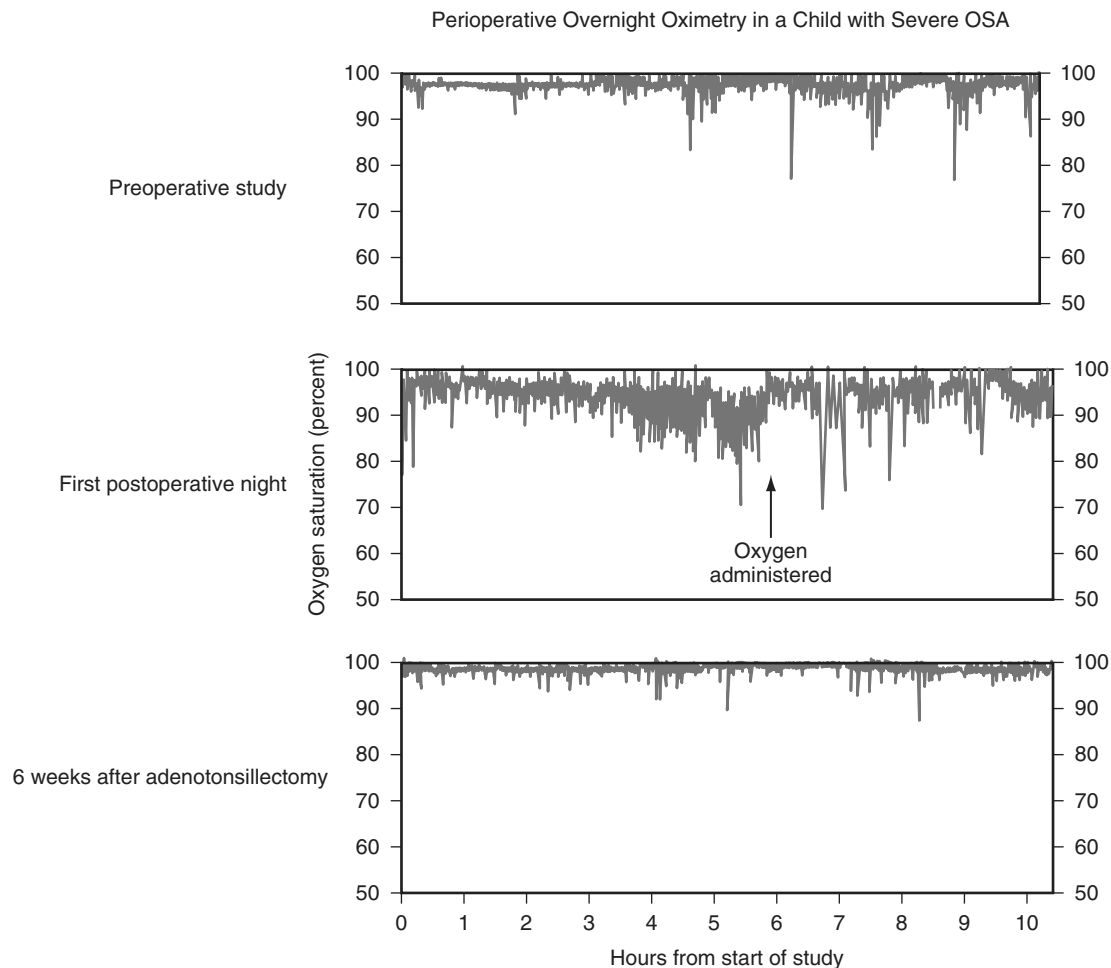

### DISCHARGE POLICY FOR AMBULATORY ADENOTONSILLECTOMY

Children younger than 3 years of age and those with complex medical disorders are not candidates for adenotonsillectomy as outpatients.<sup>38,198</sup> *Although children undergoing adenotonsillectomy for obstructive breathing without apnea may undergo ambulatory surgery, those with OSA should not.* A diagnosis of OSA increases the likelihood of respiratory complications after adenotonsillectomy from 1% in otherwise healthy children to 20% in those with OSA.<sup>37</sup>

The majority of children who are scheduled for adenotonsillectomy have symptoms of obstructive breathing,<sup>42,199,200</sup> yet only 55% with clinical criteria suggestive of OSA subsequently meet sleep laboratory criteria for OSA.<sup>201</sup> Sleep screening of children undergoing routine adenotonsillectomy for chronic tonsillitis revealed unexpectedly that 20% had severe obstructive episodes associated with desaturation.<sup>202</sup> Because only a minority of children undergoing adenotonsillectomy undergo diagnostic testing for sleep-disordered breathing, the recently published guidelines on management of OSA have empowered clinical diagnostic criteria, such that a child with severe symptoms must be assumed to have moderate to severe OSA until proven otherwise by sleep laboratory testing (see Fig. 31-4). Ambulatory programs may now find it cost effective to screen children with a positive clinical history.

In otherwise healthy children, conversion from ambulatory to inpatient status was most frequently prompted by respiratory events in children whose indication for surgery was obstructive breathing.<sup>42</sup> A systematic reduction in postoperative morphine use was associated with a reduced rate of hospital admission from 8% to 2.4%.<sup>55</sup> Same-day discharge, which abbreviates the

**FIGURE 31-10** Three oximetry trend records from an otherwise healthy child. The x-axis is time ranging from bedtime on the left to arousal the following morning on the right. The *top* panel is the preoperative record showing clusters of desaturation. The *middle* panel is the record from the first night after adenotonsillectomy. With sleep onset, a decrease in saturation is evident that worsens after midnight. Oxygen therapy is administered after midnight. The *bottom* panel is the recording 6 weeks after adenotonsillectomy, which is within normal limits. (From Nixon GM, Kermack AS, McGregor CD, et al. Sleep and breathing on the first night after adenotonsillectomy for obstructive sleep apnea. *Pediatr Pulmonol* 2005;39:332-8.)

postoperative stay in hospital and the minimum period of observation before discharge from hospital, has been the subject of much debate. Because the onset of respiratory complications in these children may be delayed,<sup>69,179,191</sup> a 6- to 8-hour period of observation for respiratory complications after adenotonsillectomy for OSA has been suggested. However, this extended period of observation does not preclude the delayed onset of sleep-related respiratory compromise after adenotonsillectomy. Table 31-5 presents common admission criteria for children undergoing elective tonsillectomy.

#### POST-TONSILLECTOMY BLEEDING

Post-tonsillectomy bleeding is a surgical emergency. This can occur either within the first 24 hours (primary) or 5 to 10 days after surgery when the eschar covering the tonsillar bed retracts (secondary). Approximately 75% of postoperative tonsillar bleeding occurs within 6 hours of surgery. Sixty-seven percent of cases of postoperative bleeding originate in the tonsillar fossa, 27% in the nasopharynx, and 7% in both.<sup>203</sup> Primary bleeding is typically more serious than secondary bleeding because it is usually more brisk and profuse. It is considered a surgical complication that is responsible for converting tonsillectomy from ambulatory surgery to a hospital admission in 1.6% of cases.<sup>42</sup>

**TABLE 31-5** Criteria for Overnight Admission after Tonsillectomy and Adenoidectomy

- Obstructive sleep apnea
- Sleep disturbance
- <3 years of age
- Craniofacial abnormalities (e.g., Down syndrome, Treacher Collins syndrome)
- Lives >1 hour away
- Lives in an unstable home environment that precludes adequate supervision
- Postoperative problems (e.g., fever, failure to take oral fluids, or continued vomiting)
- Possible or documented coagulopathy
- Extreme obesity

From Zalzal G: Personal communications, survey of major pediatric hospitals, 2006.

In a review of more than 9000 adenotonsillectomies in children performed with blunt and sharp (cold) dissection, the incidence of postoperative bleeding was 2.15%, with 76% of the hemorrhages occurring in the first 6 hours postoperatively.<sup>204</sup> The authors of an audit of 4800 pediatric tonsillectomies for which

hemostasis was secured with electrocautery (hot) techniques, reported a primary postoperative hemorrhage rate of 0.9%, with 83% presenting within 4 hours of surgery.<sup>55</sup> The consensus is that the period of observation for primary hemorrhage depends on the surgical technique: 6 hours and 4 hours, for cold and hot dissection, respectively,<sup>55,203,204</sup> although abbreviated periods of observation have been advocated by some.<sup>42</sup>

The management of anesthesia in this situation can be challenging even in the hands of an experienced pediatric anesthesiologist.<sup>205</sup> It often requires dealing with anxious parents, an upset surgeon, and a frightened anemic, hypovolemic child with a stomach full of blood. A thorough review of the anesthetic record of the original surgery will provide pertinent information about any existing medical condition, use of medications (such as aspirin), difficulty with airway management, and a rough estimate of intraoperative blood loss and fluid replacement, as well as the duration of known bleeding and the volume of blood vomited since the bleeding began. A quick history and examination of the child will provide vital information about the child's current volume status. A history of dizziness and the presence of orthostatic hypotension may suggest a loss of more than 20% of the circulating blood volume and the need for aggressive fluid resuscitation and crossmatch of blood before induction.<sup>206</sup> Even when severe hypotension is not present, the child with the bleeding tonsil is hypovolemic and has a decrease in cardiac output secondary to ongoing blood loss. If blood loss is severe, and/or fluid resuscitation is not vigorous, lactic acidosis and an eventual state of shock will develop. The compensatory response to acute blood loss is an outpouring of catecholamines. This causes peripheral vasoconstriction, which delays the clinical onset of hypotension in the awake child. When anesthesia-induced vasodilation occurs, profound hypotension may develop. Vigorous fluid resuscitation with crystalloids (repeated boluses of 20 mL/kg of balanced salt solution) and/or colloids is therefore the key to improve the cardiac output and achieve hemodynamic stability before induction of anesthesia. Hemoglobin or hematocrit determination should be interpreted in light of the child's volume status and the type of fluid resuscitation administered. If the hemoglobin concentration is low, blood may be required; however, blood is rarely the primary solution for volume replacement in these children. If severe hypovolemia is suspected or if there may be a delay in obtaining blood, blood should be crossmatched for two or more units of packed red blood cells before the child reaches the OR. If a child bleeds after the tonsillectomy, and a bleeding blood vessel is not identified, it may be necessary to measure the prothrombin time, partial thromboplastin time, platelet count, and a bleeding time to rule out a bleeding diathesis. It cannot be overemphasized that the child must be adequately volume resuscitated before proceeding to the OR.

A child who presents with a bleeding tonsil has a full stomach (filled with swallowed blood) and may still be hypovolemic. A child who is spitting bright red blood may quickly exsanguinate, but the bleeding may be temporarily controlled by compression of the carotid artery ipsilateral to the bleeding source. The anesthesiologist may have difficulty visualizing the larynx because of the bleeding tonsillar bed and clots in the pharynx. A styletted ETT, two sets of well-illuminated laryngoscope blades and handles, and two large-bore Yankauer-type suction tubes must be available before induction of anesthesia (see also Chapter 4 and Fig. 38-5). On arrival in the OR and application of routine monitors, the child should be preoxygenated while positioned in the left lateral position and head down to drain blood out of

**FIGURE 31-11** Preoxygenation with the patient in the lateral position to control post-tonsillectomy bleeding before induction of anesthesia.

the mouth (Fig. 31-11). The child is then turned supine, and a rapid-sequence induction is carried out with cricoid pressure (Sellick maneuver) applied by an assistant, to minimize the risk of aspirating blood into the lungs.<sup>207</sup> There is no evidence that a rapid-sequence induction with cricoid pressure decreases the risk of aspiration in children with full stomachs, although this practice is commonplace. It should also be recognized that aspiration of blood into the lungs is not synonymous with acid particulate aspiration, unless the volume of blood aspirated compromises pulmonary oxygenation. The use of a full induction dose of propofol in a hypovolemic child could result in significant hypotension. A reduced dose of these induction agents (e.g., propofol, 1 to 2 mg/kg), or ketamine (1 to 2 mg/kg) or etomidate (0.2 mg/kg) for induction followed by atropine (0.02 mg/kg) combined with succinylcholine (1.5 to 2 mg/kg) or rocuronium (1.2 mg/kg) for tracheal intubation should facilitate a rapid control of the airway without hypotension. However, the systolic blood pressure after induction of anesthesia will provide a direction indication of the volume status of the child.

When possible, a cuffed ETT (one-half size smaller than usual for age or weight) should be used to minimize the chance of aspirating blood. The use of a stylet is strongly recommended in spite of a previous history of easy intubation. Titration of an inhalational anesthetic, such as sevoflurane or desflurane with nitrous oxide and oxygen,<sup>97</sup> supplemented with an opioid, such as fentanyl, 1 to 2 µg/kg, will facilitate rapid recovery at the end of surgery.<sup>208</sup> Often these surgeries are not excessively painful because surgery is limited to the area of bleeding. Controlling the bleeding vessel in the tonsillar bed can be accomplished rapidly if the blood pressure is maintained in the normal range. Hence, these surgeries are often quite brief and the anesthetic should be planned accordingly. Suctioning the stomach with a large-bore catheter under direct vision after the procedure does not guarantee an empty stomach, because much of the blood may be clotted and the clots are often too large to be suctioned. The use of prophylactic antiemetic therapy (e.g., ondansetron 0.1 mg/kg) is indicated.

The most important postoperative consideration is to extubate these children when they are fully awake and able to control their airway reflexes. Extubating the trachea while the child is in the lateral position may be the safest practice to minimize the risk of aspiration. If there is a medical indication

to substitute high-dose rocuronium (1.2 mg/kg) for succinylcholine, then a prolonged period of relaxation may be anticipated. Sugammadex may allow early reversal of residual deep neuromuscular blockade with high-dose rocuronium, although at the time of this writing, sugammadex is neither approved for use in children nor available in the United States or Canada. Postoperatively, a repeat determination of the hemoglobin level may be indicated.

### PERITONSILLAR ABSCESS

Peritonsillar abscess (quinsy tonsil) occurs in older children and young adults. It is the most common deep neck-space infection treated by otolaryngologists. Infection originates in the tonsil and spreads to the peritonsillar space between the tonsillar capsule and the superior constrictor muscle, and usually into the soft palate in the region of the superior pole of the tonsil. Commonly cultured organisms include aerobes, such as *Streptococcus pyogenes*, *S. milleri*, *S. viridans*,  $\beta$ -hemolytic streptococci, *Haemophilus influenzae*, as well as anaerobes, such as *Fusobacterium* and *Prevotella* species.<sup>209</sup>

Clinically, these children present with fever, pharyngeal swelling, sore throat, dysphagia, odynophagia, and often trismus. Trismus is caused by compression of nerves by the tense peritonsillar mass, spasm of the pterygoid muscles, and inflammation of the muscles of the face and neck. Dehydration can ensue because of fever and the persistent difficulty with swallowing.

Preoperative evaluation includes careful assessment of the airway, with special emphasis on the degree of trismus. Blood specimens should be analyzed for total and differential white blood cell count to ascertain the response to the infection, and for cultures for appropriate antibiotic therapy. Computed tomography of the tonsillar area will identify airway deviation or compromise and the extent of spread of the abscess (Fig. 31-12).

While awaiting the results of the cultures, treatment should begin with establishing IV access, hydration, and appropriate antibiotic coverage. The majority of organisms, including anaerobes, are penicillin sensitive. Consequently, penicillin is usually the antibiotic of choice.<sup>209</sup> The three different procedures currently used to drain a peritonsillar abscess are needle aspiration, incision and drainage, and abscess tonsillectomy.<sup>210</sup> Most children undergo general anesthesia for treatment of peritonsillar abscess by incision and drainage, although in some centers, moderate to deep sedation has been successfully used.<sup>211</sup> If the abscess is small and well confined, immediate tonsillectomy is performed.

The anesthetic management of these children can be challenging. Rupture of the abscess and possible aspiration of purulent material during laryngoscopy and intubation should be avoided during induction of anesthesia. Although the airway may appear to be compromised, most peritonsillar abscesses are in a fixed location in the lateral pharynx and do not interfere with mask ventilation. Visualization of the vocal cords is usually not impaired, because the pathology is supraglottic and well above the laryngeal inlet, although a right-sided abscess may interfere with the usual sweeping of the tongue to the left during laryngoscopy. Laryngoscopy must be carefully approached to avoid excessive manipulation of the larynx and surrounding structures. Occasionally, the pharyngeal swelling and the distortion of normal anatomy, along with excessive secretions, may create difficulty for laryngoscopy and intubation. The OR should be prepared as for any difficult airway case, with different sizes of ETTs, stylets, two sets of well-illuminated laryngoscopes, a Glidescope or other device to facilitate difficult intubation, and a

**FIGURE 31-12** A, Peritonsillar abscess with trismus. B, Axial enhanced computed tomography scan through the oropharynx showing a 3-cm ring-shaped, enhancing, low-density mass (arrow) replacing the left tonsil, typical of a tonsillar abscess.

tonsil-tip suction catheter attached to a powerful suction device. The surgeon must be present in the OR during induction of anesthesia, should airway obstruction occur. Equipment for cricothyrotomy or tracheotomy must be readily available.

These children are often older and do not require preoperative sedation. If trismus is present, an inhalational induction should be performed, using sevoflurane and oxygen while the anesthesiologist assesses mobility of the temporomandibular joint under anesthesia. An oropharyngeal airway is best avoided, lest the abscess is traumatized. Usually, awake trismus resolves once an adequate depth of anesthesia has been achieved. When this is confirmed, or if there was minimal trismus to begin with, then a short-acting muscle relaxant (or propofol) should be given to facilitate tracheal intubation. Alternatively, if there is minimal trismus and the preoperative airway assessment indicates minimal distortion, a rapid-sequence IV induction after adequate preoxygenation may be the best way to avoid trauma to the pharyngeal structures while struggling with a mask induction, needing to insert an oropharyngeal airway, and possibly rupturing the abscess.<sup>2</sup>

To avoid aspiration of purulent material during intubation and drainage, a cuffed ETT is recommended and the child is

placed in Trendelenburg position. At the end of surgery, the child should be extubated awake, preferably in the lateral decubitus position.<sup>2</sup>

## Anesthesia for Endoscopy

Anesthesia for rigid bronchoscopy in young children presents a significant challenge. Not only does the child have a compromised airway, but we also must share it with the surgeon. The importance of constant communication between the endoscopist and the anesthesiologist cannot be overstated. In general, the goals of anesthesia for endoscopy are analgesia, an unconscious child, and a quiet surgical field.<sup>212</sup> Coughing, bucking, or straining during instrumentation with a rigid bronchoscope may cause difficulty for the surgeon and damage the child's airway. At the conclusion of the procedure, children should be returned to consciousness quickly with airway reflexes intact to protect the recently instrumented airway. General principles for the anesthetic management will be outlined first. Disease-specific requirements will be discussed under appropriate subheadings.

For most children, a pulse oximeter, blood pressure cuff, electrocardiogram, and precordial stethoscope are applied before induction. Continuous monitoring of ventilation by capnography is not always possible during bronchoscopy, particularly when the Hopkins optical telescope is in place for optimal viewing. Clinical observation of the chest wall movement and the use of a precordial stethoscope are useful. In many cases, intermittent capnography is possible when the bronchoscope is withdrawn by the surgeon. Although greater than normal CO<sub>2</sub> tensions are inevitable with intermittent ventilation, they are generally well tolerated in the presence of sevoflurane. In contrast, if halothane is used, ventricular arrhythmias may occur and should be treated by hyperventilation and deepening halothane anesthesia, or by substituting isoflurane or sevoflurane for halothane (see Chapter 6).<sup>213</sup> Hypoxia, on the other hand, is not well tolerated, and the procedure should be stopped while the child is oxygenated.

In many instances, endoscopists prefer that the child breathes spontaneously throughout the procedure. Inhalation induction by mask is accomplished with oxygen and an inhalational agent, usually sevoflurane. Nitrous oxide can be used initially, if tolerated, to speed the induction and then discontinued before the examination. Once a sufficient depth of anesthesia has been achieved, IV access is established and the depth of anesthesia is increased. Alternatively, in those children in whom IV access was established before anesthesia, anesthesia may be induced IV with a sleep-dose of propofol, followed by mask ventilation with a volatile agent.

An antisialagogue (atropine or glycopyrrolate) may be administered IV to decrease secretions that may impair the view through the bronchoscope. Topically treating the vocal cords and subglottic airway with local anesthetic decreases the incidence of coughing or bucking during instrumentation, and allows the child to tolerate a lighter level of anesthesia. Lidocaine, either 2% or 4%, is the most frequently used topical anesthetic. It may be applied to the vocal cords either by atomizer or sprayed with a 3-mL Luer-Lok syringe fitted with a 24-gauge IV catheter (without the needle). With constant pressure applied on the plunger, a fine stream of lidocaine is directed to the supraglottic structures and through the vocal cords to the tracheal mucosa. The dose of lidocaine should be limited to 3 to 4 mg/kg divided between the laryngeal and tracheal surfaces because rapid absorption via the

mucosa occurs. It is important to confirm whether the surgeon intends to observe for movement of the vocal cords or evaluate tracheal or bronchial dynamics so that the anesthetic may be planned accordingly (i.e., spontaneous respirations preserved during light levels of anesthesia versus no respiratory efforts and the use of short-acting muscle relaxants).

## DIAGNOSTIC LARYNGOSCOPY AND BRONCHOSCOPY

Although diagnostic laryngoscopy and bronchoscopy procedures are usually of brief duration, the anesthetic management can be challenging in small infants with an already compromised airway. Stridor, or noisy breathing due to obstructed airflow, is a common indication for a diagnostic laryngoscopy and bronchoscopy in infants and children. Inspiratory stridor results from UAO, expiratory stridor results from lower airway obstruction, and biphasic stridor is present with mid-tracheal lesions (see Chapters 11 and 12). Subglottic stenosis may follow prolonged tracheal intubation in an infant that was born preterm.

The evaluation of a child with stridor begins with taking a thorough history. The age at symptom onset helps suggest a cause; for instance, laryngotracheomalacia and vocal cord paralysis are usually present at or shortly after birth, whereas cysts or mass lesions develop later in life (Table 31-6). Information indicating positions that make the stridor better or worse should be obtained, because placing a child in a position that allows gravity to aid in reducing obstruction can be of benefit during induction.

Physical examination reveals the general condition of a child or infant, as well as the degree of the airway compromise. Laboratory examination may include a chest radiograph and barium swallow, which can aid in identifying lesions that may be compressing the trachea. Computed tomography, magnetic resonance imaging, and tomograms may be helpful in isolated instances but are not routinely indicated.

**TABLE 31-6 Causes of Stridor**

### Supraglottic Airway

Foreign body  
Infection (croup, epiglottitis)  
Hemangiomas

Laryngomalacia is the most common cause of stridor in infants and most often results from a long epiglottis that prolapses posteriorly and prominent arytenoid cartilages with redundant aryepiglottic folds that prolapse into the glottic opening during inspiration.<sup>214</sup> The definitive diagnosis is obtained by direct laryngoscopy and by rigid or flexible bronchoscopy.

Preliminary examination is usually carried out in the surgeon's office. A small flexible fiberoptic bronchoscope is inserted through the nares into the oropharynx. Nasal insertion provides an excellent view of the movement of the vocal cords and pharyngeal structures. Topically treating the nasopharynx with lidocaine facilitates passage of the nasal pharyngoscope or bronchoscope. Alternatively, the examination can be accomplished in the OR in a lightly anesthetized child during spontaneous respirations. Children must be spontaneously breathing so that the vocal cords move freely. After movement of the vocal cords is observed and recorded, the anesthetic level can be increased as appropriate, a rigid bronchoscope (or just the telescope in small infants) is inserted through the vocal cords, and the subglottic area, the lower trachea, and bronchi are evaluated.

The use of premedication in these children should be individualized. Small infants may be brought into the OR unpremedicated; older children may experience respiratory depression and worsening of airway obstruction if heavily premedicated.

Usually an inhalational induction with sevoflurane is performed. Nitrous oxide can be used initially, if tolerated, to speed the induction and then discontinued before the examination. Because sevoflurane is relatively insoluble and is rapidly eliminated, ventilation will be intermittently interrupted during the examination, and the Hopkins optical telescope prevents adequate ventilation through the smallest diameter bronchoscopes, supplementation with IV agents, such as propofol (1 mg/kg boluses or a 50- to 100- $\mu$ g/kg/min infusion), is necessary to maintain an appropriate depth of anesthesia. If an inhaled technique is used by insufflation, scavenging may be attempted by positioning a suction device near the child's mouth.

A propofol-based total intravenous anesthesia (TIVA) technique has the advantage that it can be given continuously during the procedure, resulting in a more stable level of anesthesia than can be achieved with inhalational agents and intermittent ventilation. Propofol can be supplemented with small (0.5 mg/kg) doses of ketamine to enhance analgesia. Opioids can also be used but will frequently induce apnea.

The key to a stress-free bronchoscopy is properly placed topical anesthesia. Although topically treating the laryngeal structures with local anesthetic helps the child tolerate the procedure, it may interfere with assessment of normal vocal cord movement. For that reason, a local anesthetic is often topically applied after initial evaluation of the upper airway and just before insertion of the bronchoscope for evaluation of the distal airway structures.

After completion of pharyngoscopy and/or laryngoscopy, the surgeon generally proceeds to rigid bronchoscopy. The size of a rigid bronchoscope refers to the internal diameter (ID). Because the external diameter may be significantly greater than that of an ETT of similar size, care must be taken to select a bronchoscope of proper external diameter, to avoid damage to the laryngeal structures (Table 31-7). The rigid bronchoscope can be used for ventilation through the side port attached to the anesthesia circuit with a flexible extension. It is often most useful to paralyze the child with a fixed lesion, which diminishes the risk of vocal

**TABLE 31-7 External Diameter of Standard Endotracheal Tube versus Rigid Bronchoscope**

Internal Diameter (mm)	EXTERNAL DIAMETER (mm)	
	Endotracheal Tube*	Rigid Bronchoscope <sup>†</sup>
2.0	2.9	
2.5	3.6	4.2

cord injury secondary to movement. For nonfixed lesions, such as an aspirated foreign body, and for assessment for bronchomalacia or tracheomalacia, it is preferable to proceed with spontaneous ventilation, a deep level of anesthesia, and good topical anesthesia of the vocal cords and carina. Adequate oxygenation should be maintained in these infants throughout the procedure. Because ventilation may be intermittent and at times suboptimal, it is recommended that 100% oxygen be used as the carrier gas during the bronchoscopic examination. During ventilation of the infant with the optical telescope in place, high resistance may be encountered as a result of partial occlusion of the lumen. This is especially likely when the 2.5-, 3.0-, and 3.5-mm ID scopes are used. Large fresh-gas flow rates, large tidal volumes with high inflation pressures, and large concentrations of inspired inhalational anesthetic (or TIVA) are often necessary to compensate for leaks around the ventilating bronchoscope and the high resistance encountered when the optical telescope is in place. Hand ventilation at greater than normal rates is most effective in achieving adequate ventilation. Sufficient time for exhalation must be provided for passive recoil of the chest. In small infants, there may be room for only the optical telescopic light source, which does not have a ventilation channel. In these cases, insufflation of oxygen via a small tube placed in the hypopharynx via the nose or mouth will delay the onset of desaturation in a spontaneously breathing child. If (when) desaturation occurs, the surgeon must stop and allow the child to be oxygenated before continuing with the examination.

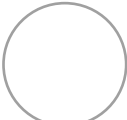

At the conclusion of bronchoscopy, the surgeon may wish to determine the size of the larynx and determine the degree of airway narrowing. An uncuffed ETT is inserted beyond the narrowest portion of the obstructed airway, and the airway is assessed by applying positive pressure between 10 and 25 cm H<sub>2</sub>O to the airway and listening with a stethoscope for an air leak around the ETT at the level of the suprasternal notch. The outer diameter of the appropriate ETT is compared with the inner diameter of the child's larynx and trachea, and the percentage of obstruction is calculated. Grade I obstruction involves up to 50% of the airway, grade II is from 51% to 70%, and grade III is greater than 70% (Fig. 31-13, B).<sup>215</sup>

An alternative method of ventilation during bronchoscopy is the Sanders jet ventilation technique. The principle of jet ventilation involves intermittent bursts of oxygen delivered at a maximum pressure of 50 psi from a hand-regulated

Percent Subglottic Stenosis by Endotracheal Tube Size (mm ID)

Age	ETT	2	2.5	3	3.5	4	4.5	5	5.5	6
Preterm (<1500 gm)	No detectable lumen	40								
Preterm (>1500 gm)			30

3-9 months		75		41	22					
9 months to 2 years		80			38	20				
2 years		84	74		50	35	19			
4 years		86	78			45	32	17		
6 years		89	81	73			43	30	16	
	Grade IV	Grade III			Grade II		Grade I			

Obstruction classification	From	To
Grade I	 No obstruction	 50% obstruction
Grade II	 51% obstruction	 70% obstruction
Grade III	 71% obstruction	 99% obstruction
Grade IV	No detectable lumen	

**FIGURE 31-13 A**, Method for estimating the percentage of airway obstruction. After easy passage of an uncuffed endotracheal tube (ETT), a manometer is placed at the connection of the elbow of the anesthesia circuit and the ETT. A stethoscope is placed over the larynx and the circuit is slowly pressurized. The pressure at which a leak is auscultated (10 to 25 cm H<sub>2</sub>O) is matched with the age of the child and the size of the ETT to estimate the percent of laryngeal narrowing shown in numbers in teal boxes. Clear boxes indicate the usual size ETT for child's age. Grade I, *light teal*, Grade II, *medium teal*, and Grade III, *dark teal*. **B**, Schematic representation of subglottic stenosis classification system. This chart is based on one institution's experience, and the manufacturer of the ETTs was not described, thus the actual external diameter of the ETTs used is unknown. ID, Internal diameter. (Reproduced and modified with permission from Myer CM III, O'Connor DM, Cotton RT. Proposed grading system for subglottic stenosis based on endotracheal tube sizes. *Ann Otol Laryngol* 1994;103:319-23.)

pressure-reducing valve to the lungs, through a 16-gauge catheter attached to a rigid bronchoscope.<sup>216</sup> Current jet ventilators include adjustable pressure-control valves that permit attenuation of the peak pressure, a desirable feature if this device is to be used in a child. Intermittent flow is accomplished by depressing the lever of an on-off valve. A jet of oxygen is released at the tip of the 16-gauge catheter, creating a Venturi effect that entrains room air into the bronchoscope. This jet of oxygen and room air

mixture allows inflation of the lungs to occur. Exhalation is passive and depends on the recoil of the chest wall. Although this technique is usually effective for both oxygenation and ventilation in experienced hands, a number of potential problems exist. Because of potentially high inflation pressure, pneumothorax, pneumomediastinum, and death can occur.<sup>217</sup> Blood or infectious or particulate matter in the airway may be forced distally by high-pressure bursts. There is also the possibility of

hypoxemia in some children, because the high-pressure oxygen entrains room air, diluting the oxygen.

High-frequency jet ventilation is also possible for upper airway endoscopy and laryngotracheal surgery. Obstruction to expiratory flow is a major concern and is dependent on good positioning of the rigid laryngoscope. Complications, such as barotrauma, pneumopericardium, CO<sub>2</sub> retention, necrotizing tracheobronchitis, and gastric rupture, dictate a fastidious technique.<sup>218</sup>

Dexamethasone in a dose of 0.5 mg/kg IV (maximum dose, 10 to 20 mg) is frequently administered during the procedure to decrease postoperative laryngeal swelling and the possibility of croup. At the conclusion of rigid bronchoscopy, an ETT can be placed in the trachea to control the airway during recovery from anesthesia or, if ventilation is adequate and the anesthetic depth is not excessive, the child can be allowed to emerge breathing 100% oxygen by a facemask.

## Upper Airway Obstruction

### LARYNGOTRACHEOBRONCHITIS (CROUP)

Croup is a symptom complex of inspiratory stridor; suprasternal, intercostal, and substernal retractions; barking cough; and hoarseness that results from swelling of the mucosa in the subglottic area of the larynx.<sup>2</sup> There are two common entities that account for most cases of croup: spasmodic croup, and laryngotracheobronchitis. Spasmodic croup has been diagnosed in about 3% of children with stridor.<sup>219</sup> The child is otherwise healthy and afebrile, presenting with nocturnal episodes of spasmodic cough, which is described as barking and high pitched. The disease is self-limiting. Besides viruses, allergic and psychological factors are blamed for this acute phenomenon. It differs from acute laryngotracheitis in that it is considered an allergic reaction to viral antigens rather than a true infection with the viruses.<sup>220</sup> Besides lack of fever, spasmodic croup is usually remarkable for lack of severe laryngeal inflammation, and, in general, supportive therapy on an outpatient basis is all that is required.

Viral laryngotracheitis is by far the most common form of infectious croup. The disease has a gradual onset, usually after a URI in a young child. Low-grade fever is common. Children who have more than two episodes of croup requiring hospitalization should be evaluated for subglottic narrowing from stenosis or cysts. Clinical scoring systems based on objective criteria are helpful in following the progress of the disease and in judging the effectiveness of therapy (Table 31-8).<sup>221</sup>

Anteroposterior radiographs of the neck will confirm the diagnosis and rule out acute epiglottitis or the possibility of a foreign body in the airway (Table 31-9).<sup>222</sup> The viral infection affects the subglottic region of the larynx, causing edema. The characteristic radiograph of croup, therefore, includes blurring of the tracheal air shadow on lateral neck films, and symmetrical narrowing of the subglottic air shadow, described as “church steeple” or “sharpened pencil” sign on anteroposterior films (Fig. 31-14 and E-Fig 31-3). The lateral neck radiographs show normal supraglottic structures and normal epiglottic shadow.

The majority of cases will resolve quickly with simple conservative measures, such as breathing humidified air or oxygen. Less than 10% of cases require hospitalization because of significant respiratory difficulty, and fewer still require an artificial airway.<sup>214</sup> Humidification of inspired gases is usually effective in improving respiratory distress, and it prevents drying of secretions, although despite the popularity of cool mist therapy, it is

**TABLE 31-8 Clinical Croup Score**

	0	1	2
<b>Inspiratory Breath Sounds</b>	Normal	Harsh with rhonchi	Delayed
<b>Stridor</b>	None	Inspiratory	Inspiratory/expiratory

\*Foreign bodies in the airway should also be considered.

**E-FIGURE 31-3** Additional view of normal upper airway (*left*) and a child with laryngotracheobronchitis and the "steeple" or "sharpened pencil" sign (*right*) (see Fig. 31-14).

**FIGURE 31-14** **A**, Radiograph of the normal upper airway (anteroposterior view). Note that the subglottic area is rounded. **B**, Laryngotracheobronchitis (croup) produces swelling (edema and inflammation), which obliterates the normal rounded subglottic area, producing the so-called sharpened pencil or steeple sign. **C**, Schematic representation showing progressive swelling of the subglottic area. For an additional view, see E-Figure 31-3.

not evidence-based practice.<sup>223</sup> Oxygen is obviously essential to prevent or to treat hypoxemia, which may result from ventilation-perfusion mismatching caused by accumulation of secretions. Hydration prevents thickening of tracheal secretions.

Racemic epinephrine is the most effective drug therapy for these children, although L-epinephrine has also been effective. Racemic epinephrine is available as a 2.25% solution, which is diluted in water or saline, and administered either by intermittent positive-pressure ventilation via a face-mask or nebulization.<sup>224</sup> Nebulized racemic epinephrine is administered in cases of mild-to-moderate obstruction. The solution is prepared by diluting a volume of 2.25% racemic epinephrine in 2 mL of saline or sterile water according to the child's weight in kilograms (i.e., 0.25 mL of racemic epinephrine for 0 to 20 kg, 0.5 mL for 20 to 40 kg and 0.75 mL for greater than 40 kg).<sup>225</sup> Because the duration of action of racemic epinephrine is brief, rebound edema may occur. Treatments are required every 1 to 2 hours, and the child should be observed for at least 2 hours after treatment. For L-epinephrine, the volume of a 1% solution is the same as that for racemic epinephrine.

If treatment with racemic epinephrine is unsuccessful, in addition to edema, the underlying problem may be obstruction caused by thick, inspissated secretions possibly related to bacterial superinfection, such as bacterial tracheitis.<sup>226,227</sup> In this situation, or if the child appears exhausted from the increased work of breathing, relief of the obstruction must be obtained through endotracheal intubation, followed by pulmonary suctioning. The clinical assessment of "exhaustion" in children with croup may be difficult. An alternative approach is to consider intubating the tracheas of those children who have arterial oxygen saturation less than 90% when breathing air, despite nebulized epinephrine and steroid treatment. Laryngotracheobronchitis is also a disease of the lower airways. An inability to clear secretions contributes to atelectasis and arterial oxygen desaturation. Intubation is often required to allow suctioning of the copious yellow secretions.

One large series (512 consecutive admissions in a single year) reported that approximately 6% of children who had sternal and chest retractions on admission and failed to respond to conventional medical therapy required endotracheal intubation.<sup>228</sup> Intubation should be performed in the OR under controlled anesthetic conditions, as for a child with severe epiglottitis. The tracheal tube selected should be at least one-half size smaller (0.5 mm ID) than would normally be chosen, to avoid aggravating the subglottic edema and possibly causing subglottic stenosis.<sup>229-231</sup> Children whose airways have been intubated are admitted to the ICU, and special care is provided for suctioning of inspissated secretions. The tracheal tube usually remains in place for 3 to 5 days.

Corticosteroid therapy for laryngotracheobronchitis has become the standard of care.<sup>232</sup> Single-dose corticosteroid therapy appears safe and effective,<sup>233</sup> although large studies of the risk of progression of viral infection or the development of secondary bacterial infections in moderate to severe laryngotracheobronchitis are lacking; reports suggest that IV dexamethasone (0.5 to 1 mg/kg) may be effective.<sup>234</sup> There is evidence that there is rapid clinical improvement 12 and 24 hours after steroid treatment, which significantly reduces the incidence of endotracheal intubation.<sup>235-237</sup> Antibiotics are generally not indicated in the treatment of uncomplicated viral croup.

The child is usually ready for extubation within 2 to 4 days. Criteria to consider include abatement of fever, diminished tracheal secretions, change in the character of secretions to a thin and watery type, and an audible air leak that develops around the nasotracheal tube as the edema subsides.

#### ACUTE EPIGLOTTITIS

Although rarely seen today, acute epiglottitis can be fatal because it can produce seemingly unprovoked sudden and complete airway obstruction. It is a clinical and pathologic entity that should more correctly be termed supraglottitis,

because the arytenoids and aryepiglottic folds, as well as the epiglottis itself, are usually affected. All supraglottic structures become swollen and stiffened by inflammatory edema. Although the main focus of infection is the oropharynx, the disease produces a generalized toxemia. Epiglottitis is most common between the ages of 3 and 5 years, but it can occur in any age; historically, the causative organism was typically *Haemophilus influenzae* type B.<sup>2,238-240</sup> However, with the widespread use of *H. influenzae* vaccination, the incidence of epiglottitis in children has all but disappeared in medically advantaged countries.<sup>241,242</sup> *Streptococcus*,<sup>243</sup> *Staphylococcus*,<sup>244</sup> *Candida*,<sup>245</sup> and other fungal pathogens<sup>246</sup> have become more frequent causes of this now rare disorder in children, although the incidence in adults has not diminished substantially.<sup>247</sup> It should be noted that vaccine failures may occur or parents may refuse proper immunizations of their child, resulting in susceptibility to *H. influenzae* type B infection.<sup>248,249</sup> Epiglottitis has become more of a disease of adults.<sup>250</sup>

The onset is usually abrupt, with a brief history of high fever, severe sore throat, and difficulty in swallowing. Stridor, if present, is usually inspiratory, and because the subglottic structures are usually unaffected, there is little or no hoarseness. An expiratory snore, rather than inspiratory stridor can often be heard. The child appears toxic, and, in an attempt to improve airflow past the swollen epiglottis, assumes the sitting position, leaning forward in the sniffing position (E-Fig. 31-4). The mouth is open, with the tongue protruding. The child frequently drools because of difficulty and pain on swallowing. The mnemonic *SNORED* is often useful for diagnosis: Septic, *NO* cough, Rapid onset, Expiratory snore, Drool.

In addition to high fever, other signs of generalized toxemia may include tachycardia, a flushed face, and prostration. The respiratory pattern is usually slow and quiet to allow more comfortable breathing.

Acute epiglottitis is a clinical diagnosis. It must remain prominent in the differential diagnosis of a child presenting with signs and symptoms of UAO. However, in some early cases, the clinical presentation alone may be inconclusive. If so, a lateral radiograph of the neck will usually demonstrate a swollen epiglottis and aryepiglottic folds (Fig. 31-15 and E-Fig 31-5). The vallecula may be obliterated, but subglottic structures are usually clear. A physician capable of establishing an airway should always be in the child's attendance (especially if in a remote area of the hospital, such as Radiology), because total airway obstruction can develop during the radiologic examination, especially if the child is forced to lie supine. This is one reason why the use of lateral neck radiographs in the differential diagnosis of UAO is avoided. Examination of the pharynx and larynx should only be attempted in an area with adequate equipment and staff prepared to intervene should UAO develop; ideally, the OR. The safest, most conservative approach to the management of acute epiglottitis is to establish an artificial airway as soon as the diagnosis is made, and then, with the airway secured, to proceed with appropriate antibiotic and supportive therapy. The child should remain in the sitting position at all times and never forced into the supine position. No attempts to examine the larynx should be made in the emergency room.<sup>2</sup>

These children should not be premedicated. Instead they should be brought to the OR calm and undisturbed. If it takes the presence of a parent to achieve this, then that is what should be done. In the OR, with equipment and personnel who can insert a surgical airway immediately present, a precordial

stethoscope, pulse oximeter, and other standard monitors are applied. General anesthesia is induced with oxygen and sevoflurane with the child still sitting up. Spontaneous respiration is continued as the child is gently allowed to recline. If the child is moribund, then an awake intubation should be considered.

When a surgical stage of anesthesia is achieved, IV access is established and secured. A large fluid bolus of balanced salt solution is infused (20 to 30 mL/kg) because these children are often dehydrated and will require a deep plane of anesthesia to permit tracheal intubation while spontaneous respirations are preserved. Some anesthesiologists would also administer an antisialagogue to reduce secretions. Epiglottitis is marked by progressive swelling of the lingual surface of the epiglottis with resultant obliteration of the vallecula (see Fig. 31-15). Viewing the glottic opening without traumatizing the epiglottis may usually be accomplished by forcing the tip of the laryngoscope blade along the center of the base of the tongue into the vallecula, where the vallecula has been obliterated by the swollen lingual surface of the epiglottis (see Fig. 31-15, C). Lifting the base of the tongue, without directly touching the epiglottis, can then expose the glottis. A stylet within the ETT may be helpful because it provides increased rigidity to facilitate introduction through a partially obstructed glottic aperture. The size of the ETT should be one-half size smaller (0.5 mm ID) than otherwise selected for the same age child. By choosing an ETT with a smaller ID than usual, one also lessens the risks of pressure necrosis on the mucosa. Figure 31-16 illustrates a case of severe epiglottitis (before [A] and after [B] the airway was secured). A styletted orotracheal tube is inserted first, and may be replaced by a nasotracheal tube of appropriate size. However, if the glottic opening was difficult to visualize, then no attempt should be made to replace the oral tube with a nasal one. The orotracheal tube may displace supraglottic edema, improving the view of the glottic opening and facilitating placement of the nasotracheal tube. An air leak at 20 to 25 cm of H<sub>2</sub>O, when present, confirms the selection of an appropriate size tube. Because the airway obstruction in epiglottitis is supraglottic, not subglottic, the nasotracheal tube size is often the usual size or one-half size smaller for the child's age. A larger tube is not necessary and may contribute to the possible development of serious laryngeal complications, such as subglottic stenosis. The child should be able to breathe around the tube, as well as through it. If the anesthesiologist is unable to intubate the trachea, then a rigid bronchoscope should be used. If both of those maneuvers fail, then a tracheostomy or cricothyrotomy should be performed (see Fig. 12-25).<sup>251,252</sup>

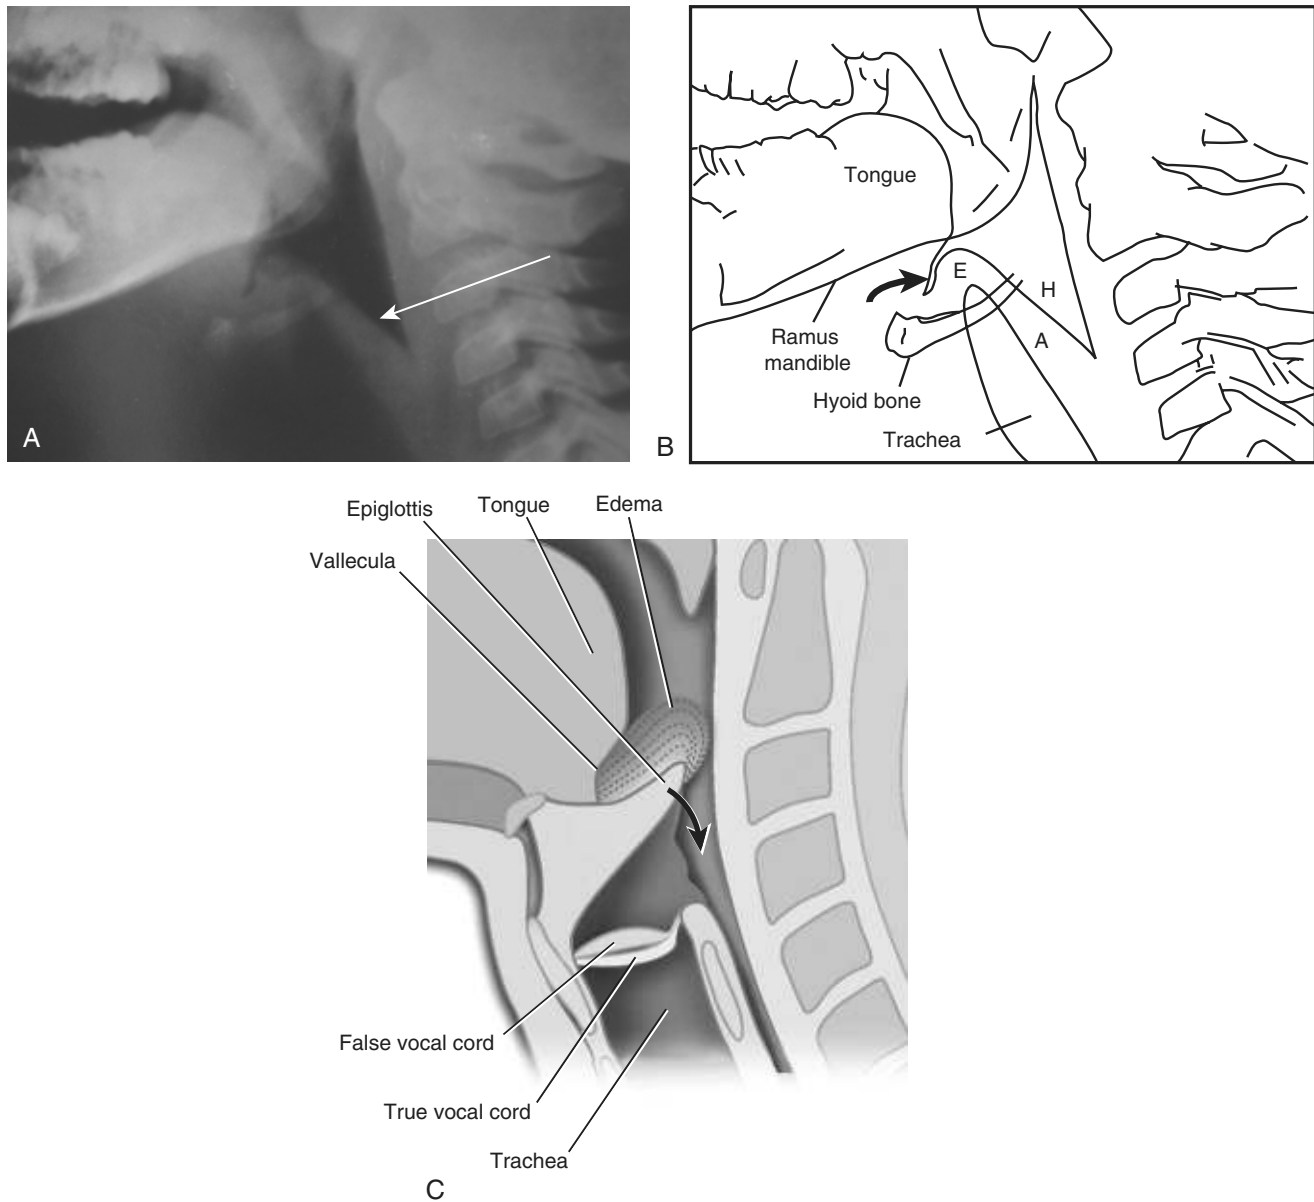

Once the airway is secured, a culture of the pharynx and blood cultures are obtained, and aggressive medical therapy beginning with antibiotics should be commenced. It is recommended that cephalosporins (such as ceftriaxone 50 mg/kg/day)<sup>253-255</sup> be used initially for antibiotic therapy, with the first dose immediately after the diagnosis is made and appropriate cultures taken.<sup>2</sup> The duration of the treatment is controversial, but at least 3 to 5 days of IV antibiotics followed by oral therapy is usually the minimum. Steroids are not indicated. Supportive measures include IV hydration, airway care, sedation as necessary, and acetaminophen for fever. Negative-pressure pulmonary edema can develop after tracheal intubation in children with severe epiglottitis.<sup>195</sup> When the child resumes swallowing and the fever abates, usually 24 to 48 hours after initiation of therapy, the acute supraglottic edema should be resolving and the child may be prepared for tracheal extubation.

**E-FIGURE 31-4** Clinical appearance of a child with epiglottitis; this child is sitting upright, leaning forward, and drooling.

**E-FIGURE 31-5** Additional view of child with epiglottitis. Arrow points to the swollen epiglottis, known as the "thumb sign" (see Fig. 31-15).

**FIGURE 31-15** **A**, Lateral neck radiograph of child with epiglottitis. Note the marked thickening of the aryepiglottic folds (*arrow*). **B**, Schematic representation of **A**. Note the marked thickening of the aryepiglottic folds (*A*), loss ("amputation") of the vallecula (*curved arrow*), swelling of the epiglottis (*E*), and distention of the hypopharynx (*H*). **C**, Schematic representation of epiglottitis demonstrating progressive swelling of the lingual surface of the epiglottis, resulting in "amputation" of the vallecula. Progressive swelling leads to trapdoor-like occlusion of the glottic opening (*curved arrow*). For additional views, see E-Figure 31-5.

### OBSTRUCTIVE LARYNGEAL PAPILLOMATOSIS

Recurrent respiratory papillomatosis, also known as juvenile laryngeal papillomatosis, is the most commonly found tumor in the larynx and upper airway in children. Recurrent respiratory papillomatosis is caused by the human papilloma virus (HPV). The incidence is only 1 in 400 births, even though active or latent viral infection is present in 10% to 25% of pregnant women.<sup>256</sup> This disease is caused by HPV 6 and 11; the incidence may markedly decrease in the future, with the introduction of a maternal vaccine to prevent HPV infection for types 6, 11, 16, and 18.<sup>257-260</sup> The papillomas are usually found in the larynx on the vocal cord margins, epiglottis, pharynx, or trachea (Fig. 31-17). If left untreated, symptoms of aphonia, respiratory distress, hoarseness, stridor, right ventricular hypertrophy, and cor pulmonale may occur.

The current treatment is primarily surgical removal of the papillomatous tissue using the CO<sub>2</sub> laser under microscopic visualization. Alternatively, papillomas can be surgically debulked using an ultrasonic microdebrider or cup forceps before laser treatment. Topical application of mitomycin C (usually in combination with debulking procedures) has also been shown to be effective in suppressing these tumors. Nonsurgical treatment using interferon alfa-n1 has been beneficial in some children.<sup>261</sup> The main goal of the treatments is to reduce the bulk of the lesion without scarring and permanent damage to the underlying mucosa.

Because of the recurrent nature of this condition, most children will return frequently for treatment. Many may require monthly scheduled visits to the OR to prevent recurring

**FIGURE 31-16** Acute epiglottitis. **A**, The entire upper airway is inflamed and there is marked swelling of the epiglottis. **B**, Photograph taken after securing the airway with an endotracheal tube.

**FIGURE 31-17** Large pedunculated papillomas obstructing the laryngeal inlet.

obstruction. If some of these scheduled sessions are missed, or if the progress of the disease is accelerated, the child will present with an acute exacerbation of obstructive symptoms requiring emergent endoscopic resection. In all cases, it is important to obtain a careful history, including inquiry about changes in voice or increased difficulty breathing during daily activities, that may indicate progressive airway obstruction.

Because of frequent hospitalizations, these children become psychologically sensitized to the perioperative experience. Pre-medication is usually avoided if the degree of airway obstruction is significant and there are concerns about compromising spontaneous ventilation. In selected cases, when the children are extremely anxious and/or upset, the parents (or a child-life surrogate) may accompany the child to the OR for induction, to provide emotional support.

The perioperative care can be very challenging and often depends on the degree of obstruction to airflow and the type and location of the papillomas.<sup>262</sup> Pedunculated papillomas can produce complete ball-valve obstruction of the upper airway in certain positions. It is therefore prudent to avoid paralysis and to maintain spontaneous respirations until the airway is examined and the anesthesiologist is certain that assisted or controlled ventilation is possible. These children must be approached and monitored in the same manner as any child with anticipated severe airway obstruction (e.g., acute epiglottitis). The surgeon must be present in the OR when anesthesia is induced, with equipment immediately available to deal with complete airway obstruction, including rigid bronchoscopes and a tracheostomy-cricothyrotomy set. The problem of sharing the already compromised airway with the surgeon is worsened by the need to use a laser to excise these lesions. A laser (an acronym for *light amplified by stimulated emission of radiation*) consists of a tube with reflective mirrors at either end with an amplifying medium between them to generate electron activity in the form of light. The CO<sub>2</sub> laser is the most widely used in medical practice, having particular application in the treatment of laryngeal or vocal cord papillomas, laryngeal webs, and resection of subglottic tissue and hemangiomas. A laser is useful for endoscopic procedures because the beam may be directed down open-tube endoscopes and is invisible, thereby affording the surgeon an unobstructed view of the lesion during resection. Laser energy is absorbed by tissue water, rapidly increasing its temperature, denaturing protein, and causing vaporization of the target tissue. The thermal energy produced by the laser beam cauterizes capillaries as it vaporizes tissues; therefore, bleeding is minimal and very little postoperative edema occurs.

These properties give the laser a high degree of specificity; however, they also provide the route by which a misdirected laser beam may cause injury to a child or to unprotected OR personnel.<sup>263</sup> Laser radiation increases the temperature of absorbent material; therefore, flammable objects, such as surgical drapes, must be kept away from the path of the laser beam. Unprotected surfaces, such as skin, can be burned and must be shielded. Wet towels should be applied to cover the skin of the face and neck when the laser is being used to avoid burns from deflected beams.

The anesthetic management of these children depends on the approach the surgeon will use to remove the lesions. The basic choice is between intubation and nonintubation techniques. For the latter approach, the choice is between intermittent apnea versus jet ventilation.<sup>217</sup> The ETT used during laser surgery can affect the safety of the technique. All standard polyvinylchloride ETTs are flammable and can be ignited and vaporized by a laser beam. Although red rubber ETTs do not vaporize, they deflect the laser beam when wrapped with metallic tape. The metallic tape can only be applied along the stem of the tube down to the cuff. As a result, the laser may damage the tube below the vocal cords. Alternatively, nonlatex ETTs are manufactured specifically for use during laser surgery. Some have a double cuff to protect the airway in the event the outer cuff is damaged by the laser

beam. Others have a special matte finish that is effective in deflecting the laser beam along its entire length. Nonreflective flexible metal ETTs and specifically wrapped ETTs are also specifically manufactured for use during laser surgery (Fig. 31-18). The outer diameters of these special tubes are considerably larger than the polyvinylchloride counterpart, especially in the small sizes. Thus they may not be appropriate for use in very small infants or children with a severely narrowed airway. Table 31-10

**FIGURE 31-18** Cuffed and uncuffed red rubber endotracheal tubes may be wrapped with reflective metallic tape for use during laser airway surgery. Note that this metallic tape is not approved by the Food and Drug Administration for this application. **A**, Cuffed and uncuffed commercially available foil-wrapped laser tubes are available (Laser-Shield II, Medtronic Xomed, Jacksonville, Fla.). **B**, An example of several commercially available stainless steel laser endotracheal tubes (V. Mueller Stainless Co., Chicago). Note that the external diameters of these devices are greater than those of standard endotracheal tubes.

presents a variety of such specialized tubes compared with standard ETTs. Although these ETTs offer some advantage, they are considerably more expensive than metallic-tape-wrapped red rubber ETTs. A syringe or a bag (500 or 1000 mL) of normal saline should be immediately available to douse ignited tissues in the event of an airway fire.

Once the airway is secured, one anesthetic approach is to use intermittent apnea with paralysis, TIVA, and topical lidocaine. An antisialagogue, such as glycopyrrolate, is often given at the beginning of the anesthesia, together with dexamethasone (0.5 mg/kg [maximum dose 10 to 20 mg]) to reduce mucosal swelling resulting from repeated intubations; this dose of dexamethasone however is empiric and not evidence based. Anesthesia is typically induced with oxygen and sevoflurane while the anesthesiologist gradually assists respiration as the depth of anesthesia increases. Once IV access is established, the anesthesia is deepened further and the larynx is anesthetized with topical lidocaine (3 to 4 mg/kg). The airway is then evaluated and tracheal intubation is performed. The ETT chosen is usually several sizes smaller than what is normally appropriate for the child's age, because most of these children have some degree of laryngeal scarring from repeated resections, and there is the need to prevent the ETT from obscuring the surgeon's view and interfering with access to the lesions.

Although the goal is to achieve the desired depth of anesthesia to secure the airway with the child still spontaneously breathing, partial obstruction is frequently encountered before an adequate depth of anesthesia for laryngoscopy is achieved. In these cases, thrusting the jaw forward and applying positive pressure in the anesthetic circuit will maintain an open airway in most situations (see Chapter 4). If complete obstruction is encountered, then a single IV bolus of propofol (2 to 3 mg/kg) or a short-acting muscle relaxant may be necessary for immediate laryngoscopy and intubation, or to allow the surgeon to perform rigid bronchoscopy.

Once the correct position of the ETT is confirmed, a neuromuscular blocking agent (e.g., rocuronium) can be administered and the TIVA technique with propofol (200 to 300 µg/kg/min) and fentanyl (2 to 3 µg/kg) or remifentanyl infusion (0.1 to 0.25 µg/kg/min or more, as needed) is started. Muscle relaxation is desirable to produce an immobile surgical field. A neuromuscular blockade monitor should be used to assess the degree of relaxation.

An apneic anesthetic technique without an ETT offers the best unobstructed view of the larynx and avoids the presence of flammable material (e.g., the ETT) in the path of the laser beam. The child is positioned for suspension laryngoscopy with eyes protected with moist eye pads, and the otomicroscope and CO<sub>2</sub> laser equipment are aligned. The ETT is then removed and surgical resection is carried out during repeated periods of apnea. The need for reintubation is guided by the adequacy of oxygenation as reflected by the pulse oximeter. Reintubation can be readily performed by the surgeon by introducing the tracheal tube through the suspension laryngoscope under direct vision. After each reintubation, the lungs are ventilated manually to restore both the oxygen saturation and end-tidal CO<sub>2</sub> to baseline. When those baselines are reached and surgery can resume, the trachea is extubated. This process is repeated until the surgery is complete.<sup>2</sup>

A modification of the apneic technique that avoids tracheal intubation is the jet ventilator. The operating laryngoscope may be fitted with a catheter through which O<sub>2</sub> flows, entraining ambient air. In this manner, the lungs are intermittently inflated by the pressure delivered by the jet. The advantage of this technique is twofold. The surgical field is extremely quiet because large excursions of the diaphragm are eliminated and ventilation is uninterrupted. However, transtracheal jet ventilation carries a greater risk of pneumothorax in children than the transglottic approach.<sup>217</sup> In the past, tension pneumothorax and pneumomediastinum occurred because of excessive peak inspiratory pressures during jetting. Maximum peak inspiratory jet pressures of approximately 15 mm Hg have reduced this risk dramatically. In morbidly obese children and those with severe disease of the small airways, effective ventilation may be difficult with this technique, and an alternate approach should be used.<sup>264</sup> In addition, jet ventilation may theoretically distribute papilloma virus throughout the tracheobronchial tree, although this technique continues to be used.

When surgery is completed, the ETT is reinserted and secured until the child is completely awakened. Postoperative measures to prevent laryngeal edema, such as racemic epinephrine inhalation and/or the use of dexamethasone, are usually indicated.

### ASPIRATED FOREIGN BODIES

Curious young children can push many loose objects into almost any orifice in their body. Objects inserted in the nose or ear are usually benign in nature and simple to remove once the child is anesthetized. Small button-sized battery foreign bodies require urgent removal because of their potential for extensive local damage.<sup>265</sup> Impacted, or displaced objects present greater challenges for the anesthesiologist and endoscopist, and the danger of misplacement into the respiratory tract must always be considered.<sup>266</sup>

Tracheobronchial foreign-body aspiration is most common in toddlers 1 to 3 years of age. The majority (95%) of foreign bodies lodge in the right main-stem bronchus.<sup>267</sup> A history of choking while eating or playing, persistent cough, or wheezing that does not respond to medical treatment may be the only manifestations. If the foreign body completely obstructs a bronchus, or creates a ball-valve phenomenon, distal hyperinflation from air trapping may occur; a hyperinflated lung during the expiratory phase may be the only indication of an aspirated foreign body on chest radiography (Fig. 31-19). The more distal the object is lodged in the airway, the more atelectatic changes are noted.

Foreign bodies lodge in the trachea (less than 5% of airway foreign bodies) if they are too large to pass the carina.<sup>268</sup> The signs of a tracheal foreign body may include a brassy cough with or without abnormal voice, bidirectional stridor, or complete airway obstruction in the case of laryngeal foreign bodies. Any sharp object, or any object that causes acute UAO with cyanosis and an inability to maintain ventilation, requires emergent removal. Unroasted peanuts (with unsaturated double bonds in the oils) should be removed promptly, because the oil can cause an inflammatory response and subsequent pneumonitis (Fig. 31-20).<sup>269</sup> In contrast, roasted peanuts (with saturated double bonds in the oils) may be present in the lungs for greater periods without inducing as severe an inflammatory response. In addition, peanuts tend to swell, fragment, and crumble over time, making removal “en bloc” extremely difficult. The child who presents with a history of cyanosis after aspiration of a nut, very likely has aspirated material into the trachea or into the lungs bilaterally (as in the case of a broken nut or multiple nuts) and should be assessed emergently. It should be noted that esophageal foreign bodies may compress the trachea as well (Fig. 31-21).

The anesthetic management of these children depends on the level, degree, and duration of obstruction. A child who aspirates a foreign body while eating, or soon thereafter, presents with the additional risk of a full stomach. Waiting for the stomach to empty may not be appropriate or even effective in the acute situation. IV metoclopramide (0.15 mg/kg) may be used to hasten stomach emptying but does not guarantee that the stomach empties.<sup>270</sup> If time permits, the administration of an anticholinergic agent may be useful to reduce secretions. In the debate of how best to anesthetize a child with a full stomach and a compromised airway from an aspirated foreign body, concern for the airway takes precedence over the full stomach and an inhalational induction is recommended.

One of the major controversies in the anesthetic management of foreign body aspiration is whether to control ventilation or allow spontaneous respirations during bronchoscopy. Some endoscopists prefer a spontaneously breathing child, to prevent movement of the foreign body as it is being retrieved out of the airway. Sevoflurane is the preferred inhalational anesthetic in these children because it maintains spontaneous respirations, does not trigger upper airway reflex responses, and maintains hemodynamic stability.<sup>271</sup> Anesthesia is usually maintained with 100% oxygen and sevoflurane, or a propofol-based TIVA technique.<sup>2</sup> Halothane has some advantages over sevoflurane during maintenance because it is more soluble and more slowly eliminated, which allows more time to manipulate the airway without the child recovering from the anesthetic and reacting to the procedure. Alternatively, a propofol TIVA technique allows a steady level of anesthesia that is independent of ventilation and does not expose the OR personnel to waste anesthetic agents that inevitably egress from the airway around the bronchoscope. In some cases, a combined approach of sevoflurane in oxygen, as well as IV propofol, may be used. Often these children have very irritable airways because of the presence of the foreign body. The use of topical lidocaine (3 to 4 mg/kg) divided between the laryngeal structures and tracheal mucosa may be used to suppress airway reflexes and prevent coughing and bronchospasm.

### Tracheostomy

Tracheostomy in infants and children is usually performed electively, as a planned procedure after an airway has already been

**FIGURE 31-19** **A**, Expiratory radiograph of the chest demonstrates marked right-sided hyperinflation because of air trapping by the ball-valve effect of the foreign body. Chest radiograph may appear normal during inspiration after foreign body aspiration. A hyperinflated right lung (**B**) and a leftward mediastinal shift during expiration (**C**) suggest a foreign body in the right main-stem bronchus. (Radiographs courtesy Sjirk J. Westra, MD, Division of Pediatric Radiology, Massachusetts General Hospital.)

**FIGURE 31-20** A classic peanut in the bronchus. Note the irritation caused by the oil of the peanut.

established with an ETT. Indications for a planned tracheostomy include lesions, such as congenital or acquired vocal cord paralysis, central hypoventilation syndrome (Ondine curse), craniofacial abnormalities (e.g., Pierre Robin malformation), persistent laryngotracheomalacia, and congenital or acquired subglottic stenosis (see Fig. 36-3). Usually these children have had a period of watchful waiting, with the hope of avoiding tracheostomy. However, persistent hypoxemia, hypercarbia, or intermittent obstruction that cannot be eliminated with the natural airway, or failed extubation will force the need to secure the airway via a tracheostomy. Children from intensive care sometimes require tracheostomy for long-term ventilation or secretion management. Still other children have acute deteriorations of the airway and require tracheostomy on an emergent basis.

In either case, the surgeon will frequently want to perform a thorough examination of the airway (i.e., diagnostic laryngoscopy and bronchoscopy) before proceeding with the tracheostomy. This requires that the tracheal tube be removed, the airway examined with a rigid bronchoscope, and then the child reintubated for the procedure. After the diagnostic laryngoscopy

**FIGURE 31-21** Anteroposterior (A) and lateral (B) neck radiographs of a child who swallowed two coins. Note tracheal compression caused by these foreign bodies in the esophagus (arrow).

and bronchoscopy and reintubation, the child is positioned supine, with the head maximally extended over a shoulder roll, and the head taped to the end of the bed. It is a good practice to have a separate clean anesthesia circuit, or an extension, to hand to the surgeon to connect to the freshly inserted tracheostomy cannula.

Anesthesia is maintained with spontaneous respirations of inhalational agents so that, if there is airway compromise at any point, the child may still be able to maintain oxygenation. One hundred percent oxygen should be administered throughout the procedure, because the airway may be lost at any time. If, however, electrocautery is required, then fire prevention precautions should be taken. IV opioids or local anesthetic infiltration, or both, should be used to manage postoperative pain. A thrashing, crying child who is in pain will compromise the integrity of the newly established surgical airway.

Children whose airways cannot be intubated may undergo an “awake” tracheostomy with sedation and local anesthesia. Ketamine is an attractive alternative, but promotes secretions, which may further compromise an already marginal airway; an antisialagogue may reduce the secretions. Children who can be anesthetized with an inhalational agent administered by mask, but who cannot be intubated because of severe subglottic stenosis or inability to visualize the vocal cords by direct laryngoscopy, may have the airway maintained with spontaneous ventilation and a face mask or an LMA until a surgical airway is obtained.

Once the trachea has been entered, a portion of the delivered tidal volume is lost through the incision, and ventilation may become inadequate. This is less of a problem if spontaneous respirations are maintained at this point. It is prudent to leave the ETT within the lumen of the trachea but withdrawn just proximal to the tracheal incision, so that it can be readily advanced should difficulty be encountered with passing the tracheotomy tube. Once the tracheotomy tube is in place and ventilation is confirmed, the ETT is removed, the sterile distal end of the clean anesthesia circuit is attached to the tracheotomy tube (and the proximal end to the anesthesia machine), and the wound is closed. In the event of the tracheostomy tube becoming dislodged or removed, the tracheal incision will close and attempts at reinsertion may cause bleeding, the creation of a false passage, or trauma to the tracheal wall. The tracheal lumen is identified by internal traction sutures, which are placed by the surgeon at the end of the surgical procedure (E-Fig. 31-6). With the surgeon pulling up on the external ends of these sutures, the tracheal incision is identified and the tracheotomy is opened so that an artificial airway can be inserted. The child should not leave the OR without the potentially lifesaving sutures in place and their laterality (right vs. left) properly identified. Flexible fiberoptic bronchoscopy through the new tracheostomy tube can be performed to confirm appropriate location of the tip of the tracheostomy tube above the carina.

## Laryngotracheal Reconstruction

Glottic and subglottic stenosis, although rare, can be life threatening and difficult to manage, from both the surgeon’s and anesthesiologist’s points of view. Congenital laryngeal atresia and congenital laryngeal webs can be incompatible with life unless an emergent tracheostomy is performed at birth. When diagnosed antenatally, such an intervention can be undertaken before placental separation, described as an operation on placental support, or the ex-utero intrapartum treatment (EXIT) procedure (see Chapter 37). Treatment depends on the severity of laryngeal obstruction. In some instances, the defects are sufficiently severe to require immediate intubation or tracheostomy (see Fig. 36-2). Others may be discovered as an incidental finding while attempting to intubate the trachea for an unrelated surgical problem.<sup>272,201</sup> Most membranous defects can be broken down by passing a bronchoscope through the lumen or incised using a surgical knife or scissors. Thin anterior webs can be managed by microendoscopic incision with a microsurgical knife or CO<sub>2</sub> laser, staging the procedure for each side separately to avoid recurrence. The anesthetic management is similar to that for children undergoing laser excision of laryngeal papillomatosis.

Acquired subglottic stenosis is usually the result of prolonged tracheal intubation for respiratory support of infants born prematurely. In older children, it is often the result of laryngeal trauma. Symptoms usually relate to airway, voice, and feeding

**E-FIGURE 31-6** Postoperative view of the tracheotomy tube in a child with Pierre Robin sequence (**A**), and of the stay sutures (**B**), which are identified and stabilized by tape as they emerge from the wound at the conclusion of the tracheotomy.

and, in the case of a laryngeal insult, often occur 2 to 4 weeks later. Progressive respiratory difficulty with biphasic stridor, dyspnea, air hunger, and retractions are typical. These children usually have a tendency toward prolonged courses of URIs. Soft tissue radiographs of the neck and computed axial tomography will locate the exact site and length of the stenotic segment. Because both gastroesophageal and gastrolaryngopharyngeal reflux disease are thought to contribute to the development and exacerbation of subglottic stenosis, these conditions must be excluded, usually by a 24-hour esophageal pH probe placement. However, direct endoscopic visualization of the larynx is ultimately required to fully evaluate the stenosis. Rigid and flexible endoscopy of the airway and esophagus is performed in the OR. Because of the small diameter of the airway, the rigid rod-lens telescope and/or a flexible bronchoscope are used to visualize the larynx and trachea beyond the obstruction. The trachea is then intubated, and the degree of air leak around the tube helps establish the degree of stenosis (see Fig. 31-13; see also Fig. 36-3, *A*).

The surgical management of these infants must be individualized according to the degree of obstruction and the general condition of the child.<sup>273</sup> Most cases of moderate or severe subglottic stenosis require a tracheostomy at or below the third tracheal ring to establish a safe airway. The presence of a tracheostomy also helps to facilitate the airway management during subsequent procedures. For less severe cases, endoscopic dilation or CO<sub>2</sub>-laser endoscopic scar excision may be sufficient.

The more severe cases of laryngeal stenosis require external reconstruction. Of the many available options, an anterior cricoid split operation and laryngotracheal reconstructions are more frequently used. The cricoid split operation is performed with the use of general endotracheal anesthesia. The largest possible tracheal tube is inserted through the nose. An incision is made through the cricoid, and the cartilage springs open. The ETT will be readily visible in the lumen. Frequently, the incision will be extended to include the upper two tracheal rings and even the lower third of the thyroid cartilage (Fig. 31-22). Stay sutures are placed on each side of the incised cricoid, and the skin is loosely approximated. The ETT is left in place for about 7 days to act as a splint while the mucosal swelling subsides and the split cricoid heals. Endoscopy is not usually required, but corticosteroids are administered before extubation.

Open reconstructive surgical techniques are done at the youngest age possible to help the development of speech and

language skills. They basically combine the use of laryngeal and cricoid splits, cartilage grafts, and stenting.

For laryngotracheal reconstruction procedures, the infant is positioned with a roll under the shoulders and the head is extended. The tracheostomy cannula is replaced with an ETT that is introduced through the stoma to allow easy and secure access to the airway. A sterile, shortened, preformed oral RAE tube is ideal to allow secure fixation. The distal end is cut to an appropriate length to avoid bronchial intubation and then sutured to the skin of the neck. A costal cartilage graft is harvested and fashioned to fit the intended site of transplantation (anterior or posterior splits). Repair of laryngotracheal stenosis in almost all cases, except anterior subglottic stenosis, requires brief stenting to keep the graft in place and lend support to the reconstructed area. Stents will counteract scar contracture and provide a scaffold for epithelium to cover the lumen of the airway. Many types of stents have been used. T-tubes are popular in adults, but are associated with more complications and blockage in children. The lower end of the stent is sutured in place during surgery. The stent is eventually removed endoscopically, after cutting the sutures and retrieving the tube.

Single-stage laryngotracheal reconstruction is sometimes used in children without significant obstruction. A full-length nasotracheal tube is used to support the graft for 3 to 7 days, depending on the type of graft. The advantages of immediate decannulation, and possible avoidance of a tracheostomy altogether, make this approach appealing in appropriate candidates (Fig. 31-23).

The anesthetic challenges in these cases are many. The general condition of the child may not be perfect. Residual stigmata of prematurity are often present. The airway will be shared with the surgeon, and the tracheal tube that is placed in the stoma will need to be intermittently removed for surgical access and stent placement. A quiet surgical field is essential. The possibility of a pneumothorax during the cartilage graft harvesting should be kept in mind. The need to ensure that the stent, or the tracheal tube in case of a single-stage laryngotracheal reconstruction, is not dislodged in the ICU cannot be overstated. Accidental extubation cannot be allowed. A combination of sedation techniques and/or pharmacologic relaxation is necessary. The choice is often dictated by the individual policy in each ICU. Dexmedetomidine sedation may offer advantages as an alternative to propofol by providing a relatively rapid recovery from short-term sedation.<sup>274</sup>

**FIGURE 31-22** Anterior cricoid split. After a midline laryngeal incision through cartilage and mucosa (**A**), the cricoid cartilage is decompressed and the endotracheal tube (ETT) is pictured in (**B**). The skin is loosely closed with a drain (**C**). (From Zalzal GH, Cotton RT. Glottic and subglottic stenosis. In Cummings CE, editor. *Otolaryngology head & neck surgery*. 4th ed. St Louis: Mosby; 2005.)

**FIGURE 31-23** **A**, Laryngotracheal resection with anterior cartilage graft. **B**, After a midline incision into the thyroid cartilage, the intraluminal scar and lining mucosa are incised along the length of the stenotic segment (**C**). Costal cartilage is shaped into a modified boat and placed in position with the lining of the perichondrium facing internally. (From Zalzal GH, Cotton RT. Glottic and subglottic stenosis. In Cummings CE, editor. Otolaryngology head & neck surgery. 4th ed. St Louis: Mosby; 2005.)

### TRACHEOCUTANEOUS FISTULA

Approximately 12% of children who have had their tracheostomy removed will retain a tracheocutaneous fistula.<sup>275</sup> Surgical repair is generally required to remove the fistula track, followed by a primary closure of the defect.<sup>276-278</sup> In some, this may be accomplished with simple endoscopic cauterization.<sup>279</sup> Usually there is a preliminary endoscopic assessment of the stoma site, removal of residual granuloma, and then a determination of the best approach to closure.<sup>280</sup> A multilayered closure is commonly used to close the fistula,<sup>281,282</sup> whereas others recommend direct primary closure of the defect.<sup>283</sup> The anesthesia approach generally includes maintenance of spontaneous respirations, and methods to avoid coughing or straining at the time of extubation. The main concern is the potential for the development of subcutaneous emphysema caused by residual air leak if the child coughs or strains.<sup>279,284-287</sup> This complication may result in life-threatening pneumothorax or pneumomediastinum, which may occur up to 7 days following closure<sup>280</sup>; these complications require emergent removal of sutures, reestablishment of a tracheostomy, and thoracostomy and/or pericardial drainage.<sup>288</sup> Some children may require postoperative ventilation, but most are extubated and admitted for observation after extubation and conclusion of the surgery. The vast majority have an uneventful recovery.

### Airway Trauma

Nasal fractures are frequently seen in older children and adolescents. They may result from a direct hit (fight) or an accident.<sup>289</sup> Because the nasal mucosa is very vascular, a lot of blood is usually swallowed. A stomach full of blood is to be assumed for the first 24 to 48 hours after the injury. A rapid-sequence intubation is the safest approach during that period. However, closed reduction of a nasal fracture is often delayed for a few days to allow swelling to subside. At that time, gastroparesis has resolved and an LMA may be considered. These operations can be very brief. Frequently, the surgeon will leave a nasal pack in situ and apply an external splint over the nose. If a throat pack was not inserted, then the stomach should be suctioned to remove blood that may have accumulated during the surgery. At the conclusion of the surgery, the stomach and pharynx should be suctioned. The tracheal tube or LMA should be removed only when the child is awake, cooperative, and understands the need for mouth breathing; a combative,

semi-awake adolescent who is unable to breathe through the nose, can hurt himself or herself and others.

Closed or open injuries to the larynx and trachea in children can result from bicycle accidents, falls, direct trauma from sharp objects, and, rarely, a “clothesline” injury. The more cephalad cervical position of the pediatric larynx behind the mandibular arch and the pliability of the cricothyroid structures usually limit the extent of injury and prevent severe fractures.<sup>289</sup> However, the small size of the laryngotracheal airway and the potential for massive soft tissue swelling because of the loose attachment of the submucosal tissue to the perichondrium make early diagnosis and treatment critical. The injury can range from minor laryngeal hematoma to a severe form of laryngotracheal separation. This extreme and often fatal condition can occur after a clothesline mechanism of injury and is often associated with bilateral vocal cord paralysis resulting from recurrent laryngeal nerve damage.<sup>290</sup> Hoarseness, cough, dyspnea, hemoptysis, and voice changes suggest laryngeal damage. Clinical subcutaneous emphysema, pneumothorax, and pneumomediastinum signify definite disruption of the laryngotracheal complex. Computed tomography is the most appropriate imaging modality to identify the extent of laryngeal injury.<sup>291</sup>

Positive-pressure ventilation by mask, excessive coughing, or struggling can worsen the subcutaneous emphysema and cause the airway to further deteriorate. Administration of nitrous oxide, application of cricoid pressure, multiple vigorous attempts at laryngoscopy and intubation, and passage of blind nasotracheal tubes or nasogastric tubes should be avoided to prevent further trauma by creating a false passage through a mucosal tear. A good approach to this type of injury, if the child is stable, is to use the fiberoptic bronchoscope to visualize the airway before tracheal intubation. Ideally, the airway should be secured in the OR after induction of general anesthesia with an inhalational agent, and with the child breathing spontaneously. However, tracheostomy below the level of the injury, under local anesthesia or over a bronchoscope, may be necessary if there is extensive injury to the mouth and larynx that requires major reconstruction.

Postoperatively, these children require management in a monitored setting, usually the ICU. The resolution of other complications, such as subcutaneous emphysema, pneumothorax, or pneumomediastinum, will dictate the duration of the child’s stay. Postoperative analgesia must be carefully titrated to balance the need for pain relief with the adequacy of ventilation.

**THE INFANT OR CHILD** presenting for elective ophthalmic surgery requires careful preanesthesia assessment. In addition to ophthalmologic issues, the infant or child may have associated or unassociated systemic disorders. In this chapter, we review some of the more important issues that should be addressed preoperatively and some of the difficulties that may be anticipated in the perioperative period for ophthalmologic procedures.

Many ophthalmologic diagnoses can be confirmed only by the ophthalmologist examining a cooperative infant or child. An examination under anesthesia (EUA) often is essential for an accurate diagnosis and evaluation of many processes, including trauma, tumors, infiltrative diseases, coloboma, glaucoma and other vascular diseases of the retina, Coats disease, and incontinentia pigmenti. Inpatient preterm infants often require serial EUAs to monitor the development and progress of retinopathy of prematurity (ROP) and the response of the disease to surgery. These examinations may be performed in the neonatal intensive care unit or operating room and may require sedation or general anesthesia.<sup>1</sup> Other inpatient trauma victims may require serial EUAs to monitor the development of glaucoma or retinal injury. Serial EUAs are also necessary to monitor progress during outpatient retinoblastoma radiation treatments. The anesthesiologist is essential to the provision of pediatric ophthalmologic diagnostic and therapeutic techniques.

Ophthalmologic procedures that require an absolutely immobile child for maximal safety include surgery in which the globe is open (e.g., cataract removal), vitrectomy, laser or cryotherapy for retinopathy, retinal detachment repair, anterior chamber paracentesis, and repair of an open globe injury. Other procedures may require a child to be cooperative only for a nonpainful examination, but because the target organs (orbits) are close to the airway, a strategy must be devised to ensure safe management of the airway.

The child in need of ophthalmologic surgery typically requires general anesthesia or deep sedation rather than exclusive use of local or regional anesthesia. Many infants and children cannot cooperate for anything beyond a brief eye examination. Although the ophthalmologist may be able to tolerate small movements by the child during an EUA, unnecessary head or eye globe movement during an ophthalmologic procedure should be prevented. Retrobulbar block is sometimes performed for postoperative analgesia in children before emergence from general anesthesia<sup>2</sup>; all complications associated with a retrobulbar block identified in adults may also occur in children.<sup>3,4</sup>

## Preoperative Evaluation

The perioperative environment should be welcoming to the child and family.<sup>5,6</sup> All team members should be comfortable with the anesthesia considerations for infants and children for ophthalmologic procedures.<sup>6</sup> Anticipation and prevention of postoperative nausea and vomiting (PONV) and understanding of anesthesia emergence and postoperative analgesia are essential.

Before an elective ophthalmologic procedure, the patient undergoes a thorough physical examination, including a review of all systems, and a complete medical history is obtained, including a surgical and anesthesia history, list of current medications, known allergies, and family history.<sup>7</sup> Because many ophthalmologic diagnoses are commonly associated with systemic conditions, all implications of the systemic illness are a concern for the anesthesiologist.

The physical examination should evaluate whether the ophthalmologic condition demands an alteration in airway management or affects the ability to obtain an appropriate mask fit. The airway should be carefully assessed for issues arising from other systemic conditions. Assessments of cardiorespiratory

**TABLE 32-1 Common Ophthalmologic Procedures in Children**

Examination under anesthesia
Strabismus repair
Retinopathy of prematurity: laser or cryotherapy
Ptosis repair
Cataract excision with or without intraocular lens placement
Corneal transplantation
Evaluation of penetrating eye injuries
Dacryocystorhinotomy and dacryocystocele repair
Enucleation
Retro-orbital cellulitis decompression
Vitrectomy

and neurologic systems are important in formulating the anesthesia plan.

## Common Ophthalmologic Diagnoses Requiring Surgery

Common pediatric diagnoses and surgical procedures are listed in Table 32-1. A diagnosis may exist in isolation or be one aspect of a more complex group of diagnoses. Many involve systemic illnesses, and the anesthesiologist should be familiar with the implications of ophthalmologic disease in these settings.

Some procedures and examinations can be performed without insertion of an artificial airway; however, communication with the ophthalmologist about requirements is essential in planning anesthesia. Other procedures may be performed very quickly and require only induction of anesthesia (often by mask in children) and then removal of the facemask from the nasal bridge to give the ophthalmologist full access to both orbits, eyelids, and nasolacrimal ducts. With experience and use of soft, inflatable-cushion facemasks, a close fit can be obtained to reduce environmental contamination with anesthetic gases and to maintain a suitable plane of anesthesia. The EUA may be brief or intermediate in length, and as information is generated, surgical correction may be contemplated during the same episode of anesthesia.

Communication and flexibility are mandatory in anesthesia planning. Anesthesia may start with a plan for a brief EUA using an inhalational anesthetic with a facemask and no intravenous catheter. However, if corrective surgery becomes necessary, airway control may require placement of a laryngeal mask airway (LMA) or tracheal tube. Intravenous access is required if the airway is instrumented to administer medications, including those to prevent or treat the oculocardiac reflex (OCR), postoperative pain, and nausea and vomiting.<sup>8</sup>

For procedures of brief or intermediate duration, the use of an LMA allows excellent access to all periorbital structures and provides good airway control in most circumstances. Compared with mask anesthesia, the LMA has the advantage of decreasing environmental contamination by inhalational anesthetics. It is relatively easy to insert and remains secure while avoiding the need for the anesthesiologist to hold a facemask near the surgical site. Compared with the tracheal tube, the LMA does not increase the heart rate, blood pressure, and intraocular pressure (IOP) to the same degree.<sup>9</sup>

Some of the more common ophthalmologic presentations and associated systemic illnesses or syndromes are listed in Table 32-2. Some systemic conditions have significant cardiorespiratory

**TABLE 32-2 Ophthalmologic Conditions Associated with Systemic Syndromes and Illnesses**

Syndrome or Illness	Ophthalmologic Conditions
Fetal alcohol syndrome	Strabismus, optic nerve hypoplasia
Galactosemia	Neonatal cataracts
Mucopolysaccharidoses	Corneal involvement; may require transplantation
Retinitis pigmentosa	Heart block
Sturge-Weber syndrome	Glaucoma
Prematurity	Retinopathy of prematurity, strabismus
Fabry disease	Whorled corneal opacities
Tay-Sachs disease	Cherry-red macular spot
Osteogenesis imperfecta	Blue sclerae
Craniofacial syndromes (e.g., Crouzon, Apert, Pfeiffer)	Proptosis, strabismus, glaucoma

or central nervous system implications for perioperative management, and they should be fully evaluated before anesthesia (see Chapter 4). Many procedures are performed on preterm infants or formerly preterm infants, and prematurity and its complications have some of the most clinically important implications for anesthesia management.

## Ophthalmologic Conditions Associated with Systemic Disorders

### PREMATURITY

The preterm infant may present for many surgical procedures early in life. ROP, congenital cataracts, and glaucoma may require surgery even when the infant weighs less than 1000 g. The preterm infant may have significant systemic illnesses. Common complications of prematurity include acute and chronic pulmonary disease,<sup>10</sup> respiratory failure and pulmonary hypertension, congenital heart disease (unrepaired or with a limited palliative repair), and intraventricular hemorrhage,<sup>11</sup> with or without obstructive hydrocephalus.

Acutely ill preterm infants and those younger than 1 year of age are at greater risk than older children and adults for perioperative complications.<sup>12</sup> Careful attention to airway management, assisted ventilation, and titration of oxygen therapy with specified goals are essential for success.<sup>13</sup> In preterm infants whose airways are already intubated and whose lungs are ventilated mechanically, the anesthesiologist should confirm the position of the tube, transport the infant safely to the operating room, and limit the exposure to high concentrations of oxygen. Although institutional goals are not uniform regarding supplemental oxygen therapy,<sup>14</sup> communication with the neonatal team is often helpful in gauging the infant's previous oxygen requirement and current targeted goals (e.g., hemoglobin-oxygen saturation levels of 90% to 95%). Because most inhalational anesthetics impair hypoxic pulmonary vasoconstriction, a greater fraction of inspired oxygen (FIO<sub>2</sub>) may be necessary to maintain the targeted hemoglobin saturation.

Hypercarbia and hypoxia may increase choroidal blood volume and increase IOP. Partial pressures of carbon dioxide (PCO<sub>2</sub>) and oxygen (PO<sub>2</sub>) should be controlled. Infants may be at

greater risk for the OCR than older children and adults, and intravenous access should be obtained before the surgical procedure or any examination that may involve traction on the extraocular muscles or pressure on the globe.

Infants with extremely low birth weight require many weeks to grow and develop to a weight of approximately 1800 g and to maintain normothermia without special environmental control. These infants commonly have a history of short-term or intermediate-term assisted ventilation and may not require supplemental oxygen before an EUA or planned operative procedure for ROP.<sup>15</sup> Many of these infants undergo ophthalmologic examinations while their lungs are ventilated in the neonatal intensive care unit.<sup>16</sup> During surgical therapy (i.e., laser or cryosurgical stabilization) for ROP, these infants require anesthesia to provide optimal conditions (Fig. 32-1). Perioperative apnea may preclude

tracheal extubation or require close postoperative monitoring after anesthesia.

Perioperative apnea in the preterm infant is widely described.<sup>17,18</sup> Whether the child is still hospitalized or presenting for elective surgery as an outpatient, the preoperative assessment should determine the pattern and frequency of apnea before the planned surgical procedure and anesthesia. If the child has been discharged, the current use of respiratory stimulants (i.e., caffeine or theophylline) and oxygen should be determined. Is an apnea monitor being used, or has it been discontinued? Guidelines have not been developed to manage some of the scenarios, but infants who continue to require supplemental oxygen, who are younger than 60 weeks postconceptional age, or who are monitored for apnea or bradycardia should have continuous cardiorespiratory and oxygen saturation monitoring postoperatively for at least

**FIGURE 32-1** **A**, Grade III retinopathy of prematurity with neovascularization of the retina requires surgical therapy to halt the growth of vessels. **B**, Retinal detachment caused by retinopathy of prematurity. This degree of damage results in permanent visual impairment. **C**, Appearance after cryotherapy. Cryotherapy causes a well-demarcated ridge of tissue scarring (arrow) that prevents further growth of the neovascularature (left to right in the middle).

12 hours or until they are apnea free (see Chapter 4). The risk of apnea after general anesthesia and sedation decreases with advancing gestational age at birth and with advancing postnatal-postconceptual age. The risk of apnea is independent of opioid use; its multifactorial origins include the presence of general and neuraxial anesthetics and the immature central nervous system and respiratory center in the preterm infant. Flexible planning for possible postoperative ventilatory support is essential, and families should be informed of this possibility preoperatively.

The airway of the preterm infant who is younger than 52 to 60 weeks postconceptual age is usually intubated for ophthalmologic surgery (except for a very brief EUA) due to the immature respiratory drive, unpredictable respiratory response to anesthetic agents, and possible lag before recovery of respiratory drive after completion of the procedure and discontinuation of anesthetic agents. If the infant does not appear to have a stable respiratory drive and strength after anesthesia, assisted ventilation should be provided postoperatively and weaned during recovery. Planning for this contingency is vital. *Ophthalmologic procedures may be brief and have a low risk of blood loss, but the risks of general anesthesia mandate full postoperative support.* Intensive care resources for assisted ventilation in preterm and formerly preterm infants should be available before embarking on anesthesia.

Although chronic lung disease due to prematurity is prevalent, its intensity has been significantly reduced with the routine use of surfactant and advances in ventilator management strategies. Long-lasting respiratory effects from prematurity may include reactive airway disease, subglottic stenosis from prolonged intubation, and alveolar or interstitial disease with an oxygen requirement lasting weeks to years.<sup>10</sup> Because many anesthetics impair hypoxic pulmonary vasoconstriction, an increased oxygen requirement in the perioperative period should be anticipated. Tracheal intubation, a light level of anesthesia, or topical use of  $\beta$ -adrenergic antagonists may exacerbate reactive airway disease, requiring further treatment to reduce air trapping and hypercarbia.

Along with assessing for airway and alveolar diseases, the anesthesiologist should determine whether pulmonary hypertension or right ventricular dysfunction is or was present.<sup>19</sup> Some infants may be receiving continuing oxygen therapy as treatment for pulmonary hypertension and to reduce intermittent episodes of hypoxemia due to crying or while sleeping. If pulmonary hypertension was diagnosed previously, an updated evaluation is warranted. Because pulmonary hypertension is exacerbated by hypoxia and hypercarbia, tracheal intubation should be considered to ensure control of ventilation and oxygenation. At emergence, pulmonary hypertension may be exacerbated as hypercapnia develops, causing physiologic or anatomic shunting with systemic hemoglobin-oxygen desaturation. Immediate and continued evaluation of the airway is imperative to rule out an independent respiratory contribution to the systemic hypoxia.

Congenital cardiac disease may be diagnosed in the preterm neonate, infant, or child who presents for ophthalmologic procedures. A patent ductus arteriosus may not close spontaneously or after administration of cyclooxygenase inhibitors. This may lead to persistent congestive failure, reduced pulmonary compliance, and complications of fluid management. Congenital cardiac anomalies require assessment before elective surgery. The various complex congenital cardiac lesions have a wide spectrum of interactions with multiple anesthetic agents.<sup>20</sup> Many cardiac conditions require surgery or palliation (e.g., systemic-to-pulmonary shunts) before elective ophthalmologic procedures.

Correction of congenital heart disease is limited by the difficulty of using cardiopulmonary bypass in infants weighing less than 2 kg. There may be an urgent need for ophthalmologic evaluation (e.g., congenital tumor, cataract, glaucoma) before repair of the congenital cardiac condition. Preoperative consultation with the infant's pediatric cardiologist can provide useful information on the infant's current ventricular function and the risk of dysrhythmias associated with cardiac defects. Medical management must be optimized before undertaking anesthesia and surgery.

Intraventricular hemorrhage is a major source of morbidity and mortality for preterm infants.<sup>11</sup> Obstructed hydrocephalus may occur and require cerebrospinal fluid diversion procedures to decompress the obstructed ventricular system and treat the associated increased intracranial pressure. Many of these infants require ophthalmologic surgery for repair of strabismus due to a neurologic insult. If a ventriculoperitoneal shunt is in place, its proper function should be determined by direct evaluation. The anesthesiologist should assess whether there is inappropriate macrocephaly or a bulging or tense fontanelle. Obstructed hydrocephalus may occur after the infant's discharge from hospital, even though a ventriculoperitoneal shunt was not required previously. The preoperative assessment should include the child's developmental and neurologic status at the time of surgery. Because intraventricular hemorrhage is associated with long-term morbidity, any history of seizures should be elicited, and the antiepileptic drugs being used should be documented.

Preterm and small infants rapidly lose heat when anesthetized. Prevention of hypothermia is essential in the perioperative environment. Hypothermia can decrease metabolism of most drugs and depresses respiratory drive in preterm infants (see Chapters 35 and 36).

## DOWN SYNDROME

Children with Down syndrome (i.e., trisomy 21) frequently present for ophthalmologic surgery because of associated pathologic processes such as neonatal cataracts, significant refractive errors (e.g., hypermetropia, astigmatism), strabismus, glaucoma, keratoconus, nasolacrimal duct obstruction, and nystagmus.<sup>21-23</sup> Infants with trisomy 21 should have an ophthalmologic evaluation in the neonatal period. If this requires an EUA, the anesthesiologist should be prepared for the extensive medical implications associated with trisomy 21.<sup>24,25</sup> Almost half of these infants are born with congenital heart disease, including septal defects, complete or partial atrioventricular canal, tetralogy of Fallot, transposition of the great arteries, and valvular insufficiency or stenosis. Any child with a left-to-right shunt may develop pulmonary hypertension, and children with trisomy 21 develop irreversible pulmonary hypertension at an earlier age. Bradycardia (25% to 60%) and hypotension (12% to 73%) have been reported during sevoflurane anesthesia in these children.<sup>26,27</sup> Complete understanding of the child's cardiac defects is essential to planning anesthesia (see Chapters 14, 16, and 21).

Airway abnormalities such as narrowed nasopharyngeal passages, macroglossia, pharyngeal hypotonia, and subglottic stenosis are frequently observed in children with trisomy 21. These abnormalities may contribute to development of chronic intermittent hypoxia, further exacerbating pulmonary hypertension, and these children should be expected to demonstrate exacerbations of airway obstruction and hypoxia after general anesthesia.<sup>28</sup>

Children with trisomy 21 have a wide spectrum of developmental delays. Cervical spine instability occurs, and occiput-C1

and C1-2 instabilities have been described.<sup>29,30</sup> Subluxation of the cervical spine has rarely been reported in these children during anesthesia. Nonetheless, the anesthesiologist and the surgeon should avoid extremes of neck flexion and extension and lateral rotation during head positioning for laryngoscopy and surgery. While the child is awake, the range of motion of the neck in flexion and extension should be assessed, along with complaints of numbness or tingling in the hands or feet in a particular position. Previous spine and neck investigations or operations should be reviewed. These infants and children may have ligamentous laxity of the cervical spine and other locations. No consensus exists for the radiologic workup of children who are asymptomatic for cervical disease, although many children have been evaluated radiologically before about 5 years of age.

Children with trisomy 21 may be born with congenital hypothyroidism, or it may develop at any time during their life span. They may develop junctional bradycardia during sevoflurane anesthesia.<sup>31</sup> The bradycardia may be associated with or result from occult hypothyroidism. If the child is found to have a goiter on examination or has symptoms consistent with hypothyroidism (i.e., prolonged jaundice, hypothermia, constipation, dry skin, macroglossia, or relative bradycardia), thyroid function studies should be obtained before anesthesia for an elective procedure.

### ALPORT SYNDROME

Alport syndrome (i.e., progressive hereditary nephritis) is one of the disorders in a group of familial oculorenal syndromes. This classification includes Lowe (oculocerebral) syndrome and familial renal-retinal dystrophy. Alport syndrome involves sensorineural hearing loss, progressive renal disease, and multiple ophthalmologic disorders, including cataracts, retinal detachment, and keratoconus.<sup>32,33</sup> Development of myopathy and renal failure constitutes the major anesthesia concern. If the patient has myopathy, it is prudent to avoid succinylcholine and the risk of a hyperkalemic response. Renal insufficiency may alter the choice of pharmacologic agents to very-short-acting agents or agents that are not renally excreted.

### MARFAN SYNDROME, EHLERS-DANLOS SYNDROME, AND HOMOCYSTINURIA

Marfan syndrome, Ehlers-Danlos syndrome, and homocystinuria are considered together only from the perspective of a general body phenotype. The metabolic and molecular causes of these syndromes are well described. They share problems with connective tissue development, possible joint laxity, and cardiovascular disorders.

Marfan syndrome is caused by a defect in the fibrillin 1 gene (*FBN1*), which affects elastic and nonelastic connective tissues. These children have an increased risk of retinal detachment, lens dislocation, glaucoma, and cataract formation (E-Fig. 32-1).<sup>34</sup> They may have significant pulmonary (scoliosis) and cardiovascular problems,<sup>35</sup> which may include aortic, mitral, or pulmonic valve insufficiency. Preoperative cardiovascular evaluation is indicated to determine the progression of cardiovascular abnormalities that inevitably occur. Blood pressure control is essential to prevent aortic dissection.

Homocystinuria has at least three forms and different inborn errors. Enzymatic deficiency of the metabolism of sulfur-containing amino acids causes the intermediate metabolite, homocysteine, to accumulate. These children suffer from cataracts, retinal degeneration, optic atrophy, glaucoma, and

lens dislocation. The cardiovascular pathology includes coronary artery disease at a young age. Thromboembolic phenomena occur more frequently because the children may be hypercoagulable.<sup>36</sup> Nitrous oxide should be avoided because it inhibits methionine synthase, further limiting the conversion of homocysteine to methionine.

At least 10 forms of Ehlers-Danlos syndrome have been described. Not all forms express significant ocular pathology. From the anesthesiologist's perspective, positioning is important to avoid trauma to the skin because these children develop hemorrhages with minor trauma and experience delayed wound healing. A thorough preoperative assessment should be performed for cardiac lesions. Hypertension should be avoided to reduce the risk of rupturing an aneurysm. The duration of effect of local anesthetics in patients with class III Ehlers-Danlos syndrome may be less than that in normal patients, and contingency plans should be in place to address these possibilities, including retrobulbar block or general anesthesia.<sup>37</sup>

### MUCOPOLYSACCHARIDOSES

The mucopolysaccharidoses are a group of disorders with enzyme defects that result in incomplete degradation of glycosaminoglycans. These children have various degrees of cognitive dysfunction, macroglossia, airway obstruction, cervical spine instability, and systemic involvement with deposition of mucopolysaccharide material. This leads to cardiac and respiratory dysfunction, airway obstruction, corneal opacities, and glaucoma.

The systemic complications of these disorders are sufficiently severe that even well-planned anesthesia management for ophthalmologic procedures may cause death.<sup>38</sup> Airway management can be extremely difficult with poor mask fit, dynamic airway obstruction with narrowed passages, a floppy epiglottis, and difficulty visualizing the larynx.<sup>39</sup> Infiltrative material may be deposited in the laryngeal inlet and pretracheal tissues; an LMA is particularly useful in maintaining a patent airway. Tracheal intubation may require the use of advanced airway management techniques, and the anesthesiologist should have several plans for airway management (see Chapter 12). Cardiac evaluation should be considered before an elective procedure to assess ventricular function and arrhythmias. Intravenous access may be difficult due to subcutaneous deposition of mucopolysaccharides.

### CRANIOFACIAL SYNDROMES

Craniofacial syndromes may manifest as craniosynostosis or have only middle and lower facial structure involvement.<sup>40</sup> Apert and Crouzon syndromes are both disorders of craniofacial development, but syndactyly occurs only in the former (E-Fig. 32-2). They share the potential for many ocular disorders, including severe proptosis, and mask airway management may be difficult.<sup>41</sup> Other mutations of the fibroblast growth factor receptor 2 gene (*FGFR2*) cause Antley-Bixler and Pfeiffer syndromes. These children may develop chronic airway obstruction, and some have complete tracheal rings. Tracheal narrowing should be anticipated, and smaller tracheal tube sizes should be used.

Children with asymmetry of facial and mandibular bone growth may present with limited mouth opening. Children with Goldenhar syndrome (i.e., hemifacial microsomia), Treacher Collins syndrome, and Pierre Robin sequence can be expected to present a challenge to airway management (see Chapters 12 and 33).<sup>42</sup> Children with craniosynostosis have an increased risk of congenital heart disease, and a cardiac evaluation should be

**E-FIGURE 32-1** Patients with Marfan syndrome may present for surgical repair of ocular lens dislocation resulting from connective tissue defects. This photograph of a slit-lamp examination shows that the circular outer edge of the lens is displaced from its usual position. The capsule of the lens appears to be intact.

**E-FIGURE 32-2** This child with Apert syndrome presented with hyper-telorism, proptosis, and other pathologic ocular processes. Airway management and intravenous access in these cases are challenging for the anesthesiologist.

performed before anesthesia.<sup>43</sup> Neurologic morbidity and seizure disorders occur more frequently in this group of patients.

### PHAKOMATOSES

The phakomatoses are neurocutaneous syndromes with multiple ocular pathologic processes. These syndromes include neurofibromatosis,<sup>44,45</sup> encephalotrigeminal angiomas (i.e., Sturge-Weber syndrome),<sup>46</sup> tuberous sclerosis,<sup>47,48</sup> incontinentia pigmenti, and ataxia telangiectasia. Central nervous system involvement varies with each of these diseases. Patients may have developmental delay, seizures, and significant neurologic morbidity. Anticonvulsant drugs should be continued in the perioperative period. Electrolyte and hepatic function studies should be done, and plasma levels of antiepileptic agents should be evaluated preoperatively.

## Ophthalmologic Physiology

Two major considerations of ophthalmologic physiology are of great interest to the anesthesiologist. The first is the dynamics of aqueous humor production and transport and the effects on IOP. The second is the OCR that may occur during any surgical procedure around the orbit. Anesthetic agents affect the IOP. In a patient with a penetrating eye injury, any increase of IOP may be associated with extravasation of elements of the globe and irretrievable loss of vision.

### INTRAOCULAR PRESSURE

IOP is the pressure exerted by the internal components of the globe on the covering (i.e., sclera and conjunctiva). The normal IOP is 12 to 15 mm Hg. An IOP greater than 20 mm Hg is considered abnormal. Aqueous humor is a clear fluid that is secreted by the ciliary body and released into the anterior chamber of the globe. It traverses the anterior chamber and bathes the iris. It flows through the canal of Schlemm into the pores of Fontana and then drains into the episcleral veins (Fig. 32-2). The posterior chamber, which is larger than the anterior chamber, is composed of a gelatinous mix known as vitreous humor. The sclera and globe that encase the intraocular constituents are relatively noncompliant and are protected by the bony orbit. However, intra-orbital masses may impinge on the globe and increase the relative IOP or alter the flow of aqueous humor, resulting in increased IOP. Any obstruction to the drainage of aqueous humor causes fluid to build up within the anterior chamber and increases IOP.<sup>49</sup> Increased central venous pressure (e.g., Trendelenburg position, coughing, Valsalva maneuver, straining, increased intrathoracic pressure) attenuates the drainage of aqueous humor from the eye. Arterial pressure does not directly effect changes in IOP. However, as arterial blood pressure increases beyond the normal range, approximately 30% of the increase in systolic blood pressure is reflected in IOP increases. Aqueous humor formation is described in the following equation:

$$IOP = K[(OP_{aq} - OP_{pl}) + P_c]$$

$K$  is the coefficient of outflow,  $OP_{aq}$  is the osmotic pressure of aqueous humor,  $OP_{pl}$  is the osmotic pressure of plasma, and  $P_c$  is the capillary pressure. These variables allow calculation to intervene by increasing the plasma osmolality acutely with mannitol to lower the IOP. This increases the gradient of osmolality and draws water out of the aqueous humor, thereby reducing the IOP.

**FIGURE 32-2** Aqueous humor is synthesized in the ciliary process and then circulates around the iris, past the lens, and into the anterior chamber. After flowing through the trabecular meshwork, aqueous humor enters the canal of Schlemm (arrows), which drains into the episcleral venous system. Pathologic conditions that increase venous pressure, obstruct the canal of Schlemm, or increase aqueous humor production may increase intraocular pressure.

In the relatively noncompliant globe, any pharmacologic or metabolic process that increases choroidal blood volume (e.g., hypercapnia, coughing, increased central venous pressure) produces choroidal congestion and an increased IOP. Although well tolerated in the healthy eye, this congestion may lead to extrusion of contents if the globe is ruptured. The anesthesiologist should carefully control the child's physiology during the induction and maintenance of anesthesia to minimize increases in IOP, regardless of whether there is a preoperative concern about increased IOP.

Congenital or trauma-induced glaucoma requires therapy to reduce the IOP. If the IOP remains elevated, blood flow in the retina will be impaired, possibly leading to loss of vision. Unfortunately, there are many causes of glaucoma in childhood. Hypercarbia, hypoxia, and drugs known or suspected to increase IOP (e.g., succinylcholine, ketamine) should be avoided or used with care. Reducing a child's apprehension and crying and avoiding increases in central venous pressure are also important considerations.

The effect of succinylcholine on IOP is well documented.<sup>50,51</sup> Succinylcholine increases IOP 6 to 10 mm Hg, an effect that begins within 1 minute after administration and continues for up to 10 minutes, at which time the IOP returns to normal. This effect has been attributed to four possible mechanisms:

- Cycloplegia induced by succinylcholine, which obstructs the outflow of aqueous humor
- Tonic contraction of extraocular muscles
- Increased choroidal blood volume
- Relaxation of orbital muscles, which increases external pressure on the globe

Specific muscles develop a sustained tonic tension after succinylcholine that may in the presence of a ruptured globe cause extrusion of intraocular contents.<sup>52</sup> Extrusion in response to increased IOP depends on the diameter of the orifice; a smaller laceration (<2 mm) is less likely to facilitate extrusion of intraocular contents than a larger laceration (>4 mm). Pretreatment with a nondepolarizing agent (one-tenth the usual intubating dose) and paralysis with succinylcholine are still advocated by some anesthesiologists to minimize the risk of aspiration when dealing with an open globe injury. Alternatively, rocuronium (1.2 mg/kg given intravenously) can provide optimal intubating conditions in 30 seconds for the child with an open globe injury while minimizing the risk for aspiration or succinylcholine-associated increases in IOP.

Most general anesthetics decrease IOP,<sup>53</sup> although ketamine has been shown to increase IOP in some studies and decrease it in others.<sup>54-56</sup> When intravenous access is unavailable or the cardiovascular status of the patient warrants the use of ketamine,

the child's overall safety takes precedence over the possible ramifications of ketamine on IOP.

Measurement of IOP is performed by applanation tonometry on the external surface of the globe. Tonometry is often performed along with the EUA during general anesthesia to avoid an overestimation of IOP in struggling, uncooperative infants or children. Borderline measurements must take into account the possibility of anesthetic agents temporarily reducing or increasing the IOP.

### OCULOCARDIAC REFLEX

First described in 1908, the OCR is as a consequence of ophthalmologic surgery and other conditions.<sup>49</sup> Traction on the extraocular muscles and levator (eyelid elevator) or external pressure applied to the globe triggers an afferent signal through the trigeminal nerve that activates parasympathetic output through the vagus nerve, resulting in many types of dysrhythmias (Fig. 32-3, *A*), which include sinus or junctional bradycardia,

**FIGURE 32-3** Traction on the extraocular muscles elicits the oculocardiac reflex. **A**, The afferent limb consists of the long and short ciliary nerves, which synapse in the ciliary ganglion (dotted arrows). The ophthalmic division of the trigeminal nerve (cranial nerve V) carries the impulse to the gasserian ganglion, and the arc continues to the sensory nucleus of cranial nerve V in the brainstem. Fibers in the reticular formation synapse with the nucleus of the vagus nerve (cranial nerve X). Efferent fibers from the vagus nerve terminate in the heart (dashed arrow). The neurotransmitter from the vagus nerve to the sinoatrial node is acetylcholine, and the reflex is blocked by antimuscarinic pharmacologic agents (i.e., atropine and glycopyrrolate). **B**, Electrocardiogram shows conversion from normal sinus rhythm to a nodal rhythm.

atrioventricular block, ventricular ectopy, and asystole (see Fig. 32-3, B). Retrobulbar block with local anesthetic may precipitate the trigeminovagal (oculocardiac) reflex due to external pressure sensed on the globe, and the local anesthetic may not completely prevent the OCR response to further surgical stimulation or manipulation. For this reason, an anticholinergic medication, such as atropine (20 µg/kg) or glycopyrrolate (10 to 20 µg/kg), is routinely given intravenously at induction of anesthesia or early thereafter. Although these medications do not preclude the occurrence of bradycardia, both decrease its intensity and duration. Because anticholinergics cause pupillary dilatation, they do not present a problem for the ophthalmologist, but they may slightly increase the IOP.

If significant bradycardia occurs, the anesthesia team should have the surgeon release the extraocular muscle or stimulation in the surgical field. An additional intravenous dose of atropine (5 to 10 µg/kg) usually interrupts the reflex and corrects the situation, but it may recur. Intravenous epinephrine (1 to 10 µg/kg) is rarely necessary but should always be available. The anesthesiologist should ensure adequate oxygenation and ventilation because hypercarbia or hypoxia may compound or intensify the reflex activity.

Other strategies to attenuate the OCR include topically applied lidocaine<sup>57</sup> or intravenous ketamine.<sup>58</sup> In a four-armed study, a ketamine-based anesthetic (10 to 12 mg/kg/hr) was associated with a decreased incidence of OCR compared with the three other anesthetic regimens: propofol/alfentanil, sevoflurane/nitrous oxide, or halothane/nitrous oxide.<sup>59</sup> The prevalence of the OCR during sevoflurane and desflurane anesthesia was similar.<sup>60</sup>

## Ophthalmologic Pharmacotherapeutics and Systemic Implications

Topical ophthalmologic medications are usually placed directly on the cornea or in the inferior cul-de-sac. Most of these agents need many minutes to 1 hour for maximal effectiveness. Medications delivered topically to the eye are absorbed through the conjunctiva and nasal mucosa into the systemic circulation. When systemically absorbed, their pharmacologic mechanisms of action predict the systemic consequences. Some medications are diluted for use in children to reduce possible systemic toxicity. Anticholinergics, sympathomimetics, and antihistamines can cause pupillary dilation and decrease the movement of aqueous humor, increasing the IOP. Table 32-3 lists the more commonly used topical agents in pediatric ophthalmology.

Topical mydriatic agents are used to induce pupillary dilatation. The most common agent used is phenylephrine, an  $\alpha_1$ -adrenergic agonist. Phenylephrine (2.5% solution) is easily absorbed, and in small infants, it may cause significant hypertension. If hypertension is severe, reflex bradycardia may occur.

Topical cycloplegic agents dilate the pupil, and these drugs eliminate lens accommodation by paralyzing the ciliary muscle. This effect aids in retinal evaluation with the indirect ophthalmoscope and scleral depression and in evaluating refractive errors for which the child is using accommodation for compensation. These agents are muscarinic cholinergic antagonists (i.e., anti-muscarinic agents). Cyclopentolate hydrochloride (0.5%) can cause central nervous system toxicity with disorientation, seizures, and blurred vision. Atropine (0.5% to 2.0%) and scopolamine (0.25%) solutions are used for cycloplegia and pupil

dilatation. Tropicamide (0.5% and 1.0%) is less commonly used in children. When systemically absorbed, these agents may result in antimuscarinic, anticholinergic toxicity, including tachycardia, dry mouth, pupillary dilation, flushing of the skin, heat intolerance or fever, and disorientation (E-Fig. 32-3).

$\beta$ -Adrenergic blockers (e.g., timolol, betaxolol) are used to reduce IOP in the treatment of glaucoma. Systemic absorption causes symptoms of sympathetic nervous system blockade.  $\beta$ -Adrenergic antagonists induce bradycardia and cardiovascular collapse and may precipitate bronchospasm. If  $\beta$ -adrenergic intoxication is suspected, direct-acting cardiovascular stimulants (epinephrine) should be used to antagonize the  $\beta$ -adrenergic blockade rather than indirect-acting stimulants such as ephedrine.

Topical local anesthetics are infrequently used in children except for the very cooperative child for tonometry or removal of sutures. Proparacaine and tetracaine are available for topical use, and lidocaine and bupivacaine are used for retrobulbar blocks. Absorption of the esters (i.e., proparacaine and tetracaine) has little potential for systemic toxicity due to the extensive metabolism by cholinesterases. Ophthalmic amide agents, however, do have the potential for systemic toxicity (i.e., cardiac dysrhythmias and seizures) but are not frequently used in children. Topical cocaine is rarely used in pediatric ophthalmology except to test for Horner syndrome and as a vasoconstrictor to reduce nasal bleeding during nasal and nasolacrimal duct surgery.

Nonsteroidal antiinflammatory drugs (NSAIDs) are used for certain inflammatory conditions of the eye, but perioperative use in a child is uncommon. Some NSAIDs (i.e., ketorolac and ibuprofen) pose a concern for ophthalmology because their anti-coagulant profiles may increase local perioperative bleeding. However, five NSAIDs are approved for ocular use: diclofenac, bromfenac, flurbiprofen, ketorolac, and nepafenac. Diclofenac, bromfenac, and nepafenac are used postoperatively for their anti-inflammatory effects. Ketorolac has been used to treat macular edema after cataract extraction.

Echothiophate (i.e., phospholine iodide) is a cholinesterase inhibitor used to induce miosis in the treatment of glaucoma. When absorbed systemically, it impairs plasma cholinesterase, reducing the metabolism of some drugs (e.g., succinylcholine) and prolonging their duration of action. Decreased metabolism of acetylcholine may result in increased relative cholinergic tone, inducing bradycardia and bronchiolar muscle activity and resulting in bronchospasm. Toxicity from echothiophate may be antagonized by administration of pralidoxime (2-PAM) (25 mg/kg given intravenously). Otherwise, its action to reduce effective systemic cholinesterases lasts 4 to 6 weeks.

Pilocarpine, a direct-acting cholinergic agonist that is commonly used to treat glaucoma, has replaced echothiophate iodide. Through multiple actions, it improves the flow of aqueous humor. If absorbed, it may acutely cause bradycardia.

Many vitreal substitutes are used in ophthalmologic procedures. They include nonexpansile and expansile gases (e.g., sulfur hexafluoride), perfluorocarbon liquids, and silicone oils. The anesthesia team should be informed when the ophthalmologist plans intraocular use of one of these substances. If a gas pocket is anticipated, nitrous oxide should be discontinued or not used at all. When a perforated globe is closed, any residual environmental air pocket can be expanded by nitrous oxide. Increased ocular pressure and reduced retinal blood flow may result.

A novel agent being studied in the treatment of retinal angiogenic diseases is bevacizumab (Avastin), which inhibits the

**E-FIGURE 32-3** Systemic absorption of ophthalmologic anticholinergic medications may result in toxic reactions, including facial or whole body erythema, tachycardia, and seizures. This child has facial flushing from cyclopentolate absorption.

**TABLE 32-3** Commonly Used Ophthalmologic Agents

Drug	Indication	Side Effect Profile
<b>Cholinergic Agonists</b>		
Carbachol	Induce miosis	Corneal edema, retinal detachment
Pilocarpine	Glaucoma	Corneal edema, retinal detachment
<b>Cholinesterase Inhibitors</b>		
Physostigmine	Glaucoma	Retinal detachment, miosis
Echothiophate	Glaucoma	Retinal detachment, miosis
<b>Muscarinic Antagonists</b>		
Atropine	Cycloplegic retinoscopy	Photosensitivity, blurred vision, increased heart rate, dry mouth
Scopolamine	Cycloplegic retinoscopy	Photosensitivity, blurred vision, increased heart rate, dry mouth
Homatropine	Cycloplegic retinoscopy	Photosensitivity, blurred vision, increased heart rate, dry mouth
Cyclopentolate	Cycloplegic retinoscopy	Photosensitivity, blurred vision, increased heart rate, dry mouth
Tropicamide	Cycloplegic retinoscopy	Photosensitivity, blurred vision, increased heart rate, dry mouth
<b>Sympathomimetic Agents</b>		
Dipivefrin	Glaucoma	Photosensitivity, hypersensitivity
Epinephrine	Glaucoma	Photosensitivity, hypersensitivity
Phenylephrine	Mydriasis	Photosensitivity, hypersensitivity
Apraclonidine	Glaucoma	Photosensitivity, hypersensitivity
Brimonidine	Glaucoma	Photosensitivity, hypersensitivity
Cocaine	Local anesthetic	Anisocoria, corneal injury, photosensitivity, hypersensitivity
Hydroxyamphetamine	Glaucoma	Anisocoria, photosensitivity, hypersensitivity
Naphazoline	Decongestant	Photosensitivity, hypersensitivity
Tetrahydrozoline	Decongestant	Photosensitivity, hypersensitivity
<b><math>\alpha</math>- and <math>\beta</math>-Adrenergic Antagonists</b>		
Dapiprazole ( $\alpha$ )	Reverse mydriasis	Conjunctival hyperemia
Betaxolol ( $\beta_1$ -selective)	Glaucoma	Bradycardia, hypotension
Carteolol ( $\beta$ )	Glaucoma	Decreased heart rate, blood pressure, bronchospasm
Levobunolol ( $\beta$ )	Glaucoma	Decreased heart rate, blood pressure, bronchospasm
Metipranolol ( $\beta$ )	Glaucoma	Decreased heart rate, blood pressure, bronchospasm
Timolol ( $\beta$ )	Glaucoma	Decreased heart rate, blood pressure, bronchospasm

Modified from Brunton LL, Lazo JS, Parker KL, editors. Goodman and Gilman's the pharmacological basis of therapeutics. 11th ed. New York: McGraw-Hill; 2006.

formation of new blood vessels.<sup>61</sup> In the doses prescribed, it should not be an anesthesia concern, but the visual outcome of any infant must be monitored for all perioperative care provided.

### EMERGENT, URGENT, AND ELECTIVE PROCEDURES

One of the greatest controversies in pediatric anesthesia is defining the optimal technique to induce anesthesia in a child with an open globe injury and a full stomach.<sup>52</sup> The issue of aspiration while securing the airway versus the possible extravasation of intraocular contents due to an increase in IOP is a difficult risk-benefit assessment. The debate is likely to continue because the risks are real and the incidence of either phenomenon is rare, difficult to study, and probably underreported.

Among adults, aspiration is an uncommon event with a small mortality rate. The incidence is less than 1 case of aspiration per 200,000 children, precluding an estimate of the mortality rate.<sup>62-65</sup> The rapid-acting, depolarizing muscle relaxant succinylcholine, when used for a rapid-sequence induction in the treatment of a perforated globe, has been challenged because of its known propensity to increase IOP. Development of rapid-acting,

nondepolarizing agents such as rocuronium has provided the anesthesiologist with alternatives to succinylcholine. High-dose rocuronium provides excellent intubating conditions<sup>66</sup> and has the advantage of reducing IOP by blocking the neuromuscular junction of extraocular muscles. However, if the child is not adequately anesthetized and fully paralyzed during instrumentation of the airway, any episode of coughing, retching, or increased systolic blood pressure may increase IOP. Lidocaine (1 to 2 mg/kg given intravenously) usually attenuates the hemodynamic responses to laryngoscopy and tracheal intubation, but this is not a consistent experience.<sup>67,68</sup> Pretreatment with opioids (0.05 to 0.15  $\mu$ g/kg of sufentanil, 0.03 mg/kg of morphine, and 0.1  $\mu$ g/kg of remifentanyl) has been proposed to achieve a similar effect, although they are not consistently recommended. Although reported to blunt the IOP response to intubation, opioids may also induce vomiting, increasing the IOP.

Intravenous access is essential for a rapid induction of anesthesia. In most instances, children with ruptured globes present with intravenous access because intravenous antibiotics must be started as soon as possible (i.e., within 6 hours of the rupture) to

prevent endophthalmitis, which untreated may result in complete loss of vision in that eye. In some instances, however, intravenous access has not been established. When intravenous access is not available, other options may be used to induce anesthesia:

- Placement of a central line
- Intramuscular ketamine (and succinylcholine or rocuronium)
- Mask induction with sevoflurane or halothane
- Placement of an intraosseous needle
- Rectal methohexital or ketamine

None of these alternatives is easy or ideal, and all have significant drawbacks and risks. Placement of a central line may be very challenging in a nonsedated or noncooperative child. Absorption of agents given intramuscularly varies greatly. Although succinylcholine can dependably induce paralysis in a few minutes, the child may cry from pain, develop hypertension, vomit, or experience direct succinylcholine-induced increases in IOP. The latency to action (possibly 2 to 8 minutes) and the gradually paralyzed airway reflexes in a child with a full stomach are clinically important risks.

An argument can be made for placement of an intraosseous needle for induction when intravenous access has not already been established. Even with local anesthesia, placement of an intraosseous needle is poorly tolerated by a conscious child. Mask induction with sevoflurane may facilitate induction of anesthesia, but if only a light plane of anesthesia is reached, coughing and vomiting may occur. The overpressure technique should be used to achieve a rapid and deep plane of anesthesia. Intravenous access should then be established. If this is unsuccessful, an intramuscular dose of muscle relaxant may be administered.<sup>69-71</sup> In this circumstance, IOP may increase, and regurgitation remains a possibility. Rectal methohexital (30 mg/kg) is used only in infants; and if the child evacuates part of the dose, induction is incomplete.<sup>72</sup> Because there is no reliable absorption of neuromuscular relaxant rectally, intramuscular or intravenous administration is necessary.

A moderate approach to the child who needs emergent or urgent ophthalmologic surgery is to secure intravenous access as quickly and painlessly as possible. An attempt is made to preoxygenate the child without causing distress. If a tight mask fit is not easily achieved, forcing the tight fit to the child's face is not desirable because of the likelihood of increasing the IOP as the child resists. Anesthesia should be induced intravenously with propofol and rocuronium. After 30 to 60 seconds by the clock or with train-of-four monitoring, tracheal intubation is performed as expeditiously as possible and the gastric contents evacuated as soon as feasible. The ophthalmologist should be intimately involved in the induction. He or she can physically protect the injured eye with a metal or plastic shield to prevent further injury and assist the anesthesiologist by holding the tracheal tube and suction apparatus immediately within reach of the field of view of the airway.

Other urgent procedures may include treatment of retinopathy or decompression of orbital cellulitis. These procedures may be urgent but still allow several hours of *nil per os* (NPO) status. Concern about aspiration may not be as great. Nonetheless, the surgeon will wish to proceed as expeditiously as is safe. Options for induction and maintenance may or may not include succinylcholine.

Most ophthalmologic procedures are performed on a scheduled basis, allowing routine preoperative evaluation and

planning. This includes establishing all relevant medical information about the child, implementing NPO status, and placing an intravenous catheter if desired.

## INDUCTION AND MAINTENANCE OF ANESTHESIA

Intravenous or inhalational induction of anesthesia may be performed in infants and children for most elective ophthalmologic procedures. Most infants do not require a premedicant for anxiolysis, and the use of premedication after the first year of life is usually discussed between the anesthesiologist and the parents and child. Separation anxiety or struggling during induction usually does not affect most ophthalmologic diagnoses, except for a penetrating eye injury, which may become worse if the child struggles.

Intravenous propofol, etomidate, or ketamine produce a smooth induction, and the anesthesiologist can then support and secure the airway as planned. Inhalational induction with oxygen, nitrous oxide, and sevoflurane or halothane also produces smooth induction states. If laryngospasm develops during induction, an intravenous or intramuscular neuromuscular relaxant or intravenous propofol (1 to 2 mg/kg given intravenously) should be administered promptly. Atropine (20 µg/kg) should be given intravenously or intramuscularly before bradycardia occurs. For planned tracheal intubation, an intravenous nondepolarizing muscle relaxant is preferred because succinylcholine may raise the IOP. Intramuscular administration of succinylcholine or rocuronium may also break laryngospasm if an intravenous catheter has not been placed.<sup>64-71,73-75</sup>

Alternative induction methods include intramuscular administration of ketamine (4 to 10 mg/kg) and, in infants, rectal methohexital (25 to 30 mg/kg). Ketamine may increase IOP, but it has been successfully used in ophthalmologic procedures in children.<sup>58</sup> Rectal methohexital has a dependable latency to induction of general anesthesia of 7 to 8 minutes, but its elimination can vary widely, and its respiratory depressant effects may linger. Currently, rectal methohexital is infrequently used.

Tracheal intubation is our preference for most pediatric ophthalmologic procedures, except for a rapid EUA or nasolacrimal duct probing. With the tracheal tube secured, the child and operating table may be safely turned 90 or 180 degrees for optimal positioning of the table and child for surgery.

An immobile child may be essential to ensure the optimal surgical outcome. If the surgeon requires immobility, a tracheal tube should be placed and neuromuscular relaxants administered for as long as is required to complete the procedure. A cuffed or uncuffed tracheal tube may be used. If the uncuffed tube has too large a leak, we do not hesitate to change to a larger uncuffed tube or replace the first tube with a cuffed tube to seal the airway. The tracheal tube is secured so that the sterile surgical field is maintained during the procedure. Access to the tracheal tube and anesthesia circuit by the anesthesia care team without trespass of the surgical field is imperative. Extensions to the anesthetic circuit have no bearing on the dead space of the breathing circuit, whereas extensions between the Y connector in the circuit and the patient (i.e., adjacent to the tracheal tube) adds dead space that may increase PCO<sub>2</sub>.

Anesthesia can be maintained with a variety of techniques. Inhalational sevoflurane, isoflurane, or desflurane may provide excellent conditions for maintenance of anesthesia<sup>60</sup> and rapid emergence. Emergence from halothane anesthesia is slower. We communicate with the ophthalmologist and reinforce the need

for an absolutely immobile field. When neuromuscular blockade is necessary, we routinely use nondepolarizing neuromuscular relaxants and train-of-four monitoring to ensure the adequacy of surgical conditions. Carefully titrated doses of opioids are used as an anesthetic adjunct if postoperative pain is anticipated.

The anesthetic and type of surgery affect the incidence of PONV. Strabismus surgery in children is associated with the greatest incidence (45% to 85%) of PONV.<sup>76</sup> The type of ventilation does not attenuate the incidence of PONV.<sup>77</sup> Fluid replacement has a significant effect on the risk of PONV. Avoiding opioids during strabismus surgery may also be effective.<sup>78,79</sup> Non-opioid analgesics such as acetaminophen,<sup>80</sup> diclofenac,<sup>81</sup> and ketorolac<sup>78,79</sup> may be used. If opioids are needed, short-acting medications are preferred: remifentanyl, alfentanil, or fentanyl. Some evidence suggests that the more extraocular muscles that require surgery and specific muscles that require more traction (e.g., inferior oblique), the greater the incidence of PONV, although these data have not been firmly established.

A host of medications can significantly affect the risk of PONV.<sup>82</sup> Preoperative use of benzodiazepines,<sup>83</sup> avoidance of nitrous oxide,<sup>84</sup> and superhydration with balanced salt solutions<sup>85</sup>; using of propofol,<sup>84,86</sup> clonidine,<sup>87</sup> 5-HT<sub>3</sub> receptor antagonists,<sup>88-92</sup> dimenhydrinate,<sup>93,94</sup> metoclopramide,<sup>92,95</sup> or dexamethasone<sup>96-100</sup>; and delaying oral fluid ingestions after surgery<sup>101</sup> attenuate the incidence of PONV. With clonidine and 5-HT<sub>3</sub> receptor blockers, but not dexamethasone, there is a dose-response relationship with PONV.<sup>87,88,96</sup> Older antiemetics such as droperidol that have been very effective in attenuating the incidence of PONV<sup>80,102-105</sup> have fallen into disfavor because of their sedative side effects and concerns associated with prolonged QT intervals,<sup>106</sup> although the latter has not been a common problem in children.<sup>107</sup>

Anesthesiologists have adopted a multimodal approach to PONV in the case of strabismus surgery. A commonly used regimen includes premedication with oral midazolam, choice of anesthesia, superhydration with intravenous fluid, and the combination of 5-HT<sub>3</sub> receptor antagonists and dexamethasone. There is no evidence in children undergoing strabismus surgery that dosing 5-HT<sub>3</sub> receptor antagonists at the end of surgery provides better protection against PONV than earlier in the surgery.<sup>108</sup> However, dosing 5-HT<sub>3</sub> receptor antagonists during emergence in children with congenital prolonged QT interval increases the risk of adverse events.<sup>109</sup> There is a dichotomy of practice with respect to maintenance of anesthesia. Some avoid nitrous oxide, maintaining anesthesia by propofol infusion and including the previously mentioned supplementary medications. Others use nitrous oxide and an inhalational anesthetic for maintenance but also include the remainder of the preoperative and intraoperative supplementary medications.

Intravenous fluid replacement can reduce PONV.<sup>110</sup> Children who present for elective surgery drink clear fluids up to 2 hours before surgery, reducing the fasting period. However, it is important to identify those who have fasted for a prolonged period and to administer sufficient intravenous fluids to reestablish euolemia, avoiding the activation of antidiuretic hormone and aldosterone that may cause fluid retention. When using balanced salt solutions, children should receive 10 mL/kg/hr of the solution intravenously during the first 4 hours of surgery and recovery to reestablish euolemia and to avoid activation of the antidiuretic hormone and aldosterone pathways. This should be followed postoperatively by a maintenance intravenous fluid infusion rate

at one half of the previously considered rate, using 2 mL/kg/hr for the first 10 kg, 1 mL/kg/hr for the next 10 kg, and 0.5 mL/kg/hr for every kilogram greater than 20 kg until the child takes fluids by mouth.<sup>111-113</sup> The incidence of PONV is reduced when large volumes of balanced salt solution (20 to 30 mL/kg) are administered compared with smaller volumes (10 mL/kg).<sup>85</sup> When the surgical procedure is not likely to involve an increased IOP, we routinely replace almost 100% of the calculated deficit. We have not observed children to experience urinary retention or hypertension from this strategy. However, if the duration of surgery exceeds 3 hours, then we catheterize the bladder to reduce the risk of urinary retention and overdistention of the bladder.

At the completion of surgery, neuromuscular relaxation is antagonized, maintenance agents are discontinued, and the child is allowed to awaken. Deep extubation is preferred by some to reduce coughing and increases in IOP at the time of extubation.<sup>114</sup> Others prefer extubating the trachea when the child is fully awake with intact airway reflexes, although coughing and increases in IOP may occur. For most procedures in children, a short interval of increased IOP does not damage a surgical correction, such as strabismus, ptosis, or ROP treatment. Appropriate postoperative analgesics may include local anesthetics, acetaminophen, and opioids. Nonsteroidal agents usually are not given to these children due to concerns about perioperative bleeding at the surgical site because of their mild anticoagulant profile, but ketorolac has been useful.<sup>78</sup> Lorazepam may also have some utility.<sup>83</sup> Postoperatively, withholding oral fluids until the child expresses a desire to drink reduces the incidence of PONV.<sup>101</sup>

## Specific Ophthalmologic Procedures

Strabismus repair is common in children.<sup>91</sup> Corrective surgery realigns the divergent visual axes of the eyes by detaching and reattaching extraocular muscles to the globes (Fig. 32-4). The procedures may be brief if only one or two muscles are involved. In infants, inhalational or intravenous induction is performed, and neuromuscular blockade is provided with nondepolarizing neuromuscular relaxants. Strabismus may be an isolated finding in a child or a manifestation of other systemic diseases or syndromes.<sup>115</sup> The anesthesiologist should carefully review the birth history, history of prematurity, central nervous system disorders, syndrome identification, possible coexistent myopathy, and cardiovascular and respiratory history. He or she should also anticipate the OCR and pretreat with atropine or glycopyrrolate. PONV is common and may be reduced by multiple strategies (Table 32-4).

We avoid succinylcholine for routine use in children in general, and in this circumstance, if succinylcholine is used, the

**FIGURE 32-4** Strabismus repair is a common pediatric ophthalmologic procedure. The child demonstrates significant right esotropia that requires surgical correction.

**TABLE 32-4** Antiemetic Strategies for Prophylaxis and Treatment of Postoperative Nausea and Vomiting

Strategy	Drug and Dose
Butyrophenone (dopamine antagonist)	Droperidol (10-70 µg/kg)
Serotonin (5HT <sub>3</sub> receptor antagonists)	Ondansetron (0.1 mg/kg) Granisetron (10-40 µg/kg) Dolasetron (0.35 mg/kg)
Propofol-based total intravenous anesthesia	Propofol (100-175 µg/kg/min)
Local anesthetic	Lidocaine local-topical and systemic (1-1.5 mg/kg)
Opioid-sparing analgesics or anesthetics	Retrobulbar block with bupivacaine
Other pharmacology	Dexamethasone (10-500 µg/kg); maximum, 8 mg Dimenhydrinate (0.5-1 mg/kg) Metoclopramide (0.15-0.25 mg/kg) Benzodiazepines (e.g., lorazepam, midazolam) (10-100 µg/kg) Avoid nitrous oxide (N <sub>2</sub> O) Avoid opioids Use ketorolac (Toradol) (0.5 mg/kg PO, IV, IM), acetaminophen (30-40 mg/kg PR or 15 mg/kg IV), or diclofenac (1 mg/kg PR), or short-acting opioids (e.g., remifentanyl, alfentanil, fentanyl)
Nonpharmacologic adjuvants	Intravenous hydration Gastric decompression

IV, Intravenous; IM, intramuscular; PO, per os (oral); PR, per rectum (suppository).

surgeon should be informed because it may alter the forced duction testing and affect the planned repair.<sup>116</sup> After induction of anesthesia and tracheal intubation, the operating room table is rotated to permit complete access to the orbits. It is common to use a preformed tube that lies flat against the mandible.<sup>117</sup> The tracheal tube is positioned away from the surgical field. Ventilation may be spontaneous or controlled if the surgery is extraocular. If the surgery is intraocular or medical conditions dictate, controlled ventilation should be considered. Some anesthesiologists are willing to perform strabismus repair using an LMA with spontaneous ventilation.<sup>118</sup> Although regional block is performed in some adults, strabismus surgery in children is routinely performed with general anesthesia.

### ANTERIOR CHAMBER PARACENTESIS

An anterior chamber paracentesis may be performed in children for evaluation of uveitis, infection,<sup>119</sup> or leukemia<sup>120</sup> or for removal of fluid to decrease IOP. Because the field needs to be sterilized and the needle must enter a small target area of the anterior chamber, the child should be placed under general anesthesia to make the field immobile for the surgeon.

### DACRYOCYSTORHINOSTOMY

Infants may be born with nasolacrimal duct stenosis (i.e., congenital dacryostenosis) (Fig. 32-5 and E-Fig 32-4). If conservative measures do not demonstrate improvement, the ophthalmologist may need to dilate the duct or pierce a hole in the intact

**FIGURE 32-5** Nasolacrimal duct obstruction manifests with different degrees of infraorbital inflammation, from mild obstruction with minor infection and mucoid material accumulation (A) to severe obstruction with periorbital or preseptal cellulitis (B). Both may require dacryocystorhinostomies.

membrane using a metal probe.<sup>121,122</sup> These infants are induced with general anesthesia, and when the level of anesthesia is sufficient, the ophthalmologist completes the procedure in a few minutes. To confirm that the duct is patent, the ophthalmologist can touch the metal probe within the duct with a second probe that is inserted into the nostril. Alternatively, the ophthalmologist may inject fluorescein into the nasolacrimal duct and detect the fluorescein on a pipe cleaner in the nasal airway. In both instances, fluorescein or blood may reach the larynx and trigger breath holding or laryngospasm. To avoid this, it is prudent to tilt the operating table to a 5- to 10-degree Trendelenburg position and place a small roll under the child's shoulders to pool the fluids away from the larynx. These secretions are suctioned out of the oropharynx and nasopharynx before emergence. Anesthesia may be maintained by facemask inhalation or with intravenous agents. The airway and respirations are carefully monitored visually and by capnography. The infant is awakened, and postoperative analgesia may be offered with acetaminophen or opioids, or both, as necessary.

Alternatively, an endonasal endoscopic approach may be used for complicated or recurrent dacryrhinocystotomy.<sup>123,124</sup> This makes the procedure significantly longer, and it requires airway control to facilitate the surgeon's approach and to protect the child from aspirating blood during the procedure.

### PTOSIS REPAIR

*Ptosis* (i.e., blepharoptosis) means "drooping of the eyelid." This condition can be congenital or acquired, and it may be associated with amblyopia or astigmatism. If eyelid closure is complete in infancy, occlusion amblyopia will occur, and this may require urgent attention. Otherwise, surgery for ptosis is often performed in later childhood. The surgical approaches require a quiet surgical field, and the surgeon makes a great effort to produce a symmetric repair.

### CATARACT SURGERY

Cataracts are opacifications of the lens of the eye (Fig. 32-6). Cataracts in children may be congenital, posttraumatic, or

**E-FIGURE 32-4** This child presented with bilateral congenital dacryocystoceles (i.e., small ectatic sacculles of the nasolacrimal ducts) that will require surgical intervention. The procedure will require more time than unilateral duct probing to relieve the medial obstructions, and it may require airway instrumentation and control.

**FIGURE 32-6** **A**, The right red reflex is absent in a child with a cataract that requires removal. **B**, The close-up photograph shows a nuclear cataract, which is associated with many inborn errors of metabolism in childhood. Cataracts that are not central or spherical may be caused by trauma or abuse.

metabolic in origin.<sup>125</sup> Congenital cataracts require surgery very early in life to permit photostimulation of the retina.<sup>126</sup> Although the surgery can be performed as an outpatient, the formerly premature and young infant may require monitoring for postoperative anesthetic-induced respiratory depression or apnea. Cataracts are associated with some systemic diseases, and intraocular lens implants are often offered to improve the long-term visual prognosis.<sup>127</sup> The child should be examined carefully for dysmorphism, with close attention to issues of airway management and the cardiorespiratory system.

### ENUCLEATION

Enucleation of the eye may be necessary when a child has an intraocular tumor (e.g., retinoblastoma) (Fig. 32-7),<sup>128</sup> a ruptured globe or ocular trauma,<sup>129</sup> recurrent or chronic infections, or a blind, painful eye. *Leukocoria* is the term meaning “white pupil.” The differential diagnosis is extensive and includes many intraocular tumors. Other disorders causing leukocoria include Coats disease, cataract, coloboma, and *Toxocara canis* infection.

**FIGURE 32-7** Retinoblastoma is one of many intraocular tumors that may require enucleation. **A**, Retinoblastoma seen by direct ophthalmoscopy. **B**, Pathologic specimen of a retinoblastoma in the globe after enucleation.

When necessary, the entire globe must be removed, and all bleeding points are coagulated. The OCR may occur during this procedure and may be attenuated by infiltration with a local anesthetic. Prophylactic antiemetics are often administered after enucleation surgery because PONV is common.

### VITRECTOMY

Vitrectomy may be necessary for retinal injury or detachment induced in circumstances of nonaccidental trauma or ROF.<sup>130</sup> Any infant or child presenting acutely with a closed head injury from suspected abuse should have an ophthalmologic consultation to completely evaluate all orbital structures.<sup>131</sup> These delicate tissues may demonstrate pathology that requires long-term follow-up or urgent medical or surgical therapy. Glaucoma may occur with hyphema or lens subluxation or dislocation with tearing of the support tissue. Early diagnosis is paramount if surgical intervention is to have the greatest benefit.

## RETINOPATHY OF PREMATURITY TREATMENT

Preterm infants may present with multiple ocular pathologic conditions, but none is more common than ROP. It has been extensively studied,<sup>15</sup> and multiple collaborative trials have reported their results and recommendations for medical and surgical intervention.<sup>132-136</sup> The cause is unknown, but oxygen-related theories have been described for more than 40 years. Because of this concern, oxygen range targeting has become common<sup>137-139</sup> to reduce the oxidative stress<sup>140</sup> on the infant in general and to reduce the effect of oxygen on neovascularization in the eye.

Laser and cryotherapy are common treatments for this condition.<sup>132,133</sup> Because of the delicacy and exacting accuracy required in laser procedures, we routinely intubate the trachea and use neuromuscular relaxants. This facilitates the immobile field necessary for the surgeon, and it provides better perioperative physiologic stability for the infant.<sup>141</sup> The complications of prematurity determine whether extubation is possible, and many infants require postoperative ventilation, if only for a brief period or overnight. The operative environment should be kept warm to reduce thermal stress on the infant.

**PEDIATRIC PLASTIC SURGERY** is performed in children of all ages, even in utero.<sup>1</sup> However, the majority of children who undergo plastic surgical and reconstructive procedures are between 2 and 9 years of age, with a median age of 5 years.<sup>2</sup> A wide spectrum of associated craniofacial abnormalities, underlying medical conditions, and surgical procedures characterize this pediatric population. Consequently, a thorough preoperative assessment, consultation with medical and surgical teams, and anticipation and preparation for potential complications are of paramount importance to ensure a successful perioperative outcome. The incidence of major morbidity and mortality has been reduced over the last 30 years from 16.5% and 1.6% to less than 0.1% and 0.1%, respectively, in children undergoing major craniofacial surgeries.<sup>3</sup>

## Cleft Lip and Palate

Cleft lip and palate are among the more common congenital malformations, occurring with an estimated incidence of approximately 1 in 700 births worldwide.<sup>4</sup> More common in males than in females, this malformation likely results from both environmental and genetic causes. Parental occupation, in particular paternal farming, increases the risk of cleft lip or palate in the offspring, whereas the maternal occupation presents no additional risk.<sup>5</sup> Folate metabolism disturbances and increased maternal homocysteine levels also may be contributory.<sup>6</sup> Cleft lip with or without cleft palate has been linked to several loci on chromosomes 1, 2, 4, 6, 14, 17, and 19, suggesting a genetic basis for some of these anomalies.<sup>7-9</sup>

These disorders are associated with more than 400 syndromes; the more common syndromes are presented in Table 33-1. Cleft lip and palate begin as a defect in palatal growth in the first trimester of pregnancy. Fetal magnetic resonance imaging (MRI) provides a greater degree of resolution of defects in the posterior palate and lateral extent of cleft with greater diagnostic accuracy than ultrasound. MRI also enables early detection of potential syndromic conditions by providing a complete study of the fetal head and biometric development of the facial bones.<sup>10</sup>

Primary cleft lip repair is usually undertaken at approximately 3 months of age, whereas primary cleft palate repair occurs at 6 months. Surgery for lip or nose revision usually takes place in early childhood, and palatal revision and alveolar bone grafts occur at approximately 10 years of age. Rhinoplasty and maxillary osteotomy to complete the repair may take place at 17 to 20 years of age. Pharyngoplasty may be required for velopharyngeal incompetence secondary to anatomic or neurologic dysfunction to improve speech development and prevent nasal regurgitation during eating.

## ANESTHETIC CONSIDERATIONS

Surgical correction of cleft lip defect is usually performed at 3 months of age to allow sufficient time for maturation and associated abnormalities to become apparent. Preoperative assessment may reveal abnormalities such as mandibular hypoplasia in Pierre Robin sequence (Fig. 33-1 and E-Fig. 33-1) or restricted neck movement as in Klippel-Feil syndrome (E-Fig. 33-2).<sup>4</sup> *Pierre Robin sequence* is defined as the triad of micrognathia, glossoptosis (caudally displaced insertion of the tongue), and respiratory distress in the first 24 to 48 hours after birth. The presence of other anomalies might warrant additional clinical or laboratory investigations. Cleft lip repair usually involves minimal blood loss, so for children with hematocrit values greater than 30%, homologous blood donation is unnecessary. Type and screen of donated blood is usually sufficient for a hematocrit value less than 30%.<sup>11</sup>

The frequency of difficult airways in children with cleft lip and palate varies from 4.7% to 8.4%.<sup>12-14</sup> The incidence of difficult intubation in children with bilateral cleft is greater than that with unilateral cleft.<sup>14</sup> Furthermore, micrognathia is an independent predictor of a difficult airway. The incidence of difficult laryngoscopy is approximately 50% in children with micrognathia but only about 4% in those without. In infants and young children, micrognathia may be subtle and not always easily detected. However, the presence of microtia, particularly bilateral microtia, which has a 42% incidence of difficult intubation with bilateral compared with 2% with unilateral microtia, should

**E-FIGURE 33-1** **A**, Child with Pierre Robin sequence. Retrognathia is prominent. **B**, Older child with Pierre Robin sequence with persistent retrognathia. **C**, Three-dimensional magnetic resonance imaging skull reconstruction demonstrating hypoplastic mandible.

**E-FIGURE 33-2** Klippel-Feil syndrome in an infant. In this syndrome, neck extension is limited, making laryngoscopy and tracheal intubation very difficult. The airway difficulties in children with Klippel-Feil syndrome increase with age.

**TABLE 33-1** Syndromes Commonly Associated with Cleft Lip and Palate

Pierre Robin sequence
Down syndrome
Klippel-Feil syndrome

Nager syndrome
Goldenhar syndrome

**FIGURE 33-1** Child with Pierre Robin sequence who required a tracheostomy because of respiratory distress in the first 24 hours postnatally. The retrognathia is often associated with glossoptosis, which makes visualization of the glottic aperture more difficult.

prompt a closer examination of the mandible for hypoplastic growth and raise the possibility of a hemifacial microsomia or Treacher Collins syndrome.<sup>15</sup> Intubation difficulty with isolated micrognathia decreases with increasing age, with the greatest difficulty presenting in infants younger than 6 months. Tracheal intubation becomes easier with age in isolated micrognathia. This has been attributed to rapid growth of the mandible, which catches up to the maxilla, thereby aligning the two bones, by 2 years of age in most cases. A careful review of previous anesthetic records may forewarn of a difficult airway. In our experience, tracheal intubation is not particularly difficult in most infants and children with cleft lip or palate, unless concomitant defects such as micrognathia are present.

Induction of anesthesia via facemask is usually uncomplicated in infants with cleft lip and palate. Laryngoscopy should be performed using a straight blade via a right paraglossal approach (blade inserted into the pharyngeal gutter with tongue displaced to the opposite side)<sup>16</sup> (or a left approach if a left-handed blade is available), taking care to avoid inserting the blade into the cleft (see also Fig. 12-28, A-C). If the mandible is hypoplastic, external laryngeal manipulation may be required to visualize the larynx. In some centers, the tongue is sutured to either the mandible or lower lip to preclude airway obstruction in infants with Pierre Robin sequence in the postnatal period. In such instances, the tongue cannot be displaced to the left to expose the larynx. To

**FIGURE 33-2** Nasal airways are often placed at the end of cleft palate or pharyngoplasty surgery to ensure that a patent airway is maintained.

facilitate laryngoscopy in such cases, the tongue is first released from the lower lip using ketamine sedation. Direct laryngoscopy follows. If direct laryngoscopy fails to expose the larynx, then alternative airway maneuvers such as fiberoptic intubation through a laryngeal mask airway (LMA) may be used after an inhalational induction of anesthesia and release of the tongue (see Chapter 12 and Fig. 12-22, A-C).

A variety of tracheal tubes can be used to secure the airway for cleft lip and palate surgery, although the ideal tracheal tube is perhaps the oral Ring-Adair-Elwyn (RAE) tube, which can be fixed centrally to the chin to facilitate optimal surgical access. Reinforced tracheal tubes are suitable alternatives, but in both cases care must be taken to fix the tube at the correct depth to avoid endobronchial intubation. Throat packs usually impinge on the surgical field and are not normally required for cleft palate repair. The lungs are ventilated for the duration of the procedure, usually 1 to 2 hours. Inhalational or intravenous anesthetics combined with a short-acting opioid such as fentanyl (1 to 2  $\mu\text{g}/\text{kg}$ ) can be used for maintenance of anesthesia. Bilateral infraorbital nerve blocks may be used to provide postoperative analgesia for cleft lip repairs (see Fig. 41-11, A-C, and Chapter 41 videos). Such blocks reduce the need for opioids and antiemetics, improve the ability to feed,<sup>17</sup> and increase parental satisfaction.<sup>18</sup> A combination of infraorbital and external nasal nerve blocks for pain control after cleft lip repair is an alternative.<sup>19</sup>

During cleft palate surgery, the pharyngeal space is reduced dramatically (Fig. 33-2 and E-Fig. 33-3). The trachea is extubated after the upper airway reflexes have returned and the child is completely awake. These children are at particular risk for acute upper airway obstruction in the immediate postextubation period as a result of upper airway narrowing, edema, blood, and residual anesthetic effects.<sup>20-25</sup> Accordingly, it is very important

**E-FIGURE 33-3** Oral views before (A) and after (B) repair of cleft palate. Closure of the cleft palate is possible through tension-releasing incisions. The oropharyngeal space is dramatically reduced at the end of the procedure. Children unable to mouth breathe before surgery (e.g., those with a very small mandible) are dependent on patent nasal airways at the end of the procedure.

to extubate the trachea only when the child is completely awake. Late postoperative edema<sup>26</sup> and severe subcutaneous emphysema are additional complications. Upper respiratory tract infections are common in this age group, and if these infections are present, they should weigh heavily in favor of delaying surgery until they are resolved. Antibiotics may reduce the incidence of postoperative respiratory complications.<sup>27</sup>

A nasopharyngeal airway may be inserted by the surgeon before extubation to ensure a patent airway after extubation and permit suctioning the airway without damaging the palatal repair (see Fig. 33-2). Arm restraints are used in many centers to prevent suture disruption. These children are monitored for signs of upper airway obstruction during the recovery period for approximately 48 hours.<sup>20</sup> As soon as the child is awake, feeding with clear fluids is allowed. Postoperative pain is managed with a combination of opioids and acetaminophen. Sphenopalatine and infraorbital nerve blocks with a long-acting local anesthetic can be placed at the end of the procedure to prevent pain after cleft lip and palate repair.<sup>17</sup> Palatal nerve block (nasopalatine, greater and lesser palatine)<sup>28</sup> or a bilateral suprazygomatic maxillary nerve block reduce postoperative pain and favor early feeding.<sup>29</sup>

Children who are scheduled for elective pharyngoplasty are usually school age, having undergone cleft palate repair at an earlier age. The primary objective of this procedure is to restore velopharyngeal competence for speech development, which can be achieved by a pharyngeal flap, sphincter pharyngoplasty, or palatal lengthening (Furlow double-opposing Z-plasty palatoplasty). The anesthetic goals and management are similar to those discussed for cleft palate repair.

## Craniosynostosis

Craniosynostosis, a congenital anomaly in which one or more cranial sutures closes prematurely, occurs in approximately 1 in 2000 births, and affects males more frequently than females. Embryologically, the cranial vault starts to ossify at 8 weeks after conception. Fusion of the parietal and frontal bones is usually completed by 7 months after conception. Postnatally, the antero-lateral fontanelle closes by 3 months, the posterior fontanelle by 3 to 6 months, the anterior fontanelle by 9 to 18 months, and the posterolateral fontanelle by 2 years. Premature osseous obliteration of a bony suture might result from the absence of osteo-inhibitory signals from the suture. Craniosynostosis may be categorized as simple (or nonsyndromic) (65% to 80% of cases), involving closure of one suture, or complex (or syndromic) (20% to 30%), involving closure of two or more sutures and often associated with a variety of clinical features and metabolic diseases (Table 33-2).<sup>30,31</sup>

In the child with craniosynostosis, the head may assume various shapes depending on the sutures involved (Fig. 33-3 and E-Fig. 33-4). The frequency of single suture closures varies with the specific suture: sagittal (50%), coronal (20%), and metopic (10%).<sup>30</sup> The coronal suture is more commonly associated with syndromic craniosynostoses.

Although approximately 80% of premature suture closures are isolated defects, the remaining 20% involve multiple suture closures associated with more than 150 syndromes that present with a myriad of clinical features (see Table 33-2).<sup>30</sup> Apert syndrome occurs in approximately 1 in 100,000 live births, usually as a sporadic mutation, although autosomal dominant inheritance patterns can occur. This syndrome phenotypically manifests as cloverleaf skull (craniosynostosis), hypertelorism, proptosis,

**TABLE 33-2** Classification of Craniosynostosis

**Nonsyndromic (primary) ~80%: Single suture closed, isolated finding**

**Syndromic ~20%: Two or more sutures closed, often with associated clinical findings. More than 150 syndromes have been described; the more common syndromes are as follows:**

Crouzon  
Apert  
Pfeiffer  
Saethre-Chotzen  
Carpenter (acrocephalopolysyndactyly type II)  
Muenke  
Crouzonodermoskeletal  
Shprintzen-Goldberg  
Loeys-Dietz  
Jackson-Weiss  
Beare-Stevenson  
Cole-Carpenter  
Kleeblattschädel  
Fibroblast growth factor receptor mutations 1 and 2  
Metabolic and Other Causes  
Rickets  
Bone metabolic disorders (hypophosphatasia)  
Achondroplasia  
Prematurity

**FIGURE 33-3** Infant with classic craniosynostosis. The shape of the child's head may not reflect the severity of the defect. The defect is best appreciated by three-dimensional magnetic resonance imaging reconstruction.

midface hypoplasia, and syndactyly (upper or lower extremity). Development is often complicated by increased intracranial pressure (ICP) and obstructive sleep apnea (OSA).<sup>32,33</sup> Whether children with Apert syndrome develop normal intelligence quotients (IQs) is unclear. One study reported that 32% of children with Apert syndrome had IQs greater than 70.<sup>34</sup> Timing of cranial

**E-FIGURE 33-4** Frontal three-dimensional magnetic resonance imaging (MRI) of a child with sagittal craniosynostosis. Note closed sagittal suture in the skull midline (*arrow*).

surgery may affect the child's IQ; surgery in the first year of life was associated with an IQ greater than 70 in more than 50% of children in one study, whereas surgery after the first year of life was associated with an IQ greater than 70 in only 7%. Two other factors predicted improved IQ indices: absence of a defect in the septum pellucidum and noninstitutional residence (i.e., family home residence). Crouzon syndrome is phenotypically similar to Apert syndrome but has different ophthalmologic defects, specifically, optic atrophy occurring in up to 20%, and the absence of digital involvement.<sup>35</sup> Fifty percent of Crouzon syndrome defects are sporadic mutations, and the remainder are familial. Pfeiffer syndrome occurs in approximately 1 in 25,000 live births. Most cases are familial with an autosomal dominant inheritance pattern, although many remain sporadic. The phenotype of Pfeiffer syndrome is similar to that of Apert syndrome but includes broad thumb, large first toe, and polydactyly. Children with Pfeiffer syndrome have normal intelligence. Carpenter syndrome is associated with craniosynostosis, syndactyly, cardiac defects, and obesity.<sup>36</sup> Cognitive impairment is common.<sup>36</sup> A relatively new but rare syndrome, Shprintzen-Goldberg, is characterized by craniosynostosis and a phenotype that resembles that of Marfan syndrome.

Indications for cranial vault reconstruction include increased ICP, severe exophthalmos, OSA, craniofacial deformity, and psychosocial reasons. If uncorrected, the deformed cranium may cause severe neurologic sequelae, including visual loss and developmental delay (see Chapter 23).<sup>37-49</sup> Because rapid brain growth during infancy determines skull shape, surgical correction is undertaken within the first months of life to achieve the best cosmetic results.

Cranial vault reconstruction may involve the anterior or posterior aspect of the skull or both (total cranial vault reconstruction). Less invasive approaches to correct craniosynostosis are available and may be associated with reduced morbidity. Surgical correction may employ an extended strip craniectomy in which the cranial vault is split in multiple segments, allowing the skull to grow with the brain (Fig. 33-4 and E-Fig. 33-5). This technique is used in children younger than 6 months of age and is believed to be less invasive than total cranial vault reconstruction, although children are required to wear a protective helmet after surgery.<sup>50,51</sup> Endoscopic strip craniectomy is increasingly being used in early infancy and has various benefits compared with the open procedures. Spring-assisted cranioplasty, a technique preferentially

**FIGURE 33-4** Child immediately before surgical closure after total cranial vault reshaping using strip craniectomy for sagittal craniosynostosis.

used in infants, involves performing a midline osteotomy along the fused sagittal suture and placing springs across the osteotomy to increase the biparietal dimension. Spring-assisted cranioplasty may be associated with reduced intraoperative blood loss, reduced transfusion requirement, and shorter duration of hospital stay.<sup>52</sup> In a single-center study of 100 children with spring-assisted craniosynostosis, no child was transfused and none was admitted to the intensive care unit.<sup>53</sup>

Preoperative assessment of children with craniosynostosis should focus on airway management, eye protection, and ICP. An important consideration in children with midfacial hypoplasia and large tonsils is the presence of OSA. OSA may be present in 50% to 70% of children with syndromic craniosynostosis.<sup>33,54,55</sup> Although some recommend preoperative adenotonsillectomy to treat OSA in children with craniosynostosis, neither airway dimensions nor airway collapse is improved. Midfacial advancement may be required to resolve OSA, and even then, residual airway obstruction may persist.<sup>33,54</sup> Preoperative endoscopy has been recommended to assess the severity of midfacial hypoplasia and whether OSA is likely to persist after midface advancement. Careful titration of opioids in the perioperative period is indicated if the child exhibits severe nocturnal desaturation (i.e., if the  $\text{SaO}_2$  nadir is less than 85%) (see Chapter 31). Upper airway obstruction may also occur postoperatively in children who received opioids as a direct effect of opioids on the hypoglossal nucleus.<sup>56</sup>

Postoperative pain is generally not severe and is managed effectively with a combination of acetaminophen, nonsteroidal antiinflammatory drugs (NSAIDs), and intravenous opioids. Opioids remain the mainstay of pain management, but careful titration of reduced doses (approximately 50% less) must be considered if OSA is present. Given the small incidence of craniosynostosis and the large variability in the management of these patients, multicenter trials are required to determine the optimal management strategy for these children.<sup>57</sup>

### AIRWAY MANAGEMENT

Meticulous preoperative planning and evaluation of the airway is essential, particularly for OSA.<sup>54</sup> A facemask may prove to be a challenge to seal on their flat faces and the nasal passages may be obstructed, together creating a difficult mask ventilation.<sup>58</sup> External fixator devices on the face may also present challenges in managing the airway (E-Fig. 33-6).

Upper airway obstruction may readily occur during mask induction because of the narrowed nares, midfacial hypoplasia, pharyngeal collapse, and large tonsils. Subluxing the temporomandibular joint or inserting an oropharyngeal airway should resolve the obstruction and permit the inhalational induction to continue. In the majority of these children, the anatomy of the mandible and the temporomandibular joint is normal, as are upper airway dimensions, resulting in an easy laryngoscopy and tracheal intubation. Rarely, mandibular hypoplasia may complicate an otherwise straightforward laryngoscopy and tracheal intubation. Abnormal neck mobility also may pose additional challenges for laryngoscopy and tracheal intubation.

### BLOOD LOSS, COAGULOPATHY, AND HYPONATREMIA

Crystalloid solutions are commonly administered for minimal to moderate surgical blood loss and fluid shifts during craniosynostosis surgeries. Although lactated Ringer's solution is most commonly used in North America, some advocate using normal saline because it may be less likely to induce hyponatremia and an acid-base disturbance than lactated Ringer's solution. However, a recent study comparing the two solutions suggests that normal

**E-FIGURE 33-5** Three-dimensional MRI of a child after extended strip craniectomy (see Fig. 33-4). This approach is commonly used in infants younger than 6 months of age. To protect the fragile skull bones, a protective helmet must be worn after surgery until cranial remodeling is complete.

**E-FIGURE 33-6** External fixation devices present unique challenges to the anesthesiologist for orotracheal intubation. If necessary, these devices must be released to secure the airway.

saline is more likely to induce (metabolic) acidosis than lactated Ringer's solution in infants undergoing craniosynostosis.<sup>59</sup> The explanation for this finding has been elusive, but it has been attributed to hyperchloremia, a dilutional acidosis, or both.

Surgery for craniosynostosis is associated with an increased incidence of cardiac arrest as a result of sudden massive blood loss.<sup>3,30,60,61</sup> Although these procedures are extradural, significant blood loss from the scalp and cranium can occur. The blood loss can be so rapid during the surgery that the expression "trauma in progress" is applicable. The risk of massive blood loss and the need for invasive monitoring are determined in part by the specific suture involved, number of sutures scheduled for repair, type of surgery, and expertise of the surgeon.<sup>61</sup> In children undergoing endoscopic strip craniectomy, weight less than 5 kg, those undergoing sagittal endoscopic craniectomy, those with syndromic craniosynostosis, and earlier date of surgery in the series were associated with blood transfusion.<sup>62</sup> Some centers advocate commencing blood transfusions at the time of skin incision (particularly in infants) to prevent hemodynamic instability and the need for a rapid transfusion, but this must be tempered by whether the surgery is open or endoscopic (see later discussion).

To manage the large volume and rapidity of the blood loss, it is essential to establish large-bore peripheral venous access. Central venous access (see also Fig. 48-2), usually via the femoral route, can provide a useful estimate of the cardiac filling pressures but should not be used for rapid transfusion in small infants, because hyperkalemic cardiac arrests may occur with old blood infused rapidly into the right atrium and the lumens may limit the rate of blood infusion. Estimation of ongoing blood loss can be difficult because of the use of large volumes of irrigation fluid and blood loss onto surgical drapes and gowns.<sup>63</sup> Invasive arterial blood pressure (BP) monitoring and serial blood gas sampling are indicated in this type of surgery (see Fig. 48-10, A-D). A urinary catheter should be inserted to monitor urine output.

Several blood conservation strategies have been proposed for this type of surgery, including preoperative recombinant human erythropoietin, directed blood donation (from the parents or siblings), acute normovolemic hemodilution, antifibrinolytics, and induced hypotension (see Chapter 10 for a more detailed discussion). These strategies should be combined with meticulous surgical technique and attention to hemostasis. Furthermore, bleeding from the scalp incision may be reduced by infiltration with a dilute (1:400,000) epinephrine-containing solution. The use of the reverse Trendelenburg position may help to decrease venous pressure and blood loss from osteotomy sites but also increases the risk of venous air embolism (which has been reported to be 5% to 80%; see later discussion). For this reason, the horizontal position is preferred.

Blood-conserving dual therapy with recombinant human erythropoietin (to optimize preoperative hematocrit) and use of a cell saver reduces transfusion in children undergoing craniosynostosis repair.<sup>64</sup> Administration of preoperative recombinant human erythropoietin, in combination with elemental iron (6 mg/kg/day to a maximum of 200 mg/day for 6 weeks) increases the preoperative hematocrit value and decreases the need for autologous blood transfusion.<sup>65,66</sup> If iron stores are at all compromised, iron therapy combined with oral vitamin C (to increase gastrointestinal absorption) should begin 3 weeks before erythropoietin therapy.<sup>67</sup>

Little evidence exists to suggest that autologous or directed blood donation decreases perioperative morbidity in craniosynostosis surgery, although it will decrease the number of blood unit exposures.<sup>68,69</sup> Infants as young as 3 months have

predonated, although the limited volume of predonated blood is unlikely to preclude all blood transfusions during craniosynostosis or repeat craniosynostosis surgery.<sup>68,69</sup>

Acute normovolemic hemodilution is a labor-intensive technique in which blood is collected from the child after induction of anesthesia but immediately before surgery and replaced with an equal volume of crystalloid or colloid, such as 5% albumin. Although acute normovolemic hemodilution may be beneficial in children with rare blood types, no evidence exists that it reduces either the incidence of homologous transfusion or the amount of homologous blood transfused in children undergoing craniosynostosis repair.<sup>70</sup>

The coagulation profile and clotting factors after fresh frozen plasma (FFP) or 5% albumin during craniofacial surgery have been compared in a nonrandomized study in infants younger than 12 months of age.<sup>71</sup> The increases in activated partial thromboplastin time (aPTT) and decreases in the plasma concentration of factors XI and XIII and antithrombin 3 were less after intraoperative FFP than after 5% albumin. Fibrinogen concentrations remained stable in the FFP-treated group but decreased in the albumin-treated group. However, it should be emphasized that no clinical indication exists to administer FFP when the blood loss is less than 1 blood volume (Chapter 10). Recombinant factor VIIa has been used successfully for intractable hemorrhage during cranial vault reconstruction in an infant, although this is an isolated report.<sup>72</sup>

Antifibrinolytic therapy may decrease blood loss during craniosynostosis repair in children. Tranexamic acid (TXA) is a widely used agent, and several dosing regimens have been described: (1) A loading dose of 15 mg/kg TXA after induction of anesthesia, followed by an infusion of 10 mg/kg/hr until skin closure<sup>73</sup>; (2) 50 mg/kg TXA loading dose, followed by an infusion of 5 mg/kg/hr<sup>74</sup> until skin closure; and (3) 15 mg/kg at induction of anesthesia, every 4 hours during surgery, and every 8 hours after surgery for 24 hours after surgery. Although dose-response data from a single study are lacking, two studies<sup>73,74</sup> report that TXA reduces intraoperative and postoperative bleeding and transfusion requirements.<sup>75</sup> Another antifibrinolytic, ε-aminocaproic acid (EACA), is effective in reducing bleeding in cardiac and spinal procedures, although its effectiveness in reducing blood loss during craniosynostosis has not been established. The dose that has been used for spinal surgery is 75 to 100 mg/kg loading dose intravenously over 15 to 20 minutes before skin incision, followed by 10 to 15 mg/kg/hr until skin closure.<sup>76</sup>

Induced hypotension defined as a 10% to 20% reduction in the mean arterial BP decreases intraoperative surgical blood loss and operating time,<sup>77</sup> although studies demonstrating its efficacy during craniosynostosis surgery are lacking. A variety of pharmacologic agents have been used to induce hypotension, including inhalational agents, vasodilators, β-blockers, and remifentanyl.<sup>77,78</sup> Invasive arterial pressure monitoring is essential whenever hypotensive anesthesia is used. Induced hypotension should be used with caution in the presence of increased ICP because of the risk of compromising cerebral perfusion pressure (i.e., the difference between mean arterial pressure [MAP] and either ICP or central venous pressure, whichever is greater). Increases in ICP mandate invasive monitoring of MAP to ensure an adequate cerebral perfusion pressure. It is considered prudent to maintain normovolemia and normocapnia when induced hypotension is used (see Chapter 10 for a more detailed description of these techniques).

Whether used alone or in combination,<sup>79-81</sup> the preceding techniques seldom obviate the need for all blood transfusions

during craniofacial surgery. Therefore intravenous access with large-bore catheters remains essential and at least 2 units of packed red blood cells (PRBCs) should be crossmatched and available in the operating room at all times. All intravenous fluids should be administered via a fluid warmer to prevent hypothermia. Maintaining normothermia preserves normal coagulation indices and theoretically reduces bleeding and transfusion-related complications.<sup>82</sup> A coagulopathy should always be anticipated once the blood loss exceeds 1 blood volume. Serial determinations of the international normalized ratio, partial thromboplastin time, platelet count, and fibrinogen concentration will identify an evolving coagulopathy and indicate which blood products, FFP, platelets, or cryoprecipitate, will best correct the abnormalities (see Chapter 10).

Endoscopic repair of craniosynostosis has become a rapidly growing surgical approach to reduce bleeding and decrease morbidity.<sup>83,84</sup> Independent risk factors for bleeding during endoscopic strip craniectomy include low body weight (<5 kg), sagittal suture surgery (related to proximity to the sagittal vein), syndromic craniosynostosis, and earlier date of surgery.<sup>62</sup>

Hyponatremia and cerebral salt wasting syndrome are associated with craniosynostosis repair.<sup>85-89</sup> Both intraoperative and postoperative hyponatremia have been described, with the latter occurring in approximately 30% of children. In a retrospective review of a cleft palate and craniofacial database, postoperative hyponatremia was significantly associated with preoperative increased ICP, blood loss, and female gender with normal preoperative ICP.<sup>89</sup> The average reduction in sodium concentration was more pronounced in children who received hyponatremic (hypotonic) (5% dextrose and 0.2% or 0.5% NaCl) compared with normonatremic (isotonic) postoperative intravenous fluids.<sup>89</sup> The perioperative use of balanced salt solutions is recommended to prevent hyponatremia (see Chapter 8 for a more in-depth discussion of new perioperative fluid management recommendations). In infants, the addition of 5% dextrose to the balanced salt solution may be required to avoid intraoperative or postoperative hypoglycemia.

### Increased Intracranial Pressure

Early surgery for craniosynostosis is often indicated to prevent increases in ICP.<sup>31,32</sup> One third of children with craniofacial dysostosis syndrome and 15% to 20% of children with single-suture craniosynostosis have increased ICP (>15 mm Hg).<sup>90</sup> Approximately 40% to 50% of children with syndromic craniosynostosis have associated hydrocephalus, although differentiation from nonprogressive ventriculomegaly may be difficult.<sup>90-92</sup> Timing of surgery may affect neurocognitive development and intelligence because these are adversely affected by sustained increased ICP. Associated OSA resulting in hypoxemia and hypercapnia may lead to an increase in cerebral blood volume and thereby exacerbate intracranial hypertension.<sup>93</sup> Untreated intracranial hypertension may lead to optic atrophy and visual impairment.<sup>35,94</sup> As a consequence, when increased ICP has been identified either preoperatively or postoperatively, placement of a ventriculoperitoneal shunt should be considered.<sup>92</sup> This is more common an occurrence in Crouzon and Pfeiffer syndromes.<sup>92</sup>

For children who present with signs of intracranial hypertension, it is important to follow basic principles of neuroanesthesia to prevent further increases in ICP and decreases in cerebral perfusion pressure (see Chapter 24 for a more in-depth discussion). It may be prudent to use protective measures to attenuate the hypertensive response to laryngoscopy and intubation,

including the administration of a short-acting opioid, a  $\beta$ -blocker, or topical local anesthesia to the upper airway. Intraoperatively, the anesthesiologist faces numerous challenges to control ICP. Mild to moderate hyperventilation (to an end-tidal carbon dioxide of 30 to 35 mm Hg), especially when signs of herniation are evident, avoidance of hypervolemia, and, where indicated, appropriate use of mannitol, furosemide, and dexamethasone may be employed to reduce ICP, reduce brain volume, and facilitate brain retraction. Although cranial vault reconstruction increases intracranial volume and reduces ICP,<sup>95</sup> children remain at risk of increased ICP after surgery and require close ophthalmologic and clinical follow-up, even after a cosmetically successful cranial expansion.<sup>96,97</sup>

### Venous Air Embolism

Venous air embolism (VAE) may occur during any operative procedure in which the operative site is above the level of the heart and noncollapsible veins are exposed to atmospheric pressure.<sup>98-105</sup> The incidence of VAE in children undergoing craniectomy for craniosynostosis repair has been reported to be as great as 83%,<sup>105</sup> although hemodynamically significant VAE is rare. The incidence associated with endoscopic craniectomy may be as small as 2%.<sup>62</sup> Significant hypovolemia resulting from surgical blood loss can lead to a decrease in both systemic and central venous pressures and the development of a pressure gradient between the right atrium and the surgical site. This gradient increases the potential to entrain air via open dural sinuses or bony venous sinusoids.<sup>105,106</sup> If the entrained volume of air is sufficiently large, right ventricular outflow obstruction may ensue, causing acute right-sided heart failure and cardiovascular collapse. Smaller volumes of air may cause a reduction in cardiac output, hypotension, and myocardial or cerebral ischemia.<sup>103</sup> Transesophageal echocardiography (documenting the presence of air in the right ventricular outflow tract), precordial Doppler ultrasonography (continuous machinery mill murmur), end-tidal carbon dioxide (precipitous decrease in carbon dioxide tension), and nitrogen monitoring (sudden increase in nitrogen concentration in the exhaled breath) have been used to identify VAE with different sensitivities, well before cardiovascular collapse occurs (see Figure 24-6).<sup>103,107-110</sup> Applying bone wax to the open edges of cut bone, reducing the degree of or avoiding the reverse Trendelenburg position, introducing positive-pressure ventilation with 5 cm of positive end-expiratory pressure, and maintaining normovolemia help to prevent VAE. Fluid resuscitation, vasopressors, and aspiration of air from the right side of the heart may prevent episodes of VAE from progressing to cardiovascular collapse.<sup>99,105,110</sup>

### Prolonged Surgery

As with all surgeries that last several hours, preventing the complications associated with prolonged anesthesia is paramount.<sup>111</sup> Nerve palsies, pressure necrosis of the skin, ophthalmic complications, hypothermia, and acidosis may occur. Careful positioning of the extremities, use of an egg-crate type mattress, and avoiding pressure to the eyes, particularly when the surgical procedure requires the prone position, will prevent the majority of these adverse outcomes. In children with proptosis, such as Crouzon syndrome, it is particularly essential to suture the eyelids closed after applying lubrication to prevent corneal abrasions. Anterior ischemic optic neuropathy that can cause transient or permanent postoperative blindness is a rare complication that occurs in the absence of external pressure to the eyes.<sup>112</sup>

Hypothermia is another major concern. Factors that predispose to hypothermia include the relatively large surface area exposed during surgery and the transfusion of large volumes of relatively cold intravenous fluids. Effective measures to prevent hypothermia include warming the operating room, insulating the child, and the use of forced air warmers and warming devices for blood and intravenous fluids. Preventing hypothermia and limiting blood loss and transfusion requirements are key factors in preventing the development of perioperative metabolic disturbance.<sup>113</sup>

## Orbital Hypertelorism

The term *orbital hypertelorism* describes abnormally separated orbits. This deformity may occur in isolation or in association with other congenital abnormalities, such as facial clefts and Apert syndrome (Fig. 33-5). Surgical repair involves mobilization and repositioning of the orbit through either a subcranial approach, which leaves the roof of the orbit intact, or an intracranial approach via a frontal craniectomy. This procedure is performed in children older than 5 years who may have already undergone extensive surgical reconstruction. Surgical manipulation of the globe may elicit the oculocardiac reflex, resulting in bradyarrhythmias or asystole. Oculocardiac reflex may also occur during midface and orthognathic procedures (see also Fig. 32-3, *A* and *B*).<sup>114</sup> These arrhythmias are prevented by administering a prophylactic anticholinergic such as atropine (10-20 µg/kg) or glycopyrrolate (5-10 µg/kg). Discontinuing the surgical stimulus almost always increases the heart rate.

The presence of a difficult airway influences the anesthetic technique, although in most instances, an inhalational induction is performed while spontaneous ventilation is maintained until the trachea is intubated. After establishing intravenous access, the

**FIGURE 33-5** Child with Apert syndrome. Notable features include proptosis, cloverleaf skull, maxillary hypoplasia, and syndactyly (syndactyly is present in Apert syndrome but not in Crouzon syndrome).

airway should be secured using a preformed orotracheal tube. Blood loss from multiple osteotomies may be significant, and, as in the case of craniosynostosis surgery, methods to reduce the use of homologous blood should be considered. Intraoperative management follows the principles outlined for craniosynostosis surgery. At the conclusion of surgery, the trachea is extubated and the child is monitored overnight in a high-dependency setting with the capability of managing acute airway obstruction.

## Midface Procedures

Midface advancement to improve facial appearance is commonly required for children with maxillary hypoplasia, such as those with Crouzon, Apert (see Fig. 33-5), and Pfeiffer syndromes (E-Fig. 33-7).<sup>115-117</sup> This procedure is typically performed in preschool children, although complications such as proptosis, corneal ulceration, ocular dislocations, and airway obstruction may necessitate earlier intervention.<sup>117-120</sup> A LeFort II procedure is similar to a LeFort III, with the difference that the osteotomy is oriented vertically through the infraorbital rim. Thus the nasal pyramid and the maxilla move forward as a single unit. Le Fort III osteotomy and monobloc procedures (Fig. 33-6) have the potential for significant complications, including massive blood loss, airway difficulties, cerebrospinal fluid leak, and infection.<sup>111,121-123</sup>

Anesthetic concerns are similar to those for orbital hypertelorism and craniosynostosis. Children with Apert and Crouzon syndromes often present with incomplete or complete nasal obstruction that results from choanal atresia or midface hypoplasia. As a consequence, mask anesthesia can be difficult, even with an oral airway in situ. However, laryngoscopy and tracheal intubation in these children is usually uncomplicated. The diameter of the tracheal tube requires careful consideration because these children may require prolonged postoperative ventilation until postoperative facial and laryngeal edema has resolved. The decision to intubate the trachea via the oral or nasal route must be discussed with the surgeon before induction of anesthesia. A nasotracheal tube can be used throughout the procedure, or the surgeon may request an intraoperative change from the oral to the nasal tracheal position after completing the midfacial osteotomies.<sup>124</sup> To perform the latter maneuver, the anesthesiologist wears a sterile surgical gown and gloves and uses sterile equipment, including laryngoscope, Magill forceps, and tube exchange catheter (see E-Fig. 12-3). Visualizing the glottis during surgery may be difficult because of the presence of airway edema and blood in the hypopharynx. A tube exchange catheter is passed through a naris and into the trachea alongside the orotracheal tube. The nasal tube is then passed over the exchange catheter, and its tip is positioned at the glottic opening. The oral tube is then removed, and the nasal tube is advanced (rotating the bevel 90 degrees clockwise or counterclockwise as needed to pass the vocal cords and arytenoids)<sup>125,126</sup> and visualized as it passes through the glottic aperture. Once the tube position is confirmed, the catheter is removed and the nasal tube is sutured securely to the nasal septum. Given the proximity of the tracheal tube to the surgical site, damage to the tracheal tube can occur during surgery.<sup>127,128</sup> Vigilance is required at all times to detect an accidental disconnection or damage to the tracheal tube. The anesthesiologist must be prepared to respond immediately to an unexpected interruption in ventilation and replace the tracheal tube. A nasogastric tube is placed after surgery to prevent gastric distention and reduce the likelihood of postoperative nausea and vomiting. A wire cutter must be available at the bedside at all

**E-FIGURE 33-7** Child with Pfeiffer syndrome. Frontal view (A) and swimmer's view (B) illustrate many of the features of children with Pfeiffer syndrome, which include characteristic skull with craniosynostosis, proptosis, maxillary hypoplasia, and digit deformities. These children have characteristics similar to those of children with Apert syndrome but also have polydactyly. The defect has been traced to chromosomes 8 and 10. Intelligence is normal.

**FIGURE 33-6** Le Fort III and monobloc procedures for correction of midface hypoplasia. **A**, The osteotomies in the Le Fort III procedure pass through the nasofrontal junction, across the medial orbital wall and floor, and into the inferior orbital fissure. A cut through the frontozygomatic suture, pterygomaxillary junction, and zygomatic arch allows separation of the midface. **B**, The monobloc procedures are similar, but the nasofrontal junction and frontozygomatic suture are not mobilized. This technique allows simultaneous correction of supraorbital and midface deformities at the expense of an increased incidence of postoperative complications.

times if intermaxillary fixation is used to stabilize the facial bones and mandible. In the intensive care unit, the presence of an audible leak around the tracheal tube is an important criterion to determine absence of laryngeal or periglottic edema and therefore readiness for tracheal extubation.<sup>127</sup> Intraoperative blood loss is not typically as great as for craniostomy surgery. Hypotensive anesthesia may reduce or prevent the need for blood transfusions during maxillary orthognathic surgery.<sup>129</sup>

## Hemifacial Microsomia, Treacher Collins Syndrome, and Goldenhar Syndrome

Hemifacial microsomias, also known as otomandibular dysostosis (Fig. 33-7), result from a malformation of the first and second

branchial (or pharyngeal) arches. This is the second most common facial defect after clefts. These disorders are classified according to the classification *orbital distortion, mandibular hypoplasia, ear anomaly, nerve involvement, and soft tissue deficiency (OMENS)*.<sup>4,130-133</sup> Pieszosurgery is a relatively new technique used to perform osteotomies using ultrasonic frequencies during mandibular distraction in children with hemifacial microsomia.<sup>134</sup> Airway difficulty increases with the complexity of the defect from unilateral to bilateral mandibular or temporomandibular involvement. The disorder may include mandibular hypoplasia, temporomandibular joint dysostosis, cleft palate, and auricular, ophthalmologic, and facial nerve defects. Goldenhar syndrome (Fig. 33-8 and E-Fig. 33-8) is the most common form of this disorder. Vertebral anomalies are present in 40% and congenital heart defects occur in 35% of children with this syndrome. Airway management is complicated by midfacial hypoplasia, asymmetry of mouth opening, and mandibular retrognathia. Overall, tracheal intubation in children with unilateral hemifacial microsomia is easy in 70% and very difficult in 9%.<sup>130</sup> In contrast, tracheal intubation in children with bilateral mandibular hypoplasia is evenly distributed among easy, difficult, and very difficult.<sup>130</sup> The airway anomalies associated with this syndrome predispose to OSA.

The craniofacial abnormalities of mandibular hypoplasia, macrostomia, and cleft palate in Treacher Collins syndrome (Fig. 33-9 and E-Fig. 33-9) often present difficulties for airway management that increase with increasing age.<sup>4,130</sup> Other clinical features of the syndrome include hypoplastic zygomatic arches, ophthalmic features (including sloping palpebral fissures, coloboma of the eyes, and notched lower eyelids) and microtia, choanal atresia, cardiovascular defects, and renal anomalies. Mandibular distraction osteogenesis is a surgical option considered when upper airway obstruction is due to mandibular deficiency. This avoids tracheostomy or other surgical intervention and allows for future growth of the mandible. Children with hemifacial microsomia have a poor psychosocial outcome.<sup>135</sup>

## AIRWAY MANAGEMENT

Airway management of children with hemifacial dysostoses is traditionally known to be difficult. It is essential that all equipment for management of the difficult airway be present in the operating room before induction of anesthesia (see Table 12-10). For infants and children with difficult airways, an inhalational induction is the most commonly used technique. In contrast, in older children and adolescents, either an inhalational induction or intravenous sedation (using dexmedetomidine or propofol) with topical local anesthesia applied to the upper airway may be used to facilitate tracheal intubation. In all cases, it is essential to maintain spontaneous respirations until the airway is secured so that oxygenation and ventilation will be maintained if the airway cannot be secured.

A variety of techniques may be used to control the difficult airway, including a flexible fiberoptic bronchoscope, Glidescope (Verathon Inc., Bothell, Wash.), the Airtraq (Prodol Meditec S.A., Vizcaya, Spain) disposable optical laryngoscope, Truview Infant laryngoscope (Truphatek International Truview Infant laryngoscope Limited, Netanya, Israel), LMA,<sup>136</sup> and others (see Chapter 12). We have used the two-person intubation technique, in which the first anesthesiologist applies external posterior laryngeal pressure while performing laryngoscopy to optimize the view of the glottis, while the second anesthesiologist inserts the tracheal tube into the trachea when the view is adequate (see Fig. 33-9).<sup>137</sup> The

**E-FIGURE 33-8** Goldenhar syndrome in a neonate. Note classic ear deformity and small mandible.

**E-FIGURE 33-9** Treacher Collins syndrome. **A**, Note the hypoplastic mandible, triangular facies, and hypoplasia of the ear. In children with this syndrome, securing the airway becomes increasingly difficult with age. Congenital heart disease is common in children with Treacher Collins syndrome. **B**, Three-dimensional reconstructed magnetic resonance imaging. Note the sloped mentum with foreshortening of the ascending ramus of the mandible. The temporomandibular joint is malformed. **C**, Lateral radiograph showing the small mandible and glossoptosis. **D**, Close-up of the central facies.

**FIGURE 33-7** Frontal (A) and lateral (B) views of unilateral hemifacial microsomia. In the lateral view, microstomia and mandibular and ocular deformities are evident. These children may present with either unilateral or bilateral hemifacial microsomia, a hypoplastic mandible and maxilla, and ear deformities.

**FIGURE 33-8** Goldenhar syndrome in an infant. This is one of the most common forms of hemifacial microsomia. With unilateral hemifacial microsomia, the airway is usually managed and instrumented without difficulty, but with bilateral mandibular hypoplasia, the airway may be very difficult to manage in one third of afflicted children.

**FIGURE 33-9** Two-person intubation technique. The intubator (first person) performs laryngoscopy and manipulates the larynx with external laryngeal manipulation (gloved hands). With the larynx in view, the intubator cocks his or her head to the left while holding position and the assistant (second person, nongloved hand) who is standing on the intubator's right, then passes the tracheal tube through the larynx.<sup>137</sup>

second anesthesiologist also may assist with more advanced airway management both in terms of helping to observe the child and assisting with the use of advanced airway devices.

Preformed tracheal tubes are generally used via the oral or nasal route, depending on the site of surgery. The use of an LMA can be very helpful to maintain airway patency or as a guide to facilitate fiberoptic bronchoscopy. When a nasotracheal tube is used, it can be secured by suturing it to the membranous nasal septum or taping it after the skin has been prepared with benzoin. An oral tube may be wired to the mandible.

For children with a history of upper airway obstruction or midfacial hypoplasia who present with a tracheostomy, the tracheostomy tube can be replaced with a cuffed tracheostomy tube or an armored tube that is sutured in place for the duration of the surgery. Changes in the position of the head and neck can

cause displacement of the tracheal tube, so care should be taken to confirm tracheal tube position after the child is positioned for surgery.<sup>138</sup> This is especially important for cranial vault procedures that involve extremes of neck extension, such as might occur during reconstruction of the supraorbital bar. Airway equipment and additional tracheal tubes must be available in the operating room at all times. It is essential to document an audible leak around the tracheal tube at the time of tracheal intubation (with the cuff on the tracheal tube deflated), because the presence of a leak is often used postoperatively to determine suitability for extubation when significant airway edema has developed. OSA associated with midfacial anomalies may result in supraglottic obstruction during induction and emergence.<sup>54,58</sup>

## Orthognathic Surgery

Malocclusion secondary to maxillary or mandibular hypoplasia (such as occurs in hemifacial microsomia and Treacher Collins syndrome), tumors, trauma, as well as temporomandibular joint dysfunction are generally accepted indications for orthognathic surgery. LeFort I procedures for maxillary hypoplasia involve a transverse incision through the maxilla to advance the upper teeth into normal occlusion with the mandible. Children who are candidates for this surgery are typically adolescents, because these procedures are performed once maxillary and mandibular growth is complete. Because this age group usually exhibits increased perioperative anxiety, preoperative assurance and education as well as premedication with oral midazolam (0.3 to 0.4 mg/kg, up to 20 mg for older children and adolescents) or intravenous midazolam (2 to 4 mg) are often necessary.

Airway management is a major concern, particularly in children with a hypoplastic mandible or temporomandibular dysfunction.<sup>4</sup> A high index of suspicion for atlantoaxial instability is required if juvenile rheumatoid arthritis is the underlying disease process. The anticipated difficult airway can be managed using fiberoptic intubation, with sedation or topical local anesthesia or an inhalation induction and maintenance of spontaneous ventilation until the trachea is intubated, as discussed earlier. Nasotracheal intubation using a preformed tracheal tube is the preferred method of tracheal intubation. Careful stabilization and fixation of the tube using transseptal suturing to prevent unintended extubation is often employed. Excessive pressure on the ala nasi (causing ischemia) can be avoided by fixing the nasal RAE tube to the forehead with the nasal curve positioned away from the ala. LeFort I advancements require close communication between the surgery and anesthesia teams because the nasotracheal tube has been dislodged once the maxilla is fully mobilized. If intermaxillary fixation is used postoperatively, wire cutters must be immediately available at all times while the child is monitored in an intensive care setting.

To reduce intraoperative blood loss, controlled hypotension is commonly employed using any of a range of pharmacologic

agents, including inhalational anesthetic agents,  $\beta$ -blockers, and remifentanyl. The literature is extensive on the salutary effect of induced hypotension in reducing intraoperative blood loss and improving the quality of the surgical field during orthognathic surgery.<sup>129,139-148</sup> Invasive BP monitoring is indicated to monitor BP continuously during controlled hypotension and to facilitate intraoperative evaluation of blood gases and hematocrit. In some cases, a mild degree of hypotension is sufficient for optimal surgical conditions (systolic BP 85 to 90 mm Hg). Dexamethasone (0.2 mg/kg) may reduce postoperative airway edema.<sup>149</sup> After the return of protective airway reflexes, the trachea is extubated and the child is monitored overnight in a high-dependency setting with the ability to establish an airway should acute airway obstruction develop.

## Cystic Hygromas and Hemangiomas

Cystic hygroma is a rare congenital malformation of the lymphatic system occurring with an incidence of 1 in 16,000 births, most frequently involving the axilla and neck (Fig. 33-10 and E-Fig 33-10). The pathology consists of multiple loculated cysts that contain lymph fluid or blood (see Fig. 33-10, B). In most cases, cystic hygromas are present at birth, although 80% to 90% are diagnosed within the first 2 years of life. The natural history is spontaneous resolution, although most require repeated aspirations, sclerotherapy, or surgical excision to debulk the mass (see E-Fig. 33-10, B).<sup>150-152</sup> Cystic hygroma can be associated with other chromosomal abnormalities such as Noonan and Turner syndromes, in which case the anesthetic management is guided by the underlying syndrome. Some children require an urgent tracheostomy in the first hours of life to relieve an obstructed airway (Chapter 37). During the preoperative assessment, the airway should be examined and evaluated by radiographs for involvement of supraglottic and infraglottic structures. Acute airway obstruction can occur during induction if cystic lesions are present in the upper airway. Fiberoptic intubation may be required if the larynx is distorted by the lesions, in which case spontaneous ventilation should be maintained until the airway

**FIGURE 33-10** **A**, Cystic hygroma. Note that the bulk of the tumor is extraoral and extralaryngeal, although extension into the tongue and supraglottic region may complicate direct laryngoscopy. The tumor on the surface of the neck may rapidly expand owing to bleeding into the cysts or accumulation of fluid in the lymphatics. Such large tumors may put the overlying skin under great tension. They may also be situated such that they preclude tracheostomy. **B**, Gross pathologic condition in cystic hygromas consists of a combination of multiloculated cysts that may contain a combination of lymph fluid and blood. Debulking may result in substantial blood loss. Sequential debulking of the hygroma may be required as the residual cysts expand with fluid and blood and reexpand the hygroma.

**E-FIGURE 33-10** **A**, Massive cystic hygroma. The bulk of the tumor is usually extraoral and extralaryngeal; however, extension into the tongue and supraglottic region may complicate direct laryngoscopy. Here, direct laryngoscopy and tracheal intubation were possible. **B**, The immediate postsurgical debulking of a cystic hygroma restores the native airway (if the hygroma compromised the airway) and a natural and cosmetic appearance to the infant. With time, many children outgrow the hygroma.

is secured.<sup>153</sup> Postoperative complications of surgical excision include laryngeal edema, airway obstruction, pneumonia, facial palsy, and infection.<sup>150,151,154</sup>

Hemangiomas, also known as juvenile or infantile hemangiomas, are the most common benign tumors in infancy, affecting up to 10% of infants.<sup>155</sup> The majority of hemangiomas are uncomplicated and require no treatment. The natural course begins with a proliferation phase that starts within the first few months of life, followed by an involution phase of variable length. It is estimated that involution occurs at a rate of 10% per year. Hemangiomas can affect all organs, and intervention is required when the lesion affects the function of vital organs such as the eyes, airway, or liver.<sup>156</sup> Hemangiomas that occur in the subglottic region must be considered in the differential diagnosis of a noninfectious cause of croup in infants younger than 3 months of age. When present around the eyes and on the face (Fig. 33-11), hemangiomas are often associated with lesions in the airway.<sup>157,158</sup> They can occur in any part of the airway and can cause airway and feeding difficulties. Airway procedures to resect or remove hemangiomas are generally undertaken between 1 and 11 months of age.<sup>159</sup> Limb hemangiomas generally present with cosmetic concerns and bleeding. Rarely, children with large hemangiomas develop high-output heart failure.

Treatment options for hemangiomas include nonintervention, systemic corticosteroid treatment, corticosteroid injection, surgical excision, and laser ablation. Propranolol is an emerging treatment option for hemangiomas.<sup>160</sup> It may be used in children without contraindications either as an oral monotherapy at a dose of 2 mg/kg/day divided into three doses or in combination with oral prednisone 3 mg/kg/day tapered after 4 to 6 weeks of therapy. Propranolol reduces the need for surgical intervention

but requires 6 months to 1 year of therapy.<sup>161</sup> Surgical treatment is reserved for superficial hemangiomas in locations that are surgically accessible.<sup>156</sup> Laser treatment for superficial lesions is commonly performed as an outpatient procedure,<sup>162</sup> and routine anesthetic precautions should be taken. Children with hemangiomas who had airway procedures received more steroids and had increased admissions and mortality compared with those without airway procedures.<sup>159</sup>

Arteriovenous malformations are present at birth but can go unrecognized for years, especially when they are intracranial. Large arteriovenous malformations may cause high-output cardiac failure, necessitating therapeutic intervention. Treatment options may include chemotherapy, corticosteroid therapy, embolization, and surgical excision. Children who undergo excision of the hemangiomas often require blood products during surgery, but platelets should be transfused with care because an accumulation within the malformation may increase its size.<sup>163</sup> NSAIDs should be avoided because of their effects on platelet function.

## Möbius Syndrome

Möbius sequence is a rare neurologic disorder (2 to 20 in 1,000,000 births) characterized by congenital palsy of the facial (VII) and abducens (VI) cranial nerves, resulting in unilateral or bilateral facial weakness and defective extraocular eye movement (E-Fig. 33-11). These classic features may be associated with other cranial nerves palsies, ophthalmic abnormalities, developmental delay, and various craniofacial, limb, and musculoskeletal malformations, resulting in a variable pattern of clinical expression.<sup>164-168</sup> Involvement of cranial nerves IX and X is associated with pharyngeal dysfunction, dysphagia, feeding difficulties, retention of oral secretions, and recurrent aspiration pneumonia. Associated micrognathia, microstomia, limited mouth opening, and other orofacial abnormalities may make tracheal intubation difficult.<sup>169</sup> Other associations include gastroesophageal reflux, hypotonia of skeletal muscles, congenital cardiac abnormalities, spinal abnormalities, and peripheral neuropathies. Central alveolar hypoventilation has been described in association with Möbius sequence and may be secondary to hypoplasia of mid-brain respiratory centers.<sup>170</sup> Central alveolar hypoventilation, compounded by upper airway hypotonia and the effects of sedatives, opioids, and anesthetic agents, can predispose to postoperative respiratory compromise. The absence of facial expression secondary to paresis of the facial nerve can make it difficult to assess and evaluate postoperative pain.<sup>171</sup> The anesthetic plan for the child with Möbius sequence must be tailored to the individual based on the clinical expression of the syndrome.

The most common surgical procedure performed in children with Möbius sequence is a segmental gracilis muscle transplantation, in which the muscle is transplanted to the face and revascularized to the facial artery and vein.<sup>172</sup> Motor innervation of the gracilis requires a functioning cranial nerve such as the masseter branch of the trigeminal nerve. The aim of this facial reanimation is to facilitate facial expression and provide lower lip support to reduce drooling and improve speech.<sup>172</sup> Anesthetic considerations include those for prolonged surgery, avoidance of neuromuscular block to facilitate intraoperative nerve stimulation, and avoidance of hypocapnia, hypothermia, and hypotension to ensure graft perfusion. The latter considerations are also applicable to the postoperative period. Other surgical procedures commonly performed in children with Möbius sequence include

**FIGURE 33-11** Facial hemangioma in the cheek of a child. The hemangioma involves the skin overlying the mandible centrally from the lower lip to the tip of the mandible. Hemangiomas vary widely in size but can enlarge precipitously as a result of bleeding into the tumor.

**E-FIGURE 33-11** Child with Möbius syndrome. Preoperative (**A**) and 1-year postoperative (**B**) appearance. These children lack the muscles for facial expressions, most notably those for smiling.

strabismus surgery and orthopedic procedures to improve limb function.

## Congenital Intraoral Fibrous Bands

Congenital intraoral fibrous bands (e.g., pterygium syndrome and syngnathia) can present an almost impossible airway to secure even with advanced pediatric fiberoptic skills (E-Fig. 33-12). Syngnathia reduces mouth opening as a result of fusion of maxilla and mandible and often presents as a part of Van der Woude and popliteal pterygium syndromes.<sup>173</sup> These children often present with airway and feeding difficulties. Depending on the severity of the bands, these children may present formidable anesthetic challenges. Intravenous ketamine anesthesia in the spontaneously breathing neonate may allow division of the adhesions in the first few days of life, precluding the need for a surgical airway or facilitating tracheal intubation if other surgery is required.<sup>173</sup>

## Intraoral Tumors

Intraoral tumors are rare in children (E-Fig. 33-13) but, if massive, may present great challenges in securing the airway. Those that present the greatest difficulties preclude visualizing the larynx (E-Fig. 33-14) and present an increased risk of intraoperative bleeding. Preoperative radiographic studies are required to delineate the extent of involvement of the upper airway and whether the supraglottic region or the nasopharynx is clear for passage of a bronchoscope. If the tumors are sufficiently large that laryngoscopy is precluded, fiberoptic nasal intubation must be considered. If the tumor is resectable, a tracheostomy could be a back-up plan. The risk of bleeding depends on the vascularity of the tumor and whether the tongue is involved. If the vascular supply of the tumor can be isolated, bleeding should be easily controlled. If, however, the tumor cannot be separated from the tongue, bleeding can be controlled only by clamping the tongue before resecting the tumor. This should prevent excessive blood loss and permit a hemostatic closure of the resection surface. The trachea should remain intubated postoperatively until both airway and lingual edema have abated.

## Brachial Plexus Surgery

Brachial plexus injury occurs in 0.5 to 5 infants per 1000 live births as a result of birth trauma.<sup>174,175</sup> Erb palsy involves damage to nerve roots C5, C6, and C7, whereas Klumpke palsy involves roots C8 and T1.<sup>175</sup> Complete plexus palsies are the most devastating injuries, resulting in a flail and insensate arm.<sup>175,176</sup> Although 75% of brachial plexus injuries resolve spontaneously and completely within the first month after birth, 25% result in permanent disability and impairment.<sup>175,177,178</sup> Surgical intervention is indicated if the motor function does not improve after 3 months of age.<sup>177,178</sup> Clinically significant diaphragmatic palsy is associated with 2.4% of neonates with brachial plexus injury. In the very young, diaphragmatic palsy requires aggressive intervention before brachial plexus repair. For brachial plexus surgery to be successful, the nerve root cannot be completely avulsed from the spinal cord. Therefore detailed imaging is required to characterize the nature of the injury: avulsion of the nerve root from the spinal cord, disruption of the nerve within the nerve sheath, or disruption of the nerve and the nerve sheath. Because irreversible loss of the neuromotor end plate may occur, surgery is often

undertaken before 12 months of age.<sup>174,177-181</sup> Microsurgical intervention is performed in infants with global lesions and Horner syndrome by 3 months of age. The aim is to improve function with no expectation of complete recovery; without intervention these children have severe functional deficits. Conversely, if recovery of biceps occurs by 3 months, treatment is performed without microsurgical intervention.<sup>182</sup> The treatment of choice includes resection of neuromas with interpositional nerve grafting.<sup>183</sup> Nerve grafting is being increasingly performed for treating neonatal brachial plexus injury. Donor nerves include motor branches of C4, intercostal nerves, inferior branches of the 11th cranial nerve, pectoral nerves, and sural nerves.<sup>184</sup> Synthetic collagen nerve conduits have been approved as nerve guidance channels in microsurgery and may be an option for the future.

Preoperative MRI for assessing bone and joint deformities may require administration of general anesthesia. Repair of brachial plexus may be challenging because the only extremity for intravenous access and monitoring (BP and pulse oximetry) is the contralateral upper extremity. Both lower extremities are usually prepped and draped for harvesting the sural nerves or other donor nerves for the repair. Because these infants are usually 9 to 12 months of age, they are chubby, making intravenous access more difficult. This surgery often takes up to 12 hours, so the considerations for prolonged anesthesia must be invoked, such as protecting pressure points during positioning. Muscle relaxants are avoided to facilitate intraoperative electrophysiologic testing.<sup>185</sup> An indwelling urinary catheter is essential to decompress the bladder. Analgesic requirement is minimal except during brief periods of surgical stimulation. Remifentanyl provides excellent intraoperative analgesia and permits rapid adjustment of the depth of anesthesia. Maintenance of normothermia and prevention of fluid overload are important during this prolonged surgery. Blood loss is minimal, and maintenance fluids usually suffice.<sup>174</sup> Prolonged administration of propofol is not recommended because of the risk of propofol infusion syndrome and delayed emergence. In its stead, remifentanyl combined with inhalation agent may be a more appropriate regimen. Postoperative analgesia requirements are minimal, and acetaminophen and NSAIDs usually provide adequate pain relief. Shoulder spica casts may be applied to avoid sudden neck movements postoperatively if the lower branches of the accessory nerve are used for reconstruction.<sup>185</sup>

## Otoplasty

Protruding ears (commonly known as “bat ears”) are common in the Caucasian population, occurring with an incidence of up to 5% (E-Fig. 33-15).<sup>186</sup> Children with protruding ears are generally healthy, with about two thirds undergoing surgical correction before the age of 8 years or as soon as the child expresses concern about the deformity.<sup>187</sup> Younger children are more likely to require general anesthesia, whereas those older than age 8 years may tolerate the procedure using local anesthetic infiltration or nerve blocks.<sup>188</sup> Laser techniques are now employed increasingly to perform cartilage reshaping.<sup>189</sup> The main complication of general anesthesia is postoperative nausea and vomiting, which can last up to 2 days after surgery in approximately 80% of children.<sup>190</sup> However, postoperative nausea and vomiting may be reduced by surgical and anesthetic techniques, including the use of propofol and avoidance of packing of the external auditory meatus and concha.<sup>190,191</sup> To provide optimal surgical access and positioning of the child, a preformed, low-profile tracheal tube,

**E-FIGURE 33-12** Orotracheal intubation in a neonate with pterygium syndrome. Intraoral fibrous bands prevent direct laryngoscopy, necessitating the use of advanced fiberoptic airway skills to secure the airway.

**E-FIGURE 33-13** Intraoral tumors that arise from the tongue may preclude direct laryngoscopy or, if sufficiently large, preclude visualizing the larynx. In this case, the tumor was carefully displaced to the left during direct laryngoscopy. The risk of manipulating a vascular tumor is bleeding.

**E-FIGURE 33-14** **A**, Child with a massively protuberant tongue resulting from a hemangioma. **B**, Radiograph of the lateral profile of the child demonstrates a patent nasopharyngeal and periglottic aperture. This suggests that nasotracheal intubation is manageable.

**E-FIGURE 33-15** Preoperative (**A**) and postoperative (**B**) appearance of a young girl with a left outstanding ear.

such as the RAE tube, may be required, but flexible LMAs provide equally satisfactory conditions in the ventilated or spontaneously breathing child.<sup>192</sup> Infiltration with local anesthetic (usually less than 10 mL of 1% lidocaine with 1:100,000 epinephrine) attenuates the surgical stimulus and reduces the intraoperative opioid requirements. The use of a long-acting local anesthetic combined with a nerve block, acetaminophen, and NSAIDs provides adequate postoperative analgesia in most children. This multimodal approach may obviate the need for opioids and thereby reduce the incidence of postoperative nausea and vomiting.<sup>193</sup> Multimodal therapy (ondansetron and dexamethasone) provides specific antiemetic prophylaxis or therapy.

## Congenital Hand Anomalies

Congenital limb malformations exhibit a wide spectrum of phenotypic manifestations. Syndactyly may occur as an isolated malformation (Fig. 33-12 and E-Fig. 33-16) or part of a syndrome, the most common being Apert syndrome but also with Poland syndrome, in association with skeletal abnormalities and gastrointestinal and cardiac malformations. Limb malformations are more frequent in males than females, and they affect both upper and lower limbs in approximately 50% of children with a deformity. Early separation of digits is favored if the ring and little fingers or index finger and thumb are involved, because the differing longitudinal growth rates will lead to greater deformities.<sup>194</sup> Surgery is usually performed between 6 and 18 months of age.<sup>195,196</sup> An association has been reported between syndactyly and prolonged QT interval, with life-threatening arrhythmias reported in one child during anesthesia.<sup>197</sup> Timothy syndrome is

a multisystem disorder with cardiac, facial, limb, and neurodevelopmental features.<sup>198</sup>

Duplicated thumb can be present as an isolated anomaly and is present in approximately 1 in 3000 births. Hypoplastic thumbs are associated with systemic syndromes such as Holt-Oram syndrome; vertebral, anal, cardiac, tracheal, esophageal, renal, limb (VACTERL) anomalies; Fanconi anemia; Nager syndrome; and thrombocytopenia-absent radius.<sup>199</sup> A complete evaluation of the child is generally warranted because abnormalities can occur in the cardiovascular, neurologic, and hematopoietic systems.<sup>199</sup> Genetic testing is not generally needed in isolated thumb duplications.

## Tissue Expanders

Tissue expansion has become a major treatment modality in the management of giant congenital hairy pigmented nevi (see E-Fig. 33-17), hemangiomas, meningomyelocele, abdominal wall defects, and secondary reconstruction of extensive burn scars.<sup>200-208</sup> Tissue expanders effectively allow removal of the affected area and preserve sensation in a durable flap with minimal donor site morbidity.<sup>209</sup> These devices consist of a silicone shell that stretches to accommodate serial injections of saline when placed subcutaneously or, in the case of the scalp, under the galea, through an incision made in normal tissue adjacent to the lesion or defect (Fig. 33-13).<sup>204,210</sup> Osmotic tissue expanders have been used in burn scars, congenital nevi, alopecia, or foot deformities with reduced infection rates and low cost. Tissue expansion requires at least two surgical procedures, one to insert the expander and a second to remove it when expansion is complete; some children may require serial insertions or multiple expanders.<sup>204</sup> Reconstruction of areas of the head and neck constitute a particular challenge because expansion without oral, visual, or airway compromise is required.<sup>211</sup> Complications of tissue expansion include infection, skin erosion, leakage, migration, and flap necrosis.<sup>207,212-215</sup> Perioperative antibiotics are given at insertion and removal, although their effectiveness in preventing infection has not been established.<sup>202,207,209,213,214</sup>

## Hairy Pigmented Nevi

Congenital melanocytic nevi characteristically vary in size, shape, surface texture, and hairiness. They are frequently excised because

**FIGURE 33-12** Syndactyly of the first and second digit of an infant: dorsal aspect (A) and volar aspect (B).

**FIGURE 33-13** Tissue expander that is approximately 18 cm long. These expanders are inserted in a partially deflated state and then expanded by sequentially injecting saline over a period of weeks.

**E-FIGURE 33-16** Preoperative (A) and postoperative (B) appearance of syndactyly of the thumb and index finger of the right hand of an infant. Skin is mobilized using a Z-plasty to cover the freed surfaces of the digits after their release.

**FIGURE 33-14** A heavily pigmented nevus covers the lateral aspect of the face from the eyebrow, over the bridge of the nose, and down to the skin covering the mandible. These large and disfiguring pigmented nevi must be resected in staged events.

they are disfiguring and have the potential to become malignant. Serial surgical excision is common, but skin grafting and tissue expanders are also used (E-Fig. 33-17).<sup>209</sup> The position and size determine the frequency of excision and anesthetic technique. If the face, head, or neck is involved, airway management should be discussed with the surgeon to allow optimal surgical access (Fig. 33-14).

In general, these children are healthy. In the cooperative and motivated child, subcutaneous infusion of a very dilute local anesthetic (e.g., ropivacaine 0.08% to 0.3%) mixed with epinephrine 1:1,000,000 can be used to provide painless tumescent anesthesia.<sup>216</sup> The local anesthetic is infused through a 30-gauge needle at an initial rate of 120 mL/hr. Blanching of skin identifies the area that is anesthetized. This method has been used successfully in children 7 years of age and older.<sup>217</sup> To avoid toxicity, local anesthetic volume and dosing guidelines should be followed (see Chapter 41). The addition of longer-acting local anesthetics to the infiltrate will enhance postoperative analgesia. Repeated reconstructive procedures are often required, and attention should be paid to providing appropriate premedication where necessary (see Chapter 4).

## Cosmetic Procedures

According to American Society of Plastic Surgeons, the most common cosmetic surgeries performed in adolescents are nose reshaping, male breast reduction, ear surgery, laser hair removal, laser treatment of leg veins, and laser skin resurfacing.<sup>218</sup> Breast implants and liposuction are the most controversial cosmetic procedures performed in this age group, although combined they only comprise 5% of cosmetic surgery in this age group. In 2011, 73% of male breast reduction and 28% of otoplasty occurred in this age group.<sup>218</sup> The breast augmentation procedures were performed on an outpatient basis.<sup>219</sup> These patients are generally healthy. Routine anesthetic induction with endotracheal intubation with no additional invasive monitoring is generally all that is required. This group of patients may be at increased risk of postoperative nausea and vomiting and will benefit from multimodal prophylaxis. Postoperative discomfort is common, requiring administration of systemic opioids or nerve blocks.

Liposuction is usually scheduled as outpatient surgery, although extensive liposuction may require an overnight admission to the hospital. This latter procedure is associated with acute complications, including itching, bruising, and swelling, damage to nerves or vital organs, blood loss, and embolization of fat or blood. Lidocaine toxicity and fluid accumulation at the surgical site are directly proportional to the volume of aspirated fat and number of treated sites.<sup>220</sup>

## Trauma

A considerable proportion of plastic surgical procedures in children are performed for trauma and emergency surgery. Procedures include treatment of simple lacerations, animal bites, tendon, nerve and vascular repair, reimplantation of digits and limbs, and treatment of burns (see Chapter 34). The cooperative and fasted child with minor trauma can often undergo minor surgical procedures using local anesthesia, commonly administered by the plastic surgeon in the emergency department. This can be supplemented with inhalation of a 50:50 mixture of nitrous oxide and oxygen (Entonox),<sup>221</sup> intravenous administration of small doses of a benzodiazepine and opioid (e.g., midazolam 50 µg/kg, and fentanyl 0.5 µg/kg) or ketamine according to locally established sedation protocols (see Chapters 45 and 47). Alternatively, a single-injection digital nerve block is safe and effective for minor surgical procedures in children.<sup>222</sup>

Surgery for extensive injuries to digits and limbs usually requires general anesthesia because children do not tolerate prolonged application of a tourniquet. The severity and urgency of the injury dictate the timing of the surgery. The general principles of care for the child with trauma should be followed (see Chapter 38), with particular attention directed to identifying more life-threatening injuries. For urgent surgery in the presence of a full stomach, precautions against aspiration of gastric contents should be considered. For postoperative pain control, a combination of regional anesthesia or systemic analgesia is usually adequate. Continuous brachial plexus or other nerve blocks may improve tissue perfusion<sup>223</sup> and facilitate cooperation during postoperative physiotherapy for procedures such as digital reimplantation. Continuous nerve block may attenuate the signs associated with compartment syndrome, and frequent and meticulous attention must be paid to perfusion of the extremity.

- Antony AK, Sloan GM. Airway obstruction following palatoplasty: analysis of 247 consecutive operations. *Cleft Palate Craniofac J* 2002; 39:145-8.
- Two hundred forty-seven children underwent palatoplasty, yielding a 6% incidence of perioperative airway obstruction. The airway obstruction occurred as late*

**E-FIGURE 33-17** Hairy nevi can cover expansive parts of the skin, in this case from the midback to the upper legs bilaterally. To cover the resected area of skin, tissue expanders are widely used. In this case, two tissue expanders (arrows) provide enough additional skin to swing a flap over the resected area.

as 48 hours postoperatively. Of the 14 children with severe airway compromise, 12 required continued tracheal intubation, reintubation, and tracheostomy. Of these 14 children (93%), 13 had coexisting craniofacial abnormalities, with 7 having Pierre Robin sequence.

Faberowski LW, Black S, Mickle JP. Incidence of venous air embolism during craniectomy for craniosynostosis repair. *Anesthesiology* 2000; 92:20-3.

*This case series of 23 children undergoing craniosynostosis reported an 83% incidence of venous air embolism using precordial Doppler monitoring. Although cardiovascular collapse did not occur, 32% developed hypotension. Detection and early intervention are important strategies to prevent cardiovascular collapse associated with this type of surgery.*

Goobie SM, Meier PM, Pereira LM, et al. Efficacy of tranexamic acid in pediatric craniosynostosis surgery: a double-blind, placebo-controlled trial. *Anesthesiology* 2011;114:862-71.

*This randomized, placebo-controlled trial examined the effects of tranexamic acid on blood loss during reconstructive craniosynostosis surgery. Both blood loss and blood transfusion requirements were significantly reduced, by almost 50%.*

Lavoie J. Blood transfusion risks and alternative strategies in pediatric patients. *Pediatr Anesth* 2011;21:14-24.

*This review summarizes blood conservation modalities such as acute normovolemic hemodilution, hypervolemic hemodilution, deliberate hypotension, antifibrinolytics, intraoperative blood salvage, and autologous blood donation. The*

*transfusion triggers and algorithms and the current literature in blood transfusion alternatives are discussed.*

Meier PM, Goobie SM, DiNardo JA, et al. Endoscopic strip craniectomy in early infancy: the initial five years of anesthesia experience. *Anesth Analg* 2011;112:407-14.

*This retrospective chart review studied 100 infants ranging from 4 to 34 weeks of age (weight: 3.2 to 10.1 kg) who underwent single and multiple endoscopic strip craniectomy. Four infants had craniofacial syndrome; 87 infants underwent single and 13 multiple craniectomy. The risk factors for bleeding are identified, along with an emphasis on venous air embolism, intensive care unit admissions and reoperation.*

Nargozian C. The airway in patients with craniofacial abnormalities. *Pediatr Anesth* 2004;14:53-9.

*This review summarizes the salient features and airway implications of the major craniofacial disorders that afflict children, including Pierre Robin sequence, Treacher Collins syndrome, Goldenhar syndrome, and Klippel-Feil syndrome. The anatomic pathology is very well described, and the clinical implications of the pathologic condition are thoroughly discussed.*

Psychiatric	

EVERY YEAR IN THE UNITED STATES millions of people are treated for burns; of these, hundreds of thousands are hospitalized, with a significant mortality rate.<sup>1-3</sup> The National Burn Repository Report for 2006 reviewed their 10-year experience; overall mortality for 140,318 records was 5.3%. Inhalation injury was reported in 5.7% of cases; approximately 30% of burns were in children or adolescents age 20 years or younger, and the majority were scald burns or contacts with hot objects. Unfortunately, approximately 1166 cases were suspected child abuse. It is estimated that around 120,000 pediatric burn injuries are treated in the emergency department each year in the United States and the majority of patients are younger than 6 years of age.<sup>4</sup> Children with burn injuries are well managed only when their care providers thoroughly understand the pathophysiologic and pharmacologic abnormalities associated with burn injury.<sup>5,6</sup> These abnormalities include metabolic derangements, neurohumoral responses, massive fluid shifts, sepsis, and the systemic effects of massive tissue destruction. In this chapter we address the pathophysiology, the initial evaluation and resuscitation, and the anesthetic and pain management of children with burn injury. Some of the principles presented are the result of more than 30 years of experience in caring for children with burn injuries, and others are derived from experiences with adults and applied to children.

Each year, in the United States, approximately 15,000 children are hospitalized with burn injuries.<sup>1</sup> The mortality rate has declined steadily over the past decades, owing to the advent of dedicated hospital burn centers,<sup>7,8</sup> improved surgical techniques, and safer anesthetic management. However, almost 1100 children still die each year from fire and burn injuries. Safety prevention efforts such as smoke detectors do not seem to have reduced pediatric flame injuries because many flame injuries are related to children playing with matches,<sup>9,10</sup> although there has been a small overall decrease in total burn injuries to children.<sup>11</sup>

## Pathophysiology

Thermal injury to the skin disrupts the vital surface barrier that is responsible for thermal regulation, bacterial defenses, and fluid and electrolyte balance.<sup>12</sup> It is essential to appreciate, however, that even minor, localized burn injuries may be associated with diffuse and dramatic systemic responses. These injuries may have an impact on all of the systems of the body.<sup>5</sup> Several mediators released from the burned areas activate the inflammatory response and cause local and remote edema. Complement, arachidonic acid metabolites, and oxygen radicals are involved in this response.<sup>6</sup> Cytokines are the key mediators of the systemic effects.<sup>13</sup> Abnormal cytokine values reflect the severity of injury, and these abnormalities may persist for years after injury.<sup>14-18</sup> Endotoxins are frequently detected in the period immediately after the burn, usually correlate with the burn size, and are predictive of the development of multiple organ failure and the subsequent demise of the patient.<sup>19</sup> The clinical symptoms and pathologic changes are relatively more severe in children, and, unfortunately, the gravity of the injury is often underestimated because of their greater ratio of body surface area to weight (Fig. 34-1).

Soon after the injury, massive volumes of fluid shift from the vascular compartment to the burned tissue, resulting in sequestration of fluid, even in nonburned areas of the body, resulting in significant hemoconcentration.<sup>5</sup> Despite the massive fluid loss, systemic blood pressure is usually maintained through an outpouring of catecholamines and antidiuretic hormone, both of which are potent vasoconstrictors.<sup>20</sup> In the first 4 days after a burn of moderate size or larger (approximately 40% of the body surface area), an amount of albumin equal to about twice the total body plasma content is lost through the wound. In addition to the direct effects of the burn (thrombosis, increased capillary permeability), changes in vascular integrity occur in areas remote

**FIGURE 34-1** The different proportions of body surface area are illustrated for calculation of percentage of burn according to a patient's age. Note the large proportion of body surface area that the head and face account for in an infant. (From Carvajal HF, Goldman AS. Burns. In: Vaughan VC III, McKay RJ, Nelson WE, editors. *Nelson's textbook of pediatrics*. Philadelphia: WB Saunders; 1975, p. 281.)

from the injury, resulting in tissue edema.<sup>21</sup> In the pulmonary capillary network, these changes may be life-threatening; severe pulmonary edema and vascular congestion may result.

### CARDIAC

Immediately after an injury, cardiac output is dramatically reduced.<sup>22,23</sup> This decrease is often related to the rapid reduction in circulating blood volume and the severe compressive effects of circumferential burns on the abdomen and chest that impair venous return.<sup>24</sup> Despite adequate cardiac filling pressures, cardiac output often remains reduced. This may result from other factors, such as direct myocardial depression from the burn injury. Some investigators have described circulating myocardial depressant factors such as interleukins, tumor necrosis factors, or oxygen free radicals existing in subjects with extensive third-degree burns.<sup>25-28</sup> Transesophageal echocardiography may be helpful in guiding supportive care in the early phase.<sup>29</sup> At our institution, acutely burned children frequently require inotropic support during the acute period of depressed cardiac function. Carefully titrated inotropic support improves cardiac output, without the need for volume overload-mediated improvement in cardiac function.

Children develop a hypermetabolic state 3 to 5 days after a burn injury. This state is associated with a twofold to threefold increase in cardiac output, which persists for weeks to months, depending on the extent of the injury and the time needed for wound closure; heart rate, cardiac output, cardiac index, and rate-pressure-product are increased for at least 2 years after burns that involve 40% or greater of body surface area.<sup>30</sup> Some children develop a reversible cardiomyopathy.<sup>31</sup> Hypertension has been reported to occur during this hypermetabolic period. The most common cause of the hypertension in this period is inadequate pain control, and this should be ruled out. However, other circulating mediators such as increased catecholamines, atrial natriuretic factor, renin-angiotensin, endothelin-1, and vasopressin and other circulating vasoactive mediators can cause intermittent or persistent hypertension in patients with burn injuries.<sup>32-36</sup> If decreased cardiac output is observed during this hypermetabolic state, gram-negative sepsis or hypovolemia should be suspected.

Closure of the burn wound usually decreases metabolic demand, resulting in a concomitant reduction in cardiac output.<sup>37,38</sup> Some children may benefit from treatment with propranolol, which reduces cardiac work and decreases the systemic inflammatory response.<sup>39,40</sup>

### PULMONARY

Pulmonary function may be adversely affected from the upper airway to terminal alveoli. The upper airway is an excellent heat exchanger; just as it warms cold air, it cools hot air. The cooling of hot inspired air may cause a thermal injury to the tissues of the larynx; the air in a closed space (e.g., house or automobile fire) may reach 538° C (1000° F) 2 feet above floor level. Inspiration of superheated air damages the upper airway. Airway obstruction occurs as a result of massive edema formation involving laryngeal and tracheal structures above the carina (see later). The thermal insult also may injure the ciliated epithelium and mucosa in the proximal bronchi. The inhalation of toxic fumes, such as nitrogen dioxide and sulfur dioxide released from burning plastic, which combine with water in the tracheobronchial tree to form nitric and sulfuric acids, may damage the distal bronchi and alveoli. Thus upper airway injury is usually a thermal insult, whereas lower airway injury is a chemical or toxic insult. Acid gases such as hydrochloric acid, sulfuric acid, and phosgene form small aerosolized particles that penetrate deep into the tracheobronchial tree, damaging the alveolar membranes and surfactants.<sup>41</sup> Wool and cotton combustion forms aldehydes, which may cause pulmonary edema in concentrations as small as 10 ppm.<sup>42</sup> Combustion of synthetic materials (insulation, wall paneling) releases hydrogen cyanide. Although cyanide is a rare toxin in fires,<sup>43</sup> cyanide poisoning can lead to histotoxic hypoxia and death,<sup>44</sup> mimicking carbon monoxide (CO) poisoning. Inhalation of hydrogen cyanide is an often unrecognized cause of immediate death.

The overall effect of a pulmonary inhalation injury is necrotizing bronchitis, bronchial swelling, alveolar destruction, exudation of protein, loss of surfactant, loss of the protective bronchial lining, and bronchospasm, all of which contribute to

**FIGURE 34-2** **A**, Cross section of a normal bronchiole. Note the ciliated epithelial layer. **B**, Compare with a cross section of a distal bronchiole from a child who died of an inhalation injury. Note the marked thickening of the bronchial wall, the massive inflammatory cell infiltrate, the sloughing of the mucosa, and the total destruction of the ciliated columnar epithelium.

**FIGURE 34-3** **A**, Normal alveoli. **B**, Inhalation alveolar injury is generally related to noxious fumes such as nitrogen dioxide and sulfur dioxide that are carried far down the tracheobronchial tree, combine with exhaled water, and form nitric acid and sulfuric acid, resulting in pulmonary congestion, alveolar injury, and hyaline membrane formation.

the development of bronchopneumonia (Figs. 34-2 and 34-3). Inhalation of particulate matter (smoke, soot) and lower airway edema also obstruct the airway mechanically. Edema of the bronchi, combined with loss of integrity of the pulmonary capillary endothelium, decrease pulmonary compliance. Circumferential chest burns may have a tourniquet-like effect that decreases chest wall compliance.<sup>24</sup> All of these injuries lead to clinically important ventilation-perfusion abnormalities and right-to-left intrapulmonary shunting, with hypoxemia and hypercarbia. In adults, the  $\text{PaO}_2/\text{FiO}_2$  ratio and baseline carboxyhemoglobin concentrations are predictive of mortality.<sup>45</sup> One pediatric trial of inhaled heparin and acetylcysteine suggested a benefit with decreased airway cast formation and mucus plugging.<sup>46</sup> However, subsequent studies have yielded contradictory results.<sup>47,48</sup> CO inhalation can further compromise both hemoglobin's oxygen ( $\text{O}_2$ )-carrying capacity and its ability to deliver  $\text{O}_2$  to tissues. CO also impairs  $\text{O}_2$  usage at the cellular level (cellular respiration). Severe smoke inhalation alone may occur without externally visible injuries.<sup>49</sup> One clue that smoke inhalation has occurred is the presence of singed nasal hairs or nasal passages. Extrapulmonary factors such as changes in cardiac output also can contribute to hypoxemia. Blood gas analysis alone may not

indicate these factors. Rational therapy of arterial  $\text{O}_2$  desaturation requires evaluation of both extrapulmonary and intrapulmonary factors,<sup>21,50</sup> including cardiac output, mixed venous  $\text{O}_2$  content or saturation, and shunt fraction.<sup>22</sup> In general, the prognosis of cutaneous burn is compounded by the presence of an inhalation injury; the presence of an inhalational injury doubles the mortality rate from cutaneous burns,<sup>41</sup> with pediatric mortality reported to be approximately 16%.<sup>51</sup>

## RENAL

Renal function may be adversely affected soon after injury, primarily as a result of myoglobinuria and hemoglobinuria.<sup>52</sup> The former is most common after electrical injury,<sup>53,54</sup> whereas the latter is common after severe cutaneous burns of 40% or greater of body surface area. Hypovolemia, hypotension, and hypoxemia may further aggravate renal dysfunction, leading to acute tubular necrosis. Catecholamines, angiotensin, and vasopressin production increase, leading to systemic vasoconstriction, compounding the renal insufficiency.<sup>55,56</sup> Release of vasoactive peptides such as endothelin-1 may cause acute vasoconstriction, which also may adversely affect renal function.<sup>57,58</sup> Fluid retention is common during the first 3 to 5 days after injury and is followed by diuresis

thereafter. Thus renal function may be impaired soon after the injury, delaying the excretion of some drugs or their active metabolites. At 3 to 7 days after the burn injury, glomerular filtration rate increases *pari passu* with an increased cardiac output and metabolic rate.<sup>59</sup> The serum half-life of many antibiotics and other medications that depend on renal excretion may be altered as a result of changes (increased or decreased) in the glomerular filtration rate.<sup>60-64</sup> Children who sustain a burn that covers greater than 40% of their body surface area demonstrate renal tubular dysfunction, in the form of an inability to concentrate the urine.<sup>20</sup> Even during hyperosmolar states, antidiuresis is not observed, suggesting an inadequate renal response to antidiuretic hormone and aldosterone. Thus an adequate urine output may be observed even in the presence of hypovolemia.<sup>65</sup> Episodic or persistent hypertension is frequent in children, in part mediated by an increase in renin and catecholamine production.<sup>66,67</sup> If hypertension persists, treatment that decreases stress on the cardiovascular system or reduces the potential for hypertensive encephalopathy should be instituted.

### HEPATIC

The liver may be damaged by hypoxemia or hypoperfusion during the early postburn phase as a result of inhaled or absorbed chemical toxins, hypovolemia, or hypotension.<sup>68,69</sup> Reperfusion injury may harm the liver when adequate circulation is reestablished. Delayed hepatic dysfunction may result from drug toxicity, sepsis, the hypermetabolic response to burns, or blood transfusions.<sup>70</sup> Studies in adults have found increased hepatic blood flow, increased protein synthesis and breakdown, and increased hepatic gluconeogenesis during the hypermetabolic phase of burn injury. With the onset of sepsis, hepatic glucose output and alanine uptake may decrease sharply but hepatic blood flow and O<sub>2</sub> usage can remain increased.<sup>68,71</sup> Fatty infiltration of the liver also has been reported.<sup>72</sup> Sustained increases in hepatic blood flow deliver more drug to the liver; this effect, combined with drug-induced enzyme induction, may decrease the half-life of drugs that are perfusion limited.<sup>73</sup> Although all studies of animals suggest decreased clearance of drugs after burn injury, clinical studies of the capacity of the liver to metabolize drugs are conflicting, even for the same class of drugs.<sup>74-79</sup> The magnitude of the burn, the time after injury, and the effects of co-administered drugs, alone or in combination, as well as alterations in protein binding and volume of distribution, may have a role in these conflicting reports.

### CENTRAL NERVOUS SYSTEM

The central nervous system (CNS) may be adversely affected by inhalation of neurotoxic chemicals or by hypoxic encephalopathy; other contributing factors include sepsis, hyponatremia, and hypovolemia.<sup>80</sup> CNS dysfunction includes hallucinations, personality changes, delirium, seizures, abnormal neurologic symptoms, and coma.<sup>81</sup> These effects may be due to the burn injury or to the administration of drugs necessary for sedation, anxiolysis, and analgesia.<sup>82</sup> Such effects usually clear after several weeks. Abnormalities of CNS neurotransmitters have been postulated to mediate the anorexia associated with extensive burn injury.<sup>83</sup> The possibility of cerebral edema and increased intracranial pressure also must be considered during the initial phases of burn injury. Under such circumstances, the usual measures for treating increased intracranial pressure would be instituted (see Chapter 24). Data suggest that rapid overcorrection of hyponatremia also may be associated with cerebral injury.<sup>84</sup>

### HEMATOLOGIC

Blood viscosity may increase as a result of hemoconcentration secondary to fluid shifts and because of alterations in plasma protein content.<sup>85</sup> The hematopoietic system is also adversely affected. Ongoing microangiopathic hemolytic anemia secondary to the burn injury is common.<sup>86</sup> An inhibitor of erythroid stem cells has been found in the sera of burn patients, which may in part contribute to the anemia of burn injury. Another study has demonstrated a normal erythropoietin response to anemia in patients with burn injury.<sup>87</sup> The half-life of red blood cells is diminished in burn patients, and multiple blood draws may contribute to the development of anemia.<sup>88,89</sup> The possible role of recombinant erythropoietin in the care of children with burns has yet to be defined.<sup>90,91</sup> One study in adults reported no reduction in either mortality or blood transfusion requirements in patients who received recombinant erythropoietin compared with controls.<sup>92</sup>

In the early stage, thrombocytopenia secondary to increased platelet aggregation and trapping of platelets in the lungs is followed by an increase in platelet count 10 to 14 days after the burn injury. A prolonged period of thrombocytopenia and reduced nadir in platelet count compared to survivors are both associated with increased mortality.<sup>93</sup> This thrombocytopenia may persist for several months.<sup>89,93</sup> An increase in fibrin split products (disseminated intravascular coagulopathy), which lasts for 3 to 5 days, may occur.<sup>62</sup> Factors V, VII, and VIII and fibrinogen are also increased several-fold over baseline for the first 3 months after severe injury uncomplicated by sepsis.<sup>94,95</sup> Children with increased platelet counts (>1 million/mm<sup>3</sup>) who then developed sepsis in our unit experienced a marked decrease in the platelet count. The sudden onset of thrombocytopenia should prompt an evaluation of the child for sepsis.<sup>96</sup> Likewise, large swings in the fibrinogen concentration can occur (up to 2 g/dL),<sup>97</sup> although these do not appear to herald an increase in the incidence of thrombotic events.

### GASTROINTESTINAL

Gastrointestinal function is diminished immediately after thermal injury secondary to the onset of gastric stasis and intestinal ileus.<sup>98</sup> Because of the risk of pulmonary aspiration of gastric contents during this time, the stomach should be adequately vented and appropriate gastric acid ulcer prophylaxis instituted. At 48 to 72 hours after a burn injury, when generalized edema is resolving, gastrointestinal function usually resumes. Enteral feeding should be established at this time to provide calories, to blunt the hypermetabolic response, and to attenuate gluconeogenesis and stress ulceration.<sup>85,99,100</sup> Early enteral feeding has the added advantages of diminishing muscle catabolism, reducing bacterial translocation through the intestinal mucosa and is associated with reduced mortality.<sup>101-104</sup>

In children who do not tolerate enteral feeding, parenteral nutrition must be initiated.<sup>99,105-107</sup> Stress ulcers (Curling ulcers) are associated with any burn injury and may be life-threatening, although the incidence has decreased in critically ill patients, in part because of improved pharmacologic control of gastric acidity.<sup>108</sup> Prospective studies of pediatric and adult burn patients and patients in intensive care indicate that cimetidine or ranitidine in the usual doses does not adequately protect critically ill patients from increases in gastric acidity.<sup>60,61</sup> The increased requirement for drugs is due to differences in their pharmacokinetics.<sup>60</sup> Therefore frequent feedings when tolerated and the liberal use of antacids, combined with larger or more frequent

doses of H<sub>2</sub>-receptor antagonists (or proton pump inhibitors), may be required to prevent development of stress ulcers.<sup>60,85,98</sup>

## ENDOCRINE

The endocrinologic response to acute thermal injury is complex, involving most organ systems. Stimuli that trigger endocrine responses include the thermal injury itself and subsequent fluid shifts, as well as the stress responses that are associated with critical illness.<sup>109</sup> These may include decreased circulating hormone concentrations (e.g., triiodothyronine, dehydroepiandrosterone, and testosterone), as well as increased concentrations of other hormones (antidiuretic hormone, catecholamines, renin, angiotensin II, and cortisol).<sup>110</sup> Replacement therapy with synthetic androgenic steroids (e.g., oxandrolone) shortens acute hospital stay and improves body composition (lean body mass) and hepatic protein synthesis.<sup>111,112</sup> Glucose control may be poor, owing to the increased levels of cortisol and insulin resistance.<sup>113</sup> Tight control of hyperglycemia may improve mitochondrial oxidative capacity,<sup>114</sup> decrease the incidence of urinary tract infection, and improves the survival of critically ill burn patients, although the last finding resulted from a single study.<sup>115,116</sup> Avoiding hyperglycemia may attenuate the risk of cerebral injury from hypoperfusion states (see Chapters 24 and 39); one group recommends a target blood glucose level of 130 mg/dL.<sup>116</sup> Blocking the renin-angiotensin system may improve the insulin response after burn injury.<sup>117</sup> It should be noted that insulin resistance might persist for 6 to 9 months after discharge.<sup>114</sup>

## SKIN

Extensive skin destruction results in the inability to regulate body heat, conserve fluids and electrolytes, and protect against bacterial invasion. Permeability of burned tissues is markedly increased and proportional to the number of layers of tissue damaged.<sup>118</sup> Because children have a much greater ratio of body surface area to weight compared with adults, they are even more likely to become hypothermic (see Fig. 34-1). Thus it is important to keep these children covered as much as possible, to increase the environmental temperature, and to use radiant warmers, plastic wrap around extremities, reflective insulated blankets, artificial “noses” (in-line moisture and heat exchangers), and hot-air heating blankets. Late complications affecting the skin include progressive scar formation, which results in movement-restricting contractures.<sup>24,119</sup> Topical antibiotic and antibacterial therapy is necessary to prevent burn wound sepsis.<sup>120-125</sup>

## METABOLIC

Many metabolic alterations follow extensive burn injury. Increased usage of glucose, fat, and protein results in greater O<sub>2</sub> demand and increased carbon dioxide (CO<sub>2</sub>) production.\* Mediators that have been implicated in these metabolic changes include interleukin-1, tumor necrosis factor, catecholamines, prostanoids, and other stress hormones.<sup>2,133</sup> Centrally mediated or sepsis-induced hyperthermia also increases O<sub>2</sub> consumption and CO<sub>2</sub> production. Some of these abnormalities may persist even after complete closure of the burn wounds, when metabolic demand is already reduced.† Intravenous alimentation, particularly with increased glucose concentrations, may also increase CO<sub>2</sub> production and therefore increase ventilatory requirements.<sup>105</sup> Increase in O<sub>2</sub>

demand<sup>135</sup> and CO<sub>2</sub> production must be compensated for during controlled mechanical ventilation. Treatment of fever reduces metabolic demand.<sup>136</sup>

## CALCIUM HOMEOSTASIS

The ionized calcium concentrations in many acutely burned patients are dramatically decreased. Marked abnormalities in the indices of calcium and magnesium metabolism, including hypoparathyroidism in both acute and recovery phases, may persist for weeks after injury (E-Fig. 34-1).<sup>137,138</sup> One study suggested that short-term therapy with pamidronate, a drug that inhibits bone resorption, conserves bone mass after burn injury in children.<sup>139</sup> Hypophosphatemia and hypermagnesemia revert toward normal during the latter phase of recovery from the acute injury. The usual reciprocal relationship between calcium and inorganic phosphate is not evident in those with major burns. Therefore supplemental calcium therapy is extremely important, particularly when rapid colloid infusions are required intraoperatively during burn surgeries, because ionized hypocalcemia dramatically impairs cardiovascular homeostasis. In general, frequent small boluses of calcium are safer and more effective than intermittent large boluses (see also Figs. 10-8 and 10-9).<sup>140</sup> Doses of 2.5 mg/kg calcium chloride or 7.5 mg/kg calcium gluconate ionize at equivalent rates and produce equivalent increases in calcium concentration. After recovery from burn injury, vitamin D supplements are strongly recommended to offset the decreased conversion of 7-dehydrocholesterol to previtamin D<sub>3</sub>.<sup>141</sup>

## PSYCHIATRIC

It is imperative to recognize that physical trauma is not the only trauma sustained by the pediatric burn patient; psychological trauma and its associated long-term sequelae is also common.<sup>142,143</sup> A large percentage of acutely burned children present with acute stress or develop posttraumatic stress disorders.<sup>142-145</sup> Risk factors for developing acute stress disorders include the size of burn, the degree of pain, the pulse rate, and parental issues.<sup>146</sup> Treatment with fluoxetine or imipramine may ameliorate these stress disorders,<sup>147-149</sup> although one randomized controlled study found no difference from placebo.<sup>150</sup> Another study found risperidone to be of value in reducing stress symptoms.<sup>151</sup> There is an increased incidence of attention-deficit disorders in pediatric burn patients, likely owing to impulsivity.<sup>152,153</sup> Finally, the normal psychosocial support network may be impaired in the families of the burn patient, even before the burn injury.<sup>154-156</sup>

## Pharmacology

Subsequent to any major thermal injury, many physiologic changes occur that have an impact on the disposition of drugs in the body. During the hypovolemic period, uptake and clearance of drugs may decrease because of impaired organ perfusion.<sup>2,73-76,157</sup> During the hypermetabolic phase, the activity of organs that clear drugs from the circulation (e.g., the liver and kidneys) may be enhanced because of enzyme induction and increased blood flow to those organs.\* The massive volume of edema present and the loss of drug through burn wounds can increase the central or total volume of drug distribution.<sup>162</sup>

Many drugs are highly bound by plasma proteins. The activity of such drugs depends primarily on the unbound rather than

\*References 2, 68, 85, 105, 121, 126-132.

†References 14, 17, 18, 38, 40, 134.

\*References 59, 60, 63, 68, 73, 79, 157-161.

**E-FIGURE 34-1** Ionized calcium values from burned children and adults are plotted for the first 35 days after burn injury. Note that the majority of values are abnormally low; shaded blue area = range of normal values. (From Szyfelbein SK, Drop LJ, Martyn JA. Persistent ionized hypocalcemia during resuscitation and recovery phases of body burns. *Crit Care Med* 1981;9:454-8.)

total drug concentrations, and small changes in the unbound fraction may have a dramatic effect on the response to the drug. The two major binding proteins,  $\alpha_1$ -acid glycoprotein and albumin, increase and decrease, respectively, after burn injury, resulting in either decreased or increased free fractions of those drugs to which they bind.<sup>73,161</sup> For example, the clearance of morphine and meperidine is enhanced or impaired, depending on the size of the burn, with a trend to reduced morphine or meperidine clearance after large burns compared with moderate burns. In general, burned children clear drugs more readily than those without burn injuries.<sup>75-77,162-164</sup> Similarly, pharmacokinetic studies of lorazepam and diazepam indicate that the clearance of the former is increased whereas that of the latter decreases.<sup>78,79</sup> In the case of oral ketamine, the pharmacokinetics were unaffected in children with small burns.<sup>165</sup>

Evidence indicates that burn injury, with its complications and hormonal responses, may affect the number of receptors in tissues.<sup>78,83,157,161,166-173</sup> Therefore reports of aberrant responses to drugs acting on adrenergic and cholinergic receptors are not surprising. These include altered sensitivity to succinylcholine at the neuromuscular junction, increased sensitivity to dopamine in the pulmonary circulation, and decreased sensitivity to non-depolarizing neuromuscular blocking drugs.<sup>73,166,168-170,174-176</sup> Other examples of drugs affected by burn-induced kinetic and dynamic changes include aminoglycoside antibiotics, diazepam, and cimetidine. Burn-induced alterations in kinetics and dynamics make the clinical response to any medication unpredictable. Therefore clinical effects should always be closely monitored and plasma concentrations, protein binding, and clearance evaluated whenever possible.<sup>60,63,73,177-181</sup> Dexmedetomidine (see later) also may have altered pharmacodynamics in the burned child. Because of the known hypotensive effects of the  $\alpha_2$ -adrenoceptor

agonists, particular attention to limit the dose and to ensure euvolemia may minimize the hemodynamic consequences.

## Resuscitation and Initial Evaluation

Resuscitation of children with a burn injury requires a clear and secure airway, as well as maintenance of adequate oxygenation, perfusion, and circulating blood volume. The diagnosis and evaluation of associated injuries also must be considered.

### AIRWAY AND OXYGENATION

Every burn patient, especially those with inhalation injuries, must be considered hypoxemic and exposed to carbon monoxide (CO). Therefore during transport to the hospital and on admission, administration of high inspired concentrations of O<sub>2</sub> is mandatory, pending evaluation of the severity of CO poisoning and pulmonary injury (see later).<sup>181</sup> Direct injury to the airway and alveoli occurs in children who have sustained pulmonary injury from the inhalation of smoke, flames, noxious gases, heated air, or steam.<sup>42,51,133,182-211</sup> When a child is burned in an enclosed space (house, automobile) or if thermal burns or carbonaceous materials are evident about the mouth and nose, inhalational injury is probable.<sup>192,212</sup> Upper airway obstruction caused by edema of the lips, nose, tongue, pharynx, glottis, and subglottis is very common. The resultant airway obstruction can be compared with the combined effects of acute macroglossia, epiglottitis, macro uvula, and laryngotracheobronchitis. The decreasing patency of the airway resulting from rapidly increasing edema, beginning in the first hours after the injury and lasting several days, makes delayed intubation hazardous if not impossible (Fig. 34-4). Prophylactic intubation should be performed in any case of severe facial burns or when pulmonary burn and upper

**FIGURE 34-4** **A**, A young child who had just sustained a facial burn in a closed space. Note the early onset of facial edema. **B**, Several hours later there is massive edema that extends into the oropharynx, larynx, and trachea (similar to the combined effects of macroglossia, epiglottitis, and laryngotracheobronchitis). Early prophylactic intubation is mandatory in any facial burn or in any child when there is potential for inhalation injury. Note that the cuffed endotracheal tube was changed from an oral to a nasal position and that it is secured with cloth tape rather than adhesive tape.

airway inhalation injury are suspected. The severity of adverse outcomes is related to the presence or absence of inhalation injury.<sup>51,200-211,213</sup>

Control of the airway in children is usually accomplished under general anesthesia. In the case of pure inhalational injury without facial or upper airway burns, the need for intubation should be considered on a case-by-case basis. Early clinical experience at our hospital showed that tracheal tubes could be left in place in these children for weeks with fewer risks than the alternative, tracheostomy.<sup>214,215</sup> Tracheostomy in thermally injured children was associated with high mortality rates; in one pediatric series the death rate approached 100%.<sup>216</sup> However, in recent years there has been a move back to performing tracheostomy for children who are expected to require long-term ventilatory management. Although one review of burn centers in North America found that the practice of performing a tracheostomy in burned children was variable, there has been increasing tendency to perform a tracheostomy in children over age 7.<sup>217</sup> Some report that an early tracheostomy secures the airway and reduces the risk of subglottic stenosis.<sup>218,219</sup> When early airway instrumentation is indicated, a cuffed tracheal tube is preferred to reduce the need for changing the tube to deliver high peak inspiratory pressures should they be required.<sup>220</sup> Traditionally, cuffed tracheal tubes have not been used in children younger than 8 years. This practice may not be necessary with proper attention to leak pressures (pressure at which gas can be heard “leaking” around the tracheal cuff by auscultating over the trachea while administering positive pressure) or the use of the MICROCUFF (Kimberly-Clark, Roswell, Ga.) tube (see later), although long-term studies with these tubes are needed (see Chapter 12).<sup>221,222</sup> We routinely use cuffed tracheal tubes, appreciating the added flexibility they offer in not requiring replacement because of decreasing edema (with associated increased leak if uncuffed tubes were used). Another important means of minimizing barotrauma is the use of permissive hypercarbia.<sup>223</sup> New tracheal tubes that are designed to have the cuff located more distally and made of thinner material (MICROCUFF) may also reduce the potential for airway injury (see also Figs. 12-15 and 12-17), although in the hot environment of a burn unit they may have a greater tendency toward kinking.<sup>224-228</sup>

## CARBON MONOXIDE POISONING AND CYANIDE POISONING

The majority of smoke inhalation victims have CO poisoning. Direct measurement of carboxyhemoglobin (COHb) is an important guide to the adequacy of treatment. Estimates of the COHb concentration may be derived by measuring (not calculating) O<sub>2</sub> saturation or arterial O<sub>2</sub> content. The half-life of COHb is approximately 5 hours when the patient is breathing room air but decreases to 90 minutes when 100% O<sub>2</sub> is administered.<sup>229,230</sup> Immediate administration of O<sub>2</sub> is therefore essential to achieve the maximum possible level of O<sub>2</sub> in the blood; positive-pressure ventilation may be indicated in severe cases.<sup>231-233</sup> Hyperbaric oxygen may be a useful adjunct for this purpose (see later).

Standard pulse oximeters do not differentiate between oxyhemoglobin and COHb; in contrast, transcutaneous O<sub>2</sub> analyzers and cooximeters are useful.<sup>234</sup> Thus pulse oximetry cannot be used to accurately monitor the oxygenation of patients with CO poisoning because COHb produces an overestimation of O<sub>2</sub> saturation; the photo detector is “fooled” into interpreting

COHb as oxyhemoglobin.<sup>234-236</sup> A more recent eight-wavelength pulse oximeter capable of measuring COHb and methemoglobin may prove useful in the management of burn patients<sup>237,238</sup>; however, the sensors are quite expensive and likely should be reserved for use in those with an established diagnosis, unless arterial blood gas analysis is not immediately available.<sup>239</sup>

COHb is produced by the combination of CO with the iron of the heme radical at the O<sub>2</sub>-binding site. CO combines more slowly with hemoglobin than O<sub>2</sub> but is bound 200 times more firmly.<sup>240,241</sup> Inhalation of 1% CO for 2 minutes can result in COHb values of 30% (E-Fig. 34-2).<sup>242</sup> The toxic effects of CO poisoning are due to tissue, organ, and cellular hypoxia from decreased O<sub>2</sub> delivery. Decreased delivery occurs because CO reduces O<sub>2</sub> binding capacity both to the hemoglobin molecule at the tissue level and to cytochromes in the respiratory chain at the cellular level; even in small amounts, COHb shifts the O<sub>2</sub>-dissociation curve to the left (E-Fig. 34-3), thus reducing release of O<sub>2</sub> from hemoglobin.<sup>42,181,231,241-245</sup> For example, if an individual had 40% carboxyhemoglobin, this would reduce O<sub>2</sub> carrying capacity from 20 mL/100 g of hemoglobin to 12 mL/100 g and with the leftward shift further compromise O<sub>2</sub> delivery.

The evidence supporting the use of hyperbaric oxygenation (HBO) therapy as an adjunct therapy for burns remains controversial.<sup>85,246-250</sup> A Cochrane review of six randomized controlled trials with 1361 patients concluded that at present insufficient data exist to demonstrate reduced adverse neurologic outcomes with HBO therapy and that additional research is needed to “better define the role, if any, of HBO in the treatment of patients with CO poisoning.”<sup>251</sup> The most common indication for hyperbaric therapy in burned children is concomitant CO poisoning.<sup>42,252,253</sup> As previously mentioned, CO binds avidly to hemoglobin<sup>254</sup> and other iron-containing enzymes, such as intramitochondrial cytochromes, interfering with the delivery and usage of O<sub>2</sub>, respectively.<sup>255,256</sup> Children suffering significant CO exposure are at risk of developing both acute and delayed neurologic sequelae. The pathophysiology of neurologic sequelae is not known, although imaging studies suggest a potentially reversible demyelinating process.<sup>257,258</sup> Data supporting the use of hyperbaric O<sub>2</sub> to prevent and treat these complications may be weak<sup>259-266</sup> but cannot be discounted, given the seriousness of these sequelae.<sup>248,249,267,268</sup>

The important practical question is whether hyperbaric treatment will decrease the frequency and severity of delayed neurologic sequelae in burned children with concomitant CO poisoning. This is a difficult question because the incidence of delayed sequelae is unknown and determining the severity of an individual exposure is often not possible. Delayed sequelae include headaches, irritability, personality changes, confusion, memory loss, and gross motor deficits. The frequency with which those exposed develop symptoms is unknown, although they are reported to occur in approximately 10% of patients with serious exposures.<sup>243</sup> A symptom-free interval of several days is commonly reported. Delayed hyperbaric treatment may relieve symptoms, and spontaneous resolution of delayed sequelae may be expected in up to 75% of patients within 1 year.<sup>269-275</sup> The severity of the CO poisoning is often difficult to pinpoint because there is a poor correlation between serum COHb and degree of CO exposure.<sup>276,277</sup> Neuropsychiatric testing has been proposed as a more accurate way to determine this,<sup>229</sup> but such detailed examinations are difficult in burned children secondary to pain medications and hemodynamic instability. Some clinicians believe that a history of unconsciousness indicates that an exposure has

**E-FIGURE 34-2** Note the rapid rise in carboxyhemoglobin values when just 1% carbon monoxide is inhaled.

**E-FIGURE 34-3** The changes in the oxygen-hemoglobin dissociation curve that occur with carbon monoxide poisoning. The oxygen-hemoglobin dissociation curve is altered in shape and shifted to the left. Therefore less oxygen is available for delivery to tissues and the oxygen carried by hemoglobin is more tightly bound. (Modified from Douglas CG, Haldane JS, Haldane JBS. The laws of combination of hemoglobin with carbon monoxide and oxygen. *J Physiol* 1912;44:275-304.)

been severe enough to warrant treatment.<sup>271,278-280</sup> However, the relatively few randomized prospective studies evaluating this have returned conflicting results.<sup>262,266</sup> Hyperbaric O<sub>2</sub> treatment is not without expense, inconvenience, and risk, and the indications for treatment of burned children with concomitant CO poisoning are debated.<sup>256,281</sup> One study described complications during treatment of a heterogeneous groups of patients: emesis (6%), seizures (5%), agitation requiring restraints or sedation (2%), cardiac dysrhythmias or cardiac arrests (2%), arterial hypotension (2%), and tension pneumothorax (1%).<sup>256</sup> Complications may be expected more frequently in the critically ill.<sup>282</sup>

Hyperbaric O<sub>2</sub> treatment is probably appropriate in burned children with documented or strongly suspected serious CO poisoning who are hemodynamically stable, not requiring ongoing burn resuscitation, and not wheezing or air trapping and in whom such treatment does not require interfacility transport, which is inconsistent with good general burn treatment.

Cyanide toxicity may occur in inhalational burn injuries as well.<sup>283</sup> If cyanide poisoning is confirmed in the child's blood, administration of hydroxycobalamin or sodium thiosulfate, alone or in combination, is warranted (see Chapter 10).<sup>284</sup> HBO therapy has been shown to facilitate movement of cyanide out of tissues and into blood, thereby potentially facilitating treatment,<sup>283</sup> although the use of HBO for treatment remains investigational.

#### ADEQUACY OF CIRCULATION

The various formulas for determining fluid replacement are estimates and often need modification, depending on clinical and laboratory findings.\* The most widely accepted fluid protocols in current use are the Parkland (Baxter) and Brooke formulas. All formulas and guidelines for fluid therapy require modification according to the individual child, depending on the child's response (Table 34-1).<sup>6</sup> The most important metric of fluid homeostasis remains a good urine output (0.5 to 1 mL/kg/hr).

Both formulas provide estimates of the fluid volume required for resuscitation, in addition to the calculated normal maintenance fluid requirement for each day. *These formulas are of great value in guiding the fluid resuscitation of older children; however, serious underestimation of the fluid volume may occur if applied to infants weighing less than 10 kg.* In such infants, it is reasonable to estimate the normal hourly maintenance fluid requirements and then add to this the fluid volume of the Parkland or Brooke formula.<sup>2</sup> Alternatively, the crystalloid fluid regimen for resuscitation can be increased to 6 mL/kg  $\times$  the percent surface area burn per 24 hours.<sup>297,298</sup>

The degree of edema depends on the volume and composition of the resuscitation fluid administered. Consequently, colloids or hypertonic saline (with or without albumin) are used in some burn centers during early burn wound resuscitation.<sup>299</sup> These modified regimens have been shown to be particularly effective in the very young and the elderly.<sup>†</sup> The purported advantage is less tissue edema. It is of interest that a Cochrane review of 15 studies using hypertonic saline in 614 patients found that less intravenous fluid was needed for resuscitation and higher sodium values occurred, although the overall morbidity and mortality was unchanged.<sup>301</sup>

A growing practice in burn programs has been to begin the fluid resuscitation with colloid, usually 5% albumin, early during

TABLE 34-1 Parkland and Brooke Formulas

Formula	FLUID THERAPY		
	Crystalloid (mL/kg)	Colloid (mL/kg)	
Parkland	4.0	+0	$\times$ Percent burn $\times$ wt (kg)
Brooke	0.45	+1.5	$\times$ Percent burn $\times$ wt (kg)

NOTE: Half this volume is administered during the first 8 hours and the remainder during the next 16 hours. Infants who weigh less than 10 kg may have even greater fluid requirements (see text).

resuscitation of seriously burned children.<sup>302</sup> No consensus has been reached on such a colloid protocol.<sup>303</sup> In seriously burned children in our unit, we begin with a 5% albumin solution at a maintenance rate immediately on admission. We administer an amount equal to that of their calculated crystalloid requirements, tapering the crystalloid first, and continuing albumin fusion for 48 hours. Further work is required before advocating hypertonic fluid regimens in burned children routinely.<sup>304</sup>

The syndrome of hyperosmolar hyperglycemic nonketotic coma (severe dehydration, marked hyperglycemia, serum hyperosmolality, and coma in the absence of ketoacidosis) may be associated with burns. Avoiding this syndrome is critically important because it carries a high mortality.<sup>285</sup> Glucose-containing solutions should be restricted at all times, particularly during the initial volume resuscitation. Serum glucose concentrations should be measured frequently during this period. Blood glucose concentrations should be managed with insulin with a target blood glucose of 130 mg/dL.<sup>116</sup>

The general appearance of the child and his or her sensorium provide important guides to the effectiveness of the resuscitative therapy. In addition, urine output is a useful metric to determine the need for additional fluid administration, recognizing that antidiuretic hormone secretion may be increased and renal tubular dysfunction may be present.<sup>20,158</sup> Every effort must be made to protect kidney function by providing adequate fluid replacement.<sup>2,304</sup> Renal failure in the presence of a major burn is usually lethal. However, overly aggressive fluid administration may induce pulmonary and tissue edema. Therefore, when a burned child is being volume resuscitated, all fluids to replace the circulating blood volume must be carefully titrated. Commonly used end points of satisfactory fluid resuscitation include heart rate, systemic arterial blood pressure, urinary output, central venous pressure, arterial oxygenation, and pH. Cardiovascular function estimated by transthoracic or transesophageal echocardiography<sup>29</sup> and technetium-99m ventriculography may be of value in critically ill patients.<sup>305,306</sup> These advanced cardiac evaluations are not required in most children; they are mostly useful in the presence of cardiovascular compromise and a need to consider the use of a vasopressor or additional volume loading.

In a child, the evaporative fluid losses exceed 4000 mL/m<sup>2</sup> of burn surface each day, compared with only 2500 mL/m<sup>2</sup> in an adult.<sup>290</sup> Concomitantly, for each square meter of burn surface, 2500 to 4000 kcal of heat is lost each day. Minimizing caloric expenditure and providing caloric supplementation simultaneously are the only ways to minimize catabolism of body tissues. The tendency for children to be poikilothermic, particularly in the absence of protective skin as a result of the burn injury, causes profound temperature derangements. Efforts to maintain

†References 2, 85, 133, 290, 291, 296-298, 300.

**FIGURE 34-5** Children with extensive burn injury can be kept warm by having the extremities wrapped with sterile plastic bags. Covering the head is also an important method of heat preservation.

a normal body temperature are essential in both the operating room and the intensive care unit. These measures are especially important during the initial volume resuscitation and in the operating room when dressings are removed for examination and excision (Fig. 34-5).

### ASSOCIATED INJURY

Associated injuries such as a tension pneumothorax, a ruptured spleen or liver, long-bone fractures, or head injury may be missed, especially during the initial assessment and early phase of burn wound fluid resuscitation. Taking a detailed history, especially from the emergency medical personnel and family, combined with a careful physical examination, is mandatory during the initial resuscitation because such injuries may compound or be hidden by the need for an increased volume of resuscitation fluids. The type of burn injury (e.g., explosion, electrical) may trigger concerns for associated injuries (e.g., shrapnel wounds).

### CIRCUMFERENTIAL BURNS

Adverse cardiovascular and respiratory responses are immediate to circumferential burns of the chest, abdomen, and extremities.<sup>2,24,196,197</sup> Circumferential burns of the thorax can restrict respiratory effort, resulting in respiratory failure as a result of decreased chest wall compliance. Functional residual capacity is reduced with airway closure and atelectasis, resulting in profound hypoxemia.<sup>42,183-187,190-198,307</sup> Deep circumferential burns of the chest and abdomen may generate excessive intrathoracic and intraabdominal pressure, which, in addition to restricting diaphragmatic movement, may further reduce the already decreased cardiac output by impairing venous return (Fig. 34-6).<sup>24,196,197</sup> When this occurs, both extrapulmonary and intrapulmonary factors can contribute to arterial desaturation.<sup>50</sup>

The edema of damaged tissues also can generate severe compressive forces, restricting or occluding the blood flow to burned extremities. The net result may be ischemia of the limb, which if left untreated, may lead to partial or total amputation. Escharotomies of circumferential burns of the chest, abdomen, and extremities must be performed urgently because impaired hemodynamics and respiratory mechanics can cause irreversible damage within hours of the burn injury. Escharotomy is often undertaken without the need for general anesthesia because a full-thickness burn usually destroys skin innervation. Abdominal compartment syndrome may develop in children who require large volume resuscitation. To detect any evolving compartment syndrome, some burn centers advocate routine monitoring of bladder pressure.<sup>307,308</sup>

**FIGURE 34-6** **A**, Circumferential chest burns result in severe impairment of respirations secondary to the tourniquet effect of the shrinking eschar and subcutaneous edema. The widely separated escharotomy lines indicate the severity of the constriction. **B**, Similar effects occur in circumferentially burned extremities. Early escharotomy may help to preserve blood flow and obviate amputation.

### ELECTRICAL BURNS

Electrical burns occur with household voltage (electric cords and sockets) and nonhousehold high-voltage current (power line or lightning). Children often disconnect extension cords by stabilizing one end in their mouths and pulling the other end with a hand, resulting in circumoral and lingual burns.<sup>4,53,309,310</sup> High-voltage injuries are often associated with loss of limbs and other injuries that are not immediately obvious.<sup>311-314</sup> The extent of this injury is unpredictable. The surface injury is often small, but the extent of underlying tissue damage and necrosis is massive. Such an injury is a combination of electrical and thermal damage.<sup>314,315</sup> Victims often have concurrent injuries such as fractures of vertebrae or long bones, ruptured organs, myocardial injury, or numerous contusions. Even children with low-voltage injuries may have abnormalities of cardiac conduction.<sup>312</sup> Children with electrical burns may be comatose or have sustained seizures at the time of admission to the hospital. Muscle tissue adjacent to bone is usually more damaged than superficial muscles because bone is a poor conductor of electrical current, and therefore heats up when high currents are passed through it, resulting in damage to the muscles surrounding bone. Early fasciotomy may be needed to preserve the blood flow to extremities (Fig. 34-7). Myonecrosis necessitates general anesthesia during the first day of injury at the time when fluid shifts, hyperkalemia, and myoglobinuria are maximal. Massive myonecrosis and hemolysis may result in hyperkalemia, as well as myoglobinuria and

hemoglobinuria. In the presence of hemoglobinuria or myoglobinuria, increased fluids and mannitol will ensure a continuous urine output ( $>1$  mL/kg/hr).<sup>316,317</sup> Alkalization of the urine may prevent these proteins from precipitating in the renal tubules. Follow-up of patients with electrical injuries often reveals

**FIGURE 34-7** Electrical injuries tend to follow neurovascular structures and have an entry as well as an exit wound. The skin might appear normal but the underlying structures may have had extensive injury. These children require a fasciotomy rather than just a simple escharotomy to preserve blood flow to the deep structures. In general, this is required on the first day of injury for best results in tissue preservation.

unpredictable sequelae, which may manifest months to years later. These injuries may occur in organs or areas that do not appear abnormal during the acute course of illness. These late complications most frequently include neurologic dysfunction, ocular damage, damage to the gastrointestinal tract, circumoral strictures, changes in the electrocardiogram, and delayed hemorrhage from large vessels.<sup>315,317</sup>

## Guidelines to Anesthetic Management

Anesthetic management of children with severe thermal injury begins with the initial resuscitation and continues for many years through reconstructive surgery. Knowledge and understanding of the pathophysiology of burn injury enable anesthesiologists to plan appropriate anesthetic management and recognize and treat complications arising as a result of burn injury or its therapy (Table 34-2).<sup>2,12,318</sup>

Children who require surgery for burn wound excision and grafting must be properly prepared physiologically and psychologically, and specific equipment must be available in the operating room. Children who have not had surgical debridement and have had the burn for a week or longer must be considered septic. Such children often demonstrate severe cardiovascular instability during burn wound excision likely because of acute bacteremia.

**TABLE 34-2** Systemic Effects of Burn Injury

System	Early Effects	Late Effects
Cardiovascular	↓ CO as a result of decreased circulating blood volume, myocardial depressant factor	↑ CO as a result of sepsis ↑ CO 2 to 3 times > baseline for months (hypermetabolism) Hypertension secondary to vasoactive substances such as renin
Pulmonary	Upper airway obstruction as a result of edema Lower airway obstruction as a result of edema, bronchospasm, particulate matter, sloughing of airway mucosa ↓ FRC ↓ Pulmonary compliance ↓ Chest wall compliance	Bronchopneumonia Tracheal stenosis, vocal cord granuloma ↓ Chest wall compliance
Renal	↓ GFR secondary to ↓ circulating blood volume Myoglobinuria Hemoglobinuria Tubular dysfunction	↑ GFR secondary to ↑ CO  Tubular dysfunction
Hepatic	↓ Function as a result of ↓ circulating blood volume, hypoxia, hepatotoxins	Hepatitis  ↑ Function as a result of hypermetabolism, enzyme induction, ↑ CO ↓ Function as a result of sepsis, drug interactions
Hematopoietic	↓ Platelets ↑ Fibrin split products, consumptive coagulopathy, anemia	↑ Platelets ↑ Clotting factors
Neurologic	Encephalopathy Seizures ↑ ICP	Encephalopathy Seizures ICU psychosis
Skin	↑ Heat, fluid, electrolyte loss	Contractures, scar formation, difficult IV access, difficult intubation
Metabolic	↓ Ionized calcium	↑ Oxygen consumption ↑ Carbon dioxide production ↓ Ionized calcium
Pharmacokinetics	Altered volume of distribution Altered protein binding Altered pharmacokinetics Altered pharmacodynamics	Tolerance to opioids, sedatives Enzyme induction, altered receptors Drug interaction

↓, Decrease in; ↑, increase in; AIDS, acquired immunodeficiency syndrome; CO, cardiac output; FRC, functional residual capacity; GFR, glomerular filtration rate; ICP, intracranial pressure; ICU, intensive care unit.

In such cases, it is advantageous to have infusions of dopamine, epinephrine, or norepinephrine prepared for administration before induction of anesthesia.

Psychological support must be provided by parents, nurses, physicians, and trained psychologists. It is important for anesthesiologists to understand that the families of children who have sustained a severe burn injury feel a great deal of psychological stress and guilt. This stress may be transferred to anger at the physicians, nurses, and other members of the burn care team. The parents are angry that their child has sustained a devastating injury and occasionally vent this anger and frustration. It is therefore vital that the entire burn care team understand this response, that they spend as much time as possible listening to the parents' concerns, and that they emphasize all that is being done to ensure the very best care for their child. Specific nurses and physicians should be designated to communicate with the family to avoid misunderstandings and confusion about issues of patient care. The anesthesia care team, while explaining the risks of anesthesia, must emphasize the extensive monitoring and the central role that anesthesiologists have in ensuring the well-being of their child. Special emphasis must be placed on methods for minimizing physical and psychological pain during transport to the operating room, in the operating room, and postoperatively.

Keeping children with severe burn injuries on nothing by mouth (NPO) status for 8 hours or longer before sedation for a dressing change or anesthesia for a surgical procedure severely compromises caloric intake; therefore we advocate the use of continuous orogastric or nasogastric alimentation. Generally children can receive calories up to about 4 hours before sedation or induction without fear of significant gastric residual volumes. Feeding can be resumed almost immediately after the procedure. In children with large injuries who will quickly develop a negative nitrogen balance with cessation of enteral feedings, short-term use of parenteral protein-sparing support is justified and safe.<sup>319</sup>

Adequate sedation and pain control are necessary before moving children to the operating room. This move is painful, both physically and emotionally, for the child. Intravenous opioids, such as fentanyl, which has minimal histamine release, are particularly helpful. Intravenous midazolam is also helpful for its sedative and amnesic properties. Drug doses should not be based on standard doses used in children without thermal injury. Burned children develop tolerance to most opioids and sedatives, thus requiring increasing doses over time to achieve a satisfactory clinical response.<sup>320,321</sup> The dose of sedative or opioid should be titrated to effect while the child is carefully observed and monitored. Children with burn injuries rapidly develop tolerance. It is not unusual for children with burns over greater than 25% of the body surface to require 1 mg/kg/hr of both morphine and midazolam to provide adequate analgesia and sedation.

Correction of intravascular volume before induction of anesthesia may require fluid boluses during and after sedation and before transport. Establishing adequate intravenous access preoperatively may be especially difficult in children with large burns. We use both topical anesthetic creams and needle-free subcutaneous local anesthetics to help make this process painless and stress free.

It is critically important to minimize heat loss and maintain normothermia. This may be difficult to achieve because of the massive evaporative heat loss that occurs through open wounds. Operating room temperatures during extensive excisions are

commonly maintained near 98.6° (37° C).<sup>133</sup> Attention must be paid to minimize heat loss both during transport and in the operating room. Multiple blankets or thermal reflective covers are helpful. Special equipment is used to maintain body temperature, including a warming blanket, radiant warmer, blood warmer, and heat/moisture exchangers and forced hot air warmers. Simply wrapping the extremities in sterile plastic bags and covering the head with plastic or thermal insulation material markedly reduces heat and fluid losses (see Fig. 34-5). Although a hot operating room is uncomfortable for staff, maintaining the child's temperature may be helpful in maintaining normal blood clotting. Each calorie that does not have to be spent to maintain body temperature is one more that can be used in the healing process.

Adequate monitoring for major blood loss and fluid shifts includes arterial and central venous cannulas, a urinary catheter, an electrocardiograph, a pulse oximeter, a capnograph, and an esophageal stethoscope. A secure intravenous route for volume infusion is essential. If the potential for rapid blood loss exists, multilumen catheters may not be adequate because of their high-flow resistance. Rapid infusion devices may be particularly helpful (see Chapter 51).<sup>322-324</sup> The femoral vein is an alternative cannulation site, in addition to the internal jugular and subclavian veins (see Chapter 48).

Specific anesthetic equipment is used, including various sterilized laryngoscope blades, tracheal tubes, airways, and blood pressure cuffs.

Invasive arterial and central venous pressure monitoring may be established after induction of anesthesia in most children. Propofol, thiopental (if available), or ketamine in incremental doses is usually well tolerated, provided the children are not hypovolemic (onset of effect is noted by lateral nystagmus. (See Video 6-1: Nystagmus after Ketamine Administration.) Studies in children long recovered from acute burn injury found a 40% increase in the thiopental dose needed to ablate the lid reflex, compared with children without burn injury (Fig. 34-8).<sup>325</sup> Our experience suggests that the clinical response to propofol appears to be equally shifted to the right; however, clinical studies are lacking. Ketamine may, on occasion, be preferred if the adequacy of intravascular volume is in question or if invasive monitoring lines must be inserted before anesthetic induction; tolerance to ketamine with repeated administration has been reported.<sup>326</sup> High-dose fentanyl or morphine combined with nitrous oxide (N<sub>2</sub>O) for those children who will undergo ventilation postoperatively is also an acceptable anesthetic technique. In general, an inhalation agent is titrated to clinical effect to supplement the opioid-based anesthetic. When using large bolus doses of fentanyl, chest wall rigidity is a possibility. A slow inhalation induction is preferable for children with a compromised airway, bearing in mind the potential for cardiovascular depression.<sup>327</sup>

Succinylcholine is contraindicated in burned children because of a potentially lethal efflux of potassium ions from muscle.<sup>166,169,172</sup> However, within the first 24 hours after a burn, succinylcholine can be used without apparent risk of triggering a hyperkalemic response. This abnormal response first appears 24 to 48 hours after the burn and continues for an indeterminate, but prolonged, period. Some have suggested that the hyperkalemic response continues until all areas of burn have been covered by scar tissue, although this is not evidence-based. Because the end point for succinylcholine-induced hyperkalemia is unknown, we advise avoiding succinylcholine in children with large burns (≥40%) for at least 1.5 years after the burn. The smallest burn reported to trigger a hyperkalemic response was a 9% burn. This

**FIGURE 34-8** The percentage of children (burned and unburned) who lost the lid reflex is compared with the intravenous bolus dose of thiopental. Note the marked shift in the dose-response curve. (From Coté CJ, Petkau AJ. Thiopental requirements may be increased in children reanesthetized at least one year after recovery from extensive thermal injury. *Anesthesiology* 1981;55:S338.)

abnormal response occurs because the entire muscle membrane, rather than just the myoneural junction, is occupied by acetylcholine receptors. The muscle tissue of burn victims also demonstrates resistance to nondepolarizing muscle relaxants.<sup>169,328</sup> We observed a child who demonstrated marked resistance to nondepolarizing neuromuscular blocking drugs (NMBDs) 463 days after burn injury. This response indirectly suggests that the hyperkalemic response may persist long after the acute injury phase of the burn.<sup>329</sup> The nondepolarizing NMBDs are therefore the relaxants of choice in children with a burn injury. It has been found that after burns over greater than 25% of body surface area, both the total dose of *d*-tubocurarine administered and the serum concentration necessary to attain a given degree of muscle twitch depression are three to five times greater than in children without burn injury.\* Although *d*-tubocurarine is no longer used, similar observations have been made with the more modern nondepolarizing NMBDs (Fig. 34-9). If rapid intubation is needed and it is clear that the child's lungs can be ventilated, high doses of rocuronium (1.2 mg/kg) can be used. However, even 1.2 mg/kg of rocuronium may not provide adequate conditions for rapid intubation and larger doses may be indicated (Fig. 34-10).<sup>330</sup> Recovery from neuromuscular blockade has been observed at serum concentrations that would cause 100% twitch depression

in children without burn injury. Studies with nondepolarizing NMBDs indicate that the hyposensitivity correlates well with the magnitude of burn ( $r = 0.88$ ).<sup>180,331-333</sup> Protein binding and pharmacokinetic studies with *d*-tubocurarine indicate that these two factors contribute little to the enhanced requirements.<sup>73,157,160,169</sup> An increase in the number of acetylcholine receptors at junctional and extrajunctional areas and an altered affinity for the NMBD by those receptors have a major role in the elevated demand for nondepolarizing NMBDs.<sup>168,174,328</sup> Even with high doses of rocuronium, the onset time is prolonged compared with that in nonburned children.<sup>334</sup> Pharmacologic reversal of neuromuscular blockade, however, poses no special problem in burned children. Studies with intermediate- and short-acting nondepolarizing relaxants have shown resistance, but it is not as pronounced as has been observed with the long-acting relaxants.

Maintenance of anesthesia is usually accomplished with N<sub>2</sub>O, O<sub>2</sub>, an NMBD, and an opioid or inhalation agent. All of the commonly used anesthetic agents can be administered to burned children. Sevoflurane offers an advantage of smooth inhalation induction; isoflurane, desflurane, or halothane can be used for maintenance. No data show that repeated halothane anesthetics in burned children cause hepatotoxicity. All anesthetics cause concentration-dependent depression of cardiac output. In very ill children, anesthetic doses, but not NMBD requirements, are drastically reduced. In this injury, high-dose fentanyl-O<sub>2</sub> anesthesia is well tolerated. Ketamine may be the anesthetic agent of choice in specific circumstances, including those in which we wish to avoid airway manipulation after application of fresh facial grafts, for very brief procedures, or children who are unable to open their mouth for a standard laryngoscopy. Ketamine sedation may also be used along with midazolam for sedation before a trial of extubation. E-Figure 34-4 illustrates extubation of a child with a severe facial burn with the use of an airway exchange catheter to provide a ready means for possible reintubation should the trial fail. Some burn centers use ketamine as the sole anesthetic and find it quite satisfactory.<sup>335</sup> Ketamine can be used to potentiate the analgesic effects of opioids.<sup>336</sup> The postoperative analgesia and somnolence for prolonged periods produced by high-dose ketamine may be considered an advantage in some instances in which postoperative agitation might dislodge fresh skin grafts; one report describes long-term ketamine for sedation and analgesia.<sup>337</sup> Conversely, prolonged somnolence will delay reinstitution of critical enteral nutrition. Low-dose ketamine may be used postoperatively for its opioid-sparing effects.<sup>338</sup> Ketamine either alone or with propofol is commonly used for burn dressing changes.<sup>339,340</sup> An emerging experience with dexmedetomidine in children appears to demonstrate safety and efficacy in reducing otherwise common opioid tolerance and dose escalation.<sup>341</sup>

The inspired O<sub>2</sub> concentration is regulated according to the arterial blood gases and O<sub>2</sub> saturation. A pulse oximeter may not function properly on tissue discolored with silver nitrate; scraping the fingernail and cleaning the skin allow proper transmission and reception of the pulse oximeter light.<sup>342</sup> Pulse oximetry has a vital role in identifying evolving hypoxemia before the desaturation becomes life-threatening.<sup>343</sup> A pulse oximeter probe generally can function even on burned digits. If a child's digits are swollen or vasoconstriction prevents normal pulse oximeter function, alternative sites must be sought, such as the earlobe, nasal septum, or tongue. We have found the tongue to be particularly valuable. An additional benefit of using the tongue is that the tissues of the mouth apparently direct the interfering electrons

\*References 73, 157, 160, 169, 179, 180.

**E-FIGURE 34-4** **A**, The child with a severe facial burn but no pulmonary injury requires a trial of extubation. The only approach to the airway was through the nose; therefore the decision was made to use a tube changer, which would allow administration of oxygen and provide a guide to reintubation without the need of the fiberoptic scope. The child was moderately sedated with midazolam and ketamine to maintain spontaneous respirations. **B**, After administration of tracheal lidocaine, an airway exchange catheter (Rapi-Fit, Cook Inc., Bloomington, Ind.) is placed within the tracheal tube after the patient had been preoxygenated with 100% oxygen. **C**, **D**, and **E**, After removal of the tracheostomy tapes that had been securing the tracheal tube, the tracheal tube is slowly withdrawn. **F**, After removal of the tracheal tube the airway exchanger is left within the trachea with the child's breathing spontaneously. **G**, Facemask oxygen is applied, and after assurance of stable respirations and oxygenation of the airway, the exchange catheter was removed and the child returned to the intensive care unit.

**FIGURE 34-9** Logarithm of dose versus twitch suppression for vecuronium in control subjects and burned children. In the presence of acute injury, the vecuronium effective dose values increased with increasing burn size. The slopes of the curves were not different, but the intercepts were significantly different ( $P < 0.01$ ). Solid squares, Children without burn injury; purple circles, children with less than 40% burn injury; triangles, children with 40% to 60% burn injury; pink circles, children with greater than 60% burn injury. (From Mills AK, Martyn JA. Neuromuscular blockade with vecuronium in paediatric patients with burn injury. *Br J Clin Pharm* 1989;28:155-159.)

**FIGURE 34-10** This dose escalation study of rocuronium in burned adults (approximately 40% body surface area) demonstrated severe resistance to the onset of neuromuscular blockade (percent of train-of-four first twitch). The time of onset could be reduced with higher doses; however, a dose of 1.2 mg/kg did not achieve complete paralysis until longer than 2 minutes had elapsed. These data suggest that if a rapid sequence induction were needed in patients with severe burns, an even higher as yet undefined dose would be required to shorten the time to complete relaxation. (Modified from Han TH, Kim HS, Bae JY, et al. Neuromuscular pharmacodynamics of rocuronium in patients with major burns. *Anesth Analg* 2004;99:386-392.)

of the electrocautery unit away from the pulse oximeter probe placed on the tongue (i.e., minimal electrocautery artifact occurs even when multiple electrocautery devices are used simultaneously).<sup>243</sup> A sealed oximeter probe that prevents electrical current leakage and leaching of adhesive can be easily modified (E-Fig. 34-5).<sup>344,345</sup> Newer reflectance oximeters may also have a role in the care of burned children.<sup>346</sup>

Because of increased metabolic rate, increased  $\text{CO}_2$  production, and inhalation injury, an increase in alveolar ventilation compared with healthy children is often required. Blood gas analysis must therefore be assessed early and frequently throughout the anesthetic procedure. Constant monitoring of expired  $\text{CO}_2$  is vital during intraoperative management. It is also necessary to be cognizant of the possibility of significant differences between arterial and expired  $\text{CO}_2$  values as a result of shunting and dead space ventilation in children with severe pulmonary injury. *For these reasons, an expired  $\text{CO}_2$  monitor may be used for trending and as a disconnect alarm but should not be relied on to adjust and assess the adequacy of ventilation.* The tracheal tube must be secured with tracheostomy tape because standard adhesive tape does not stick to burned tissue and wet dressings. Electrocardiographic leads also do not adhere and for this reason are placed under dependent portions of the body or sutured or stapled onto the skin after the patient is anesthetized. The standard measures for protecting the cornea from drying (including ophthalmic ointment and closing the eyelids when possible) and for positioning the limbs to prevent nerve compression must be observed.

The most important consideration of the intraoperative course is monitoring and correcting a child's blood losses. For this reason, invasive intravascular monitoring is essential. Children may lose as much as 1 to 3 blood volumes during each burn excision. It is therefore necessary to be familiar with the surgical approach to burn excision. During a tangential excision (Fig. 34-11 and Video 34-1), a child might lose 3 to 5 times more blood than during excisions down to fascia (Video 34-2). The liberal use of very dilute concentrations of epinephrine (500  $\mu\text{g/L}$  in normal saline) injected subcutaneously in both donor and excision sites markedly reduces surgical blood loss (Fig. 34-12 and Video 34-3)<sup>347</sup>; our institution uses a 1:2,000,000 epinephrine-containing solution (0.5  $\mu\text{g/mL}$ ). As much as, or even more than, 10  $\mu\text{g/kg}$  epinephrine may be injected every 20 minutes because of the desensitization to catecholamines.<sup>173</sup> It should be noted that significant fluid overload may occur several hours after surgery if excessive clays or tumescent fluid is injected by the surgeons to facilitate harvesting of skin (Video 34-4). We have observed a number of infants ( $\sim 10$  kg) who developed

**E-FIGURE 34-5** In children with severe vasoconstriction or inadequate peripheral blood flow, a pulse oximeter probe may be modified by taping the malleable metal nosepiece from a paper operating room mask on the back side (A), shaping it into a horseshoe (B). Care must be taken not to occlude either the transmitting or receiving light module with the tape. The oximeter is then placed around the edge of the cheek (C) or the tongue (D). (NOTE: The manufacturer may not approve of these modifications; a sealed probe may be preferable to a standard oximeter probe because this would diminish the possibility of electrical current leakage and leaching of adhesive.)

pulmonary edema several hours after their surgical procedure. Blood loss also depends on the expertise of the surgical team,<sup>348</sup> and relatively “blood-free” excision and grafting has been described. It is difficult to estimate blood and fluid loss despite accurate weighing of surgical sponges because of significant losses hidden by the surgical drapes and evaporation. Other indicators of circulating blood volume, such as urine output, central venous pressure, arterial pressure, and shape of the arterial waveform (see Fig. 10-10), must be closely monitored.

Early excision of full-thickness burns has improved survival and shortened hospital stays.<sup>349-351</sup> In the past, we routinely observed that 5% of the blood volume was lost for every 1% of the body surface excised and grafted.<sup>352,353</sup> This extensive blood loss was a major source of morbidity and expense.<sup>354,355</sup> During the last several years, effective blood-conserving techniques for excision have been developed that have drastically reduced intraoperative blood loss. These techniques include (1) clearly planning the excision to be performed before its initiation; (2) performing all extremity excisions under pneumatic tourniquet, exsanguinating the extremity before tourniquet inflation, and wrapping the extremity in a hemostatic dressing before tourniquet deflation; (3) conducting all fascial excisions with coagulating electrocautery; (4) performing major layered excisions as soon as possible after injury, before significant wound hyperemia develops; (5) executing all layered torso excisions after subeschar

epinephrine clisis; (6) maintaining normothermia, primarily through maintaining a hot operating room (near 98.6° F [37° C]); and (7) subcutaneous injection of diluted epinephrine (with and without dilute bupivacaine) in donor areas.<sup>356</sup>

Large doses of epinephrine are well tolerated and markedly diminish bleeding. In a series of 25 consecutive children undergoing extensive layered excision, we used a total dose of epinephrine averaging  $25 \pm 3 \mu\text{g/kg}$  without complication.<sup>347</sup> Based on preoperative and postoperative hematocrit and known volume of transfusion, the percent of the total blood volume lost per percent of total wound excised generated an average  $0.98 \pm 0.19\%$  of the blood volume per percent of the body surface excised. This was about one fifth of our earlier experience with this type of excision.<sup>357,358</sup> Operating with epinephrine clisis or tourniquets requires the surgeon to accurately determine wound bed viability in the absence of free bleeding. This is an important acquired skill that may be difficult to develop if the surgeon is not performing these procedures frequently.

Chronic ionized hypocalcemia is commonly observed with major thermal injury.<sup>137</sup> Prophylactic intermittent administration of calcium chloride or calcium gluconate is strongly recommended during the rapid infusion of citrated blood products.<sup>359-362</sup> We observed children experience electromechanical dissociation or cardiac arrest during the rapid administration of fresh frozen plasma (FFP). This observation prompted a controlled prospective study in which highly significant reductions in calcium were found when FFP was administered at a rate of 1 mL/kg/min or greater (see Fig. 10-9).<sup>362</sup> Of interest, no relation was seen between adverse cardiovascular responses, rate of FFP infusion, or calcium concentration. A careful review of the previous cases of cardiac arrest revealed that all children were anesthetized with halothane, whereas in our prospective study most were anesthetized with “balanced” techniques. Because all inhalation agents depress cardiac function in part through their calcium channel-blocking activity, a sudden citrate-induced decrease in ionized calcium would be expected to cause additional cardiac dysfunction. Studies in our laboratory have, in fact, documented this interaction.<sup>21,362,363</sup> Additional exogenous calcium is administered during rapid infusion of FFP or citrated whole blood, especially in infants (see Chapter 10).<sup>362</sup> It is our clinical impression that the rapid administration of (cold) FFP or citrated whole blood through a central line, without additional exogenous calcium, may be more likely to induce severe hypotension, bradycardia, and electrical mechanical dissociation. Our experience has been that rapid administration of citrated blood products is safer through peripheral lines. Rapid administration of washed packed

**FIGURE 34-11** Tangential skin excision in which multiple thin areas of burn tissue are excised until a viable vascular bed is achieved. This is indicated by brisk bleeding. This type of excision results in less scarring because the majority of fat tissue remains intact. However, this also results in significantly greater blood loss.

**FIGURE 34-12** **A**, Subcutaneous injection of normal saline with a dilute concentration of epinephrine ( $0.5 \mu\text{g/mL}$ ) from an area to be excised. **B**, Note the blanching of the donor skin secondary to the epinephrine. This helps greatly reduce the amount of blood loss observed from both the donor sites and burn wound excision. It should be noted, however, that in the case of a large quantity administered to a small patient, late absorption can result in fluid overload. **C**, Skin is now harvested with minimal blood loss owing to the vasoconstriction of the tumescence solution with low dose epinephrine.

or citrated packed red blood cells does not cause ionized hypocalcemia. It would also seem advantageous to administer exogenous calcium through a peripheral line to avoid excessive concentrations in coronary vessels. However, calcium administered simultaneously in the same intravenous line with FFP or citrated blood products may cause clot formation unless the calcium is rapidly flushed through the intravenous system.

## SPECIAL CONSIDERATIONS

### Pharmacologic Responses

As a general rule, children with burn injuries require larger than normal doses of all medications, including antibiotics, NMBDs, opioids, and benzodiazepines.\* Cardiovascular response to catecholamines may be attenuated because of a reduced affinity of  $\beta$ -adrenergic receptors for ligands and diminished second messenger production,<sup>173</sup> thus the need for greater than standard doses to achieve the desired clinical response. Pharmacokinetic studies in acutely burned children indicate that the increased requirement for antibiotics is due in part to leakage through the burn wound, rapid urinary excretion, and altered volume of distribution.<sup>43</sup> Thermal injuries of more than 30% of body surface area cause an upregulation of acetylcholine receptors and consequent resistance to NMBDs.<sup>167-169,171-174,364</sup> In addition, there appears to be increased tolerance to sedatives and opioids. In adult burn patients, the free fraction (pharmacologically active component) of diazepam was greater than in nonburned patients, whereas the clearance of free diazepam was reduced. An increased tolerance to diazepam despite a greater fraction of the pharmacologically active compounds combined with a decreased clearance suggests resistance at tissue receptors similar to that observed for NMBDs at the neuromuscular junction.<sup>78</sup> A similar tolerance has been observed with opioids. The persistence of such pharmacodynamic changes for both NMBDs and anesthetic drugs long after recovery from burn injury must be kept in mind and doses titrated according to patient responses.<sup>73,177,325,329</sup>

The pharmacology of many medications commonly used in burned children remains to be investigated.<sup>177</sup> In general, it is necessary to be aware of both pharmacokinetic and pharmacodynamic changes. Furthermore, these children are frequently taking multiple medications, and therefore drug interactions, potentiations, and incompatibilities must be considered. Of particular importance in this context are the  $H_2$ -receptor antagonists, which are commonly used in burned children and are known to inhibit the clearance of many other medications (see Chapter 6).

### Methemoglobinemia

A less common, but important source of intraoperative cyanosis and hypoxemia is the development of methemoglobinemia. When silver nitrate dressings are used on the burn sites, there are some strains of gram-negative bacteria capable of reducing nitrates to nitrites, which diffuse into the bloodstream and convert hemoglobin into methemoglobin.<sup>120,121,285</sup> The methemoglobin decreases the available  $O_2$ -carrying capacity and increases the affinity of the unaltered hemoglobin for  $O_2$ , thereby further impairing the delivery of  $O_2$ . As a consequence, the  $O_2$ -hemoglobin P50 curve is shifted to the left. Therefore methemoglobinemia should be considered in the differential diagnosis of cyanosis. Approximately 5 g of deoxyhemoglobin for each deciliter of blood is necessary to produce visible cyanosis, but a

comparable skin color is produced by 1.5 to 2 g of methemoglobin for each deciliter of blood. Blood that contains more than approximately 10% methemoglobin usually appears dark red or even brown, despite a high measured  $PaO_2$ , and does not change color even with vigorous agitation in room air. Measured  $O_2$  saturation or content is low. However, pulse oximetry, although demonstrating a decrease in saturation, provides a falsely increased value.<sup>235,236</sup> Treatment consists of removing the toxic agent and administering methylene blue (2 mg/kg) and high inspired  $O_2$  concentrations.

### Tracheal Tube Size

Because burned children frequently undergo multiple anesthetic procedures, special considerations must be given to the tracheal tube type and size. As mentioned previously, cuffed tracheal tubes are preferable. The size of the tracheal tube, the volume of air inflated into the cuff, and the pressure at which leakage occurs around the cuff should be recorded at each anesthetic. It is common to note that the requirement for a smaller diameter tracheal tube as weeks go by suggests the development of a subglottic lesion (stenosis, granuloma, polyps), which should be investigated with bronchoscopy. When  $N_2O$  is used, the intraoperative cuff pressure should be checked to avoid excessive pressure on the tracheal mucosa, although MICROCUFF tubes provide a greater margin of safety than conventional tracheal tubes (see Chapter 12). We generally inflate the cuff to the minimum pressure that allows controlled ventilation and check the cuff pressure regularly.

### Airway Control

The pediatric burn patient may present an especially difficult airway challenge to the anesthesiologist. This may be due to external airway factors such as temporomandibular joint limitation, macroglossia from thermal injury, and neck contractures.<sup>12,327</sup> It also may be due to direct thermal or inhalational injuries to the glottis and respiratory tree. A detailed history and physical examination focusing on airway injury is vital. History details such as victim of fire in a closed space (e.g., house or automobile fire [very commonly associated with inhalational injuries]), vocal changes, stridor, and hoarseness may be important predictors of difficulty in establishing an airway.

Fiberoptic intubation is a very useful method of securing the airway. We use this technique frequently after induction when we are confident we can maintain a mask airway as well for "awake" but sedated children who are breathing spontaneously. Recently, we have used dexmedetomidine as our sole sedative while performing fiberoptic intubations on spontaneously breathing children. Dexmedetomidine, an  $\alpha_2$ -adrenoceptor agonist, may provide a relatively stable hemodynamic environment, without respiratory depression, making it an ideal sedative when loss of respiratory drive could be catastrophic.

Fiberoptic intubation is often aided in these children with manual distraction of the tongue (especially if macroglossia is present) and a jaw lift (Fig. 34-13). If the tongue is difficult to grasp, moderately high suction applied to the tip of the tongue or a gauze wrapped around the tongue and then gently pulling the tongue forward facilitates visualization of glottic structures (see Fig. 12-29).<sup>365</sup> Fiberoptic intubation sometimes is more easily performed if the bronchoscope is guided through a laryngeal mask airway (LMA) that has already been seated and used to ventilate the lungs. This can be especially advantageous if there is a lot of perioral edema from inhalational burn injury.

\*References 2, 59-61, 73, 77-79, 160-164, 169, 177-180, 331-333, 356.

**FIGURE 34-13** **A**, Child with inadequately treated facial burn. Note that skin contracture has resulted in complete distortion of the face with inability to close the right eye. **B**, Child with another example of an inadequately treated neck burn; note that her chin is fused with the sternum, resulting in very difficult airway management. **C**, An acute burn injury with an even more extreme example of inability to access the airway. To manage this child safely for the initial neck release, extracorporeal membrane oxygenation was used. This child is also unable to close her eyes. **D**, Some children with severe neck burns may have their airway visualized only by pulling back on the tongue (zero silk suture, suction applied to the tip of the tongue, or grasping forceps may be used [see also Fig. 12-29]) so as to pull the tongue and larynx cephalad.

In addition to direct laryngoscopy, fiberoptic intubations, and LMA-assisted intubations, other techniques have been described, including retrograde wires and light-wand intubations. These techniques may be difficult to use in a child with a severely burned neck and contractures. In children with severe neck or oral contractures, the surgeon may release the contracture during ketamine sedation and spontaneous ventilation to facilitate access to the airway (Video 34-5). The airway may then be instrumented either directly or indirectly (see Chapter 12).

### Hyperalimentation

Hyperalimentation fluids are frequently administered to burned children.<sup>99,366</sup> These fluids should be continued intraoperatively;

however, we generally reduce the rate of infusion to half to two thirds of the initial infusion rate because metabolic rate is usually decreased during anesthesia. These fluids should be administered with a constant-infusion pump to avoid accidental overinfusion or underinfusion. If the hyperalimentation fluids must be terminated (e.g., to permit blood transfusion), monitoring of blood glucose levels is recommended. Dangerous rebound hypoglycemia may occur if infusion of these solutions is abruptly interrupted and no compensation is made with other glucose-containing solutions. It should be noted that most blood products, particularly whole blood and FFP, provide a significant glucose load. Compatibility of hyperalimentation solutions with drugs, blood, and other infusions must be addressed.

### Ultrasound-Guided Vascular Access, Regional Analgesia, and Cardiovascular Assessment

The use of high-resolution portable ultrasound continues to increase among anesthesiologists. The perioperative care of the pediatric burn patient is arguably one of the areas with the greatest use of this new and advancing technology. At Shriners Hospital for Children in Boston we employ ultrasound as an adjunct for vascular access, regional anesthesia, and cardiopulmonary diagnosis.

Vascular access for the pediatric burn patient can be extremely challenging. However, placing central venous and arterial catheters in the operating room under carefully controlled conditions is associated with a rate of acute mechanical complications and deep vein thrombosis of less than 1%.<sup>367</sup> This applies to both central and peripheral access as a result of thermal damage from the burn, surgical grafting over peripheral vessels, and increased clotting and thrombi from multiple factors such as multiple prior cannulations, hypercoagulable state from the burn, and long periods of being bedbound. Ultrasound is useful not only to more rapidly and safely access arteries and veins but also to diagnose clotted vessels, saving the child many futile attempts at obtaining vascular access.<sup>368</sup> Ultrasound also helps establish the location of cannulae. For peripherally inserted central catheters (PICCs), we first use ultrasound to assist in cannulating a vein, then place the probe over the internal jugular to verify that the PICC is not traveling cephalad, and scan the subclavian vein to verify placement.

Ultrasound-guided regional anesthesia is also a valuable tool in the care of the burned child undergoing reconstructive surgery. Typically, the complaints children have after reconstructive procedures involve the pain of the graft donor site. For the past 5 years we have improved the postoperative experience by placing ultrasound-guided blocks of donor sites, sometimes with catheters for further postoperative analgesia. Specific blocks we have found very useful include the lateral femoral cutaneous nerve and fascia iliaca to cover the most common donor site—the lateral thigh. Using ultrasound, reliability of these blocks is significantly improved over typical blind techniques.<sup>369,370</sup> We find that block of the lateral femoral cutaneous nerve provides better pain control for the donor site than infiltrating the donor site with local anesthetics. Longer analgesia can be provided by leaving a catheter in place. Usually we place fascia iliaca catheters; lateral femoral cutaneous nerve catheters also work, but we have found the learning curve for successful placement to be a bit steeper.<sup>371</sup>

Ultrasound is one of several strategies to rapidly assess intraoperative cardiac function during burn surgery. We have used real-time ultrasound while decompressing a spontaneous pneumothorax in a burn patient as a rapid and reliable indicator of when the lung has reexpanded as indicated by return of the pleural “sliding” sign.<sup>372-374</sup> Hemodynamic measurements also can be estimated intraoperatively; we use the Bedside Assessment for Trauma/Critical Care (BEAT) examination as a quick assessment of volume status.<sup>375,376</sup>

### Awakening

In the immediate postoperative period, O<sub>2</sub> consumption increases even in the absence of shivering.<sup>37</sup> If O<sub>2</sub> debt develops (metabolic acidosis), appropriate measures must be taken to correct it. Special consideration also must be given to the likelihood of severe pain. Analgesic drugs should be administered in increasingly liberal doses because of increased drug tolerance. Adequacy

of air exchange and patency of the airway, however, must be given first priority. It is important to assess the leak pressure at the end of the surgical procedure. The airway patency of the burned child is highly dynamic, and the child whose airway had minimal edema at the beginning of a procedure may have a very edematous airway at the end and be a poor candidate for extubation.

### PAIN MANAGEMENT AND POSTOPERATIVE CARE

Treatment of the child with a burn who has pain, both perioperatively and in the intensive care unit, remains a major challenge for anesthesiologists and intensivists. Our experience is that the pain is proportional to the size of the thermal injury. Nearly every maneuver involving the care of the child with a burn is associated with pain. This includes dressing changes, excision and grafting, physical therapy, weighing, and line placements.

Part of the challenge in managing burn pain is due to the overlay of physiologic and psychosocial responses to thermal injury. Besides physical stimulation of nociceptors and other direct pain mechanisms, there is also the very real anticipation, anxiety, and fear associated with these procedures. Evidence suggests that skillful communication and explanations of why certain treatments are necessary, despite the pain caused, decreases analgesic requirements.<sup>320,377-379</sup>

Opioid administration for pain control has been an evolving science for the child with a burn. Twenty years ago there was significant fear that treatment of pain with opioids would create addictions. However, no reports of children developing opioid addiction after therapeutic uses of opioids have been published and studies in adults revealed a very low addiction rate.<sup>380-384</sup> This has led to liberalization of opioid dosing. It is not unusual for children to receive more than 1 mg/kg/hr of morphine intravenously while recovering from burn injuries in our intensive care unit. Once the thermal wounds are closed, opioid requirements rapidly decrease (Fig. 34-14).

Although the fear of post-burn care addiction to opioids has not been realized, there are other reasons why this class of drugs may be detrimental to the child with a burn. Recent evidence from rats suggests that thermal injury itself may lead to a hyperalgesic state with both reduced efficacy of morphine (presumably from downregulation of spinal  $\mu$  receptors) and increases in *N*-methyl-D-aspartate (NMDA) receptors. The increases in NMDA receptors induced by burns provide the rationale for the widespread use of ketamine to treat pain in these children. Opioids may also increase sensitivity to pain. Morphine has been shown in a mouse model to downregulate  $\mu$ -opioid receptors within the spinal cord and cause injury to spinal inhibitory interneurons.<sup>383,384</sup> Opioids in mice have also been shown to cause postburn immunosuppression in the mouse model.<sup>385</sup>

The fact that opioids may have disadvantages when used for pain management has led to a search for alternative analgesics. Among these are potentially dexmedetomidine,<sup>386-392</sup> gabapentin,<sup>393</sup> and, until their recent withdrawal from the market, cyclooxygenase-2 inhibitors.<sup>394-396</sup>

Dexmedetomidine is a parenterally administered  $\alpha_2$ -adrenoceptor agonist with good sedative and anxiolytic properties. In adults, it has been demonstrated to decrease opioid requirements postoperatively.<sup>387-391,397</sup> In children with burns, it has been used successfully for sedation,<sup>386</sup> although larger dexmedetomidine doses may be needed than those required in nonburned adults or nonburned children.<sup>386</sup> Dexmedetomidine does not appear to be a remarkable analgesic for children with

**FIGURE 34-14** Morphine and midazolam requirements of a 16-year-old boy who had suffered an approximately 90% body surface area burn injury. Note the marked rapid rise in analgesia and sedation requirements during the first 4 to 5 weeks after injury and then the rapid decline in requirements as his wounds were successfully grafted.

**FIGURE 34-15** Change in mean arterial pressure (MAP) after bolus dose of dexmedetomidine in eight consecutive acute pediatric burn patients. *NOTE:* Given these observations, we now avoid a bolus dose; however, should a bolus dose be considered necessary, we suggest that the need for volume resuscitation (10 mL/kg or greater of balanced salt solution) or mild pressor support must be anticipated. (From Shank ES, Sheridan RL, Ryan CM, Keaney TJ, Martyn JA. Hemodynamic responses to dexmedetomidine in critically injured intubated pediatric burned patients: a preliminary study. *J Burn Care Res* 2012 Aug 27 [Epub ahead of print].)

burns. In a prospective study of dexmedetomidine in acutely burned children,<sup>398</sup> a bolus dose of intravenous dexmedetomidine (1  $\mu$ g/kg over 10 minutes) was followed by an ascending infusion protocol (0.7  $\mu$ g/kg/hr to 2.2  $\mu$ g/kg/hr).<sup>399</sup> We found no instances of heart block or other arrhythmias, but noted a consistent and significant decrease in mean arterial blood pressure (MAP) after the bolus (approaching 30% change in mean

pressure) (Fig. 34-15). This occurred in all ages studied (2 to 18 years), although the decrease in the MAP did not correlate with size of burn, time out from burn, or central venous pressure, before the study. Given these observations, we avoid a bolus dose of dexmedetomidine. However, should a bolus dose be indicated, we recommend 10 mL/kg or more of balanced salt solution or mild pressor support before commencing dexmedetomidine.

**TABLE 34-3** Pain Treatment Plan

Clinical State	Background Anxiety	Background Pain	Procedural Anxiety	Procedural Pain	Transition to Next Clinical State
Mechanically ventilated acute burn	Midazolam infusion	Morphine infusion	Midazolam intravenous titration	Morphine intravenous titration	Wean infusions 10%-20% per day and substitute nonmechanically ventilated acute guideline
Nonmechanically ventilated acute burn	Scheduled enteral lorazepam	Scheduled enteral morphine	Lorazepam intravenous titration or enteral dose	Morphine enteral or intravenous titration	Wean scheduled drugs 10%-20% per day and substitute chronic acute guideline
Chronic acute burn	Scheduled enteral lorazepam	Scheduled enteral morphine	Lorazepam enteral dose	Morphine enteral dose	Wean scheduled and bolus drugs 10%-20% per day to outpatient requirements and pruritus medications
Reconstructive surgical patient	Scheduled enteral lorazepam	Scheduled enteral morphine sulfate	Lorazepam enteral dose	Morphine enteral dose	Wean scheduled drugs and bolus drugs to outpatient requirement

Other investigators have retrospectively examined cardiovascular stability of pediatric burn patients sedated with dexmedetomidine and concluded that in the absence of a loading dose, blood pressure was maintained in the dexmedetomidine treatment group.<sup>400</sup> Dexmedetomidine pharmacokinetics in nonburned children appear similar to those in adults, but they have not been reported in pediatric burn patients.<sup>401-403</sup> When dexmedetomidine was compared with midazolam as an adjunct to ketamine in sedation and analgesia for burn dressing changes, the authors determined that both were effective adjuncts but that the dexmedetomidine ketamine group had better sedation with less hemodynamic instability.<sup>404</sup> Dexmedetomidine has also been used in anxious children with burns as an intranasal premedication.<sup>405</sup> The authors concluded that dexmedetomidine (2 µg/kg) intranasally as a premedication compared with oral midazolam (0.5 mg/kg), induced preoperative sleep faster and was equally effective for induction conditions and rapidity of emergence. In our experience, the majority of our children prefer oral midazolam despite its bitter aftertaste, to intranasal dexmedetomidine. A substantial detractor from dexmedetomidine use is its cost (more than \$44 for a 100-µg vial at our institutions). One study in adult volunteers compared intravenous with intranasal dexmedetomidine; pharmacodynamic responses were similar, but the peak blood concentration occurred sooner in the intravenous group.<sup>406</sup> Bioavailability after nasal administration was 65% (range 35% to 93%).

Dressing changes sometimes present one of the greatest analgesic challenges. This is because they are very painful, cause a rapid rise above baseline pain, and are associated by the child with anticipation of impending pain. Various methods to manage this pain have been used, including additional opioids and benzodiazepines, ketamine,<sup>335</sup> intranasal fentanyl,<sup>407</sup> immersive virtual reality,<sup>408,409</sup> and music therapy.<sup>410</sup> Management of the child's pain depends on physiologic and pharmacologic factors, as well as the psychological state of the child. Unfortunately, some children become so tolerant that one author observed that doses of intravenous fentanyl as large as 100 µg/kg administered as a bolus did not cause respiratory depression nor did it control the pain (CJC).

When poorly controlled, pain and anxiety have adverse psychologic<sup>146,411,412</sup> and physiologic effects.<sup>19</sup> Posttraumatic stress disorder has been reported to occur in up to 30% of those with serious burns<sup>413,414</sup> and may be related to both the accident and the treatment, particularly in the setting of inadequate control of

pain and anxiety. An inconsistent approach to pain and anxiety will be associated with inappropriate degrees of child discomfort, nonuniform drug selection with inconsistent dosing of unfamiliar drugs, varying tolerance of child discomfort among staff members, and bedside disagreements over management of the child's distress.

To address this issue, a pain and anxiety guideline should be developed by all facilities routinely treating burned children.<sup>415-418</sup> We developed one such guideline that we have followed for several years, which is briefly described in Table 34-3.<sup>321</sup> The ideal characteristics of such a guideline include (1) safety and efficacy over the broad range of ages and injury acuties seen in the particular unit; (2) explicit recommendations for drug selection, dosing, and escalation of dosing; (3) a limited formulary that generates staff familiarity with agents used; and (4) regular assessment of pain and anxiety levels and guidance for intervention as needed through dose ranging. We have found this structured approach to manage this predictable problem to be very effective over the broad range of injury severity and child ages seen in our unit. Substantial escalation of drug doses, particularly in children with large injuries, is commonly required; doses should be titrated to the child's needs. When the child is being weaned toward extubation, background medications should be tapered toward a sensorium consistent with airway protection; many children's tracheas are safely extubated while they are still receiving opioid and benzodiazepine infusions. Finally, it is essential to emphasize that the most effective of all analgesics and anxiolytics is prompt, definitive wound closure.

Tolerance to opioids occurs over time and must be considered so that adequate analgesia is provided throughout the recovery period. It is common to observe children who receive 1 mg/kg of morphine at the beginning of a 2-hour operative procedure not only to be ready for extubation but also to require additional opioids for continued pain relief postoperatively. Similar trends have been observed for fentanyl.<sup>162</sup> Thus an increased rate of excretion and degradation may influence the effect of some opioids. As the child recovers, the painful stimuli diminish and the opioid requirements are gradually reduced. This is generally such a prolonged process that withdrawal is not an issue. Anesthesiologists can have a central role in the treatment of thermal injury pain and, with an understanding of pharmacology, pharmacokinetics, and pharmacodynamics, are a vital resource for the care of these children (see Chapters 43 and 44).

## Summary

The care of burned children involves detailed knowledge of the early and late effects of burn injury on the respiratory, cardiac, renal, central nervous, hepatic, gastrointestinal, hematopoietic, and metabolic systems. An awareness of the pharmacokinetics and pharmacodynamics of anesthetic agents, combined with an understanding of the problems of massive blood transfusion, also contribute to the safe conduct of anesthesia. Finally, the importance of adequate analgesia, sedation, and concern for the psychological well-being of these devastatingly injured children cannot be overemphasized. Knowledge of all of these factors combines to produce a successful outcome.

## ACKNOWLEDGMENT

We wish to thank S.K. Szyfelbein for his previous contributions to this chapter.

**THE PRETERM INFANT IS** defined by birth before 37 weeks gestation. Preterm infants can be classified as low-birth-weight infants (less than 2500 g), very low-birth-weight infants (less than 1500 g), and extremely low-birth-weight (ELBW) infants (less than 1000 g). Morbidity and mortality in this population has decreased over the past 25 years, especially in the ELBW infant group, in which the mortality in 2011 is less than 30% in Level 3 hospitals, compared with 80% in 1980.<sup>1-3</sup> This decrease in mortality is the result of many factors, including the use of surfactant shortly after birth, antenatal glucocorticoid administration, specialization of neonatal care units, and changes in mechanical ventilator therapy. However, many of these surviving infants develop coexisting diseases that require care by an anesthesiologist. For the purpose of this chapter, we will focus on the very low and extremely low-birth-weight infant, or “micropremie,” and discuss developmental physiology and its impact on anesthetic care; neonatal emergencies are discussed in Chapter 36.

## Physiology of Prematurity Related to Anesthesia

### RESPIRATORY SYSTEM

The small airways predispose the micropremie to obstruction and difficulty with ventilation. Resistance to airflow is inversely proportional to the fifth power of the radius in the upper airway and

to the fourth power of the radius beyond the fifth bronchial division (see also Fig. 12-7). As a result, insertion of an endotracheal tube (ETT) increases resistance and work of breathing far greater for the micropremie (2.5 or 3 mm inside diameter [ID]) than for a larger infant (4 mm ID), child (5 mm ID), and adult (7 mm ID) (Fig. 35-1). Similarly, partial occlusion of the ETT by secretions, blood, or kinking increases the work of breathing to a much greater extent in the micropremie. Partial occlusion of the natural airway from loss of muscle tone during anesthesia and sedation also increases the work of breathing more in the micropremie. Consequently, general anesthesia often requires placement of an ETT to ensure airway patency, and assisted ventilation to overcome the increased work of breathing.

Diseases that narrow the airway, such as subglottic stenosis, tracheal stenosis, and tracheobronchomalacia, occur commonly in the micropremie, and the associated reduction in airway diameter further increases both resistance to airflow and work of breathing. Subglottic stenosis necessitates the placement of a smaller ETT than would otherwise be placed, further increasing airflow resistance. Tracheal stenosis often occurs near the carina and, although not necessitating a smaller ETT, it increases airway resistance from the stenosis distal to the ETT. With tracheobronchomalacia, the intrathoracic airways collapse during exhalation, again increasing resistance and the work of breathing (see also Fig. 12-10). Positive end-expiratory pressure (PEEP) or continuous positive airway pressure (CPAP) helps stent open the airway.

**FIGURE 35-1** Change in work of breathing after placement of an appropriate size endotracheal tube in extremely low-birth-weight infants (less than 1000 g), premature infants (1500 g), full-term infants, children, and adults (see text for details). (Redrawn with permission from Spaeth JP, O'Hara IB, Kurth CD. Anesthesia for the micropremie. *Semin Perinatol* 1998;22:390-401.)

Mechanical ventilation, rather than spontaneous ventilation during anesthesia, prevents fatigue from increased work of breathing, and maintains ventilation and oxygenation. During anesthesia the use of *smaller inspiratory-to-expiratory ratios* prevent air trapping and hyperinflation of lung segments.

The structure and function of the immature lung predisposes to alveolar collapse and hypoxia. The alveoli are primarily composed of thick-walled, fluid-filled saccular spaces that are surfactant deficient and require greater pressures to initially expand. Production of surfactant begins at between 23 to 24 weeks gestation, although surfactant concentrations often remain inadequate until 36 weeks gestation. These factors lead to reduced lung volumes and lung compliance, increased intrapulmonary shunting, and ventilation-perfusion mismatch. Decreased lung volumes and ventilation-perfusion mismatch may also occur as a consequence of anesthesia. The effects of immature structure, disease, and anesthesia on lung function all increase the risk of hypoxia during surgery and anesthesia.

Micropremie lungs are particularly susceptible to oxygen toxicity, volutrauma, and the development of bronchopulmonary dysplasia (BPD). Mechanical lung injury is no longer thought to be caused by the use of high peak-inspiratory pressures, but rather related to increased end-inspiratory lung volumes and frequent collapse and reopening of alveoli. A ventilation strategy using small tidal volumes (4 to 6 mL/kg), greater respiratory rates, PEEP sufficient to avoid alveolar collapse, and permissive hypercapnia reduces lung injury in the premature lung.<sup>4</sup> Randomized controlled trials of permissive hypercapnia (PaCO<sub>2</sub> 45 to 55 mm Hg) showed smaller periods of assisted ventilation, reduced incidence of BPD, and no increase in adverse neurodevelopmental effects.<sup>5</sup> The use of high inspired oxygen concentrations leads to the development of free radical species, which contribute to pulmonary epithelial cell injury.

A severity index for BPD based on the need for supplemental oxygen and/or positive-pressure ventilation or nasal CPAP has been developed and shown to identify a spectrum of risk for adverse pulmonary and neurodevelopmental outcomes in preterm infants (Table 35-1).<sup>6</sup> Although this severity index has not been studied in the context of anesthetic risk, experience suggests that such infants requiring supplemental oxygen, positive pressure, or medications for reactive airways are at greater

**TABLE 35-1** Severity-Based Diagnostic Criteria for Bronchopulmonary Dysplasia (BPD)

Gestational age	<32 weeks
Time point of assessment	36 weeks postmenstrual age or discharge home, whichever comes first
	Therapy with oxygen >21% for at least 28 days <i>plus</i> :
Mild BPD	Breathing room air
Moderate BPD	Need for <30% oxygen
Severe BPD	Need for ≥30% oxygen and/or positive-pressure ventilation or nasal continuous airway pressure

From Ehrenkranz RA, Walsh MC, Vohr BR, et al. Validation of the National Institutes of Health consensus definition of bronchopulmonary dysplasia. *Pediatrics* 2005; 116:1353-60.

risk for perioperative pulmonary complications. Anesthetic goals include minimizing the inspired oxygen concentration and tidal volumes while maintaining oxygen saturation (SaO<sub>2</sub> 90% to 94%) and ventilation (PaCO<sub>2</sub> 50 to 55 mm Hg). The use of smaller tidal volumes decreases the risk of pneumothoraces and interstitial emphysema.

## RESPIRATORY CONTROL

Micropremies possess a biphasic ventilatory response to hypoxia. Initially, ventilation increases in response to hypoxia, but after several minutes, ventilation decreases and apnea may ensue.<sup>7</sup> The ventilatory response to carbon dioxide is decreased in the micropremie, and hypoxia further blunts this response.<sup>8,9</sup> Anesthetic drugs depress the ventilatory responses to both hypoxia and hypercapnia. Hypoxia and hypercapnia occur commonly as a result of apnea and hypoventilation during emergence and recovery from anesthesia. Thus the combination of anesthetic effects and an immature respiratory control system, as well as immature intercostal and diaphragmatic muscles,<sup>10,11</sup> increase the risk of hypoxia, hypercapnia, and apnea in the postoperative period.

Apneic episodes occur commonly in the micropremie but decrease with advancing postconceptional age.<sup>12</sup> These apneic episodes usually involve both a failure to breathe (central apnea) and a failure to maintain a patent airway (obstructive apnea). Central apnea results from decreased respiratory center output, although it may be precipitated by abrupt changes in oxygenation, pulmonary mechanics, brain hemorrhage, hypothermia, or airway stimulation. Apnea may also occur without a precipitating event (i.e., idiopathic). Preterm infants with apnea do not increase ventilation in response to hypercapnia, compared with those without apnea, thereby delaying resumption of breathing and prolonging the apneic episode.<sup>13</sup> During obstructive apnea, the airway becomes obstructed in the hypopharynx and larynx as a result of pharyngeal muscle incoordination. Anesthetic drugs may further decrease pharyngeal muscle tone, precipitating airway obstruction during recovery from anesthesia. The combination of anesthetic effects and immature respiratory control place the micropremie at risk for central and obstructive apnea for a prolonged period of time during recovery from anesthesia.

Not surprisingly, apnea occurs commonly after anesthesia and surgery in preterm infants.<sup>14,15</sup> Like apnea of prematurity, postoperative apnea may be central, obstructive, or mixed in origin.<sup>16</sup> The term *postoperative apnea* usually means prolonged apnea (greater than 15 seconds) or brief apnea accompanied by

bradycardia (heart rate 80 beats per minute or less). Postoperative apnea typically occurs as a cluster of episodes over several minutes, with minutes of normal breathing in between the clusters. Bradycardia may occur with apnea, usually beginning at the onset of apnea and not in response to hypoxia. Arterial oxygen desaturation usually follows the apnea, although many apneic episodes may not have any associated desaturation. Arterial desaturation is worse with obstructive apnea than with central apnea.<sup>16</sup>

Several different terms have been used to describe the age of the fetus, leading to some confusion in the literature. Gestational age, menstrual age, conceptional age, and postnatal age are all used with somewhat different meanings, even in this book, so we present here the definitions of these terms according to the American Academy of Pediatrics, Committee on the Fetus and Newborn from 2004.<sup>17</sup> The gestational or menstrual age of the neonate is the interval from the first day of the mother's last menstrual cycle until birth of the fetus. The postmenstrual age is the sum of the menstrual age and the postnatal age. The conceptional age is defined as the interval between conception and birth, although the former is generally unknown. The postconceptional age (PCA) is the sum of the conceptional age and the postnatal age. Postconceptional age actually refers to a concept, not conception, but this term has been used interchangeably with postconceptional age in the apnea literature in anesthesia. The postnatal (or chronological) age is the age of the infant since birth. Controversy over this terminology continues, as some argue that the menstrual age overestimates the "in utero" age of the fetus because 10 to 14 days may lapse between the onset of menses and conception. On the other hand, terms such as conceptional (and postconceptional) age are imprecise because the date of conception is usually unknown, and thus these terms are not recommended.<sup>17</sup>

The incidence of postoperative apnea depends on PCA, hematocrit, and the type of surgical procedure (Fig. 35-2; see also Fig. 4-7 and E-Fig. 4-5).<sup>14-16,18</sup> The most significant risk factor is the PCA; the lesser the PCA, the greater the risk, with the incidence of postoperative apnea in the micropremie greater than 50%.<sup>14,15</sup> Postoperative apnea can occur in the micropremie even without a history of apnea of prematurity.<sup>14</sup> Anemia (hematocrit less than 30%) and younger gestation increase the risk of apnea for a given PCA.<sup>15,18</sup>

**FIGURE 35-2** Time from the end of anesthesia to the last episode of postoperative apnea in prematurely born infants. ( $r^2 = 0.49$ .) (Redrawn with permission from Kurth CD, Spitzer AR, Broennle AM, et al. Postoperative apnea in preterm infants. *Anesthesiology* 1987;66:483-8.)

Postoperative apnea usually begins within an hour of emergence from anesthesia.<sup>14</sup> In the micropremie, it can continue to occur up to 48 hours postoperatively, despite the elimination of anesthetic agents (see Fig. 35-2). In fact, postoperative apnea can occur after surgery with desflurane- or sevoflurane-based anesthetics, or even after surgery for which a regional anesthetic was administered and no general anesthetic drugs were used.<sup>19,20</sup> Postoperative apnea is more common after major procedures, such as a laparotomy, compared with peripheral surgical procedures, such as inguinal hernia repair. These observations indicate that the neurohormonal response to surgery and postoperative pain may play an important role in the origins of postoperative apnea. Management of postoperative apnea includes close observation with a cardiorespiratory monitor and pulse oximeter, administration of intravenous (IV) methylxanthines (e.g., caffeine, theophylline),<sup>21</sup> and prevention of anemia or hypovolemia. Nasal CPAP or tracheal intubation and mechanical ventilation may be required for several days postoperatively if these measures fail.

N7-methylation of theophylline (or aminophylline) to produce caffeine is well-developed in the neonate, whereas oxidative demethylation (CYP1A2) responsible for caffeine metabolism is deficient. Theophylline is effective for the management of postoperative apnea in the preterm neonate, in part because it is a prodrug of caffeine, which is effective in controlling apnea in this age group and can only be cleared slowly by the immature kidney. Consequently, the half-life of caffeine is ~72 hours in the extreme premature neonate, which decreases to 4 to 6 hours by 6 months of age. Clearance increases from 0.004 L/kg/hr in the premature neonate to 0.119 L/kg/hr by 6 months.<sup>22-26</sup> Although therapeutic drug monitoring is not required, target concentrations 5 to 20 mg/L are considered therapeutic.<sup>27</sup> One study suggests a loading IV or oral dose of 10 mg/kg followed by 2.5 mg/kg by mouth, once daily.<sup>26</sup>

### CARDIOVASCULAR SYSTEM

The micropremie remains at greater risk of cardiovascular collapse during anesthesia and surgery than does the full-term infant for several reasons. The fetal heart differs from the infant heart in that it has more connective tissue, less organized contractile elements, and increased dependence on extracellular calcium concentration. In addition, the less compliant fetal heart has a flatter Frank-Starling curve and is less sensitive to catecholamines because of near-maximal baseline  $\beta$ -adrenergic stimulation (see Chapter 16).<sup>28,29</sup> Consequently, cardiac output depends more on heart rate in the micropremie than it does in the term neonate. The increased resting heart rate in the micropremie also does not permit cardiac output to increase to the same extent as in an infant or child. The micropremie has a small absolute blood volume (Table 35-2). Therefore, relatively little blood loss during surgery can cause hypovolemia, hypotension, and shock. Because autoregulation is not well developed in the micropremie, the heart rate may not increase with hypovolemia, and blood flow and oxygen delivery to the brain and heart may decrease with relatively little blood loss.<sup>30</sup> Anesthesia blunts baroreceptor reflexes in the micropremie, further limiting the ability to compensate for hypovolemia.<sup>31</sup> The combination of limited ventricular stroke volume reserve, an increased heart rate, small blood volume, and limited autoregulation predispose the micropremie to cardiovascular collapse during major surgery.

Failure of the ductus arteriosus to close in the micropremie further increases this risk. A patent ductus arteriosus (PDA) promotes pulmonary hypertension and congestive heart failure.

**TABLE 35-2** Circulating Blood Volume in Micropremies, Premies, Full-Term Neonates, Infants, and Children

	Blood Volume (mL/kg)	Weight (kg)	Total Blood Volume (mL)	25-mL Blood Loss Proportion of Total Blood Volume (%)
Micropremie	110	1	110	23
Premie	100	1.75	175	14
Full-term neonate	90	3	270	9
Infant	80	10	800	3
Child	70	20	1400	2

Changes in systemic or pulmonary vascular resistance alter the direction of flow through the PDA or the foramen ovale.<sup>32</sup> Increased pulmonary vascular resistance predisposes to right-to-left shunting that worsens with hypoxia, hypercarbia, acidosis, and hypothermia. Paradoxical embolism is another concern.<sup>33</sup> Fluid restriction and diuretic therapy, often used to treat congestive heart failure from left-to-right shunting through a PDA, further increase the risk of hypotension during surgery. In contrast to full-term neonates, the success of inhaled nitric oxide in the micropremie with hypoxic respiratory failure and pulmonary hypertension remains unclear.<sup>34,36</sup>

### NEUROLOGIC DEVELOPMENT

Although mortality in extremely preterm infants has improved over the years, many survivors experience cognitive impairment and long-term disability.<sup>37,38</sup> Regions of the central nervous system develop at different times during gestation; consequently, the impact of premature birth on the central nervous system (CNS) depends on gestational age at birth and the severity of cardiovascular, respiratory, and other postnatal stressors. The area of the brain most susceptible to injury in the micropremie is the periventricular white matter.<sup>38</sup> The white matter consists of preoligodendrocytes, astrocytes, and neuronal axons. Late in the second trimester (24 to 27 weeks gestation), preoligodendrocytes and astrocytes multiply tremendously and most cortical and subcortical structures begin to develop.<sup>38</sup> During this period, the periventricular white matter is particularly susceptible to neurologic injury. The periventricular white matter is perfused by arteries penetrating from the cortical surface and by lenticulostriate arteries from the circle of Willis. As a result, the periventricular white matter is a “watershed region” and susceptible to poor perfusion and hypoxic-ischemic injury during conditions of hypotension, reduced cardiac output, hypoxemia, and hypocarbia.

Neural pathways allowing for perception of pain develop during the first, second, and third trimesters (see Chapter 43).<sup>39</sup> During the first trimester, peripheral sensory receptors and spinal reflex arcs develop that lead to the presence of a “withdrawal reflex” to non-noxious stimuli. Neurons that transmit nociception appear in the dorsal root ganglia at 19 weeks gestation, and afferent neurons from the thalamus reach the cortical subplate and cortical plate between 20 and 24 weeks gestation. However, it is not until early in the third trimester (29 weeks) that pathways between the thalamus and somatosensory cortex are functional. Significant controversy exists regarding the exact gestational age at which perception and memory of pain occur. Nevertheless,

our approach in the micropremie is to administer anesthesia during surgery and provide pain management postoperatively.

### LONG-TERM NEUROLOGIC COMPLICATIONS OF PREMATURITY

Long-term neurologic and developmental disabilities remain common in the micropremie and include cerebral palsy, cognitive deficits, behavioral abnormalities, as well as hearing and visual impairment. In one cohort of ELBW infants, only 25% were classified as normally developed at 5 years of age, whereas 20% exhibited major disabilities.<sup>37</sup> Brain magnetic resonance imaging (MRI) identifies a spectrum of abnormalities. The most common abnormality is diffuse high signal intensity on T2-weighted imaging in the periventricular cerebral white matter. Diffusion-weighted imaging shows increased apparent diffusion coefficient values, indicative of increased water content and delayed white matter maturation, suggesting ischemia-reperfusion injury in periventricular white matter, which has activated microglia and damaged preoligodendrocytes.<sup>38,40</sup> Damage to preoligodendrocytes impairs myelination of cerebral white matter axons and accounts for many of the fine motor, speech, and cognitive deficits. On MRI, tissue volumes in the basal ganglia, corpus callosum, amygdala, and hippocampus are reduced and correlate with smaller full-scale, verbal, and performance IQ scores.<sup>41</sup> Collectively, these MRI findings indicate that different regions of the brain vary in their susceptibility to injury during development and that such injuries lead to specific long-term disturbances in neurocognitive function.

### INTRAVENTRICULAR HEMORRHAGE

Intraventricular hemorrhage (IVH) occurs in as many as one-third of micropremie infants. The severity of IVH, as defined by head ultrasound, is graded as follows:

- Grade 1: hemorrhage limited to the germinal matrix
- Grade 2: hemorrhage extending into the ventricular system
- Grade 3: hemorrhage into the ventricular system and with ventricular dilatation
- Grade 4: hemorrhage extending into brain parenchyma.

Although micropremie infants with grade 3 or 4 IVH are more likely to exhibit severe long-term neurocognitive sequelae, even micropremie infants with grade 1 and 2 IVH display poorer neurodevelopmental outcomes compared with those without IVH.<sup>42</sup> Early onset of IVH appears during the first day of life. Risk factors include fetal distress, vaginal delivery, reduced Apgar scores, metabolic acidosis, severe hypercapnia, and the need for mechanical ventilation.<sup>43,44</sup> Late onset of IVH appears days to weeks after birth. Risk factors include respiratory distress syndrome, seizures, pneumothoraces, hypoxemia, acidosis, severe hypocarbia, and the use of vasopressor infusions.<sup>43</sup> Rapid fluctuations in cerebral blood flow, cerebral blood volume, and cerebral venous pressure appear to play a role in the development of IVH.<sup>45</sup> Factors that may decrease the incidence and severity of IVH include administration of antenatal glucocorticoids, or indomethacin.

### RETINOPATHY OF PREMATURITY

Retinopathy of prematurity (ROP) occurs in approximately 50% of ELBW infants, with the incidence being inversely proportional to birth weight and gestational age (see Chapter 32).<sup>46</sup> Although the pathogenesis of ROP is not completely understood, extremes in arterial oxygenation (hypoxia or hyperoxia)<sup>47</sup> and exposure to bright light appear to play a role.<sup>48</sup> One theory holds that the

combination of hyperoxic vasoconstriction of retinal vessels (also known as vaso-obliteration), induction of vascular endothelial growth factor, and free oxygen radicals damage the spindle cells in the retina.<sup>49</sup> A Cochrane review concluded that liberal oxygen delivery to a preterm infant is more harmful to the retina than restrictive oxygen delivery, although the data reviewed failed to specify the optimum blood oxygen concentrations that should be delivered.<sup>50</sup> Evidence points to additional factors in the pathogenesis of ROP, including genetic polymorphisms<sup>51</sup> and antenatal and neonatal exposure to inflammation.<sup>52</sup>

ROP appears to be multifactorial in origin and oxygen tension is just one of many contributory factors. During anesthesia, our goal is to deliver the minimum inspired oxygen concentration that provides oxygen saturations between 90% and 94% and to avoid significant fluctuations in oxygen saturations. It should be noted however that ROP has occurred in children with cyanotic congenital heart disease<sup>53</sup> and that no anesthesia-associated cases have been reported over the past 25 years. Nevertheless it is reasonable to aim for saturation values in the ranges described here.

### TEMPERATURE REGULATION

The micropremie is susceptible to hypothermia. Heat loss in children occurs by four possible routes: radiation (39%), convection (34%), evaporation (24%) and conduction (3%). In the micropremie, evaporative heat loss and insensible fluid loss are increased because the epidermis has less keratin.<sup>54</sup> Conductive and convective heat losses are also increased because the micropremie has little subcutaneous fat for insulation and a large surface area to mass ratio. Thermal regulation is not well developed in the micropremie. Nonshivering thermogenesis, which depends on brown fat stores, is decreased and regulation of skin blood flow is less efficient.<sup>55</sup> During anesthesia, measures should be undertaken to minimize radiation and convective heat loss by warming the operating room (OR) to 78° F to 80° F (25.5° C to 26.6° C) before the neonate arrives, and minimize convective heat loss during transport (i.e., use a thermoneutral incubator). Using a warming pad on the operating table reduces conductive heat loss; use of overhead heat lamps reduces radiant heat loss; and keeping the skin dry reduces evaporative heat loss. The most effective means for warming is a forced-air warmer. Temperature should be carefully monitored as overheating the infant may readily occur.

### RENAL AND METABOLIC FUNCTION

In the micropremie, kidney function is decreased as a result of fewer nephrons and smaller glomerular size.<sup>56</sup> Glomeruli continue to form postnatally until approximately 40 days.<sup>57</sup> During this period, reduced cardiac output, hypotension, and nephrotoxic drugs may inhibit glomerular growth and development. Creatinine concentrations depend on production that is reduced in micropremies with limited muscle mass, and on excretion that is reduced because of immature renal function. Baseline plasma creatinine concentrations increase with increasing prematurity and remain increased until 3 weeks of age.<sup>58</sup> In addition, the normal increase in creatine clearance in term infants occurs more slowly in the micropremie. Creatinine concentrations in the first few days after birth are increased and reflect maternal transplacental transfer.<sup>59</sup> It is for this reason that antibiotic dosing must be adjusted to take renal immaturity into consideration, so as not to administer excessive doses that might result in ototoxicity.<sup>60</sup>

Very preterm infants easily become hyponatremic because of reduced proximal tubular reabsorption of sodium and water, and

reduced receptors for hormones that influence tubular sodium transport. As many as one-third of ELBW neonates develop hyponatremia.<sup>61</sup> Frequent assessment of sodium and free water requirements is important during critical illness. Increased plasma potassium concentrations occur in preterm infants during the first few days after birth. The increase results from a shift in potassium from the intracellular to extracellular space.<sup>62</sup> These increases are greater as gestational age and birth weight decrease.<sup>63</sup> Reduced cardiac output and urine output may further increase serum potassium concentrations and predispose to cardiac arrhythmias.<sup>64</sup>

### GLUCOSE REGULATION

The micropremie is at risk for both hypoglycemia and hyperglycemia. Decreased glycogen and body fat predispose to fasting hypoglycemia, whereas decreased insulin production with infusion of dextrose predisposes to hyperglycemia.<sup>65,66</sup> Glucose production is poorly regulated within a large range of glucose and insulin concentrations. The micropremie is also relatively insulin resistant and requires a greater infusion rate of insulin to achieve normoglycemia.<sup>67</sup> The use of total parenteral nutrition and glucocorticoids places the micropremies at increased risk for hyperglycemia.

### GLUCOSE AND THE BRAIN

Multiple animal models and clinical studies implicate hyperglycemia as detrimental to the adult brain during global and focal ischemia.<sup>68</sup> In contrast, hyperglycemia in neonates appears to protect the brain from ischemic damage.<sup>69-71</sup> Studies in both neonatal rat and pig hypoxia-ischemia models observed less brain damage with greater glucose concentrations. Many mechanisms exist for this strikingly different outcome between neonates and adults.<sup>72</sup> Relatively mild hypoglycemia is known to cause brain damage in preterm infants.<sup>73</sup> Micropremies with critical illness are especially prone to hypoglycemia because they contain limited stores of glucose and consume glucose anaerobically. Thus the administration of dextrose-containing fluids (carefully controlled with an infusion pump so as to minimize wide fluctuations in glucose values) and close monitoring of blood glucose concentrations is vital during anesthesia. Mild or moderate hyperglycemia during surgery is best managed by reducing the rate of infusion of dextrose-containing solutions and not administering insulin, with its attendant risk of hypoglycemia.

### HEPATIC AND HEMATOLOGIC FUNCTION

Immature hepatic function leads to a reduction in many hepatic proteins important for drug metabolism. In addition, reduced albumin synthesis decreases albumin concentrations compared with term neonates (see Fig. 6-6), thus enhancing the “free” (unbound) concentration of anesthetic drugs that are highly bound to albumin (see Chapter 6). The micropremie is at particular risk for spontaneous liver hemorrhage.<sup>74,75</sup> This occurs most commonly during laparotomy for necrotizing enterocolitis (NEC), is associated with large IV fluid resuscitation, and is difficult to control surgically. Recombinant factor VIIa has been used to stop liver hemorrhage when administration of other blood products has been unsuccessful.<sup>76</sup>

The ideal hematocrit level for the micropremie remains controversial. In the micropremie with reduced oxygen saturations and cardiac output, tissue oxygen delivery will be maximized by maintaining the hematocrit between 44% and 48%. In a randomized study of liberal versus restrictive transfusion in neonates

between 500 and 1300 grams, intraparenchymal brain hemorrhage, periventricular leukomalacia, and episodes of apnea occurred more frequently in the restrictive transfusion group.<sup>77</sup> The risks of blood transfusion in the micropremie must be balanced against the benefits of improved oxygen delivery and fewer medical complications.

Thrombocytopenia (platelet count less than 150,000/mm<sup>3</sup>) occurs in as many as 70% of micropremies.<sup>78</sup> Although the etiology of thrombocytopenia is often unknown, pathophysiologic processes such as sepsis, disseminated intravascular coagulation, and NEC are common causes. Preoperative evaluation should include a recent platelet count and the availability of platelets for major procedures.

## Anesthetic Agents and the Micropremie

Anesthesia provides insensibility to pain during surgical procedures. Although anesthesia may be provided by regional or general techniques, general anesthesia is the most commonly used technique in the micropremie. During the past 25 years, general anesthesia has been delivered using both inhaled and IV drugs in very premature infants for a variety of surgical procedures.

### ANESTHETICS AND THE IMMATURE BRAIN

Research in immature animals indicates that anesthetics are both neuroprotective and neurotoxic. Inhalational anesthetics protect against hypoxic-ischemic injury in neonatal pigs and rats.<sup>79-81</sup> The anesthetic must be administered before and during the ischemic event at a concentration of 1 MAC (minimal alveolar concentration) to be effective. Thus for surgery in which there is a risk of brain ischemia, use of an inhalational anesthetic may afford some advantage over IV agents. Cardiac surgery, ventricular shunt insertion, and vein of Galen embolization represent examples of procedures that are performed in preterm infants and that carry a risk of brain ischemia. The MAC for sevoflurane has not been established in preterm infants and many sick preterm infants cannot tolerate even relatively modest concentrations of potent anesthetic agents.

Of particular concern are the reports in immature rats and other animals, including primates, that prolonged exposure to commonly used anesthetics, such as isoflurane, ketamine, and midazolam, induces apoptosis in many regions of the brain (see Chapter 23).<sup>82,83</sup> In rodents, exposure for at least 2 hours at 1 MAC of isoflurane produces apoptosis. A combination of isoflurane, midazolam, and nitrous oxide produces more neuronal degeneration than isoflurane or midazolam alone; nitrous oxide alone is not neurotoxic. When affected rats matured to adulthood, neurocognitive impairment was detected.<sup>82</sup> The neurotoxicity is brain-region specific and very dependent on the developmental age of the rodent. Rats are most sensitive to the neurotoxic effects of anesthetics on postnatal day 7, more so than on postnatal day 4 or beyond postnatal day 10.<sup>84</sup> The most susceptible age in rats, 7 days, corresponds to human brain development around mid-gestation. This suggests that if this phenomenon applies to humans, the preterm infant could potentially be more susceptible to anesthetic neurotoxicity than is the full-term infant.

The mechanism for the neurotoxicity appears to be attributable to the neurotransmitters glutamate and  $\gamma$ -aminobutyric acid, which act as trophic factors in the developing brain.<sup>85</sup> In the immature brain, these trophic factors promote synaptic growth

and plasticity and are obligate for neuronal survival. The inhaled anesthetics, ketamine, and midazolam exert their anesthetic effects by altering synaptic transmission through blockade of glutamate and  $\gamma$ -aminobutyric acid receptors. In the immature brain, this blockade also precipitates neuronal cell death by apoptosis.<sup>86</sup> In contrast, several anesthetics and medications may protect against apoptosis (see Chapter 23). A confounding factor is that neurodegeneration and apoptosis is a normal developmental phenomenon in the maturing fetal brain. Furthermore, anesthesia-induced neuronal cell death in neonatal animals may not directly translate into long-term neurologic abnormalities. Indeed, evidence suggests that sevoflurane-induced cognitive impairment, in the form of short-term memory deficiency in neonatal rodents, is offset by delayed exercise.<sup>87</sup> Moreover, immature animals that undergo painful procedures without anesthesia experience neuronal degeneration.<sup>88,89</sup> Preterm infants who receive anesthesia and sedation for painful procedures experience less morbidity and mortality than those who do not.<sup>90</sup> Curiously, the combination of surgery and anesthesia in neonatal rats produces more apoptosis than either intervention alone suggesting that in this model, anesthetics are neither neuroprotective themselves nor do they offset the apoptotic effects of surgery.<sup>91</sup> In summary, the neurodegeneration precipitated by inhaled anesthetics, ketamine, and benzodiazepines depends on developmental age, brain region, and duration of exposure. Based on the animal models, the micropremie exposed to several hours of large concentrations of inhaled agents with nitrous oxide and midazolam is potentially at risk, as is the micropremie exposed to surgery with insufficient anesthesia. Thus our approach at the present time for emergency surgery is to use small concentrations of inhaled agent with opioids and regional anesthesia whenever possible.

Of even greater concern may be the sedatives that are administered for prolonged periods of time in the intensive care unit (ICU), although one study found “no evidence of an association between dose and duration of sedation and/or analgesia drugs given during the preoperative, intraoperative, and postoperative period and major adverse developmental outcomes” in children undergoing repair of congenital heart disease in the first 6 weeks of life.<sup>92</sup>

### INHALATION ANESTHETIC AGENTS

The MAC defines the anesthetic depth for inhaled agents at which 50% of patients respond to a painful stimulus with movement; this measure allows comparison of the effects of inhaled anesthetics at equipotent doses. The MAC of isoflurane in the micropremie (less than 32 weeks PCA) is approximately 20% less than that in full-term neonates (E-Fig. 35-1; see also Fig. 6-16), and that at equipotent doses of isoflurane (1 MAC), systolic arterial pressure decreased similarly in all age-groups, 20% to 30%.<sup>93</sup> Sevoflurane affords a rapid induction and emergence from general anesthesia. Desflurane is contraindicated for induction of anesthesia but is widely used for maintenance of anesthesia administered through an ETT. However, desflurane causes more airway irritability than isoflurane or sevoflurane, and as a result, it is not recommended for infants with severe BPD. Desflurane, sevoflurane, and isoflurane decrease arterial blood pressure in a dose-dependent manner, possibly through decreasing the systemic vascular resistance or by myocardial depression. One possible mechanism to explain the myocardial depression is that the baseline ionized calcium concentrations in preterm infants, especially critically ill neonates are reduced.<sup>94,95</sup> Because inhalational

**E-FIGURE 35-1** The minimal alveolar concentration (MAC) for isoflurane in preterm infants, full-term infants, children, and adults. (Note data are plotted in postconceptional years.) (Reprinted with permission from LeDez KM, Lerman J. The minimum alveolar concentration [MAC] of isoflurane in preterm neonates. *Anesthesiology* 1987;67:301-7.)

anesthetics block the calcium channels,<sup>96</sup> and because the neonatal heart depends on the plasma ionized calcium for contractility to a greater extent than do the hearts of older children,<sup>97</sup> preterm infants may be more susceptible to the cardio-depressant effects of inhalational anesthetics.

Nitrous oxide is not routinely used in the micropremie for several reasons. First, nitrous oxide must be delivered in inspired concentrations ranging from 50% to 75% to reduce the MAC of other agents; therefore, its role in micropremies, a group often requiring supplemental oxygen, is limited. Second, because of its blood gas solubility, nitrous oxide rapidly enters air-filled cavities; therefore it is not recommended for use in infants with bowel obstruction, NEC, pulmonary interstitial emphysema, or pneumothoraces, which are common disorders in micropremies.<sup>98</sup> Third, in neonatal and young rats, nitrous oxide demonstrates no antinociceptive effects, which contrasts its antinociceptive effect in adolescent and adult rats.<sup>99</sup> This observation requires validation in humans.

### INTRAVENOUS AGENTS

IV agents include opioids, benzodiazepines, barbiturates, propofol, ketamine, and dexmedetomidine. Fentanyl possesses analgesic and sedative properties, however, it does not reliably produce unconsciousness or amnesia and, by itself, is not considered an anesthetic in children or adults. Nevertheless, the use of fentanyl as an anesthetic has been justified in preterm infants because they were deemed to be inherently amnestic by virtue of their age, even though the age at which "consciousness" and memory occurs is unknown. Preterm infants (less than 1500 g) who receive IV fentanyl (30 to 50 µg/kg) and pancuronium for ligation of a PDA exhibit remarkable hemodynamic stability, with only a 5% decrease in blood pressure.<sup>100</sup> Another study examined the dose response of 25 neonates undergoing a variety of thoracic and abdominal procedures. A dose of 10 to 12.5 µg/kg administered together with a muscle relaxant produced hemodynamic stability for 75 minutes.<sup>101</sup> Hypertension and tachycardia did not occur with skin incision, suggesting that analgesic concentrations necessary for surgery are achieved with this dose of fentanyl.

The pharmacokinetics of fentanyl (30 µg/kg) in preterm infants yielded plasma concentrations that remained constant for up to 120 minutes, indicating a reduced clearance.<sup>102</sup> The elimination half-life of fentanyl ranged from 6 to 32 hours in preterm infants, significantly greater than the 2- to 3-hour half-life observed in children and adults.<sup>102</sup> The clearance of fentanyl is 7 mL/min/kg at 25 weeks, 10 mL/min/kg at 30 weeks, and 12 mL/min/kg at 35 weeks postmenstrual age.<sup>103</sup> These studies demonstrated that the half-life and volume of distribution of fentanyl are increased, whereas the clearance is reduced in preterm infants compared with adults.<sup>104</sup> These changes may be explained by immature CPY450 3A4, reduced proteins, immature kidneys, and a patent ductus venosus. In a subset of infants with increased intra-abdominal pressure (after repair of a gastroschisis or omphalocele), the elimination half-life of fentanyl is 1.5- to 3-fold greater than that in other infants of the same age.<sup>104</sup> This likely results because increased intraabdominal pressure decreases hepatic blood flow, the rate limiting step in the metabolism of drugs with a large hepatic extraction ratio, such as fentanyl.<sup>104</sup> The increased volume of distribution decreases the initial plasma concentration of fentanyl compared with that in adults. These pharmacokinetic differences, combined with an increased propensity to apnea, serve to prolong analgesia, as well as prolong

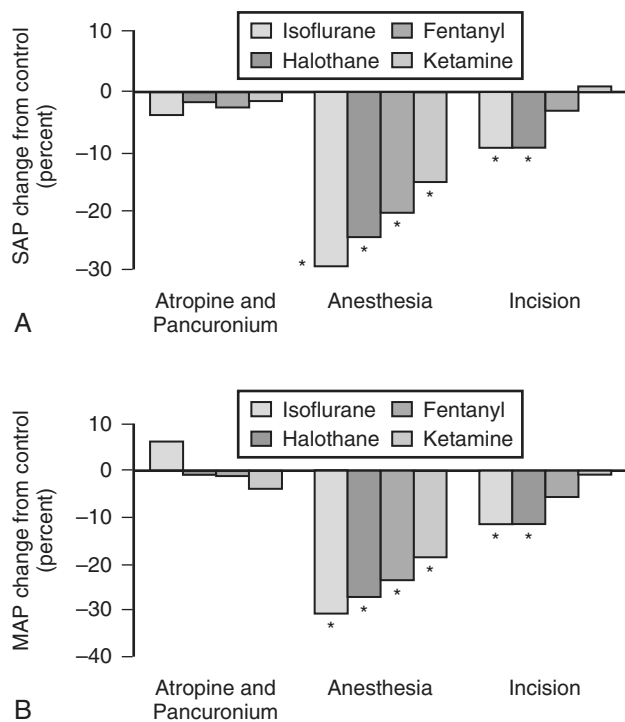

respiratory depression, increase the risk of postoperative apnea, and slow recovery of consciousness. In the micropremie, mechanical ventilation may be required for several days after large doses of fentanyl.

Similarly, the elimination half-life of morphine is markedly prolonged in preterm infants compared with that in children and adults.<sup>105-108</sup> The elimination half-life of morphine ranges from 6 to 16 hours in the micropremie, compared with 2 to 4 hours in the adult. We prefer fentanyl instead of large-dose morphine (2 to 3 mg/kg) for anesthesia because it has fewer hemodynamic adverse effects.

Remifentanyl, a relatively new synthetic, short-acting opioid, is rapidly inactivated by plasma and tissue esterases and, because of its short half-life, is administered by continuous infusion. The half-life of remifentanyl in adults is 3 to 4 minutes, independent of the duration of infusion, and similar to that in infants or children.<sup>109</sup> A multicenter study that compared halothane and remifentanyl for maintenance of anesthesia in infants undergoing pyloromyotomy showed similar intraoperative hemodynamic stability intraoperatively with the two techniques, but significantly fewer "new onset apneas" with remifentanyl compared with halothane.<sup>110,111</sup> Interestingly, the most rapid clearance of remifentanyl was in infants and children younger than 2 years of age, thus allowing an intense opioid effect intraoperatively that rapidly dissipates on terminating the infusion.<sup>112</sup> Remifentanyl has been used to provide anesthesia in infants weighing 400 to 580 grams with apparent good hemodynamic stability.<sup>113,114</sup> A study examining cord blood from preterm infants found high nonspecific esterase activity, comparable to that of term infants, thus suggesting that preterm infants should be able to rapidly metabolize remifentanyl.<sup>115</sup>

Ketamine, a phencyclidine derivative, affords several advantages compared with inhaled and other IV agents. It provides analgesia, amnesia, and unconsciousness yet minimally depresses cardiovascular function (Fig. 35-3).<sup>116</sup> However, ketamine anesthesia depresses ventilation and airway reflexes, which predisposes to airway obstruction, apnea, and gastric aspiration. Thus we recommend the use of an ETT when ketamine is used for surgical procedures in the micropremie. In the setting of brief painful procedures, IV ketamine can be used as an anesthetic without an ETT.<sup>117</sup>

Other IV agents include thiopental, propofol, and benzodiazepines. These agents induce loss of consciousness but possess less analgesia than ketamine. Thiopental is a short-acting barbiturate primarily used for the induction of anesthesia. The micropremie requires less thiopental for induction than does the infant (2 to 3 mg/kg vs. 5 to 6 mg/kg, respectively), a relationship similar to the MAC of isoflurane.<sup>118</sup> In the micropremie, we only use thiopental for neurosurgical procedures involving increased intracranial pressure. However, thiopental is no longer available in the USA. Propofol is primarily used to induce anesthesia and has largely replaced thiopental for this purpose. A word of caution is needed regarding the use of propofol for induction of anesthesia in neonates. Several reports highlight episodes in otherwise stable infants of protracted hypotension and low cardiac output state that were associated with hypoxia after propofol boluses (1 to 3 mg/kg IV). The mechanism underlying these responses remains unclear although acute pulmonary hypertension with reversion to persistent fetal circulation remains a strong possibility.<sup>119,120</sup> In our experience, the micropremie can be anesthetized with a propofol infusion (50 to 200 µg/kg/min) supplemented with fentanyl as needed for analgesia. The selection of

**FIGURE 35-3** **A**, Changes in systolic arterial pressure (SAP) in preterm infants after anesthesia with either isoflurane, halothane, fentanyl, or ketamine, and after surgical incision. **B**, Changes in mean arterial pressure (MAP) in premature infants after anesthesia with either isoflurane, halothane, fentanyl, or ketamine, and after surgical incision. (Reprinted with permission from Friesen RH, Henry DB. Cardiovascular changes in preterm neonates receiving isoflurane, halothane, fentanyl, and ketamine. *Anesthesiology* 1986;64:238-42.)

infusion pumps that allow for delivery of small volumes accurately is vital. The infusion rate of propofol in these small infants must be carefully and meticulously checked, as a 10-fold overdose of propofol has been reported, with a successful recovery.<sup>121</sup> Recovery from propofol anesthesia is delayed in micropremies compared with term infants, because micropremies have both less fat and muscle tissue to redistribute the drug, and reduced clearance. In pediatric ICUs, propofol infusions have been implicated in unexpected deaths (propofol infusion syndrome).<sup>122</sup> Until the safety of long-term administration of propofol has been examined in preterm infants, other alternatives for prolonged sedation should be considered.

Benzodiazepines, such as midazolam and diazepam, have been used in the neonatal intensive care unit (NICU) for sedation. As with thiopental and propofol, these drugs do not provide analgesia and are not recommended as the sole anesthetic for surgery. However, the combination of a benzodiazepine and opioid provides complete anesthesia for surgery. Midazolam clearance is markedly decreased in the micropremie when compared with the term neonate or infant, and will be further prolonged in the setting of decreased liver function.<sup>123</sup> Midazolam can cause systemic hypotension, depress ventilation, and impair airway reflexes in preterm infants. The hypotension caused by midazolam is greater in the presence of fentanyl; thus both drugs must be titrated in small doses when administered concomitantly.<sup>124</sup> One study noted an 8% to 23% decrease in arterial pressure after a bolus of 0.1 mg/kg of midazolam in preterm infants.<sup>125</sup>

## Anesthetic Considerations for Surgical Procedures

The extremely preterm infant rarely requires surgical intervention unless the condition is life-threatening or incurs long-term disability if not treated promptly. Preoperative preparation focuses on optimization of cardiac and respiratory status and on treatment of anemia, electrolyte abnormalities, metabolic acidosis, and coagulopathy. In conditions such as NEC, surgical intervention may be necessary before these can be corrected. For non-emergency procedures, such as inguinal hernia repair, preoperative evaluation occurs well in advance of surgery, to optimize the medical status before administration of anesthesia. Communication between the anesthesiologist, surgeon, and neonatologist before and after surgery is vital for safe care.

To ensure the safe delivery of care in these micropremies, particular attention must be paid to ensuring the accurate delivery of medications and fluids. These infants require only small fractions of the medications in most vials and ampoules. As a result, either tuberculin syringes should be used to carefully measure the very small aliquots of medications or the medication in the vial should be diluted so that a measurable and accurate fraction of the content of the vial can be given. Tuberculin syringes present several challenges, including difficulty in removing air bubbles from the syringe, and the very small volume that will be administered. The volume of medication may be so small that it is no larger than the volume of the stem of the clamp or stopcock, resulting in less drug than intended being administered to the infant. To prevent this problem, a saline flush should follow each medication administration. Diluting every medication introduces the risk of a drug dosing error that could lead to an overdose or underdose. In all instances, it is prudent to verify the dose and dilution of the medication with a colleague. To ensure drug is not lost in the dead space of the IV set, each clamp or stopcock should be flushed with saline after the medication has been given. All medications should be administered into the IV set as close to the skin insertion as possible, to minimize the volume of fluids needed to flush the medication into the child (see Figure 51-3).

Fluid overload is always a concern in these small infants. To minimize the fluids administered, all IV infusions should be delivered through a pump. Free-flowing IVs are dangerous sources for fluid overload, which may open a ductus arteriosus and cause congestive heart failure. Finally, meticulous care must be taken to remove air bubbles from all IV administration systems, solutions, and medications that are administered. See Chapter 51 for further discussion on infusion pumps and the implications of IV administration dead space on drug delivery.<sup>126,127</sup>

In the past, some surgeons chose to perform surgery at the bedside in the NICU without an anesthesiologist because it was deemed unsafe to transport the infant, there was lack of an OR or anesthesiologist to perform the surgery in a timely manner, or it was thought that the micropremie did not need anesthesia. The neonatologist often administered sedation and/or muscle relaxants during surgery. We believe that this approach does not provide optimal patient care; there is ample evidence that the micropremie requires anesthesia for surgery. As far as operating at the bedside is concerned, there is reduced access to the child, suboptimal lighting, reduced sterility, limited monitors (usually capnography is absent), and an inability to control room temperature, although NICU incubators use built-in overhead

radiant heaters. In our institution we addressed the issue of transporting an unstable infant to the OR by building a surgical suite in the NICU, thus minimizing the period of transport and providing optimal surgical conditions. In most institutions, anesthesiologists attend to preterm neonates in the NICU when the infants are too small or unstable (because of hemodynamic instability) to transport, the transport requires inter-hospital travel, or they are ventilated with an oscillator or high-frequency jet ventilator. Adapting to the working environment requires planning and organization in concert with communication with the surgeons, neonatologists, and nurses in the NICU. If bedside anesthesia is to be provided, then appropriate IV equipment for transfusion, pumps, and monitors compatible with electrocautery and expired carbon dioxide monitoring should be available, just as in the OR.

### EXPLORATORY LAPAROTOMY FOR NECROTIZING ENTEROCOLITIS

Necrotizing enterocolitis, a life-threatening condition mainly afflicting preterm neonates, occurs in about 5% of ELBW infants (see Chapter 36).<sup>128</sup> Although NEC may be treated medically, the micropremie with NEC is more likely to require surgery; mortality ranges from 10% to 50%.<sup>129-131</sup> The pathogenesis of NEC is incompletely understood; intestinal mucosal ischemia is thought to play a key role. Other key contributing factors include inflammation of bowel mucosa, alterations in normal intestinal flora by antibiotic therapy, gastric alkalinity, low systemic cardiac output, and red blood cell transfusion in the preceding 48 hours.<sup>132-135</sup> Early signs of NEC include feeding intolerance, increased work of breathing, lethargy, and temperature instability; later signs include hypotension, abdominal distention, apnea, thrombocytopenia, coagulopathy, and multisystem organ failure. Classic radiographic findings include gas in the intestinal wall (pneumatosis intestinalis) and biliary tract, and free air within the abdomen. Indications for surgical exploration include the presence of perforation or continued clinical deterioration despite medical management (Fig. 35-4).

Surgical management of the micropremie with NEC involves either initial primary peritoneal drainage or a laparotomy with resection of necrotic bowel. Primary peritoneal drainage requires a small surgical incision and fewer anesthetic requirements and

can be performed at the bedside. Some infants who undergo initial peritoneal drainage will subsequently require laparotomy if their condition worsens. Peritoneal drainage has generally been favored in the smaller and more unstable preterm infants for logistical reasons; thus the ability to compare the two management strategies has been difficult because of multiple confounding variables.<sup>128,136</sup> A prospective randomized, multicenter trial comparing laparotomy and peritoneal drainage in infants weighing less than 1500 g with perforated NEC found no difference in survival, development of short-gut syndrome, or length of hospital stay between the two approaches.<sup>137</sup>

NEC is a surgical emergency, and preoperative preparation in a timely fashion is vital. NEC predisposes to hypovolemia, cardiovascular and respiratory failure, capillary leak syndrome, disseminated intravascular coagulation, and hypoglycemia. It is important to prepare for all these sequelae. We have albumin, fresh frozen plasma, platelets, and packed red blood cells available; calcium gluconate, dopamine, and epinephrine are prepared for treatment of hypotension and reduced cardiac output. Because pulmonary function may deteriorate, we ensure the availability of sophisticated ventilators for increased mechanical ventilatory support. Newer anesthesia machines provide modes of ventilation similar to the ventilators used in the ICU. Coagulopathy and thrombocytopenia increase bleeding and necessitate blood product administration during surgery. Before transporting the micropremie to the OR, a transfer note is written to include the current medications, size and location of IV catheters, and dextrose infusion rate. We also obtain a current plasma glucose concentration and assess the ETT for size, equality of breath sounds, how well it is secured, and when it was last changed.

Vascular access remains critical for this surgery. At least two venous cannulas and an arterial catheter should be considered for optimal care. Usually the venous cannulas are 24-gauge catheters. In-line filters designed to prevent air within tubing, easily become blocked when one attempts to transfuse blood through them. Packed cells, even if they are reconstituted with plasma, do not flow rapidly through 24-gauge catheters; therefore it is important to avoid falling behind in fluid administration in these infants, so that there is no need to force a catch-up to stave off hypotension. A central venous catheter facilitates the delivery of infusions, such as dopamine or epinephrine. In our institution, many preterm infants have peripherally inserted central catheters (PICCs), allowing for delivery of vasopressors. These catheters are not well-suited for rapid delivery of anesthetic drugs or blood, or for measurement of central venous pressure. An arterial catheter provides continuous blood pressure monitoring and the ability to sample blood gases, electrolytes, complete blood cell count (CBC), platelet count, and prothrombin time/partial thromboplastin times (PT/PTT). In recent years, automated blood pressure cuffs have improved enormously in their ability to measure blood pressure non-invasively in young infants, although cases still occur in which they fail to measure arterial pressure during this surgery. A Foley catheter allows for the assessment of urine flow. A nasogastric tube should be present. Time spent by the anesthesia and surgical team to place these lines must be weighed against the need for urgent laparotomy.

General endotracheal anesthesia with neuromuscular blockade remains the anesthesia technique for NEC surgery. NEC increases the risk for aspiration. Tracheal intubation may be achieved by "awake intubation" or by rapid-sequence anesthetic induction. We prefer an awake intubation in the micropremie because effective cricoid pressure is difficult to apply, a very small

**FIGURE 35-4** Early necrotizing enterocolitis with bowel perforation. Note that the perforation was diagnosed early and that there is soiling of the peritoneum but there does not appear to be any dead bowel. This type of perforation is generally associated with a positive outcome.

force may distort the airway in the infant rendering intubation difficult,<sup>138</sup> and arterial desaturation occurs rapidly during apnea. After the administration of IV atropine, awake intubation is performed using an *oxyscope*, a laryngoscope with an oxygen port to allow for oxygen delivery during direct laryngoscopy (see E-Fig. 12-12, *A* and *B*). Awake intubation should be completed efficiently and rapidly in less than 15 seconds. To accomplish this, all equipment and monitors should be prepared, including an ETT with a “hockey stick” bend using a stylet. After preoxygenating the infant and administering 10 to 20  $\mu\text{g}/\text{kg}$  IV atropine, the infant’s arms are brought up by an assistant and held against the head (hands pointing to the anesthesiologist) with the elbows adjacent to the ears. This secures the child’s arms and shoulders, preventing the infant from laterally rotating the neck, raising the shoulders, or moving the arms during laryngoscopy. Once the infant is positioned, a #1 straight blade is inserted into the mouth at the right commissure and the tip is advanced toward the glottic opening in one smooth motion. When the infant gags, the ETT, which is being held in the other hand, is poised to pass through the cords. Once the position of the tube is confirmed with the presence of carbon dioxide on the capnogram, the assistant immediately administers a predetermined dose of IV propofol to rapidly induce anesthesia. Inhalational anesthesia and muscle relaxant, as indicated, should be administered while the ETT is taped in place. Chest auscultation in the axillae will confirm a properly placed ETT.

The anesthetic regimens that we prefer for maintenance include (1) IV fentanyl (5 to 10  $\mu\text{g}/\text{kg}$ ), an inhaled anesthetic (such as isoflurane, sevoflurane, or desflurane), and neuromuscular blocking drug (balanced technique), or (2) IV fentanyl (20 to 50  $\mu\text{g}/\text{kg}$ ), IV midazolam (0.1 mg/kg), and a neuromuscular blocking drug (high-dose opioid technique). We select the high-dose opioid technique for hemodynamically unstable infants. Pancuronium is an ideal neuromuscular blocking drug when combined with large doses of fentanyl because of its anticholinergic properties, but should be avoided in infants with renal dysfunction. If hypotension persists despite a trial of 10 to 20 mL/kg of IV fluid, we begin an infusion of epinephrine (0.02 to 0.1  $\mu\text{g}/\text{kg}/\text{min}$ ) or dopamine (5 to 20  $\mu\text{g}/\text{kg}/\text{min}$ ). Hypocalcemia during administration of citrated blood products may contribute to hypotension, and requires replacement with either calcium chloride or calcium gluconate (see Chapter 10). When severe shock persists despite IV fluid resuscitation, calcium, and inotropic support, rescue treatment with “stress dose” glucocorticoids may be beneficial. Treatment with hydrocortisone and dexamethasone has been effective in improving arterial pressure in low-birth-weight infants with refractory hypotension.<sup>139,140</sup>

Intraoperative fluid management in micropremies should begin with continuing the solution that arrives with the infant from the NICU; usually this is a calcium- and/or glucose-containing solution. Alternately, some infants may arrive with a hyperosmolar glucose or dextrose (10%) parenteral nutrition solution. In both cases, these solutions should not be discontinued, but rather continued at the same rate (by infusion pump) or slightly less throughout the surgery to avoid reactive hypoglycemia from increased circulating insulin concentrations. There is no evidence regarding the optimal infusion rates for these solutions during anesthesia. If no solution is being infused, a balanced salt solution (e.g., lactated Ringer’s solution) could be initiated at 4 mL/kg/hr, supplemented with the same solution for third space loss (at least 10 mL/kg/hr), and replacement of blood loss. If no glucose solution is being administered, then a

balanced salt solution containing glucose may be administered through a pump. Serum glucose concentrations should be monitored regularly to avoid hypoglycemia. Third space losses include evaporation and vascular leak and are replaced with an isotonic salt solution. Blood losses are replaced with packed red blood cells and fresh frozen plasma to maintain the hemoglobin greater than 10 g/dL and the PT/PTT within normal range. Platelets are administered to keep the platelet count greater than 100,000/ $\text{mm}^3$ . Continuous measurement of arterial pressure and serial measurement of urine output, blood gases, CBC, platelet counts, and PT/PTT aid in the fluid replacement process. Arterial blood gas analysis helps guide ventilation and inspired oxygen concentration. Warming of the operating suite to 80° F (26.7° C), a forced air warmer underneath the infant, and warmed fluids help maintain normothermia during surgery. In preterm infants with NEC, postoperative mechanical ventilation remains the rule. Postoperative analgesia can be provided with a continuous infusion of fentanyl (1 to 3  $\mu\text{g}/\text{kg}/\text{hr}$ ) or intermittent doses of morphine (0.1 mg/kg every 4 to 6 hours). The time it takes for the micropremie to emerge from anesthesia depends on the anesthetic technique (balanced vs. high-dose opioid) and the need for postoperative analgesics. After a high-dose opioid technique, the micropremie may take 12 to 24 hours to emerge, as compared with several hours for a balanced technique. Remifentanyl may provide an alternative, which allows an intense opioid effect that rapidly dissipates on discontinuation of the infusion<sup>113,114,141-143</sup>; an alternate form of analgesia is required for postoperative pain management.

#### LIGATION OF PATENT DUCTUS ARTERIOSUS

Failure of the ductus arteriosus to close after birth is common in the micropremie.<sup>144</sup> A PDA may incur significant left-to-right shunting of blood, causing excess pulmonary blood flow, congestive heart failure, and respiratory failure. In fact, the diameter of the PDA may be greater than the aorta. In the micropremie with respiratory distress syndrome or persistent pulmonary hypertension, right-to-left shunting across the PDA may occur, producing cyanosis. Significant controversy exists regarding whether a PDA should be aggressively treated, the timing of therapy, and merits of medical versus surgical therapy.<sup>145</sup> Medical therapy involves the administration of a cyclooxygenase inhibitor, such as indomethacin or ibuprofen. Indomethacin therapy is less likely to close the PDA in micropremies compared with preterm infants, and more likely to produce complications, including thrombocytopenia, renal failure, hyponatremia, and intestinal perforation.<sup>146</sup> Ibuprofen is equally effective for PDA closure in the micropremie, with a reduced frequency of renal failure.<sup>147</sup> When surgery is performed by experienced teams, the incidence of major intraoperative complications is small.<sup>148</sup> However, as many as one-third of preterm infants develop severe cardiovascular instability following PDA ligation, as evidenced by systemic hypotension, pulmonary hypertension, and myocardial dysfunction.<sup>149</sup>

During preoperative preparation, arterial pressure, heart rate, arterial blood gases, ventilator settings, and inspired oxygen concentration should be noted. The PDA is ligated through a left thoracotomy and requires retraction of the left lung, which decreases lung compliance, ventilation, and oxygenation. Preoperative difficulty with ventilation and oxygenation forecasts trouble in the OR. Because the aorta and pulmonary artery lie in proximity to the PDA, severe bleeding may occur abruptly and unexpectedly during the procedure. Packed red blood cells

should be immediately available for transfusion. Intraoperative monitoring includes a blood pressure cuff (right arm reflects cerebral perfusion of preductal blood), continuous end-tidal carbon dioxide monitoring, and a pulse oximeter placed on digits on the right arm and a lower extremity. This will help the surgeon to confirm that the vessel about to be ligated (clipped) is in fact the ductus and not the aorta. It should be noted that with a left-sided arch, the pulse oximeter may need to be applied to the left hand instead of the right to ensure monitoring of a preductal blood vessel. Invasive monitoring of arterial pressure and blood gases is helpful in the micropremie with significant heart failure and/or lung disease, although we do not consider it a requirement for surgery. An IV catheter through which blood can be rapidly administered should be available.

The anesthetic technique of choice for PDA ligation remains fentanyl (20 to 50 µg/kg) and pancuronium (0.2 mg/kg).<sup>100</sup> Although this technique usually does not cause hypotension or bradycardia, reduction in arterial pressure after anesthetic induction may occur because of loss of sympathetic tone, especially in the setting of hypovolemia from diuretic therapy. Thus we commonly administer 5% albumin or balanced salt solution (10 mL/kg) before induction. During mechanical ventilation, mild hypoventilation and a reduced inspired oxygen concentration help to reduce pulmonary over-circulation from the PDA. However, during surgical retraction of the lung it is usually necessary to increase the ventilator inspiratory pressure setting as well as the inspired oxygen concentration. Surgical complications of PDA ligation include inadvertent ligation or laceration of the aorta or pulmonary artery. The lower extremity oxygen saturation provides a monitor of perfusion to the legs, and loss of this signal immediately after PDA ligation may indicate aortic ligation. With ligation of the pulmonary artery, oxygen saturation in both extremities and end-tidal CO<sub>2</sub> decrease. With successful PDA ligation, arterial diastolic and mean pressure increase, and the PDA murmur disappears.

The time until emergence from anesthesia depends on the fentanyl dose. In the micropremie with normal renal function, pancuronium will disappear in 2 to 3 hours, whereas the fentanyl (20 to 50 µg/kg) will last for at least 6 hours. Thus a trial of spontaneous ventilation and extubation is generally not planned until the following day.

### INGUINAL HERNIA REPAIR

Inguinal hernias are common in preterm infants. In ELBW infants, an inguinal hernia occurs in approximately one-third of patients, whereas in full-term neonates, it occurs in 1%.<sup>150</sup> Complications related to inguinal hernias and their surgical repair include incarcerated bowel, intestinal obstruction, gonadal infarction, infection, hematoma, and recurrent hernias.<sup>151</sup> Because of the risk of incarceration and bowel infarction, the hernia should be repaired as soon as the infant is medically stable.

General and/or regional anesthesia may be used for inguinal hernia repair. Induction of general anesthesia can be achieved with IV propofol or inhalation of sevoflurane. We prefer IV induction for the infant with an IV catheter in place. Indications for emergency surgery include incarceration of the bowel or gonads. When the micropremie with intestinal obstruction or incarceration requires emergency surgery, we secure the airway by awake tracheal intubation (see previous section on Exploratory Laparotomy for Necrotizing Enterocolitis). When hernia repair is performed electively, we induce anesthesia with propofol if IV access is present, or by mask with sevoflurane.

A non-depolarizing muscle relaxant may be administered as needed. Cisatracurium or atracurium are preferred because their action is terminated by Hofmann elimination in plasma, whereas the action of rocuronium and vecuronium is terminated primarily by hepatic metabolism. After induction of anesthesia, the trachea is intubated and the lungs ventilated mechanically.

General anesthesia is maintained with an inhalational anesthetic agent. We avoid nitrous oxide when intestinal obstruction is present, or when the infant has complex hernias that may take several hours to repair. Preterm infants with BPD often exhibit a compensated respiratory acidosis and will have increased end-tidal CO<sub>2</sub> during anesthesia. In these infants the ventilation parameters are set to allow permissive hypercapnia. Mechanical ventilation with small tidal volumes (4 to 6 mL/kg), increased respiratory rates, and PEEP minimizes atelectasis and reduces the risk for lung injury. If extubation is planned after surgery, caffeine (10 mg/kg) is administered IV to reduce the risk of postoperative apnea.<sup>21,152</sup> IV fluids consist of lactated Ringer's solution (4 mL/kg/hr) with dextrose (5 mg/kg/min administered by infusion pump) to maintain normoglycemia. A warm OR and forced-air warming blanket should be used to prevent hypothermia during the procedure.

Postoperative analgesia may be provided by regional analgesia or systemic analgesics; the choice depends on whether extubation of the trachea occurs immediately after surgery. Ilioinguinal and iliohypogastric nerve blocks or caudal epidural blocks may be used (see Chapter 41). We do not advocate percutaneous blockade because the local anesthetic injectate may distort the local tissues, making an already difficult surgery more difficult. Ilioinguinal and iliohypogastric nerve blocks consist of injecting 0.25% bupivacaine with epinephrine (1:200,000) (1 mg/kg/side) around the nerve by the surgeon under direct vision. This block provides 6 to 8 hours of analgesia. Caudal epidural blockade consists of injecting 0.125% bupivacaine with epinephrine (1:200,000) (1 mL/kg) through the sacral hiatus, providing several hours of analgesia. Orally administered acetaminophen (10 to 15 mg/kg) can also be given, providing analgesia for several hours. We do not administer opioids to the micropremie whose trachea will be extubated immediately after surgery because of the risk of postoperative apnea.

The micropremie with BPD who requires supplemental oxygen, but who is not intubated, is an excellent candidate for regional anesthesia.<sup>153-156</sup> Regional anesthesia circumvents the need to intubate the trachea and administer a general anesthetic, which may exacerbate the BPD and create a situation in which extubation after surgery may be difficult to achieve. Either a spinal or epidural anesthetic may be used to provide surgical conditions with a regional block. For spinal anesthesia, an intrathecal injection of a hyperbaric solution of tetracaine (1 mg/kg) or isobaric bupivacaine (1 mg/kg) provides 1 to 2 hours of surgical anesthesia (see Chapter 41). The addition of epinephrine (10 µg) to the tetracaine solution increases the duration of anesthesia by 30 to 60 minutes.<sup>154</sup> Hypotension rarely occurs after spinal anesthesia in an infant.<sup>157</sup> For epidural anesthesia, 0.75 mL/kg of 0.375% bupivacaine with epinephrine is injected into the epidural space through the sacral hiatus.<sup>155,156</sup> Ultrasound can be used to map out the anatomy of the spinal cord and cauda equina, dura mater, and intrathecal space. During injection one can visualize the local anesthetic tracking up the epidural space to confirm its proper location (see also Chapters 41 and 42). Preterm infants are more sensitive to local anesthetic blockade than are children and adults; therefore surgical anesthesia may

be achieved with reduced concentrations of local anesthetic. Another route to the epidural space is by the lumbar approach (L3-4 interspace).<sup>19</sup> The use of the lumbar route allows a smaller dose of local anesthetic compared with the caudal route, thus decreasing the risk of toxicity, however, this route is technically more challenging.

Epidural anesthesia offers several advantages over spinal anesthesia in the awake infant, in that it is often easier to perform, and a catheter can be placed to repeatedly administer local anesthetic to extend the duration of the block (see Chapter 41). General anesthesia offers several advantages over regional anesthesia, including better operating conditions and greater ease in titrating anesthetic duration. An often cited advantage of regional anesthesia is the decreased incidence of postoperative apnea. However, the evidence in support of this notion is conflicting. When the incidence of postoperative apnea after spinal anesthesia, spinal anesthesia with IV ketamine, and general endotracheal inhalational anesthesia was compared,<sup>158</sup> no postoperative apnea was reported in the spinal anesthesia group, whereas an 89% incidence was noted in the spinal/ketamine group and a 31% incidence was noted in the general anesthesia group. Thus, if there is a benefit to regional anesthesia over general anesthesia, spinal anesthesia must be administered without supplemental sedatives, such as ketamine.

In contrast, Krane and colleagues compared general endotracheal inhalational anesthesia with spinal anesthesia and found no difference in the incidence of postoperative apnea.<sup>159</sup> In a study of more than 250 preterm infants receiving spinal anesthesia for inguinal hernia repair at a single institution experienced with this technique, spinal block was successfully placed on the first attempt in more than 90% of infants.<sup>160</sup> Despite a high rate of successful block placement, more than 20% of the infants required supplemental anesthesia at some time during the surgery. Postoperative apnea occurred in 4.9% of infants, and all infants who developed this complication had a preoperative history of apnea. Given the technical challenges of spinal block placement for practitioners who do not perform it routinely, failure rate even with successful block placement, and persistent risk of postoperative apnea, we commonly administer general anesthesia for hernia repair in the micropremie, except for those with severe BPD, in whom we use spinal anesthesia.

### EYE SURGERY FOR RETINOPATHY OF PREMATURITY

ROP may be treated with cryotherapy, laser photocoagulation, or scleral buckling surgery and/or vitrectomy. Diode laser photocoagulation is typically performed at the bedside in the NICU for moderate ROP, whereas cryotherapy and scleral buckling surgery are performed in the OR. Cryotherapy involves applying a freezing probe under direct visualization to the avascular retina anterior to the fibrovascular ridge. Scleral buckling surgery and vitrectomy, performed for severe ROP with retinal detachment, are less frequently employed because early detection and treatment with laser photocoagulation prevents ROP progression to severe disease. Laser surgery has been shown to be as effective as cryotherapy for moderate ROP, and is most commonly used because the systemic side effects are significantly less, the ocular tissues are less traumatized, and this technique has a smaller incidence of late complications (see Chapter 32).

Laser photocoagulation may be performed under topical anesthesia alone, with IV sedation, or under general anesthesia. Cryotherapy and scleral buckling surgery require general anesthesia. For laser photocoagulation, the incidence of cardiorespiratory

complications is greater with topical anesthesia alone than with topical anesthesia with sedation or general anesthesia.<sup>161</sup> Factors that influence the selection of anesthetic technique include the infant's medical condition, gestational age, and availability of pediatric anesthesia services. The vast majority (95%) of preterm infants who require laser photocoagulation or cryotherapy develop threshold disease between 32 and 42 weeks PCA. The usual age for scleral buckling or vitrectomy is much older, between 6 months and 1 year.

Laser photocoagulation takes 10 to 30 minutes to perform and often involves a series of treatments every few weeks. For laser photocoagulation, the anesthetic goals are to provide optic analgesia and to prevent eye and head movement. Many preterm infants younger than 32 weeks PCA are naturally inactive. With topical anesthesia alone they will remain motionless and do not require sedation or general anesthesia. As the infants mature beyond 32 weeks PCA, their activity naturally increases, along with the need for sedation and general anesthesia. Given the brevity and frequency of the procedure, we prefer a combination of topical anesthesia with an infusion of propofol and spontaneous ventilation through a natural airway. After applying the local anesthetic, we administer a series of IV propofol boluses (1 mg/kg) until there is no movement to tactile stimulation, and then begin a propofol infusion (150 µg/kg/min). We use an oral airway as necessary. We administer supplemental oxygen and monitor end-tidal CO<sub>2</sub> through a nasal cannula. Alternative sedative agents include IV midazolam (0.1 to 0.2 mg/kg), pentobarbital (2 mg/kg), or oral chloral hydrate (75 mg/kg). We employ standard monitors and conduct the procedure with the ophthalmologist, in a treatment room in the NICU; size-appropriate airway equipment should be immediately available should airway obstruction or apnea occur. Cryotherapy and scleral buckling surgery take more time to complete and require surgical preparation in the OR. As a result, our preferred technique is inhalational anesthesia with tracheal intubation and neuromuscular relaxant, along with topical anesthesia. After an inhalational induction with sevoflurane using standard monitors, we paralyze the child, intubate the trachea orally, and mechanically ventilate the lungs. Administration of caffeine reduces the incidence of postoperative apnea. At the end of surgery, we discontinue the inhaled agent, antagonize the neuromuscular blockade as appropriate, and extubate the trachea after the return of appropriate breathing and airway reflexes.

### ANESTHESIA OR SEDATION FOR RADIOLOGIC IMAGING

Very preterm infants frequently experience neurocognitive complications. With advances in the capabilities of MRI, and new therapies to improve neurologic outcome based on MRI findings, preterm infants are increasingly undergoing MRI evaluation. At many centers, virtually all preterm infants less than 30 weeks gestational age at birth undergo brain MRI during their hospitalization. In past years, head ultrasound and computed tomography were the modalities of choice to diagnose IVH and hydrocephalus. MRI is gradually replacing these modalities for this purpose because there is no exposure to radiation. Moreover, MRI is able to identify congenital lesions, vascular malformations, and ischemic injury, which the older modalities were less effective in detecting.

Although not painful, MRI requires absolute immobility for the duration of the scan, typically 45 to 60 minutes. Immobility may be achieved through simulated feeding, sedation, or anesthesia. In very preterm infants (less than 30 weeks PCA) and

in good-tempered older preterm infants, swaddling the infant in warm blankets and applying sugar water ("sweet-ez") to a pacifier often promotes natural sleep, enabling the scan to be obtained. In healthy preterm infants ("premie growers") aged 30 to 70 weeks PCA, orally administered chloral hydrate (75 mg/kg) 30 to 60 minutes before the procedure provides sedation lasting 2 hours. We perform a history and physical examination and prescribe the sedation regimen, and specially trained sedation nurses in our department administer the regimen and monitor the infant during the scan, under our supervision. It should be noted that chloral hydrate has an extremely long half-life in this population, placing the infants at risk for late re-sedation and/or apnea.<sup>162-164</sup>

In preterm infants with medical problems, we administer propofol anesthesia for the scan, titrated to effect similarly to that with laser photocoagulation for ROP. We monitor expired CO<sub>2</sub> through a nasal cannula, sometimes insert an oral airway, and less often use a laryngeal mask airway or an ETT. In critically ill preterm infants with an ETT and mechanical ventilation, we administer IV midazolam and fentanyl or inhaled sevoflurane for the scan. In anesthesia cases, monitors include electrocardiogram, blood pressure, pulse oximetry, and expired CO<sub>2</sub>. IV pumps being used for administration of fluids or drugs must remain outside the MRI room, thus requiring extra-long tubing. All anesthesia equipment, the infant, and personnel must not contain ferrous materials. As with general anesthesia, monitoring for postoperative apnea for 24 hours after sedation is recommended (see Chapters 45 and 47).

**ADVANCES IN PERINATAL CARE** have greatly reduced the morbidity and mortality of critically ill neonates. Anesthesiologists have contributed to the improvement in neonatal outcome by applying advanced principles of developmental biology and pharmacology to the care of critically ill neonates undergoing surgical procedures. The goal of this chapter is to describe developmental processes in neonates and how they affect the anesthetic management of neonatal emergencies.

## Neonatal Physiology Related to Anesthesia

### CARDIOPULMONARY

#### Oxygen Consumption

The cardiopulmonary system of the neonate is driven by the need to deliver sufficient oxygen ( $O_2$ ) to maintain a high metabolic rate. The  $O_2$  consumption of an average neonate is 5 to 8 mL/kg/min, whereas that of an adult is 2 to 3 mL/kg/min (Table 36-1). It is this high rate of  $O_2$  consumption that primarily leads to the rapid decrease in blood  $O_2$  partial pressures in the neonate during periods of hypoventilation. Although ventilatory gas exchange volume is nearly 10-fold greater in adults than in neonates, the tidal volume relative to body weight for both is approximately equal (6 mL/kg). In neonates, increasing the respiratory rate facilitates the elimination of carbon dioxide ( $CO_2$ ) generated by their relatively high metabolic processes; alveolar ventilation is approximately 130 mL/kg/min in the perinatal period, compared with 60 mL/kg/min in adulthood. In neonates, the thoracic gas volume on a weight basis is similar to that in adults. These metabolic and volume changes are consistent with those predicted by allometric scaling (see Chapter 6).<sup>1</sup>

#### Pulmonary Gas Exchange

Preterm neonates may have abnormalities in lung surfactant activity. Surfactant production by type II alveolar pneumocytes occurs predominantly after 32 weeks of gestation. Infants born prematurely may develop respiratory distress syndrome (RDS) because of surfactant deficiency. However, infants of mothers with gestational diabetes may develop RDS even when born near term. RDS is characterized by grunting respirations, nasal flaring, and chest retractions, developing soon after birth. Radiographic

examination demonstrates decreased lung volume resulting from widespread atelectasis. The resultant intrapulmonary shunting of blood through atelectatic lung units causes intrapulmonary shunt and systemic hypoxemia and reduces  $O_2$  delivery to the tissues. Judicious application of positive end-expiratory pressure (PEEP) and treatment with exogenous surfactant may reduce intrapulmonary shunting in RDS and decrease hypoxemia.<sup>2-6</sup> In addition, the incidence and severity of RDS has been decreased by the now routine treatment of mothers who are in preterm labor with glucocorticoids.

Atelectasis in neonates also might be caused by anatomic forces that decrease lung volume. For example, the relatively large abdomen in a neonate displaces the diaphragm cephalad, placing the lungs' closing capacity within the expiratory reserve volume. Moreover, increases in intraabdominal pressure from gastric distention associated with overzealous assisted ventilation with a facemask, replacement of bowel in the abdomen during repair of gastroschisis or omphalocele, or surgical retraction or manipulation of the abdominal contents also might shift the closing capacity to within the infant's expiratory reserve volume. The resulting atelectasis and intrapulmonary shunting may require controlled ventilation with PEEP to recruit closed lung units and improve oxygenation, emptying of the stomach, or changes in surgical maneuvers.

In the neonate, apnea decreases pulmonary gas exchange and can lead to hypoxemia and bradycardia. Conceptually, apnea is differentiated in terms of its cause: (1) *central apnea*, resulting from immaturity or depression of the respiratory drive; (2) *obstructive apnea*, caused by an infant's inability to maintain a patent airway; and (3) *mixed apnea*, a combination of both central and obstructive apnea.<sup>7</sup>

Apnea of central origin may be secondary to the poor organization and integration of input from proprioceptive receptors, which are located in the diaphragm and intercostal muscles, and from medullary and peripheral chemoreceptors. Preterm infants are at greater risk for central apnea because chemoreceptor signaling is incompletely developed. Exaggerated responses to chemoreceptor signaling during periods of mild hypercarbia and hypoxia can cause apnea in preterm infants, in whom it might stimulate the respiratory rate in those born at term. Susceptibility to central apnea is also exacerbated by metabolic disturbances such as hypothermia, hypoglycemia, and hypocalcemia, even in

**TABLE 36-1** Lung Function in Infants and Adults

Parameter	Infants	Adults	Infant-to-Adult Ratio
Oxygen consumption (mL/kg/min)	5-8	2-3	2
Respiratory rate (breaths/min)	40-60	12	3-5
Tidal volume (mL/kg/min)	6-8	7	1.0
Total lung capacity (mL/kg)	53	85	0.6
Airway diameter (mm)	5	14-16	0.3
Trachea

**TABLE 36-2** Primary Categories of Apnea in Infants

Cause	Treatment
Central	Increase O <sub>2</sub> delivery Increase fraction of inspired O <sub>2</sub> Increase hematocrit (?) Xanthine derivatives Theophylline Caffeine
Obstructive	Neck extension Prone or lateral position Oral airway Nasal continuous positive-airway pressure

full-term neonates. For these reasons, central apnea may be associated with anemia and sepsis in babies. Blood transfusions may decrease the incidence of apnea in preterm infants with a hematocrit less than 27%<sup>8,9</sup>; however, data suggest a poor correlation between anemia and the incidence of apnea or bradycardia episodes.<sup>10</sup> Central apnea resulting from immaturity of the respiratory drive center is often treated with xanthine derivatives, such as caffeine and theophylline (Table 36-2).<sup>11-14</sup> Of particular importance to the anesthesiologist is that central apnea in neonates can be exacerbated by opioids. In some cases, apnea in neonates exposed to opioids may be alleviated by treatment with naloxone. Because of these reasons, all neonates require careful continuous monitoring of blood O<sub>2</sub> saturations and heart rate in the postoperative period.

Apnea of an obstructive or mixed origin is responsible for the majority of apneic episodes in preterm infants.<sup>15-17</sup> Obstructive apnea may be due to incomplete maturation and poor coordination of upper airway musculature. These forms of apnea often respond to changes in head position, insertion of an oral or nasal airway, or placing the infant in a prone position. Application of continuous positive airway pressure (CPAP) also may reduce obstructive apnea.<sup>18</sup>

Postoperative apnea is a common morbidity associated with anesthesia in neonates with a history of prematurity, apnea, or chronic lung disease.<sup>19</sup> Nearly 20% of such infants have apnea exacerbated by anesthesia or surgery in the postoperative period. Apnea may result from prolonged action of anesthetic agents, a shift of CO<sub>2</sub> response curve, immaturity of respiratory control, or fatigue of respiratory muscles.<sup>20</sup> Early studies suggested that preterm infants who were younger than 46 weeks

postconceptional age (PCA\*) at the time of general anesthesia require continuous cardiopulmonary monitoring in the hospital afterward until they are apnea-free.<sup>15</sup> Kurth and colleagues<sup>21</sup> extended these recommendations to include monitoring for premature infants younger than 60 weeks PCA for at least 12 apnea-free hours after surgery. Although several studies suggest that regional anesthesia techniques reduce the incidence of postoperative apnea, others reported that apnea may still occur if the regional technique is supplemented with a sedative (e.g., ketamine).<sup>22-25</sup> An analysis of several hundred former preterm infants studied prospectively from four centers over 6 years revealed the following<sup>26</sup>:

- The incidence of postoperative apnea is inversely and independently related to PCA and gestational age; for example, the younger a preterm infant was born and the earlier after birth that the preterm infant undergoes surgery, the greater the incidence of apnea.
- Preterm infants younger than 56 weeks PCA are at greatest risk for apnea; the risk of postoperative apnea does not fall to less than 1% until approximately 55 weeks PCA (see Chapter 4).
- Even infants who were born at full term can experience postoperative apneas, although this is extremely rare.<sup>27-30</sup>
- Preterm infants without a history of apnea are still susceptible to the development of postoperative apnea.
- Preterm infants with anemia (hematocrit less than 30%) are particularly vulnerable even up to and possibly beyond 60 weeks PCA.<sup>31</sup>

Apnea also might be associated with nasal obstruction in infants. Although most neonates prefer to breathe through their nose, a few are *obligate* nasal breathers and do not overcome nasal airway obstruction by changing to mouth breathing.<sup>32,33</sup> In such neonates, nasal obstruction caused by choanal stenosis or atresia or a nasogastric tube may lead to apnea and cyanosis. Obstruction resulting from nasal edema may be relieved by instillation of saline or phenylephrine nose drops.

The work of breathing comprises compliance and resistive components. Although the work of breathing from compliance is 20- to 40-fold greater in the adult than in the neonate, the compliance work relative to tidal volume is nearly the same. However, the resistive work of breathing in the neonate is nearly 6 times greater than in the adult because of the relatively small airways in the neonate. Breathing through a tracheal tube especially increases resistive work in neonates because the airway resistance is inversely proportional to the fifth power of the radius of the tube and directly proportional to the length of the tracheal tube. The relatively narrow and long tracheal tubes through which neonates breathe can greatly increase their work of breathing (see Fig. 12-7). The work is also increased when a neonate breathes spontaneously through a circle system because of the inspiratory force required to open the one-way valves in the system. Although valveless ventilatory circuits, such as the Mapleson D systems, are recommended for spontaneously breathing neonates, studies suggest that a circle system may be used in these patients provided compensation is arranged for the problems associated with this circuit; that is, a neonate requires assisted ventilation and adequate inflation pressures to reduce the work of breathing and ensure adequate ventilation (see Chapter 51).<sup>34-36</sup>

\*When evaluating the age of a newborn, be aware that by convention postconceptional age is 2 weeks shorter than postmenstrual age.

Bronchopulmonary dysplasia (BPD) is an important chronic lung disease of neonates born prematurely.<sup>37</sup> Although the use of antenatal steroids, exogenous surfactant treatment, and advanced ventilator therapies has decreased the incidence of BPD, it still afflicts nearly 10,000 premature infants in the United States every year and is a significant contributor to infant morbidity and mortality. BPD is identified in preterm infants with abnormal chest radiographs that require supplemental O<sub>2</sub> at 36 weeks post-menstrual age (PMA). Other factors that increase the risk for developing BPD include chorioamnionitis and the persistence of a patent ductus arteriosus (PDA).<sup>38</sup> Lung injury in the preterm infant decreases pulmonary maturation; infants who have died from BPD have impaired pulmonary alveolar and disrupted microvascular development.<sup>39</sup> BPD is most often seen in preterm infants who are subjected to high levels of O<sub>2</sub> and ventilation therapy and may be caused by lung injury-induced increase in cytokine activation.<sup>40</sup> Decreased lung development in infants with BPD diminishes the surface area for pulmonary gas exchange that increases O<sub>2</sub> requirements. Moreover, some infants with BPD have reduced lung compliance and increased airway resistance and hence have prolonged pulmonary time constants. Some infants with severe BPD have abnormal muscularization of the vessels in the periphery of their lungs, pulmonary hypertension, and right ventricular hypertrophy.

Pulmonary disease in infants with BPD is associated with abnormal pulmonary function tests and chest radiograph findings (small radiolucent cysts and hyperexpanded lungs), hypercarbia, chronic hypoxemia, and reactive airway disease.<sup>41-46</sup> Nitric oxide (NO) is a free radical gas formed in endothelial cells and diffuses into subjacent smooth muscle cells, where it stimulates cyclic guanosine monophosphate (cGMP) production and mediates vasorelaxation (Fig. 36-1). Inhaled NO decreases abnormal cell proliferation in the injured developing lung<sup>47,48</sup> and improves alveolar development in preterm animal models of BPD.<sup>49,50</sup> Given the biologic plausibility and the results from animal studies, clinical trials have examined whether preterm neonates would benefit from NO. However, 14 randomized controlled trials of inhaled NO in preterm infants 34 weeks gestational age or younger failed to demonstrate benefit in survival or

pulmonary or neurodevelopmental outcomes.<sup>51</sup> It is likely that decreased NO signaling enzyme activity in the injured newborn lung reduces the effectiveness of inhaled NO in protecting pulmonary development. Emerging laboratory studies suggest that modulating cytokine signaling might improve the development of the injured lung and decrease BPD. For example, investigations in newborn animal models suggest that lung injury increases cytokine signaling. Moreover, in a mouse pup model of BPD, antibody-mediated inhibition of excess transforming growth factor-beta (TGF- $\beta$ ) activity was observed to improve NO signaling and pulmonary alveolar and microvascular development.<sup>52</sup> Studies are under way to examine the mechanisms through which TGF- $\beta$  modulates injured lung development.

The treatment of BPD in neonates often requires ventilatory and medical therapies.<sup>53</sup> Early and aggressive CPAP may eliminate the need for positive-pressure ventilation. Air trapping during assisted ventilation is associated with the long lung time constants in babies with BPD and may be reduced by using a prolonged expiratory time. Respiratory infection (e.g., *Ureaplasma urealyticum*) may contribute to the inflammatory response. Bronchodilators such as aminophylline, albuterol, or ipratropium may be beneficial in reducing airway resistance in some infants with BPD.

Infants with BPD are often treated with diuretics. As a result of chronic furosemide treatment, metabolic abnormalities may exist. Hypercalciuria may occur from the action of furosemide on the ascending loop of Henle, leading to secondary hyperparathyroidism and nephrocalcinosis in some infants. Hydrochlorothiazide and spironolactone produce less severe metabolic abnormalities. Finally, large doses of steroids, especially dexamethasone, have been shown to provide relief for some infants with severe BPD that is refractory to other medical and ventilator therapies.<sup>54,55</sup> However, dexamethasone treatment may result in systemic hypertension, hyperglycemia, hypertrophic cardiomyopathy, and alteration of neurologic and pulmonary development in some children.<sup>56,57</sup> Preoperative evaluation of infants with BPD requires a very careful history and physical examination, particularly focused on the pulmonary and cardiovascular systems.

**FIGURE 36-1** Nitric oxide (NO) produced by nitric oxide synthase (NOS) in endothelial cells (EC) diffuses into subjacent smooth muscle cells (SMC), interacts with soluble guanylate cyclase (sGC), and increases the concentration of cyclic guanosine monophosphate (cGMP) to cause vascular relaxation. The effect of NO is decreased by metabolism of cGMP by specific phosphodiesterases (PDE). L-arg, L-Arginine.

### Oxygen Uptake and Circulation

Uptake of O<sub>2</sub> in the pulmonary microvasculature of neonates is facilitated by the greater hemoglobin concentration in the neonate and the increased amount of fetal hemoglobin. Fetal hemoglobin has a reduced affinity for 2,3-diphosphoglycerate and hence a greater affinity for O<sub>2</sub>. Although this affinity facilitates fetal hemoglobin O<sub>2</sub> uptake in the placenta, it can reduce O<sub>2</sub> release from hemoglobin to the tissues. Red blood cells containing fetal hemoglobin have an average life span of 100 days, compared with 120 days for those containing adult hemoglobin. The higher hematocrit in neonates causes an increased bilirubin load for an immature hepatic clearance pathway. However, preterm infants frequently experience anemia of prematurity, a normocytic, normochromic hypoproliferative anemia with the hallmark of inadequate production of erythropoietin.<sup>58</sup>

The O<sub>2</sub> delivery to systemic tissues in neonates is facilitated by a cardiac output greater than in adults on a per-kilogram body-weight basis. The relationships among myocardial preload, contractility, afterload, and heart rate determine cardiac output. Passive myocardial fiber tension is reflective of myocardial compliance, which is significantly reduced in the perinatal period.<sup>59</sup> Active myocardial tension, reflecting contractility, is

also significantly reduced in the neonate.<sup>59</sup> At smaller end-diastolic volumes, mild increases in preload in the neonate are associated with increased cardiac output. At greater end-diastolic volumes, as a result of poor ventricular compliance in the neonatal heart, this positive effect is soon overcome and cardiac output becomes more dependent on heart rate (see Chapters 14 and 16).<sup>60-62</sup> The heart rate of a term neonate is approximately 120 beats/min; it increases to 160 beats/min by 1 month of age.<sup>63</sup> Parasympathetic control of heart rate in lambs, and probably in developing humans, matures earlier in gestation and to a greater extent than  $\beta$ -adrenergic control.<sup>64,65</sup> For this reason, neonates tend not to respond to adrenergic signaling associated with hypovolemia or an inadequate depth of anesthesia with tachycardia. Additionally, the vagotonic response caused by succinylcholine or its metabolites (succinylmonocholine) and synthetic opioids may lead to bradycardia. These cardiac reflexes can be offset by the vagolytic effects of pancuronium or atropine.<sup>66,67</sup>

Preterm infants may have pulmonary hypertension. In utero, the lungs are not required for gas exchange; the placenta performs this function. Thus the fetal circulatory pattern consists of atria and ventricles working as units in parallel (see Fig. 16-1). As little as 10% of the fetal right ventricular output may circulate through the lungs.<sup>68</sup> Most of the blood returned from the lower extremities and a portion of the umbilical venous blood supply passes into the pulmonary arteries and subsequently through the PDA into the systemic circulation (see Chapters 14 and 16). The superior vena caval blood supply circulates through the patent foramen ovale (PFO) into the left atria and subsequently into the systemic circulation. With expansion of the lungs during the first breath, pulmonary vascular resistance decreases and blood flow to the lungs increases, matching perfusion with new ventilation.<sup>68,69</sup> Any factor that increases pulmonary vascular resistance, (e.g., hypoxia, hypercarbia, or acidosis) may cause the circulation to revert to a fetal circulatory pattern with shunting of deoxygenated blood from the right to the left side of the heart via the PFO or PDA. This right-to-left shunting of blood explains in part why some infants remain hypoxemic despite ventilation with 100%  $O_2$  after severe desaturation.

The ductus arteriosus may remain patent in neonates, especially in those born prematurely.<sup>70</sup> Bounding peripheral pulses, a harsh systolic ejection murmur at the left sternal border, and widened pulse-pressure difference, suggest the presence of a PDA. The presence of a PDA and of right-to-left shunting of blood may contribute to ventilation-perfusion ( $\dot{V}/\dot{Q}$ ) mismatch as deoxygenated blood is shunted from the pulmonary arteries to the systemic circulation through the PDA and differential upper and lower extremity  $O_2$  saturations result. Later, as the pulmonary vascular resistance decreases, left-to-right shunting of blood from the systemic to pulmonary circulation across the PDA may cause flow-mediated endothelial cell injury and abnormal pulmonary artery remodeling and hypertension. Infants with a PDA often require increased ventilatory support.

A PDA in the neonate may be treated with indomethacin or ibuprofen. If the PDA persists despite medical treatment, surgical ligation may be required.<sup>71-73</sup> Treatment with indomethacin is associated with renal and platelet dysfunction. Although experience suggests that infants who have received large volumes of intravascular fluid have a greater incidence of PDA,<sup>74</sup> the mechanism behind this is unknown, and the relationship may not be causal. In fact, if the PDA is associated with ventricular dysfunction and poor organ perfusion, it is imperative to provide adequate intravascular volume and to improve cardiac output rather

than expose the infant to hypotension mediated by left-to-right shunting across the PDA. Occasionally, systemic perfusion in infants with PDA may be improved with a dopamine infusion and judicious intravenous fluid administration.

In neonates, increased pulmonary vascular resistance causes shunting of desaturated blood through the PFO and PDA and thereby causes severe systemic hypoxemia. Although the cause of persistent pulmonary hypertension of the newborn (PPHN) is incompletely understood, it is associated with increased muscularization of pulmonary arterial vessels<sup>75</sup> and sepsis and aspiration syndromes.<sup>76</sup> PPHN is suspected in severely hypoxic neonates who do not have a significant increase in postductal  $O_2$  saturation when they breathe 100%  $O_2$ . A difference in preductal and postductal  $O_2$  saturations supports the diagnosis because it reflects the extrapulmonary right-to-left shunting of deoxygenated blood via the PDA. PPHN is diagnosed when pulmonary hypertension and no other structural heart lesions are observed by cardiac ultrasound.

Treatment of PPHN is directed at decreasing pulmonary vascular resistance and the extrapulmonary shunting of deoxygenated blood. In cases of pneumonia and aspiration syndromes, in which airway disease can lead to atelectasis and intrapulmonary shunt, PEEP and exogenous surfactant are sometimes used to recruit alveoli. To treat the pulmonary vasoconstriction that is pathognomonic of PPHN, hyperoxia and alkalosis therapies have been used. Although inspired  $O_2$  is a potent vasodilator, maximum dilation of the pulmonary vasculature is achieved by relatively low levels of  $O_2$ . For this reason, increasing the  $FiO_2$  often does not improve gas exchange in PPHN. Through a mechanism that is incompletely understood, alkalosis causes pulmonary vasodilation. In many infants with PPHN, alkalosis induced by hyperventilation or the infusion of base decreases pulmonary vascular resistance and increases systemic  $O_2$  partial pressures. In general, the vasodilation induced by alkalosis occurs when the arterial pH is 7.55 or greater. With the advent of inhaled NO, alkalosis has been largely replaced with avoiding acidemia, but not inducing marked alkalosis. Intravenous vasodilator drugs cause inconsistent vasodilation in infants with pulmonary hypertension.<sup>77</sup> Unfortunately, because these agents dilate the systemic as well as the pulmonary vasculature, they often cause severe systemic hypotension.

Inhaled NO selectively decreases pulmonary vascular resistance and increases systemic  $O_2$  partial pressures in infants with PPHN.<sup>78-80</sup> NO is a gas that is synthesized by NO synthase from L-arginine and  $O_2$  in endothelial cells and diffuses into subjacent smooth muscle cells, where it stimulates soluble guanylate cyclase to increase cGMP levels. It is probably through cGMP's stimulation of cGMP-dependent protein kinase I and the phosphorylation of several cytoplasmic targets that regulate intracellular calcium levels and vasomotor protein function that NO causes vascular relaxation (see Fig. 36-1). Inhaling small concentrations of NO caused selective pulmonary vasodilation, decreased right-to-left shunting of blood, and increased systemic  $O_2$  partial pressures in neonate animals and infants with pulmonary hypertension.<sup>81-83</sup> Acutely breathing up to 80 parts per million (ppm) by volume of NO rapidly and selectively decreases pulmonary vascular resistance and increases systemic  $O_2$  partial pressures by decreasing extrapulmonary shunting of deoxygenated blood. Although methemoglobin is produced during the metabolism of NO, no important increases in methemoglobin were observed in infants breathing low concentrations of NO. Large multicenter studies suggest that breathing 20 ppm NO

decreases the requirement for extracorporeal membrane oxygenation (ECMO). Although ECMO can be lifesaving for severely hypoxemic neonates,<sup>84-86</sup> it is expensive and invasive, sometimes causes important complications, and is not available at most hospitals. For these reasons, inhaled NO is used in most intensive care nurseries to treat the severe hypoxemia associated with PPHN.

Studies also suggest that chronic NO inhalation protects the neonatal lung from injury.<sup>47</sup> In cell cultures, NO has been observed to decrease pulmonary smooth muscle cell proliferation and increase programmed cell death (apoptosis). Inhaled NO has been observed to decrease pulmonary artery neomuscularization in animals with lungs injured by breathing gases with low concentrations of inspired O<sub>2</sub>. Although inhaled NO may decrease lung artery remodeling by preventing hypoxic pulmonary vasoconstriction, studies suggest that it prevents abnormal pulmonary artery remodeling in injured lungs without hypertension.<sup>78</sup> Although the protective mechanism of inhaled NO is unknown, it does decrease smooth muscle cell proliferation *in vitro*,<sup>87</sup> possibly by altering the expression of transcriptional regulators and the progression of the cell cycle.<sup>88-90</sup> It is likely that studies that identify the protective mechanisms of NO/cGMP signaling will guide the development of novel therapies to prevent pulmonary disease in the injured lung.

Appreciation has been increasing of the potential harmful effects of even brief periods of hyperoxia.<sup>91</sup> Six randomized controlled clinical studies have shown no apparent advantage of initiating resuscitation of neonates with 100% supplemental O<sub>2</sub> instead of 21% O<sub>2</sub>. In fact, some studies suggest slightly greater mortality rates with 100% O<sub>2</sub>. In light of these findings, the 2010 Neonatal Resuscitation Program has been updated to recommend initiating resuscitation of full-term neonates with 21% O<sub>2</sub> and that pulse oximetry be used if supplemental O<sub>2</sub> is needed.<sup>92</sup>

## TEMPERATURE REGULATION

The neonatal body habitus favors heat loss. The large surface area of the head relative to that of the body of neonates increases heat dissipation. A head cover may significantly reduce temperature loss.<sup>93,94</sup> Neonates do not shiver or sweat effectively to maintain body temperature and rely primarily on brown fat metabolism to maintain body heat. Brown fat cells begin to differentiate at 26 to 30 weeks of gestation and hence are not available in extremely preterm infants to provide fat for metabolism and heat generation.<sup>95</sup> Warming the operating room to 85° F (30° C), using radiant warming units, forced-air heating pads, and adding humidity to the inspired gases in the ventilator circuits help maintain the neonate's temperature in the neutral thermal range.<sup>96-98</sup> The sources of heat loss in infants is 39% radiation, 37% convection, 21% evaporation, and 3% conduction. Warming intravenous and irrigation fluids before they are used may also be beneficial.

## RENAL AND METABOLIC FUNCTION

### Renal Function

The placenta acts as an excretory organ for the fetus. A neonate's kidneys are not fully developed at birth, and development is closely related to PCA.<sup>98,99</sup> At full-term birth, the glomerular filtration rate (GFR) is only 30% of normal adult rates (see Chapter 6).<sup>100</sup> The GFR reaches adult values at approximately 1 year of age (see Figs. 6-10 and 6-11). The kidneys' tubular function, and hence sodium-retaining ability, does not develop until about 32 weeks of gestation.<sup>101,102</sup> The immaturity of the

kidney at birth also affects the metabolism of many drugs in the neonate. The renal excretion of medications such as penicillin, gentamicin, and some neuromuscular blocking drugs (NMBDs), such as pancuronium, may be prolonged, resulting in increased duration of action or the development of excessive blood concentrations. This effect is particularly important when administering medications to an extremely preterm infant. Thus the use of NMBDs that do not require renal function are most advantageous (e.g., cisatracurium).

The total body water content in neonates is greater than it is in infants, children, or adults. In the preterm infant 75% to 85% of body weight is water; in general, the less the PCA of the neonate, the greater the percentage of water. In a term infant, 70% of body weight is water.<sup>103</sup> By 6 to 12 months of age, 50% to 60% of body weight is water (see also Figs. 6-7 and 6-8). Differences between the total body water, renal maturity, and serum protein concentrations (see also Fig. 6-6) in a neonate affect the volume of distribution of many medications. Because of the increase in the volume of distribution of drugs confined to the extracellular fluid, the initial doses of some medications (e.g., NMBDs, aminoglycosides) may be greater on a weight basis in neonates than for adults to achieve the desired blood concentration. In contrast, because of immaturity of renal function, the interval between doses of these drugs may be increased (see also E-Fig. 6-4).

## Fluid Management

The basic principles of fluid maintenance in neonates are similar to those in older children and adults. The highly variable body fluid composition, degree of renal maturity,<sup>104</sup> neuroendocrine control of intravascular fluid status, and insensible fluid loss with age<sup>105</sup> make precise estimates of fluid requirements in neonates very difficult (see Chapter 8). Urine volume and concentration may be difficult to determine intraoperatively and may not always correlate with volume status. Moreover, blood pressure and heart rate may not correlate with intravascular volume status in preterm infants, and anesthetics may mask subtle cardiovascular changes that occur with changes in intravascular volume. Increased insensible fluid loss, which often occurs in the operating room environment, requires judicious titration of intravenous fluids. Congenital abnormalities (e.g., gastroschisis, omphalocele) may markedly increase insensible fluid loss through exposure of large mucosal surfaces. The use of humidified gas mixtures reduces insensible fluid loss through the respiratory tract. However, overzealous intraoperative administration of fluids can result in pulmonary complications and worsened third-spacing of fluids.

## Methods of Intravenous Access and Monitoring

Infants who are dehydrated after a prolonged period of fasting or vomiting or because of increased insensible fluid losses may require special procedures for intravenous access. With severe hypovolemia, scalp and peripheral veins may be difficult to cannulate. Many of the superficial veins may be thrombosed from prior use. Fiberoptic light sources or ultrasound may help visualize deeper veins and peripheral arteries. Femoral and axillary veins may be accessed percutaneously or via a surgical approach for the delivery of fluids and medications.<sup>106-108</sup> Knowledge of femoral artery and vein anatomy decreases the incidence of accidental injury of the femoral head joint and possible septic arthritis (see Fig. 48-5).<sup>109</sup> The external or internal jugular veins can also provide alternative sites for venous access.

In neonates, fluids and many medications may be infused through the umbilical vessels. The tip of umbilical arterial lines should be placed either in a “low” position, at the level of the bifurcation of the femoral arteries (L3-4), or in a “high” position, in the descending aorta above the diaphragm (T6-9). The catheter tip of the umbilical artery catheter should not be left in the descending aorta in the area of the renal or mesenteric arteries (L1-2) because renal or mesenteric artery thrombosis might result (see Figs. 48-8 and 48-9). Aortic thrombosis occurs in approximately 1% of umbilical artery catheterizations, although thrombi can be detected with radiologic techniques in 20% to 95% of infants.<sup>110-112</sup> Infants with renal artery thrombosis may present with hypertension, oliguria, hematuria, and elevated blood creatinine concentrations. The tip of an umbilical venous catheter should rest in the inferior vena cava above the level of the ductus venosus and hepatic veins so that solutions are not directly infused into the liver parenchyma. The delivery of hypertonic solutions into the liver might result in liver damage and portal cirrhosis. Aspiration of arterial oxygenated blood suggests that the venous catheter has entered the left atrium through the foramen ovale. Catheters in the left atrium should be pulled back to the level described earlier.

Some drugs may be delivered through the tracheal tube. Rapid uptake and minimal effects on gas exchange or the pulmonary parenchyma occur with epinephrine, atropine, and lidocaine (see Chapter 39). The doses of some drugs administered through the tracheal tube are increased in comparison with that delivered intravenously (e.g., epinephrine 0.05 to 0.1 mg/kg via the tracheal tube versus 0.01 to 0.03 mg/kg intravenously).<sup>92</sup> It is important to understand that administration of solutions via the endotracheal tube can cause adverse effects. For example, complications associated with the tracheal administration of exogenous surfactant include occasional transient hypoxia and bradycardia and are likely due to the relatively large volume of fluid (2.5 to 6 mL/kg) associated with the proper dose of surfactant.

Intraosseous cannulation of the tibia with a special intraosseous infusion needle (e.g., Easy-IO, Vidacare, San Antonio, Tex.) or a styleted spinal needle provides a rapid route for emergency fluid and drug administration and can be lifesaving (see Fig. 48-6 and E-Fig. 48-1, *A* through *E*).

### Glucose Homeostasis

Although the placenta allows the delivery of glucose from the maternal circulation to the fetus, the development of significant glycogen stores does not occur until late in gestation. Various conditions may lead to hypoglycemia in a neonate. Preterm and small-for-gestational-age (SGA) infants have very high glucose requirements; they require glucose infusion rates of 8 to 10 mg/kg/min. In full-term infants, a glucose infusion rate of 5 to 8 mg/kg/min prevents hypoglycemia. Full-term infants who have been excessively fasted, SGA infants, and infants of diabetic mothers are all prone to develop hypoglycemia. Although hypoglycemia may result in respiratory distress, apnea, cyanosis, seizures, tremors, high-pitched cry, irritability, limpness, lethargy, eye-rolling, poor feeding, temperature instability, and sweating, the signs and symptoms in infants are often blunted and nonspecific.<sup>113,114</sup> In infants younger than 24 hours old, a plasma glucose concentration of less than 40 mg/dL is a cause for concern and should be treated.<sup>115</sup> After 24 hours of life, plasma glucose values less than 45 mg/dL should be considered abnormally low. Although hypertonic glucose administration has been used to treat hypoglycemia in neonates, studies reveal that

administration of hypertonic sodium bicarbonate solutions increases the incidence of intraventricular hemorrhage in preterm infants.<sup>116</sup> For this reason, it is prudent to avoid bolus administration of hypertonic glucose to treat hypoglycemia to prevent sudden changes in blood tonicity and hyperglycemia. A bolus of 2 to 4 mL/kg of D<sub>10</sub>W (0.2 to 0.4 g/kg of glucose) and an increase in the basal glucose infusion are prudent measures to treat hypoglycemia. It is extremely important to reassess the blood glucose concentration after these treatments to determine the effectiveness of the therapy.

Infants undergoing surgical procedures often require less glucose supplementation.<sup>117</sup> This reduced need may be attributed to hormonal responses that decrease glucose uptake as a result of catecholamine release in excess of insulin activity, as well as a decrease in metabolic demand from the effects of the anesthetic agents.<sup>118-120</sup> Nevertheless, it is important to administer glucose-containing solutions using a constant-infusion device to avoid large fluctuations in blood glucose values and monitor blood glucose values in critically ill neonates. All other fluids (e.g., to replace third-space losses, blood loss, and fluid deficits) should be glucose-free to avoid hyperglycemia.<sup>117</sup> Infants treated with high levels of glucose via total parental nutrition (TPN) may develop severe hypoglycemia if the infusion rate is abruptly lowered; thus it is important to continue these infusions (possibly at a slightly reduced rate) during surgery and to check the serum glucose concentrations.

### Calcium Homeostasis

Calcium exists in the serum in three fractions: (1) protein bound; (2) chelated to bicarbonate, phosphate, and citrate; and (3) free or ionized calcium ( $iCa^{2+}$ ). The ionized fraction is the physiologically active component. The serum calcium concentration is mainly regulated by the action of parathyroid hormone (PTH) and vitamin D metabolites. PTH acts directly in the bone and kidneys and indirectly through calciferol in the gut.<sup>121</sup>

Hypocalcemia has been observed in nearly 40% of critically ill neonates.<sup>122</sup> Causes of hypocalcemia include (1) PTH insufficiency and peripheral resistance to PTH, (2) inadequate calcium supplementation, and (3) altered calcium metabolism caused by transfusion with citrated blood products (see also Fig. 10-9), bicarbonate administration, or diuretics (furosemide). Hypocalcemia may be asymptomatic or accompanied by nonspecific symptoms (e.g., seizures and tremors). Thus the diagnosis rests on the determination of total and  $iCa^{2+}$  levels. In critically ill children, total calcium concentrations do not accurately reflect the  $iCa^{2+}$  concentrations; therefore the diagnosis of hypocalcemia in these infants should be determined by direct measurement of  $iCa^{2+}$  with an ion-specific electrode.<sup>123</sup> Neonatal hypocalcemia may be defined as a serum  $iCa^{2+}$  less than 1 mmol/L in full-term infants and less than 0.75 mmol/L in preterm infants. Persistent hypocalcemia necessitates determination of magnesium, phosphorus, PTH, and vitamin D concentrations.

Treatment of hypocalcemia is not effective in the presence of hypomagnesemia. In this situation, administration of supplemental magnesium and calcium and treatment of the underlying cause of hypocalcemia are necessary.<sup>122</sup> Symptomatic hypocalcemia is treated with 100 mg/kg calcium gluconate (10%) by slow intravenous infusion (5 minutes) in a patent intravenous line. Thereafter, maintenance calcium is administered at 100 to 200 mg/kg/day elemental calcium and the clinical response and serum  $iCa^{2+}$  levels are carefully monitored.

## GASTROINTESTINAL AND HEPATIC FUNCTION

The fetal gut is not functionally developed until late in gestation. In full-term neonates, the maturation of esophageal function occurs soon after birth. However, in comparison with adults, gastric emptying in neonates is prolonged and lower esophageal sphincters are incompetent, making reflux of stomach contents common. Early feeding of hypertonic formulas in preterm infants increases intestinal energy demands and is associated with bowel ischemia and necrotizing enterocolitis.<sup>124</sup> On the other hand, the use of hypocaloric or trophic feeds in preterm infants is associated with subsequent feeding intolerance, indirect hyperbilirubinemia, cholestatic jaundice, and metabolic bone disease.<sup>125,126</sup>

After birth, increased concentrations of unbound serum bilirubin introduce the risk of kernicterus, particularly in infants who are preterm, hypoxemic, and acidotic and have low serum protein concentrations.<sup>127</sup> Highly protein-bound agents such as furosemide, sulfonamides, ceftriaxone, and benzyl alcohol (found as a preservative in many drugs such as diazepam) may displace bilirubin and increase the possibility of kernicterus.<sup>128</sup> Hepatic metabolism is immature in neonates and particularly in preterm infants. Drug metabolism may be prolonged as a result of both immaturity of enzymatic processes and a relatively low hepatic perfusion (less drug delivered to the liver). Any factor that further compromises hepatic blood flow (e.g., increased intraabdominal pressure) may have profound adverse effects on drugs with perfusion-limited hepatic clearance.<sup>129</sup> Therefore careful titration of these drugs (e.g., opioids, propofol) is required to optimize therapeutic effects and prevent toxicity. Just as consideration is given to immature renal function, the use of NMBDs that do not require hepatic metabolism can be advantageous, (e.g., cisatracurium). The use of remifentanyl during the procedure followed by a low dose of longer-acting opioid or regional block at the end of the procedure might facilitate early extubation.

## NEUROLOGIC DEVELOPMENT

The central nervous system is incompletely developed at birth. However, early in gestation, the pain pathways are integrated with the somatic, neuroendocrine, and autonomic systems. The hormonal responses to pain and stress may be exaggerated in neonates,<sup>118,119</sup> although the clinical significance of this has not been defined. The potential lack of autoregulation of cerebral blood flow and an infant's fragile cerebral blood vessels may be important factors in the development of intraventricular hemorrhage.<sup>130,131</sup> Although an association has been noted between the incidence of intraventricular hemorrhage and fluctuations in blood pressure,<sup>130,132</sup> it is difficult to confirm any causal relationship. This association has been a concern during "awake" or nonanesthetized laryngoscopy and intubation of neonates; however, one study reported no significant change in blood pressure or heart rate in neonates even after awake intubation.<sup>133</sup> In addition, another study questioned the lack of autoregulation of cerebral blood flow in preterm infants. Using near infrared spectroscopy, investigators found that preterm infants could maintain adequate cerebral perfusion at a mean arterial blood pressure in the range of 23 to 39 mm Hg.<sup>134</sup>

In neonates, the spinal cord extends to a lower segment of the spine than in older children and adults (see E-Fig. 41-3). The volume of cerebrospinal fluid and the spinal surface area are proportionally larger in neonates (see also E-Fig. 41-4), whereas the amount of myelination is less than in older children and

adults.<sup>135,136</sup> These factors may account in part for the increased amount of local anesthetics (milligram per kilogram) required for successful spinal anesthesia in infants.

Hyperoxia has been associated with retinopathy of prematurity (ROP).<sup>137-139</sup> Although two case reports of ROP associated with anesthesia in preterm infants implicated hyperoxia as a primary etiologic factor, the cause of ROP appears to be multifactorial<sup>140-149</sup>; the association between arterial O<sub>2</sub> tension and ROP is unclear (see also Chapter 32). ROP begins as retinal vascular narrowing and obliteration followed by increased vascularity (neovascularization), hemorrhage, and, in the most severe cases, retinal detachment and blindness (see also Fig. 32-1). In two clinical trials (the SUPPORT<sup>150</sup> and BOOST II<sup>151</sup> trials) infants born at less than 28 weeks gestation were randomized to saturation ranges of either 85% to 89% or 91% to 95%. In the SUPPORT trial, for every 11 infants treated in the lower saturation range, one case of severe ROP was prevented (results for the BOOST II trial are not yet available). However, in both the SUPPORT and BOOST II trials, the latter of which was terminated early, the mortality was greater in infants who were randomized to the 85% to 89% range than those in the 91% to 95% range. Although the optimal saturation range has not been defined in preterm infants, it seems prudent to target the O<sub>2</sub> saturation in the range of 91% to 95% and avoid a saturation less than 89%.

## Preparation for Surgery

### THE OPERATING ROOM

Conditions that require emergency surgery in neonates are often accompanied by medical problems, and, as a consequence, management and monitoring considerations can be complex. Routine standard monitoring equipment includes an electrocardiograph, chest or esophageal stethoscope, blood pressure monitor, temperature probe, pulse oximeter and a CO<sub>2</sub> analyzer. Rapid decreases in arterial O<sub>2</sub> content in neonates after brief periods of ventilatory compromise, coupled with the possible risk of ROP as a result of hyperoxia, dictate the need for continuous O<sub>2</sub> saturation monitoring. A pulse oximeter probe placed in a preductal position (right hand) can be compared with one placed in a postductal position (foot or left hand) to determine the severity of extrapulmonary shunting of deoxygenated blood via the PDA. Pulse oximetry may prove to be particularly useful for infants in whom the risk of intraarterial monitoring cannot be justified.<sup>152</sup> This device can diagnose hypoxemia but not hyperoxia; however, maintaining the O<sub>2</sub> saturation at 91% to 95% (preductal) places most infants on the steep portion of the O<sub>2</sub> hemoglobin dissociation curve and avoids severe hyperoxia.<sup>153</sup>

Expired CO<sub>2</sub> can be measured using capnography. However, dilution of the exhaled gases with those of the dead space of the tracheal tube or by the fresh gas may underestimate the true alveolar CO<sub>2</sub> partial pressure. If desired, a more accurate estimate of expired CO<sub>2</sub> concentration may be obtained by using a special tracheal tube with a sample port located at its tip, by inserting a narrow catheter through the CO<sub>2</sub> sampling port in the elbow and into the lumen of the tracheal tube or by using a needle introduced through the side wall of the tracheal tube 2 to 3 cm distal to the 15-mm tube connector (see Chapter 51).<sup>154,155</sup> Using a circle system provides a reasonably accurate measurement of expired CO<sub>2</sub> concentrations because the fresh gas flows are small and less mixing of exhaled and inhaled gases occurs. However, regardless of the circuit configuration, the value obtained by the

capnograph may not accurately reflect  $\text{PaCO}_2$  in the presence of congenital heart disease (e.g., cyanotic heart disease or a mixing shunt) or significant intrapulmonary shunting.<sup>156</sup>

In neonates, changes in blood pressure, heart rate, and the intensity of heart sounds are excellent indicators of cardiac function, intravascular volume status, and depth of anesthesia. Under most circumstances, a urinary catheter permits adequate determination of urine output and aids in the monitoring of fluid balance during prolonged operations. In cases in which major blood or fluid losses are expected, or the physiology is complicated by the presence of cardiac disease, a central venous catheter is warranted. Any neonate with significant underlying cardiovascular instability should have an arterial catheter placed for continuous monitoring of blood pressure and to provide the means to obtain arterial blood samples for determination of blood pH and gas levels and serum glucose and electrolyte concentrations. Many neonates arrive in the operating room from the intensive care unit (ICU) with an umbilical artery line in place. Because of the risk of renal artery thrombosis with these lines, it is important to verify the location of the tip of the umbilical artery catheter. Infrahepatic umbilical venous lines may not be reliable under operative conditions because they may become wedged in the liver. In this position, infusion of hypertonic solutions may lead to parenchymal necrosis and ultimately fibrosis.<sup>157,158</sup>

Nonbreathing (open) circuits are simple and effective for delivering anesthetic agents to infants weighing less than 10 kg. The system must have provisions for a humidifier to warm and hydrate the cold, dry anesthetic gases. However, a trend exists away from the use of nonbreathing circuits to save money and reduce air pollution.<sup>34-36,59</sup> With the increasing need for cost savings there appears to be no significant disadvantage to using circle systems, which allow the use of small fresh gas flows. This substitution should only be made if the provider has a clear understanding of the marked increase in compression volume/compliance volume losses (see also Fig. 51-7) compared with nonbreathing circuits.<sup>159</sup> The anesthesia machine should also provide compressed air in addition to  $\text{O}_2$  and  $\text{NO}$ . The use of air allows regulation of inspired  $\text{O}_2$  concentrations during cases in which  $\text{NO}$  treatment is contraindicated and a high  $\text{PaO}_2$  is not desired. Table 36-3 lists basic equipment for conducting emergency anesthesia on a neonate.

## THE FAMILY

Close interaction between the parents and the anesthesia, medical, surgical, and nursing staff promotes effective communication of medical concerns and continued emotional support for parents. The birth of a preterm neonate or illness in a full-term infant often does not allow time for emotional preparation for or acceptance of the situation by the family. With the institution of aggressive medical and surgical interventions, parents sometimes feel excluded from the care of their infant and develop feelings of isolation and lack of control. The development of rapport between the parents of critically ill infants and hospital staff is essential to ensure adequate psychological support during this intensely anxiety-provoking event.

## Emergency Surgery

### RESPIRATORY PROBLEMS

Lesions of the respiratory system can be categorized into those that involve the large airways or the small airways and lung parenchyma.

**TABLE 36-3** Suggested Equipment for Emergency Neonatal Anesthesia

Airway Equipment	Environment	Agents	Intravenous Fluids
Suction catheters	Room temperature (80°-85° F)	Gases Air/ $\text{O}_2$ / $\text{NO}$	Lactated Ringer solution
Oral airways		Volatile anesthetics	$\text{D}_{10}\text{W}$
Facemasks	Forced warm air delivery	Drugs IV anesthetics	Normal saline
Breathing circuit	device	Propofol	5% albumin
Miller 0, 1, blades and handle	Underbody warming blanket	Ketamine	
Uncuffed endotracheal tubes (2.5, 3.0, 3.5, 4.0 mm)	Circuit humidifier IV fluid warmer	Muscle relaxants Succinylcholine Cisatracurium Vecuronium Pancuronium	
Stylet	Infusion pumps for both maintenance fluid and for opioid or vasoactive drugs	Opioids Fentanyl Morphine Remifentanyl Local anesthetics Tetracaine 1.0% Bupivacaine 0.25%	
		Emergency drugs Atropine Epinephrine (1:10,000) Dopamine Calcium Bicarbonate Isoproterenol	

## Abnormalities of the Airway

### Choanal Atresia and Stenosis

Not all neonates are able to change to oral breathing when nasal obstruction occurs.<sup>32,33</sup> Choanal atresia can present as cyanosis at rest that resolves with crying or placement of an oral airway. Choanal atresia and stenosis result from the failure of the bone or membranous portion of the nasopharynx to undergo regression during development. The incidence is approximately 1 in 8000 births. Unilateral lesions are seldom symptomatic and may escape early detection. Although bilateral lesions may be asymptomatic, occasionally they may lead to respiratory distress.<sup>160</sup> Choanal atresia and stenosis are generally not associated with other craniofacial anomalies. Choanal atresia may be found as part of a constellation of congenital anomalies, the CHARGE association: coloboma, heart disease (tetralogy of Fallot, PDA, double-outlet right ventricle with atrioventricular canal, ventricular septal defect, atrial septal defect, right-sided aortic arch), atresia choanae, retarded growth (including other central nervous system anomalies), genital anomalies (hypogonadism), and ear anomalies.<sup>161,162</sup> These neonates may develop airway obstruction during anesthetic induction. Early placement of an oral airway, facilitated by preinduction topical application of viscous lidocaine to the tongue, aids in airway management.

Functional choanal obstruction may result from traumatic nasal suctioning. Obstructive symptoms are often ameliorated by treatment with cool mist therapy or vasoconstrictors such as phenylephrine. The upper airway may also be stented open by

nasal placement of a shortened endotracheal tube. Such treatment, however, is only temporary; prolonged use of a nasal airway may increase edema and obstruction.

#### *Laryngeal and Upper Tracheal Obstruction*

Obstruction at the level of the larynx or upper trachea may be due to laryngeal and tracheal webs or subglottic lesions. Subglottic lesions may be due to congenital stenosis, hemangioma, web, or vascular ring (Figs. 36-2 and 36-3; see also Videos 12-1, 12-2, and 12-5). Anesthetic management of obstructive lesions in older children and adults usually includes an inhalation anesthetic induction while maintaining spontaneous respirations. This method may be difficult in neonates for the following reasons: (1) the combined effects of inhalation anesthetic agents and immature ventilatory drive regulation may predispose to hypoventilation; (2) hypoventilation leads to an increased alveolar  $\text{CO}_2$ , which displaces alveolar  $\text{O}_2$ ; and (3) anesthetic agents decrease intercostal muscle function, resulting in decreased

**FIGURE 36-2** Laryngeal web in a neonate. (Courtesy Dr. Christopher Hartnick.)

**FIGURE 36-3** **A**, Congenital subglottic stenosis is usually concentric in nature and presents with inspiratory stridor **B**, A tracheal hemangioma is often associated with other hemangiomas on the face but may present as an isolated lesion. In this example, near-total obstruction of the airway is seen. **C**, Note the patency of the airway after resection. (Courtesy Dr. Christopher Hartnick.)

**E-FIGURE 36-1** H-type tracheoesophageal fistula is most often diagnosed with a contrast study. Note the contrast material migrating from the esophagus to the tracheobronchial tree. (Courtesy Dr. Daniel P. Doody.)

functional residual capacity (FRC).<sup>163,164</sup> The hypoventilation and reduced FRC combined with high O<sub>2</sub> consumption predispose infants to desaturation during anesthetic induction while the infant maintains spontaneous ventilation.

**WEBS.** Laryngeal or tracheal webs generally produce incomplete fibrous membranes that lead to obstruction of the airway with acute respiratory distress or stridor shortly after birth (Fig. 36-2).<sup>165</sup> Complete airway obstruction occasionally results in an emergency in the delivery room. A tracheal tube may be used as a stent to open an incomplete lesion. If tracheal intubation is not possible, an intravenous catheter passed through the cricothyroid membrane may allow oxygenation and be lifesaving (see Figs. 12-25 through 12-27).<sup>166</sup> A tracheostomy is then established.

**CONGENITAL SUBGLOTTIC STENOSIS.** The severity of the symptoms resulting from congenital subglottic stenosis depends on the degree of airway occlusion (see Fig. 36-3, *A*). Treatment depends on the location and length of stenosis. For severe narrowing, a tracheostomy is placed and a series of dilations attempted.<sup>167</sup> Tracheal dilations may cause airway disruption, pneumomediastinum, and pneumothorax. Anesthesia may be induced using an inhalation technique with a facemask and appropriate ventilatory assistance. If a tracheostomy is considered, a small-diameter tracheal tube may be placed to facilitate ventilation until a tracheostomy is performed. This tracheal tube should be of smaller diameter so that it passes beyond the level of obstruction. As resistance increases inversely with the airway radius to the fifth power, ventilatory assistance is required to overcome this substantial increase in the work of breathing. The greater time constants that result from the increased airway resistance require a greater time for expiration to avoid gas trapping.

**SUBGLOTTIC HEMANGIOMA.** Subglottic hemangioma may produce respiratory distress during the first few weeks of life as it rapidly increases in size (see Fig. 36-3, *B* and *C*). The presence of other hemangiomas on an infant's body, especially on the face, is a clue that a subglottic hemangioma may be the source of the respiratory distress.<sup>168</sup> These infants often present with symptoms of upper airway obstruction, which may be life-threatening when additional exacerbating factors such as upper respiratory tract infections or other causes of inspissated mucus result in further airway compromise.<sup>169</sup> Any infant who is younger than 3 months of age and presents with symptoms of "croup" must be considered to have causes other than infection as a source of the airway obstruction. If tracheal intubation is required, it should be carried out as gently as possible because bleeding may occur secondary to trauma from the intubation procedure.

**ESOPHAGEAL ATRESIA AND TRACHEOESOPHAGEAL FISTULA.** Esophageal atresia and tracheoesophageal fistula (TEF) are often associated with other congenital abnormalities, in particular the VACTERL association (vertebral abnormalities, imperforate anus, congenital heart disease, tracheoesophageal fistula, and renal abnormalities and limb abnormalities (typically radial atresia)).<sup>170,171</sup> The specific cause of these associations is unknown. Although esophageal atresia may be an isolated occurrence, in 90% of cases it is associated with TEF.

Affected neonates usually present with excessive oral secretions, regurgitation of feedings, and occasionally respiratory distress exacerbated by feedings; recurrent pneumonia is associated with an H-type TEF (~2% to 6% of cases) and is usually diagnosed later in life. The diagnosis of esophageal atresia is confirmed by the inability to pass a moderately rigid orogastric tube into the stomach or the demonstration of a blind esophageal pouch by air contrast or radiopaque dye and radiographic studies.

The presence of bowel gas suggests a TEF; on occasion, the abdominal distention may be severe enough to cause atelectasis and impede ventilation. In the most common form of TEF, the esophagus ends in a blind proximal pouch with the distal end of the esophagus connected to the trachea (usually posteriorly) just above the carina. In the less common form of isolated TEF without esophageal atresia, radiologic studies may be inconclusive (Fig. 36-4 and E-Fig. 36-1).

Neonates with TEF should be nursed prone or in a lateral position on an incline of 30 degrees head up to decrease the risk of pulmonary aspiration. A sump suction catheter placed in the upper esophageal pouch preoperatively and connected to constant suction decreases the accumulation of saliva and reduces the potential for aspiration. Neonates with esophageal atresia and TEF may have a staged repair of their lesions. A gastrostomy tube to vent the stomach and a central line for parenteral nutrition may be placed with the patient under sedation with local anesthesia or general anesthesia. The procedures will permit the infant to receive long-term nutrition so that growth may occur and an esophageal anastomosis can be performed when the infant is older and the distance between the esophageal pouch and stomach decreases.

Several approaches may be used to secure the airway in these infants. Awake intubation may be conducted with topical anesthesia of the airway or with intravenous suction if the neonate is medically stable. Alternatively, inhalational induction and spontaneous ventilation may be used until the trachea is secured, particularly if rigid bronchoscopy is used to define the anatomy of the airway before ligation of the fistula. To properly position the tracheal tube, an intentional right main-stem bronchial intubation is sometimes performed; subsequently, the tracheal tube is slowly withdrawn while auscultating the left thorax until breath sounds are heard. During this maneuver, it is key to ensure the bevel of the tube is on the left side (particularly if a Murphy eye is not present on the tube) to facilitate detection of air exchange with the left lung as soon as the tube is withdrawn above the level of the carina. At this position, the tip of the tracheal tube is just above the carina and usually below the level of the fistula. When the tracheal tube is secured in this location, less gastric insufflation will occur through the fistula. The use of fiberoptic bronchoscopy after tracheal intubation has simplified positioning and verifying the position of the tracheal tube and has reduced the need for rigid bronchoscopy. *The tracheal tube should be carefully secured; if the tracheal tube is withdrawn to the position of the fistula opening, adequate pulmonary ventilation cannot be guaranteed.* A stethoscope placed over the left chest (usually best in the axilla) may be helpful in detecting accidental advancement of the tracheal tube into the right main-stem bronchus. An arterial line allows monitoring of blood gas values during the procedure. Pulse oximetry is particularly helpful in detecting partial displacement of the tracheal tube. Preterm infants with poorly compliant lungs occasionally require positive-pressure ventilation.<sup>172,173</sup>

Preferential ventilation through the fistula (the path of least resistance) may result in inadequate pulmonary gas exchange because the air leak through the fistula and into the stomach might increase the intraabdominal pressure, causing the diaphragm to press on the lungs and thereby lead to atelectasis. A staged preoperative gastrostomy was commonly used in the past to avoid this complication. However, although gastrostomy may avert life-threatening gastric rupture, it also may contribute to ineffective ventilation as a result of a bronchocutaneous fistula. A spontaneous breathing technique often results in little gastric

**FIGURE 36-4** **A**, The three most common forms of esophageal atresia are presented. The most common form (approximately 85%) consists of a dilated proximal esophageal pouch and a fistula between the distal trachea and distal esophagus (*left*). The second most common form consists of esophageal atresia alone (*middle*). Neonates with tracheoesophageal fistula alone (*right*) often present with pneumonia as the initial manifestation. **B**, The classic presentation is of a newborn with excessive secretions who spits up during the initial feeding; inability to pass a nasogastric tube (*arrow*) is pathognomonic. (**A**, From Coran AG, Behrendt DM, Weintraub WH, Lee DC: *Surgery of the neonate*. Boston: Little, Brown; 1978, p. 46. **B**, Courtesy Dr. Daniel P. Doody.)

insufflation. Although positive-pressure ventilation may cause gastric dilation, ventilation is usually successful because the compliance of the lungs is greater than that of the distended stomach. Pneumoperitoneum can be managed by emergent needle decompression of the left upper abdominal quadrant. Strategies to ensure adequate ventilation include one-lung ventilation, tracheal intubation distal to the fistula, or Fogarty catheter occlusion of the fistula. If a staged gastrostomy has been performed, a Fogarty catheter passed retrograde through the gastrostomy can be used to occlude the esophagus from below. This approach offers the advantage of avoiding bronchoscopy to pass a Fogarty catheter into the fistula through the trachea in an infant with pulmonary compromise.<sup>174</sup> An epidural catheter threaded from the caudal to the thoracic space may provide a means to give postoperative analgesia in patients who have had TEF repairs (E-Fig. 36-2).

Following correction of the defect, absorptive atelectasis in pulmonary segments may require ventilation with long inspiratory times to reexpand alveoli. This measure is generally a transient necessity. Early extubation is desirable because it prevents prolonged pressure of the endotracheal tube on the suture line. However, a substantial proportion of these infants will require reintubation because of secretions or tracheobronchomalacia. Therefore, at the end of the procedure, a joint decision is made with the surgeon regarding whether to extubate, balancing the child's cardiopulmonary stability with the desire to remove the tracheal tube as soon as possible. Recurrent laryngeal injury, overlooked additional fistulas, and recurrent fistulas may also complicate recovery.

### Diseases of the Lung Parenchyma

Parenchymal lesions may be congenital or acquired. Lesions may include lung hypoplasia if interruption of parenchymal growth

occurs early in gestation. Pulmonary cysts may be clinically insignificant until inflation with NO or excessive positive-pressure ventilation leads to gas trapping followed by atelectasis of adjacent areas as a result of compression. Shift of mediastinal contents from marked cyst distention may compromise cardiovascular function.

The small diameter of a neonate's airway makes double-lumen tracheal tubes impractical. Nevertheless, selective bronchial intubations may be successful, especially on the right. Fiberoptic bronchoscopes and guidewires aid in the placement of left-sided tracheal tubes. Bronchial blocking with 5F embolectomy catheters or the intrathoracic use of a clamp by the surgeons may allow selective ventilation of the lung.<sup>175-177</sup>

Avoiding increases in pulmonary artery pressure by preventing hypoxemia, hypercarbia, acidosis, hypothermia, and surgical stress is an essential aspect of managing neonates with compromised pulmonary systems.

### Specific Lesions

**CONGENITAL DIAPHRAGMATIC HERNIA.** As the diaphragm completes its formation during weeks 7 to 10 of gestation, anatomic defects that occur will permit the intrusion of abdominal contents into the thoracic cavity, resulting in congenital diaphragmatic hernia (CDH). Although infrequent, this defect in the diaphragm has profound consequences for the further development of the fetus's cardiopulmonary structure, necessitating extensive tertiary care center interventions.

Failure of the diaphragm tissues to fuse appropriately most often appears as the posterolateral Bochdalek type of hernia (90%). Approximately 9% are the anterior, Morgagni type of defects. Less than 1% are bilateral hernias, which are often fatal. The incidence of CDH ranges from 1 in 2000 to 1 in 5000 live births, the variation being attributable to underdiagnosed postdelivery

**E-FIGURE 36-2** Some surgeons prefer for the neonate to be extubated following tracheoesophageal fistula repair. A useful means for providing analgesia while minimizing respiratory depression is to thread a caudal catheter to the level of the surgical incision (*arrow*) and administer a continuous infusion of local anesthetic. It should be noted that even with such therapy some infants may require reintubation to clear secretions.

deaths among those neonates severely affected. Equal representation occurs among the genders, although some larger, population-based studies have demonstrated a male preponderance.<sup>178</sup>

Environmental and genetic variables (some poorly understood) contribute to the frequency and presentation of CDH. In neonates in whom the hernia is the only health issue, the risk of recurrence for future pregnancies is small (2%). Neonates with the Bochdalek type of hernia are more likely to have concurrent birth defects, including a 20% to 40% chance of congenital heart defects and a 5% to 15% chance of chromosomal abnormalities.<sup>179</sup> CDH is associated with genitourinary and gastrointestinal malformations, as well as chromosomal anomalies, including trisomy 13, trisomy 18, tetrasomy, and 12p mosaicism.

Prenatal diagnosis of CDH has become an effective tool in furthering the treatment modalities of affected neonates and counseling expectant parents. Level 2 ultrasonography is required for antenatal diagnosis of CDH.<sup>180</sup> Ultrasound examination findings suggestive of the presence of CDH include polyhydramnios, an intrathoracic gastric bubble, and mediastinal shift away from the herniation site. Additional diagnostic testing may include amniocentesis and karyotyping for the delineation of any coexisting chromosomal abnormalities. Abnormally low levels of maternal serum  $\alpha$ -fetoprotein are also associated with CDH. The importance of prenatal diagnosis cannot be overemphasized because prior knowledge of the defect will permit the arrangement for delivery at a tertiary care center equipped to provide support. In addition, a handful of research centers offer advanced treatment options such as fetal-based corrective surgical procedures.<sup>181,182</sup> Antenatal diagnosis has allowed the development of risk stratification for fetuses with CDH. The constellation of CDH with liver herniation and a small lung-to-head ratio is often indicative of high postnatal mortality. However, newer surgical techniques performed in utero have attempted to address this issue. Temporary fetoscopic tracheal plugging, performed between 25 and 28 weeks gestation, prevents the normal outflow of surfactant-rich fetal lung fluid.<sup>183</sup> The retained volume subsequently enlarges the fetal lungs, accelerates growth, and reduces the mass effect of herniated viscera. This is coupled with another advanced technique (the ex utero intrapartum tracheoplasty [EXIT] procedure) used to unplug the trachea at the time of birth. During the EXIT procedure, placental support of the fetus continues until the airway has been secured (see Chapter 37). Only a small number of centers offer this treatment option, so only a few randomized, controlled studies have been performed to determine long-term outcomes for fetuses with CDH.<sup>183-185</sup> Further clinical experience is needed before the comparative long-term efficacy of such fetal therapies can be determined.

Emergent surgical closure of the defect was the standard of care in the 1980s, because of the prevalent belief that reduction of the herniated viscera would facilitate lung growth and a return toward normal lung size and function. A thorough understanding of the specific pathophysiology of the defect prompted the application of new medical therapies and changed the timing of open surgical repair.<sup>186</sup> Although the mere presence of abdominal viscera (which may include intestine, liver, spleen and stomach) in the thoracic cavity is not in itself life-threatening, the compressive effects of these viscera on the developing pulmonary structures presents a significant obstacle to the smooth transition from a fetal to neonatal circulatory pattern. The abnormal compression of pulmonary structures is the hallmark of CDH and its cardiopulmonary sequelae.<sup>187-190</sup> Lung growth is severely restricted, especially during the pseudoglandular phase,

when multiplication of proximal airway divisions and the formation of supporting pulmonary arterial vasculature usually occur. Subsequently, fewer functional alveolar units and a grossly diminished surface area for effective gas exchange in the hypoplastic lungs develop. Lung hypoplasia is also associated with a decreased number of alveolar type II cells that results in a deficiency of surfactant apoprotein A (SP-A), which can be associated with alveolar instability, atelectasis, intrapulmonary shunting of deoxygenated blood, and inadequate gas exchange. These biochemical deficiencies are only partially ameliorated with exogenous surfactant treatment. A unilateral CDH may still restrict the normal growth of both lungs depending on the degree of mass effect. The severity of the lung hypoplasia, and its associated morbidity and mortality, were negatively correlated with the gestational age at the time the hernia occurred. The abdominal mass effect, which hinders normal lung growth, also reduces the total cross-sectional area and may alter the reactivity of the arterioles, resulting in pulmonary hypertension. Decreased pulmonary blood flow prevents the normal transition from an intrauterine to extrauterine circulatory pattern. Right-to-left shunting via the PFO and PDA, with associated severe hypoxemia, poses an immediate threat to the neonate. The increased volume of intrathoracic contents may also cause caval compression, with subsequent reductions of preload and cardiac output.

CDH most often presents as severe respiratory distress in the neonate, a direct consequence of lung hypoplasia and inadequate pulmonary gas exchange. Tachycardia, tachypnea, and cyanosis can be observed shortly after delivery. The abdomen may appear concave because of the displacement of viscera into the thorax (the classically described scaphoid abdomen). The mediastinum may be shifted as a result of the herniated viscera (E-Fig. 36-3). Neonates with the Morgagni type of hernia may present with less severe respiratory compromise but with symptoms of bowel obstruction.

The initial management of neonatal respiratory failure associated with CDH is directed at refining oxygenation and ventilation. Definitive airway control is a priority and should be achieved soon after delivery. Mask ventilation is generally avoided in an attempt to limit gastric insufflation that can cause visceral distention and increase the mass effect within the thorax. Once the airway has been secured, mechanical ventilation should be instituted at the lowest peak airway pressures to achieve clearance of CO<sub>2</sub> and adequate oxygenation at an acceptable inspired O<sub>2</sub> concentration. A nasogastric tube should be passed to decompress the intestinal contents. Serial arterial blood gas analysis and chest radiographs are essential in establishing the prognosis. Studies suggest that alveolar-arterial O<sub>2</sub> differentials (A-aO<sub>2</sub>) and serial PaCO<sub>2</sub> measurements are useful predictors for survival.<sup>191,192</sup> If the blood gas values are unacceptable, further strategies, including high-frequency ventilation, oscillation, and ECMO may be considered (see later). An echocardiogram will identify the cardiac anatomy and specific flow characteristics, permitting assessment of pulmonary hypertension and right heart dysfunction, as well as major vessels that may be used for ECMO. Concurrent congenital heart defects also may be diagnosed at this time. Cranial ultrasonography is useful to diagnose intraventricular bleeding, an important consideration for potential institution of ECMO. Appropriate intravenous access and invasive blood pressure monitoring should be established as soon as feasible.

Several ventilator strategies have been successfully used and include conventional mechanical ventilation, high-frequency

**E-FIGURE 36-3** Chest radiograph of a neonate with a left diaphragmatic hernia. Note shifting of trachea and bronchi into the right chest (*arrow*).

oscillatory ventilation, gentle ventilation with permissive hypercapnia, and intratracheal pulmonary ventilation. All of these methods seek to avoid the harmful effects of volutrauma and conditions known to increase pulmonary vascular resistance (hypoxemia, acidosis, hypotension, and significant hypercarbia).<sup>190,193-195</sup> CDH may have variable presentations and degrees of severity; thus no single technique may address all ventilation requirements. Settings that allow for rapid low tidal volumes and limit peak inspiratory pressures will reduce the degree of volutrauma and the potential for pneumothorax. Deliberate alkalosis may increase pulmonary blood flow and decrease  $\dot{V}-\dot{Q}$  mismatch, but possibly worsening the risk of volutrauma. In neonates in whom oxygenation remains compromised, global tissue hypoxemia will result in significant metabolic acidosis, which may be treated with intravenous bicarbonate infusions, if adequate ventilation is ensured.

Sedation with opioids and benzodiazepines is important to ensure the neonate tolerates the instrumented airway and limit catecholamine responses, which may increase pulmonary vascular resistance. The benefit of vasodilator therapies (prostaglandin  $E_1$  [ $PGE_1$ ] and nitrates) remains controversial. Although these agents may reduce pulmonary vascular resistance, they often do so at the expense of systemic hypotension, because they are not specific pulmonary vasodilators. Severe cardiovascular compromise should be treated with volume replacement and inotropic support, although the physician must be aware of the risk of volume overload and pulmonary edema.

Inhaled NO has been used for infants with CDH complicated by refractory pulmonary hypertension because it is a specific pulmonary vasodilator. Reducing pulmonary vascular resistance in the neonate with CDH will decrease right-to-left shunting and improve oxygenation. Despite the decrease in pulmonary resistance,  $PGE_1$  infusion may be required to keep the PDA open and avoid right ventricular failure. A significant advantage of inhaled NO therapy is the avoidance of systemic hypotension. The agent is short acting and must be delivered through a specially metered flow apparatus. Although several studies suggest that inhaled NO is not effective in treating hypoxemia associated with CDH, it has been an effective rescue therapy in some cases, particularly when ECMO is not readily available. Animal studies suggest that exogenous surfactant enhances the effectiveness of inhaled NO in CDH, perhaps by recruiting pulmonary tissue. However, these observations have not yet been conclusively confirmed.

ECMO has been used in several centers to treat infants with CDH in whom other medical and ventilator therapies have not been effective. Although the mechanism whereby ECMO improves the outcome of infants with CDH is not fully understood, ECMO can act as a temporizing measure, permitting the lungs to rest and mature while providing appropriate gas exchange through membrane oxygenators.<sup>196</sup> ECMO has also been used as a rescue technique in postoperative infants who decompensate following surgical closure (most often from the incompletely understood phenomenon of rebound pulmonary hypertension). There are multiple inclusion and exclusion criteria (e.g., the presence of high-grade intraventricular hemorrhage is a contraindication because of systemic heparinization).<sup>197</sup> Venovenous (VV) and venoarterial (VA) are two variations of the extracorporeal circuit, and refer to the location of the inflow and outflow catheters. In VV circuits, a double-lumen catheter resides in the internal jugular vein. VA circuits require the placement of two catheters (internal jugular vein and carotid artery) and the ligation of the carotid ipsilateral artery to prevent backflow. In

general, VA ECMO is used for neonates who require additional hemodynamic support and greater delivered  $O_2$  concentrations. The widespread institution of ECMO has promoted the early stabilization of infants with CDH. The procedure is invasive, however, and complications may arise as a result of systemic anticoagulation and intracranial bleeding. Emboli, infection, vascular damage, and circuit failure are additional concerns.

Currently, surgical repair is delayed until the neonate has been optimized using applicable treatment modalities. Timing of the procedure is variable, based on individual infant condition and institutional experience. A transabdominal approach will replace the herniated viscera and conclude with primary closure of the defect, or if the defect is large, a synthetic patch will be needed to augment the repair. Anesthetic management focuses on supportive care during transport and surgery. Adequate central access should be established, and ventilator settings should mimic those used in the ICU. Serial blood gas sampling will guide changes in respiratory management during closure of the diaphragm. It should be noted that the compliance of the chest actually decreases after surgical correction of the hernia and return of the displaced abdominal organs to the abdomen.<sup>198</sup> This paradoxical effect is the result of distending the abdomen and increasing tension on the diaphragm without relief above the diaphragm (i.e., the hypoplastic lung remains unchanged and nondistensible). If the compliance decreases substantively, the outcome may be fatal.

High-dose opioid techniques decrease catecholamine and other stress hormonal responses to surgical manipulation. Inhalational anesthetics may be tolerated in small concentrations, depending upon the hemodynamic status. Nitrous oxide ( $N_2O$ ) should be avoided because it will expand any air-filled cavities (e.g., the bowels) and limit the inspired  $O_2$  concentration.

The use of current multimodal therapies presents a special challenge to the anesthesiologist. Transporting a neonate on ECMO and other agents such as inhaled NO remains a dangerous part of the anesthetic care. Machine malfunctions and disconnects can be sudden and catastrophic. In addition, standard anesthesia machines may not be able to deliver special ventilation modes such as high-frequency oscillatory ventilation. Some tertiary care centers possess facilities for the surgical repair to be conducted within the ICU.<sup>199</sup> Neonates receiving ECMO may require higher doses of opioids delivered via the extracorporeal circuits because of the increased volume of distribution within the circuit, altered plasma clearance rates, and variable degrees of drug adhesion to the synthetic tubing.<sup>200-203</sup>

Despite many years of clinical investigation and the introduction of multiple new approaches, the overall survival for neonates with CDH has remained essentially unchanged, with widely varying mortality rates among institutions.<sup>204</sup> The optimal therapy for the neonate with CDH is unclear. Survivors often have medical issues that require further treatment after hospital discharge, including gastroesophageal reflux, growth impairment, developmental delay, and sensorineural hearing loss. Additional research and multicenter trials are needed to improve clinical outcomes and advance our understanding of long-term issues associated with survival.<sup>205</sup>

### *Congenital Bronchogenic and Pulmonary Cysts*

Congenital bronchogenic and pulmonary cysts represent arrests of embryologic pulmonary tissue during early fetal lung development.<sup>206</sup> These cysts may be centrally located within the mediastinum and produce obstruction by a mass effect.<sup>207</sup> They may

also be located at the carina and cause obstruction or distal gas trapping by a ball-valve effect. Those located in the hilum, in the paratracheal region, or in the lung parenchyma may lead to chronic respiratory illness from infection and abscess formation.<sup>208,209</sup> Congenital cysts are occasionally diagnosed only after rupture of the cyst produces hemorrhage or bronchopulmonary fistula formation.<sup>206,209</sup>

Anesthetic management is directed at minimizing further enlargement of the cyst because a communication may exist with the airway. Awake (sedated) intubation or intubation with an inhalation induction, followed by maintenance of spontaneous ventilation, if possible, until the thorax is opened, may reduce the potential for sudden enlargement of the cyst. If assisted ventilation is required, low peak inspiratory pressures should be used. Should the cyst be fluid filled or infected, selective bronchial blocking may be helpful in protecting the unaffected lung.<sup>175,176</sup> Nitrous oxide and positive-pressure ventilation without adequate expiratory time should be avoided to decrease the possibility of enlarging the cyst. If these attempts are not successful and the cyst enlarges to the point of occluding the airway or compromising the circulation, needle aspiration to reduce the size of the cyst and facilitate oxygenation and ventilation should be considered. If this method is unsuccessful, emergency thoracostomy may be lifesaving.

### ***Congenital Lobar Emphysema***

Congenital lobar emphysema most commonly affects the left upper lobe but may involve the entire lung (Fig. 36-5).<sup>210,211</sup> Congenital heart disease coexists in approximately 15% of infants.<sup>212</sup> Patients usually have with progressive respiratory failure, unilateral thoracic hyperexpansion, atelectasis of the contralateral lung, and possibly mediastinal shift with cardiovascular compromise.<sup>213</sup> The anesthetic care is focused on minimizing expansion of the emphysema and is similar to that for patients with pulmonary cysts.

### **GASTROINTESTINAL PROBLEMS**

The types of emergency surgical conditions can be categorized as (1) lesions that are obstructive, (2) those that represent a compromise in intestinal blood supply, and (3) a combination of these two.

Obstructive lesions may be congenital or acquired. Congenital obstruction of the gastrointestinal tract may be suggested by an abnormal increase in maternal weight, polyhydramnios, fetal size greater than normal for gestational age, and fetal abdominal distention detected by ultrasonography. Neonates with acquired lesions may soon after birth have vomiting, abdominal distention, and late passage of meconium (Fig. 36-6). Associated findings may include aspiration pneumonia, dehydration, hypovolemia, and metabolic abnormalities. Unless life-threatening compromise of organ blood flow occurs, these lesions do not require emergent care. Instead, a priority is to reestablish euolemia and a metabolically stable state before surgery. Neonates with obstructive lesions usually undergo general anesthesia with tracheal intubation. Induction of general anesthesia may follow an awake intubation if a difficult intubation is anticipated or if active vomiting occurs; a rapid-sequence induction may be used if no airway anomaly is apparent. A rapid-sequence intubation may proceed in a manner similar to that for children and adults. Desaturation after apnea is more rapid, however, because the  $O_2$  consumption of a neonate is twice that of an adult and the alveolar stores are reduced. If

**FIGURE 36-5** **A**, Radiograph from an infant with congenital lobar emphysema demonstrates hyperinflation of the left lung with herniation across the midline (arrows) and mediastinal shift. **B**, Intraoperative photograph shows the emphysematous lobe bulging through the thoracotomy incision. (From Coté CJ: The anesthetic management of congenital lobar emphysema. *Anesthesiology* 1978;49:296.)

**FIGURE 36-6** Neonate with evidence of a bowel obstruction. Note the distended loops of bowel. This infant will require either an awake intubation or a rapid sequence induction to secure the airway.

surgery is an emergency and the intravascular volume status of the neonate is tenuous, ketamine may be used for induction in place of propofol. A stylet within the tracheal tube should be used to facilitate placement during awake intubations but is infrequently needed in neonates with normal airways. If a stylet is used, it may cause injury to the airway if it extends beyond the bevel of the tube. After tracheal intubation, general anesthesia with either an inhalation (without N<sub>2</sub>O) or opioid technique and neuromuscular blockade is generally used. Air should be blended with O<sub>2</sub> to decrease the inspired O<sub>2</sub> concentration to a safe concentration. As described earlier, these neonates may have poor renal perfusion; therefore pancuronium and many antibiotics may have prolonged action. In addition, if hepatic blood flow is compromised, metabolism of opioids and muscle relaxants may be delayed.<sup>214,215</sup>

Infants with lesions that compromise bowel blood flow and cause ischemia are extremely ill. These infants may have a tender and distended abdomen, bloody stools, vomiting, hypotension, metabolic abnormalities, anemia, leukopenia, and thrombocytopenia. Abdominal radiographic examination may reveal distended intestinal loops, decreased bowel gas, and perforation.

Emergency surgery is required and directed at removing necrotic tissue, closing perforations, and reestablishing normal perfusion to the intestine. Blood and blood products should be immediately available, including uncrossmatched blood if cross-matched blood is not available, fresh frozen plasma, and platelets. These infants are not appropriate candidates for regional anesthesia. Before anesthetic induction, adequate venous access should be ensured because they require increased intraoperative fluids and may require rapid transfusion of blood products (which is in general not possible through 24-gauge intravenous catheters or peripherally inserted central catheter [PICC] lines). It may be prudent to replace the umbilical arterial line with a peripheral arterial line if it is possible that the line may obstruct mesenteric blood flow. The volume status should be optimized and dopamine 5 µg/kg/min infused to increase blood flow to the gut. If poor peripheral perfusion occurs secondary to shunting of blood through a PDA, carefully titrated intravenous fluids and sympathomimetics may improve cardiac output and organ perfusion.

### Specific Lesions

#### *Hypertrophic Pyloric Stenosis*

Pyloric stenosis usually manifests within weeks 2 to 6 of life with nonbilious vomiting. This lesion occurs more frequently in first-born males; the incidence is approximately 1 in 500 live births (Fig. 36-7).<sup>216</sup> Pyloric stenosis represents hypertrophy of the muscularis layer of the pylorus and can often be palpated as an olive-shaped mass between the midline and right upper quadrant. The lesion is most commonly delineated by ultrasonography<sup>217</sup> or rarely with a barium swallow and radiographic examination.

With protracted vomiting, these infants may become hypokalemic, hypochloremic, and alkalotic.<sup>218</sup> The renal response to vomiting is twofold. Initially, serum pH is defended by excretion of alkaline urine with sodium and potassium loss; later, with depletion of these electrolytes, the kidneys secrete acidic urine (paradoxical aciduria), further increasing the metabolic alkalosis. Hypocalcemia may be associated with the hyponatremia. With further fluid loss prerenal azotemia may portend hypovolemic shock and metabolic acidosis. Hemoconcentration may result in polycythemia. This lesion does not mandate an emergency surgical procedure; therefore intravascular volume and metabolic stabilization and correction are a priority.

**FIGURE 36-7** A, Barium swallow and abdominal radiograph of an infant with pyloric stenosis demonstrates a high degree of obstruction of the gastric outflow tract with a "wisp" of barium escaping through the pylorus (arrow). B, The hypertrophied pylorus. C, Surgical myotomy relieved the obstruction. (Courtesy Dr. Daniel P. Doody.)

Suctioning an in situ orogastric or nasogastric tube seldom empties the stomach. A freshly inserted wide-bore orogastric tube almost always removes additional residual gastric contents; this step is especially important for infants who have had a barium contrast radiographic study. One study found nearly complete emptying of the gastric contents if the infant's stomach is suctioned in the right and left lateral as well as the supine positions with a vented catheter (e.g., Salem sump).<sup>219</sup> Therefore the stomach is aspirated immediately before induction using a large-bore orogastric tube as described. These infants are most commonly managed with an intravenous induction (although some centers have performed inhalational inductions for more than 30 years for this abdominal defect) because vomiting during induction might result in serious pulmonary aspiration. A rapid-sequence induction is preferred. Intermediate acting NMBDs are infrequently required. However, if the intubation is anticipated to be difficult, a sedated "awake" intubation is carried out before the induction of anesthesia. Inhalation or balanced anesthesia may then be used for maintenance. These surgeries are brief and thus the concentration of inhalational anesthetic must be carefully titrated because these infants are notoriously slow to recover from anesthesia. Infants should be extubated once fully awake and vigorous. Feedings are usually begun soon after surgery, and the postoperative course is generally uncomplicated. Local infiltration of the incision site with a long-acting local anesthetic generally provides complete analgesia.

Some surgeons will perform this procedure laparoscopically or through a periumbilical incision. Laparoscopic techniques may have profound hemodynamic and respiratory effects (see Chapter 27).<sup>220,221</sup> One further consideration is the number of case reports describing apnea in this population<sup>222</sup>; some centers advocate postoperative apnea monitoring.

#### ***Duodenal and Ileal Obstruction***

Congenital duodenal and ileal obstructions (atresia, stenosis, annular pancreas, meconium ileus) are often associated with other anomalies. For example, 20% to 30% of neonates with duodenal atresia have trisomy 21, with a high likelihood of associated cardiac lesions such as atrial septal defect, ventricular septal defect, or atrioventricular canal. Neonates with intestinal atresia are frequently preterm or may have other associated anomalies, such as malrotation of the gut, volvulus, and abdominal wall defects.<sup>223</sup> Meconium ileus occurs in 10% to 15% of neonates with cystic fibrosis. It may present either as terminal ileal obstruction by viscid meconium or as bowel atresia. Hyperosmolar enemas are frequently administered to these infants in an effort to clear the viscid meconium plugs. These enemas may result in serious shifts in intravascular volume, leading to hypovolemia requiring aggressive treatment before anesthetic induction.

Duodenal atresia is associated with bilious vomiting beginning within the first 24 to 48 hours after birth. Radiographs of the abdomen demonstrate the pathognomonic double-bubble sign formed by air contrast of the dilated stomach and proximal duodenum; the remaining bowel is devoid of air (Fig. 36-8). With jejunoileal atresia, air-fluid levels are observed throughout the abdomen. With distal ileal obstruction, a barium enema may demonstrate a microcolon. The typical radiographic presentation of meconium ileus is a soap-bubble mass in the right lower abdomen and absence of air-fluid levels. Initial stabilization of neonates with these lesions is directed at fluid and metabolic resuscitation. Anesthetic management proceeds after suctioning of contrast agent and other stomach contents. Awake intubation

**FIGURE 36-8** Abdominal radiograph of a neonate with congenital duodenal atresia demonstrating a classic double-bubble sign (arrows). Note that the remainder of the bowel is devoid of air, indicating complete obstruction.

may be indicated in volume-depleted or actively vomiting infants; rapid-sequence induction is used in hemodynamically stable infants with normal airway anatomy. N<sub>2</sub>O should be avoided to minimize intestinal distention. Neuromuscular blockade is generally necessary to facilitate abdominal exploration; use of a neuromuscular blocking agent also decreases or avoids the need for high concentrations of potent inhalation agents, which are poorly tolerated by hypovolemic neonates.

#### ***Infantile Hernia***

Infantile hernia usually presents within the first 6 months after birth. Although the potential for incarceration through the inguinal canal is present in greater than 90% of neonates, it occurs in only 3% to 5% of full-term infants and 30% of preterm infants.<sup>224</sup> With incarceration or strangulation of bowel or gonads, emergency correction is indicated. Incarcerated hernias with or without strangulation should be treated similarly to bowel obstruction. A rapid-sequence or awake intubation should be used at the induction of general anesthesia. An inhalation technique without N<sub>2</sub>O or an opioid technique may be used after intubation.

Elective repair of a nonincarcerated hernia can be carried out with either general or regional anesthesia when there is no acute bowel obstruction (e.g., a reduced inguinal hernia).<sup>225-228</sup> An intravenous line should be placed before anesthetic induction if there is any concern about the volume status. Because blood pressure instability is unusual in infants undergoing spinal anesthesia,<sup>229</sup> placement of an intravenous line in the lower extremity may follow the onset of sensory block. Similarly, blood pressure monitoring may be accomplished by using a blood pressure cuff placed on the lower (anesthetized) extremity. Swaddling and a pacifier often are all that is required for sedation.

Spinal anesthesia may be administered through a 1½-inch, 22-gauge spinal needle (see also Fig. 41-8). Once the block is placed, the infant should be maintained in the supine position. Leg lifting, especially during placement of the electrocautery grounding pad, should be avoided because it has been associated

with a high spinal blockade (see also Fig. 41-9).<sup>230</sup> Rather, log-roll or lift the entire infant to apply the cautery pad. Apnea or sudden cessation of crying may be the presenting sign of a high spinal blockade in a neonate.

Because hernia repair is a common operation in former preterm infants, this population is at greatest risk for postoperative life-threatening apnea.<sup>19-21,231,232</sup> Outpatient repair of inguinal hernia in former preterm infants is contraindicated in those infants 55 weeks or younger postconceptional age (see also Fig. 4-7 and E-Fig. 4-6). Because apnea may occur even after regional anesthesia, provision for postoperative monitoring must be available.<sup>233</sup>

### Imperforate Anus

Imperforate anus is generally recognized at the initial physical examination or by failure to pass meconium within the first 48 hours of life. Neonates with imperforate anus are likely to have associated anomalies of the urogenital sinus, as well as those associated with the entire spectrum of the VACTERL association.<sup>171</sup> Some infants require a decompressive colostomy before definitive surgery. It may be prudent to perform echocardiography to rule out associated congenital heart disease before anesthetic induction. Preductal and postductal O<sub>2</sub> saturation determinations may be of value. If these infants exhibit signs of bowel obstruction, they should undergo anesthesia in a manner similar to that in others with obstructive lesions.

### Necrotizing Enterocolitis

Necrotizing enterocolitis is not an anomaly but an illness found predominantly in preterm infants.<sup>234</sup> The incidence is 5% to 15% in infants less than 1500 grams birth weight, and the mortality rate is 10% to 30%.<sup>235</sup> Morbidity associated with necrotizing enterocolitis includes short-bowel syndrome, sepsis, and adhesions associated with bowel obstruction. Necrotizing enterocolitis is associated with birth asphyxia, hypotension, RDS, PDA, recurrent apnea, intestinal ischemia, umbilical vessel cannulation, systemic infections, and early feedings.<sup>110,236-238</sup>

Initial signs of necrotizing enterocolitis include temperature instability, poor feeding with gastric residuals or vomiting, malabsorption of feedings (positive stool-reducing substances), lethargy, hyperglycemia, and heme-positive or overtly bloody stools. Affected infants may appear very ill and have a distended and tender abdomen. Radiographic examination may initially suggest an ileus with edematous bowel and later demonstrate gas in the intestinal wall (pneumatosis intestinalis) and in the hepatobiliary tract or portal venous system (Fig. 36-9). When perforation has occurred, free air within the abdominal cavity can be appreciated by radiologic examination of the abdomen.

Infants generally have metabolic and hematologic abnormalities, including hyperglycemia, thrombocytopenia, coagulopathy, and anemia. Hypotension, metabolic acidosis, and prerenal azotemia are other significant findings in severe cases. Initial treatment includes discontinuation of enteral feedings and decompression of the abdomen by means of low-pressure continuous nasogastric or orogastric suctioning. Wide-spectrum antibiotics are administered, although no specific bacteria are associated with necrotizing enterocolitis. Dopamine infusions may be required to increase the cardiac output and improve intestinal perfusion. Umbilical arterial lines are replaced with a peripheral arterial line so that mesenteric blood flow is not compromised. Indications for surgery can vary from surgeon to surgeon but may include abdominal viscus perforation resulting

**FIGURE 36-9** Abdominal radiograph of a neonate with necrotizing enterocolitis demonstrates generalized bowel distention (ileus), small amount of pneumatosis intestinalis in left upper quadrant (arrow), and gas outlining the intrahepatic portal vein (arrowhead). (Courtesy Dr. Sjik J. Westra.)

in free air, persistence of a bowel loop on serial abdominal radiographs, or persistent metabolic acidosis with clinically important hyperkalemia, indicating the presence of necrotic tissue.<sup>239</sup>

Adequate preparation before surgery is important. Blood, fresh frozen plasma, and platelets likely will be required. Dopamine infusions may be necessary to improve renal and intestinal perfusion and cardiac output. Patients often are already intubated; otherwise, rapid-sequence or awake intubation is indicated. Because these infants are septic and volume depleted, potent inhalation agents are poorly tolerated and generally avoided. An opioid and muscle relaxant technique, avoiding N<sub>2</sub>O, is preferred. These infants usually have very large volume requirements; it is common for 1 or more blood volumes of fluid infusion to be required as a result of massive third-space losses. In addition, severe coagulopathy may result in sudden, catastrophic generalized hemorrhage (Fig. 36-10). Platelet transfusion is often needed before surgical incision.

### Omphalocele and Gastroschisis

Neonates with omphalocele and gastroschisis have defects in the abdominal wall and may present with impaired blood supply to the herniated organs, intestinal obstruction, and major intravascular fluid deficits. The differences between omphalocele and gastroschisis are summarized in Table 36-4.

Omphalocele represents a failure of the gut to migrate from the yolk sac into the abdomen during gestation (Fig. 36-11, A).<sup>240,241</sup> It occurs in 1 in 6000 births.<sup>242</sup> Infants with omphalocele may have associated genetic, cardiac, urologic (exstrophy of the bladder; see Fig. 36-11, B), and metabolic abnormalities (Beckwith-Wiedemann syndrome with visceromegaly, hypoglycemia, polycythemia).<sup>243</sup> The herniated viscera emerge from the umbilicus and are covered with a membranous sac; the bowel is morphologically and usually functionally normal.

**FIGURE 36-10** A preterm neonate with severe necrotizing enterocolitis and intestinal necrosis. **A**, Abdominal discoloration consistent with dead bowel. **B**, Necrotizing enterocolitis with segment of dead bowel (*top*) and evidence of free stool in the abdomen (*arrow*). These infants often have bowel perforation and hemorrhage from bowel or liver. They can have severe hypotension requiring vasopressor support and enormous volume requirements. Moreover, because of hemorrhage and disseminated intravascular coagulopathy, these infants will generally require transfusions of blood, platelets, and fresh frozen plasma. Some practitioners also advocate administration of vitamin K. (Courtesy Dr. Daniel P. Doody.)

**FIGURE 36-11** **A**, Omphalocele covered with a membranous sac; the defect arises at the umbilicus. **B**, Omphalocele with associated exstrophy of the bladder. **C**, Gastroschisis; note the absence of a membranous sac. In contrast to omphalocele, the gastroschisis anomaly is periumbilical.

**TABLE 36-4** Comparison of Omphalocele and Gastroschisis

Comparison Factors	Omphalocele	Gastroschisis
Cause	Failure of gut migration from yolk sac into abdomen	Occlusion of omphalomesenteric artery
Location	Within umbilical cord	Periumbilical
Associated lesions	Beckwith-Wiedemann syndrome (macroglossia, gigantism, hypoglycemia, hyperviscosity) Congenital heart disease Exstrophy of bladder	Exposed gut inflammation, edema, dilation, and foreshortened

Gastroschisis develops as a result of occlusion of the omphalomesenteric artery during gestation.<sup>241,244</sup> It occurs in 1 in 15,000 births and is usually not associated with other congenital anomalies. The herniated viscera and intestines are periumbilical, usually on the right, and are exposed to air after delivery, resulting in inflammation, edema, and dilated, foreshortened, and functionally abnormal bowel (see Fig. 36-11, C).<sup>245, 246</sup>

Management of these lesions from birth until surgery is directed at maintaining perfusion to the herniated viscera and reduction of fluid loss from exposed visceral surfaces by covering the mucosal surfaces with sterile, saline-soaked dressings. A plastic wrap further decreases evaporative volume losses and the tendency to develop hypothermia. These anomalies represent a wide spectrum of pathology and require individualized assessment of intravascular volume status and fluid replacement. When these infants arrive in the ICU, fluid resuscitation is instituted; neonates with gastroschisis lose more fluid than those with omphaloceles and thus require repeat boluses of 20 mL/kg isotonic fluids to replace evaporative and third-space losses.<sup>247</sup>

Anesthetic management is directed at continued volume resuscitation and measures to prevent hypothermia. Aspiration of stomach contents should be performed. Rapid-sequence induction or awake intubation is carried out. Neuromuscular blockade facilitates reduction of the eviscerated organs and bowel; however, abdominal closure may be associated with markedly increased intraabdominal pressure (E-Fig. 36-4). The effects of increased intraabdominal pressure are twofold: (1) decreased organ perfusion and (2) decreased ventilatory reserve. The increase in intraabdominal pressure may lead to decreased intestinal, renal, and hepatic perfusion and secondarily impaired organ function. This may lead to markedly altered drug metabolism and prolonged drug effect. The bowel may become edematous, and urine output may be reduced as a result of renal congestion. Venous return from the lower body also may be reduced, resulting in lower extremity congestion and cyanosis. Blood pressure and pulse oximetry determinations from a lower extremity may be different from those in the upper extremity. Significantly decreased diaphragmatic function and bilateral lower lobe atelectasis may occur, leading to respiratory failure.<sup>248</sup> Transduction of intragastric or bladder pressures may be a diagnostic adjunct.<sup>249</sup>

If complete reduction is not possible, a staged reduction is carried out. The intestine is covered with a silastic pouch, and the size of the pouch is subsequently reduced in stages either in the operating room or intensive care unit, thus

allowing the abdominal cavity gradually to accommodate the increased mass without severely compromising ventilation or organ perfusion.<sup>250,251</sup>

### *Malrotation and Midgut Volvulus*

Malrotation and midgut volvulus result from abnormal migration or incomplete rotation of the intestines from the yolk sac back into the abdomen.<sup>252</sup> Rotation of the intestine around the mesentery may produce the abnormal location of the ileocecal valve in the right upper quadrant and kinking or compression of its vascular supply. If the malrotation occurs during development, atretic segments of bowel are formed. If the kinking or compression occurs after the bowel is normally developed, bowel necrosis may result.

These infants present with bilious emesis, a tender and distended abdomen, and increasing abdominal girth; bloody stools are an ominous sign. They may have hypotension, hypovolemia, and electrolyte abnormalities. Because delay in surgery may result in necrosis of the entire small intestine, fluid and electrolyte resuscitation begins preoperatively and continues during surgery. This is a true neonatal emergency, and surgery should proceed as expeditiously as possible. Blood and blood products should be available in the operating room. Note that the hematocrit may be falsely increased secondary to marked intravascular volume depletion. The indications for intraarterial monitoring depend on the severity of the infant's illness. Central venous pressure monitoring may improve assessment of intravascular volume status and assist in directing replacement and postoperative fluid management. However, if peripheral venous access is adequate, the operation should not be delayed to insert the central venous pressure line.

### *Hirschsprung Disease and Large-Bowel Obstruction*

Hirschsprung disease is the most common cause of neonatal colon obstruction and consists of the absence of parasympathetic ganglion cells (Auerbach and Meissner plexus) in the large intestine.<sup>253,254</sup> This deficiency creates a nonperistaltic segment of variable length, a tonically contracted anorectal sphincter, and delayed passage of meconium. Functional obstruction occurs at the level of the affected segment. The bowel may occasionally become distended to the point at which its blood supply is

**FIGURE 36-12** Toxic megacolon results in massive abdominal distention, fluid requirements, and sepsis. These infants require special consideration in airway management because of the high risk for aspiration and increased abdominal pressure.

**E-FIGURE 36-4** Closure of a large omphalocele or gastroschisis may result in a very tight abdominal closure that will require that the infant remain intubated after repair with relatively high peak end expiratory pressure; such patients may have reduced drug clearance as a result of impaired hepatic and renal blood flow and may experience impaired venous return to the heart.

compromised; perforation may occur, with resultant peritonitis. If the condition is not recognized and is left untreated, enteric bacteria may invade the bowel wall and subsequently enter the bloodstream, producing the toxic megacolon syndrome. Infants thus affected present with a distended, tender abdomen and hypotension and require massive volume replacement and vasopressor support (Fig. 36-12).

The majority of these neonates are diagnosed early because of bowel distention and failure to pass meconium. Bowel obstruction may be intermittent. Initial management is directed at

stabilizing the infant's fluid status. Infants with lower intestinal obstruction may require rapid-sequence induction or awake intubation. If the infant is volume depleted, potent inhalation agents are poorly tolerated. N<sub>2</sub>O should be avoided to prevent increasing bowel distention.

Future Considerations

THE ADVENT OF FETAL intervention introduced the concept of surgically correcting a known congenital defect in utero to avoid certain fetal demise. With improvements in prenatal imaging and surgical techniques, fetal interventions have grown to include diagnoses associated with intrauterine demise, as well as diseases associated with significant postnatal morbidity. The goal of fetal intervention is to improve the chances of normal fetal development and minimize postnatal morbidity.<sup>1</sup> Advances have changed some procedures from open in-utero interventions, which are associated with significant maternal risk, to percutaneous or fetoscopic techniques, thus improving the maternal risk-to-benefit ratio while diminishing postoperative uterine contractions associated with open procedures.

Fetal surgery differs from any other subspecialty of anesthesia because the anesthesiologist must care for two or possibly three patients at once, all with distinctive and, at times, conflicting requirements. The first is the mother who can express her level of discomfort, who can be monitored directly, and to whom drugs can be administered easily. The second (and possibly third) is the fetus. For the latter, detecting pain depends solely on indirect evidence, monitoring is limited at best, administering drugs is more complicated, and there is the possibility of long-term effects from procedures and drugs administered during early development. The anesthesiologist is required to provide both maternal and fetal anesthesia and analgesia while ensuring both maternal and fetal hemodynamic stability; a plan must be prepared to resuscitate the fetus if problems occur during the intervention.

## A Range of Anesthetic Options for Mother and Fetus

### MOTHER

Fetal interventions have been successfully performed with various anesthetic techniques; both maternal and fetal anesthetic requirements must be considered and may, in fact, be quite different. With some endoscopic interventions, the site of surgical intervention is not innervated; thus the fetus may not sense a noxious stimulus, and its anesthetic requirements are presumably minimal. Nevertheless, fetal immobility remains essential to procedural safety and success. Other interventions may require that a needle be inserted into the fetus, which may elicit a noxious stimulus and possibly even cause pain. Open procedures can produce significant noxious stimuli. In addition to surgical demands, each mother and fetus exhibit a unique physiologic, pharmacologic, and pathophysiologic profile; the anesthesiologist must evaluate the advantages and disadvantages of each anesthetic technique and select the safest anesthetic.<sup>2</sup>

### Local Anesthesia

Local anesthesia is almost exclusively used for trocar insertion sites with percutaneous procedures. The most obvious advantage is maternal safety, because the mother receives no intravenous (IV) medications. The disadvantages of this technique include increased risk of injury to the nonanesthetized, nonparalyzed fetus, no fetal analgesia, and no uterine relaxation. Patients on tocolytic therapy or those with polyhydramnios and uterine contractions may be at further risk of worsening contractions with this approach.

### Monitored Anesthesia Care

IV sedation involves the maternal administration of benzodiazepines, opioids, and occasionally low-dose induction agents. Advantages include possible provision of anesthesia and analgesia to the fetus via transplacental transfer of agents, as well as decreased maternal anxiety and pain. Depending on the amount and effect of the drugs administered, this sedation may increase the mother's risk of aspiration because of an unprotected airway. This technique also provides no uterine relaxation.

### Regional Neuraxial Blockade

Neuraxial techniques (spinal, epidural, or combined spinal and epidural anesthesia) have been used with fetoscopic techniques and, rarely, without an adjunct general anesthetic, for open techniques. A T4 sensory-level blockade is required for most surgical uterine manipulations. Neuraxial techniques provide no uterine relaxation, nor do they provide fetal analgesia or anesthesia. Neuraxial anesthesia is associated with an increased maternal risk (e.g., failed block, high spinal, total spinal, or intravascular injection of local anesthetic).

### Regional Neuraxial Blockade with Sedation

The addition of IV sedation to regional anesthesia may provide the fetus with analgesia/anesthesia via placental drug transfer. Although IV fentanyl, propofol, and benzodiazepines can be administered to patients receiving regional anesthesia, they may place the mother at increased risk of bradyarrhythmias, respiratory depression, and pulmonary aspiration; the need for a T4 sensory block may produce alterations in respiratory mechanics additive to those caused by pregnancy. In addition, the level of

sympathetic blockade is often two to six levels greater than the sensory level.<sup>3</sup> Hence, a T4 sensory block may completely block cardiac accelerator fibers (T1 to T4); severe bradyarrhythmias and cardiac arrest have been reported.<sup>4,6</sup> When IV agents with vagotonic properties are administered in this clinical setting, the risk of significant bradyarrhythmias may be increased.<sup>7</sup>

### General Anesthesia

General anesthesia with inhalational anesthetics provides both maternal and fetal anesthesia and dose-dependent uterine relaxation even in patients who have received tocolytic therapy for preoperative premature uterine contractions.<sup>8-11</sup>

### Combined Regional and General Anesthesia

A combined regional and general anesthesia technique is often used for open procedures, as well as for patients with anterior placentas, in whom externalization of the uterus for safe trocar insertion is anticipated. In addition to providing the advantages of both the regional and the general anesthetic techniques listed previously, this method allows for planned postoperative pain control.<sup>12</sup> The physical window for trocar insertion is often smaller in this patient cohort, necessitating either externalization of the uterus or extreme lateral decubitus position. Externalization of the uterus requires a larger surgical incision than for standard cesarean sections.

### FETUS

Maternal anesthetic techniques that do not include inhalational anesthetics may not provide adequate analgesia and/or anesthesia for the fetus. However, fetal analgesia and anesthesia may also be accomplished by delivery of anesthetics and analgesics directly to the fetus. Potential methods include transplacental, direct intramuscular, direct intravascular, and intraamniotic administration; each route of administration has advantages and disadvantages that can have a direct impact on overall outcome.

### Transplacental Access

Many fetal interventions (open or endoscopic) employ transplacental drug administration to provide anesthesia and analgesia for both mother and fetus. Many, but not all, drugs cross the placenta via Fick's law of passive diffusion (Fig. 37-1). Lipid solubility, the pH of both maternal and fetal blood, the degree of ionization, protein binding, perfusion, placental area and thickness, and drug concentration are factors that influence the extent of transplacental drug diffusion.<sup>13</sup> The most obvious disadvantage with this approach is that the mother must be exposed to every drug that the fetus is intended to receive, often at large concentrations, to achieve adequate drug concentrations in the fetus. In addition, the uptake of drugs may be impaired if there is reduced placental blood flow. This has implications for successful anesthesia and analgesia both in terms of the delivered fetal dose and the time interval that must be allowed from maternal administration to the start of the fetal intervention. All inhaled anesthetics cross the placental barrier, but uptake in the fetus is slower than in the mother.<sup>13</sup> However, this is offset by the reduced minimal alveolar concentration (MAC) for anesthesia in the fetus, resulting in a similar onset of anesthesia as in the mother.<sup>2</sup> Fetal anesthesia is also important to reduce the fetal stress response, which, through catecholamine release, can reduce placental blood flow and exacerbate any asphyxia.<sup>14-17</sup>

**FIGURE 37-1** Fick's law of passive diffusion described at the intervillous space (IVS).  $D$ , Membrane thickness;  $K$ , diffusion constant of the drug;  $M$ , membrane surface area;  $Q/t$ , rate of diffusion.

### Intramuscular Access

Intramuscular (IM) injection involves inserting a needle under ultrasound guidance into a fetal extremity or buttocks. Unlike umbilical cord injection, the noxious stimulus to the fetus by the IM injection stimulates the fetal stress response. Although the bleeding risk from IM injection is less than that with intravascular injections, there remains a risk of bleeding and injury from the needle itself. Furthermore, if the fetus is already stressed, blood will be diverted away from muscle (the site of drug administration) and toward the fetal heart and brain. In this case, it may be impossible to estimate the time course for the drug to be absorbed from the IM site.

### Intravascular Access

Intravascular fetal drug administration ensures immediate drug levels, and no additional dosing calculations are necessary because placental perfusion does not significantly alter dosing. Intravascular access can be obtained via the umbilical cord (which is not innervated), larger fetal veins (e.g., hepatic vein), or intracardiac, as the specific intervention dictates.<sup>18</sup> One advantage of administering drugs via the umbilical vein is the ability to provide analgesia before the surgical insult. Muscle relaxants, analgesics, and vagolytic agents, as well as resuscitation drugs, can be given with assurance of immediate access to the fetal circulation. This method is also useful when alterations in peripheral blood flow occur (i.e., a "central sparing response"), which significantly diminishes the blood distribution to sites of potential IM access.

Establishing intravascular access in the fetus requires inserting a needle in a fetus that is often not sedated from maternally administered agents. The needle may injure the moving fetus, and there is a risk of bleeding from the fetus, umbilical cord, and

placenta. Uncontrolled bleeding could impair the surgical view and it places the fetus and mother in jeopardy, because an open hysterotomy may be necessary to control the bleeding. Establishing access via the umbilical cord vessels may also produce vascular spasm, potentially compromising fetal perfusion.

### Intraamniotic Access

Intraamniotic fentanyl, sufentanil, thyroxine, vasopressin, and digoxin have been safely administered in pregnant large-animal models, with only minimal drug detected in the mother.<sup>19,20</sup> If the safety and efficacy of this method of drug delivery hold true in human trials, intraamniotic drug administration may become the preferred method for fetal drug delivery.

## Fetal Development

### PATHOLOGIC LUNG DEVELOPMENT

In the context of fetal interventions, there are two important causes of respiratory morbidity to consider: insufficient amniotic fluid and prematurity. With both, the timing of the insult in terms of the stage of lung development is critical to estimating the degree of likely morbidity. Deficiency of amniotic fluid may result from prelabor premature rupture of the amniotic membranes (PPROM), which may be spontaneous or iatrogenically induced either directly through trauma or by introducing infection into the uterus. Small amniotic fluid volume may also be secondary to reduced fetal urine output, from either poor renal function (e.g., with renal agenesis or urinary tract obstruction) or growth restriction secondary to placental insufficiency. Amniotic fluid deficiency contributes to pulmonary hypoplasia. In general, the likelihood of pulmonary insufficiency is inversely related to gestation at membrane rupture, a long latency to delivery, and the amount of residual amniotic fluid.<sup>21-23</sup> The risk is relatively small if PPRM occurs after 24 weeks gestation,<sup>24</sup> as demonstrated by one series of fetuses with PPRM before 26 weeks reporting pulmonary hypoplasia in 27% of fetuses.<sup>25</sup> In contrast, with severe oligohydramnios of more than 2 weeks duration after PPRM arising before 25 weeks gestation, the predicted neonatal mortality exceeds 90%.<sup>26</sup>

Studies in sheep show that oligohydramnios causes spinal flexion, which compresses the abdominal contents, displacing the diaphragm upward and thus compressing the developing lungs.<sup>27</sup> This increase in the pressure gradient between the lungs and the amniotic cavity causes a net loss of lung fluid through the trachea, preventing lung expansion.<sup>27</sup> Lung fluid produced in the airways is thought to act as a stent for the developing lungs.<sup>28</sup> Normally, it passes out through the trachea and is either swallowed or passes into the amniotic cavity. Ligation of the trachea causes lung hyperplasia<sup>29</sup> or ipsilateral lung hyperplasia if a main bronchus is ligated.<sup>30</sup> Experimental drainage of amniotic fluid in animals has been shown to result in pulmonary hypoplasia.<sup>31</sup> Later restoration of amniotic fluid prevents the onset of pulmonary hypoplasia.<sup>32</sup> There is evidence to support amniocentesis in humans to maintain fluid volumes around the fetus after PPRM, in an effort to improve lung development.<sup>26,33</sup>

Surfactant is a complex of phospholipids secreted by type II alveolar cells, which reduces lung surface air tension, thereby preventing the lungs from collapsing at low volumes. Glucocorticoids, thyroid hormone, and  $\beta$ -adrenergic agonists stimulate surfactant synthesis. It is first detected in the lungs around 23 weeks gestation, but mature levels necessary for unassisted ventilation are not present until about 34 weeks. The degree of

## FETAL CIRCULATION

**FIGURE 37-2** Fetal circulation. Red arrows represent flow of oxygenated blood and blue arrows represent flow of deoxygenated blood. Black arrows indicate direction of blood flow and represent travel of blood from the central circulation through capillary membranes and return to central circulation. Shading (from red to purple to blue) represents the corresponding relative oxygenation of the blood at that site, from oxygenated to deoxygenated. Note the mixing of blood as the ductus venosus delivers oxygenated blood from the placenta to the central fetal circulation and the progressive desaturation of blood in the fetal aorta secondary to shunts, consumption, and the return of deoxygenated blood from the fetal pulmonary circulation.

lung maturity can be evaluated by amniocentesis using the lecithin to sphingomyelin ratio or, more recently, by the lamellar body count.<sup>34</sup> Acceleration of surfactant synthesis may be achieved with corticosteroids administered to the mother.<sup>35</sup>

#### FETAL CARDIOVASCULAR DEVELOPMENT

The differences between the fetal and postnatal circulations are complex (Fig. 37-2). In the fetal circulation, oxygenated blood returns from the placenta via the umbilical veins and ductus venosus (bypassing the liver) into the right atrium. At 20 weeks, 30% of the umbilical venous return (40 to 60 mL/kg/min) is

shunted through the ductus venosus.<sup>36</sup> This flow decreases over the second half of gestation as hepatic blood flow increases so that, by term only 20% of umbilical venous return (less than 20 mL/kg/min) is shunted through the ductus venosus.<sup>36</sup> Hypoxia and hemorrhage increase the resistance in the liver, shunting a greater proportion of blood toward the brain and heart via the ductus venosus.<sup>37</sup> The proportion of blood that perfuses the liver, which exits 15% less saturated in oxygen, rejoins the ductus venosus blood in the inferior vena cava. However, this deoxygenated blood has less kinetic energy and flows more slowly into the right atrium toward the right

ventricle.<sup>37</sup> The greater-velocity oxygenated blood from the ductus venosus is preferentially directed through the foramen ovale into the left side of the heart and out via the aortic arch to the developing head and upper body. The integrity of the foramen ovale is thus imperative. Blood returning from the placenta along the umbilical vein is 80% to 85% saturated. Despite this streaming within the right atrium, some mixing does occur, resulting in blood that is 65% saturated in the ascending aorta. The blood in the left ventricle, however, is 15% to 20% more saturated than the blood in the right ventricle. Most of the deoxygenated blood in the right ventricle bypasses the high-resistance pulmonary vasculature to enter the ductus arteriosus, and from there the descending aorta to supply the lower body, or pass via the umbilical arteries for reoxygenation in the placenta. In contrast to extrauterine life, when the two ventricles function in series and thus have equal outputs, before birth they function in parallel. Their outputs, therefore, do not have to be equal and, in fact, are not. In the third trimester, the right side of the heart has a greater output, as determined by Doppler ultrasonography studies, showing a 28% greater stroke volume than the left side.<sup>36</sup>

Fetal heart rate (FHR) is maintained above the intrinsic rate of the sinoatrial node by a combination of vagal and sympathetic inputs, as well as circulating catecholamines.<sup>38-40</sup> FHR decreases throughout gestation,<sup>41,42</sup> accompanied by an increase in stroke volume as the heart grows. Hypoxic stress in late gestation produces a reflex bradycardia, with a normal heart rate or tachycardia developing a few minutes later. The chemoreceptor reflex nature of the bradycardia is demonstrated by its abolition after section of the carotid sinus nerves.<sup>43</sup> The later tachycardia is a result of an increase in plasma catecholamines causing  $\beta$ -adrenergic stimulation.<sup>44</sup> Hemorrhage can also produce increases in FHR, probably via a baroreceptor reflex.

Cardiac output in the fetus is determined largely by heart rate.<sup>45</sup> The combined ventricular output of the left and right ventricles in the human fetus is 450 mL/kg/min.<sup>46</sup> During development, the ability of the fetus to increase stroke volume is limited by a reduced proportion of functioning contractile tissue and a limited ability to increase the heart rate because of a relatively reduced  $\beta$ -adrenergic receptor density and immature sympathetic drive. Thus if blood volume is reduced by hemorrhage, the heart cannot compensate by increasing stroke volume, or, conversely, if volume is increased, the walls are less able to distend and cardiac efficiency is reduced (although this second effect is reduced substantially by the huge, relatively compliant placental circulation). Thus the only way for the fetus to increase cardiac output is to increase heart rate. Despite this homeostatic limitation, the fetus is able to withstand significant hemorrhage. Sheep studies have shown that the fetal lamb can restore arterial blood pressure and heart rate very quickly, without any measurable disturbance in acid-base balance after acute loss of 20% of their blood volume.<sup>47</sup> Even after a 40% reduction in blood volume, the ovine fetal blood pressure recovers to normal within 2 minutes and the heart rate within 35 minutes.<sup>48</sup> Oxygen delivery to the brain and heart is maintained secondary to vascular redistribution (*central sparing effect*) and blood volume replacement from the placenta and extravascular space, with 40% of the hemorrhaged loss being corrected within 30 minutes.<sup>48</sup> The development of acidemia indicates that the fetus is not able to compensate; acidosis shifts the oxygen dissociation curve to the right, thereby decreasing fetal hemoglobin oxygen saturation but improving release of oxygen from hemoglobin. Blood flow

during periods of asphyxia increases more than 100% to the brainstem, but only 60% to the cerebral hemispheres.<sup>49</sup>

## FETAL OXYGENATION

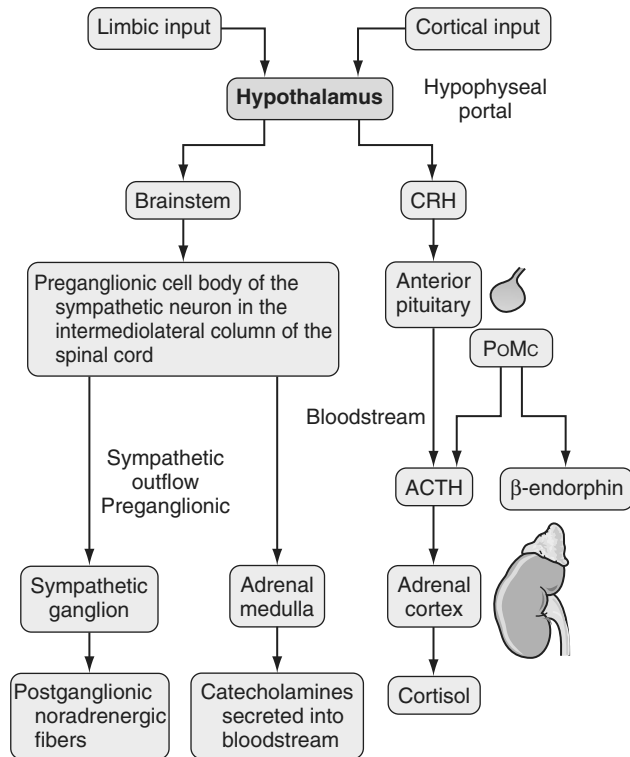

The fetus exists in an environment of low oxygen tension, with arterial oxygen partial pressure ( $PO_2$ ) being approximately one-fourth that of the adult. The maximum  $PO_2$  of umbilical venous blood is approximately 30 mm Hg. The affinity of fetal hemoglobin for oxygen is modulated in utero by two principal factors: fetal hemoglobin and 2,3-diphosphoglycerate (2,3-DPG). The hemoglobin oxygen dissociation curve is shifted to the left because of fetal hemoglobin (hemoglobin F), thereby increasing the affinity for oxygen. 2,3-DPG is also present and might be expected to shift the oxyhemoglobin dissociation curve to the right, decreasing the affinity of the fetal hemoglobin for oxygen and favoring oxygen unloading. However, 2,3-DPG only appears to exert approximately 40% of the effect on fetal hemoglobin as it does on adult hemoglobin, thereby preserving a net leftward shift on the oxyhemoglobin dissociation curve. Thus for any given  $PO_2$ , the fetus has a greater affinity for oxygen than does the mother. The  $P_{50}$  (the  $PO_2$  at which hemoglobin is 50% desaturated) is approximately 27 mm Hg for the adult and 20 mm Hg for the fetus. The concentration of 2,3-DPG increases with gestation, as does the concentration of hemoglobin A<sup>50</sup>; the greater hemoglobin concentration (18 g/dL) results in a greater total oxygen carrying capacity.

Oxygen supply to fetal tissues depends on a number of factors (Table 37-1). First, the mother must be adequately oxygenated. Second, there must be adequate flow of well-oxygenated blood to the uteroplacental circulation. This blood flow may be reduced from maternal hemorrhage (reduced maternal blood volume) or compression of the inferior vena cava (reduced venous return), which increases uterine venous pressure, thus reducing uterine perfusion. Additionally, aortic compression reduces uterine arterial blood flow.<sup>51</sup> Care must be taken to position the mother in such a way as to prevent aortocaval compression. The surgical incision of hysterotomy itself reduces uteroplacental blood flow

**TABLE 37-1 Causes of Impaired Blood Flow and Oxygenation to Fetal Tissues**

<b>Causes of Impaired Uteroplacental Blood Flow/Oxygenation</b>	<b>Causes of Impaired Umbilical Blood Flow/Fetal Circulatory Redistribution</b>
Reduced maternal oxygenation/hemoglobin concentration	Umbilical vessel spasm
Maternal hemorrhage	Reduced fetal cardiac output
Aortocaval compression	Fetal hemorrhage/reduced hemoglobin concentration
Drugs reducing uterine blood flow	Fetal hypothermia
Uterine trauma	Impaired uteroplacental blood flow/oxygenation
Uterine contractions	Umbilical cord kinking
Placental insufficiency (PET, IUGR)	
Polyhydramnios: pressure effect	
Maternal catecholamine production increasing uteroplacental vascular resistance	Fetal catecholamine production increasing fetoplacental vascular resistance

IUGR, Intrauterine growth restriction; PET, preeclamptic toxemia.

**FIGURE 37-3** Human fetal endocrine responses to stress. *ACTH*, Adrenocorticotropic hormone; *CRH*, corticotropin-releasing hormone; *PoMc*, proopiomelanocortin.

by as much as 73% in sheep, whereas fetoscopic procedures with uterine entry have no effect.<sup>52</sup>

Even if the uterine circulation is adequate, the fetus still depends on uteroplacental blood flow and umbilical venous blood flow for tissue oxygenation. Care must be taken not to interrupt umbilical vessel blood flow by manipulation or kinking the cord, which can cause vasospasm. Umbilical vasoconstriction can also occur as part of a fetal stress reaction resulting from a release of fetal stress hormones (Fig. 37-3). Increases in amniotic fluid volume increase amniotic pressure and impair uteroplacental perfusion.<sup>53,54</sup> Placental vascular resistance can be increased, raising fetal cardiac afterload, by the surge in fetal catecholamine production stimulated by surgical stress.<sup>55</sup> Fortunately, animal studies suggest that adverse effects on the arterial blood gas in the fetus do not occur until uteroplacental perfusion has been reduced by 50% or more.<sup>56</sup>

Inhalational anesthetics may cause maternal vasodilatation and, thus, in theory, could cause or exacerbate preexisting fetal hypoxia. Studies of anesthetics in hypoxic ovine fetuses have shown that isoflurane exacerbates preexisting acidosis.<sup>57</sup> It also causes blunting of the usual vascular redistribution response to fetal hypoxia, but, owing to a reduction in cerebral oxygen demand, the balance of cerebral oxygen supply and demand is unaffected.  $\beta$ -Adrenergic blockade renders a fetus less able to cope with asphyxia. Compared with controls, these fetuses have a smaller increase in heart rate, cerebral blood flow, and cardiac output, and recover from acidosis more slowly.<sup>58</sup>

## CENTRAL AND PERIPHERAL NERVOUS SYSTEM DEVELOPMENT

By the beginning of the second trimester, the spinal cord is largely formed; development of the brain and spinal cord begins

as early as postconception week 3. Neural crest cells migrate laterally to form peripheral nerves from about 4 weeks, with the first synapses between them forming a week later.<sup>59</sup> Synapses within the spinal cord develop from about 8 weeks gestation, suggesting the first spinal reflexes may be present at this time. Between 8 and 18 weeks gestation is the time of maximal neuronal development. The first neurons and glial cells develop in the ventricular zone (an epithelial layer) along which the newly formed neurons migrate out in waves to form the neocortex. Synaptogenesis occurs after neural proliferation, first in peripheral structures and then more centrally from around 20 weeks; this process is at least partly dependent on sensory stimulation.<sup>60</sup>

The development of the nociceptive apparatus proceeds in parallel with basic central nervous system development. The first essential requirement for nociception is the presence of sensory receptors, which develop first in the perioral area at around 7 weeks gestation. From here, they develop in the rest of the face and in the palmar surfaces of the hands and soles of the feet from about 11 weeks gestation. By 20 weeks, they are present throughout all of the skin and mucosal surfaces.<sup>61</sup> The nociceptive apparatus is initially involved in local reflex movements at the spinal cord level without higher cortical integration. As these reflex responses become more complex, they, in turn, involve the brainstem, through which other responses, such as increases in heart rate and blood pressure, are mediated. However, such reflexes to noxious stimuli have not been shown to involve the cortex and, thus, are not thought to be available to conscious perception. The nature of fetal consciousness itself is complicated, both physiologically and philosophically, and a discussion of such is beyond the scope of this chapter. However, there is a working consensus that for consciousness to be present there must be electrical activity in the cerebral cortex.<sup>62</sup> It appears that, far from being “switched on” at any one moment, consciousness evolves in a gradual process that has been likened to a “dimmer switch,” making attribution of fetal consciousness to any particular developmental moment a difficult undertaking.

## PROGRAMMING EFFECTS

When considering the effects of noxious stimuli on the developing fetus and the rationale for fetal anesthesia and analgesia, we must consider not just the humanitarian need to alleviate the possible distress of pain sensation, but also whether being subjected to surgical stress during early development might cause permanent alterations in physiology. This concept is known as *programming*, defined as “the process whereby a stimulus or insult at a critical, sensitive period of development has permanent effects on structure, physiology, and metabolism.”<sup>63</sup> Studies in rats and nonhuman primates have shown permanent reductions in the numbers of hippocampal and hypothalamic glucocorticoid receptors in the offspring of antenatally stressed animals. This attenuates the negative feedback response, resulting in increased basal and stress-induced cortisol levels in the offspring, which last into adulthood. Behavioral changes, such as poor coping behaviors, have also been observed.<sup>63</sup>

## Fetal Monitoring

The goal during any fetal intervention is to optimize fetal well-being by avoiding fetal hypoxia and hypothermia while optimizing stable fetal hemodynamics. It is essential that the physiologic response of the fetus to anesthetic and surgical stresses be understood and addressed, to avoid the known detrimental effects of

stress on an already compromised fetus. However, access to the fetus is limited at best and the technologies for continuous intraoperative and postoperative fetal vital sign monitoring are still in development.

A hysterotomy is not needed for many surgical interventions; thus the fetus remains within the uterus, often making access for direct monitoring impossible. Even for those fetuses that are partially delivered for an invasive procedure, monitoring is obtainable only intermittently and is frequently unreliable, because the fetus must remain within a fluid environment during the procedure, making the direct placement of available monitors difficult. Current methods for monitoring fetal well-being include FHR monitoring, direct measurement of fetal blood gases, fetal electrocardiography (ECG), fetal pulse oximetry (FPO), fetal echocardiography, and Doppler ultrasonography of fetal cerebral blood flow.

### USE OF FETAL HEART RATE MONITORING FOR FETAL INTERVENTIONS

Currently, FHR monitoring with Doppler ultrasonography is the standard for the intrapartum assessment of fetal well-being. FHR monitoring is also used perioperatively during fetal interventions. The FHR is documented before maternal induction of anesthesia, to serve as a baseline for comparison and to reassure the perinatologist, surgeon, and anesthesiologist that the fetus is stable. The FHR may be continuously monitored intraoperatively by fetal echocardiography and with intermittent palpation of the umbilical cord in open cases. It is known that the most commonly used anesthetic induction agents at appropriate doses (propofol and thiopental) rapidly cross the placenta and thus also rapidly reach the fetus.<sup>64,65</sup> The inhalation anesthetics also cross the placenta,<sup>66</sup> but the uptake of the anesthetic occurs more slowly in the fetus than in the mother.<sup>67,68</sup> These anesthetics decrease FHR and FHR variability. Although it is reassuring if the FHR is within the normal range for the gestational age, fetal bradycardia is a reliable indicator of fetal distress that needs to be immediately addressed.

With the advent of minimally invasive fetal endoscopic surgery, new problems in monitoring have surfaced. The fetus is no longer physically accessible to the surgical team, and the trocars used for fetoscopic surgery currently prohibit the placement of radiotelemetric probes. At present, fetoscopic or cardiac intervention use direct visualization of the heart with fetal echocardiography, which gives an accurate estimation of the FHR. Although very beneficial, the continuous use of fetal echocardiography requires the presence of a skilled ultrasonographer working in the operative field.

### USE OF FETAL BLOOD SAMPLING DURING FETAL INTERVENTIONS

In suspected cases of fetal compromise during an open intervention, fetal blood can be obtained from capillary vessels, a peripheral vein, a central vein, or a puncture of the umbilical vessels. The fetus' small size and friable tissue make vascular access difficult. Puncture of the umbilical vessels can lead to cord spasm, hematoma, and even fetal death, and thus should be reserved for circumstances when no other options are available. During an endoscopic intervention, access to the fetal circulation is possible through puncture of the umbilical vessels. With most fetal cardiac interventions, a needle and/or catheter is placed directly through the fetal myocardium, allowing access for blood samples; only a very small sample should be withdrawn because of the small circulating fetal blood volume.

### FETAL ELECTROCARDIOGRAPHY

Several groups have used fetal ECG analysis to determine whether changes in time interval (PR and RR interval) and signal morphology (T to QRS ratio) correlate with fetal or neonatal outcome. Studies in animals and humans have shown that under normal conditions, there is a negative correlation between the PR interval and the FHR: as the FHR slows, the PR interval lengthens, and as the FHR increases, the PR interval shortens. *The opposite relationship occurs in acidemic infants.*<sup>69-75</sup> During periods of fetal compromise, it is hypothesized that the sinoatrial node and the atrioventricular node respond differently.<sup>73</sup> Periods of mild hypoxemia will induce increases in epinephrine levels, which will increase the FHR and shorten the PR interval. However, with periods of prolonged hypoxemia, the oxygen-dependent calcium channels of the sinoatrial node will demonstrate reduced sensitivity to epinephrine, resulting in a decrease in FHR. The fast sodium channels of the atrioventricular node are not affected by the reduction in the oxygen supply, and the increased levels of epinephrine will shorten the PR interval. As a result, the relationship between the PR interval and FHR changes from negative to positive.<sup>73</sup> Measurements of this relationship have been divided into short-term and long-term measures.<sup>73,74</sup> The short-term measure or the conduction index can be intermittently positive over short periods of time without an adverse outcome. However, a prolonged positive conduction index (greater than 20 minutes) has been associated with an increased risk of fetal acidemia.<sup>75</sup>

### FETAL PULSE OXIMETRY

Standard pulse oximeters use the transmission and absorption of light through a vascular bed to a photodetector on the opposite side of the tissue. However, the development of reflectance oximetry allowed measurement of oxygen saturation from light-emitting diodes that are positioned next to each other on the same skin surface and absorption is determined from the light that scatters back to the tissue surface<sup>76,77</sup>; any fetal condition that decreases vascular pulsations (e.g., hypotension, vasoconstriction, shock, or strong uterine contractions) can produce inaccurate oximetry readings.<sup>78</sup> Because direct contact of the oximeter must be made with the fetal skin surface, anything that interferes with light transmission or skin adhesion (e.g., fetal or maternal movement, vernix caseosa, caput succedaneum) can influence the quality and accuracy of the oximeter.<sup>79-83</sup> Oximetry readings also vary in relation to the site of sensor application; several studies have found reduced baseline oxygen saturation values with the use of the oxygen sensor on the fetal buttock compared with the fetal head.<sup>84-87</sup>

The development of a 735/890-nm wavelength system (compared with the older 660/890-nm system) has improved the accuracy in monitoring arterial oxygen saturation (FSaO<sub>2</sub>) in the fetus<sup>88</sup>; because the normal range of FSaO<sub>2</sub> of 30% to 70% lies in the middle of the oxygen-hemoglobin dissociation curve, small changes in pH or oxygen partial pressure cause large changes in FSaO<sub>2</sub>.<sup>89</sup> FPO can also identify an acidotic fetus. Increased concentrations of both the hydrogen ion and 2,3-DPG cause a rightward shift of the oxygen dissociation curve (Bohr effect) such that a chronically acidemic or hypoxemic fetus will have a low FSaO<sub>2</sub> even though the PO<sub>2</sub> is within normal limits.<sup>89</sup>

### FETAL ECHOCARDIOGRAPHY

When technically feasible, fetal echocardiography should be available to assess fetal myocardial contractility and function, heart rate, intravascular volume status, and amniotic fluid

volume. We have also used echocardiography to correctly identify proper endotracheal tube placement during an EXIT procedure<sup>90</sup>; a sterile sleeve is placed over the ultrasonographic probe that is then placed over the fetal chest.

### DOPPLER ULTRASONOGRAPHY OF FETAL CEREBRAL BLOOD FLOW

Antepartum Doppler ultrasonography studies of the fetal circulation in cases of intrauterine growth restriction with presumed hypoxia have shown a compensatory redistribution, with an increase in peripheral vascular resistance in the fetal body and placenta and a compensatory reduction in peripheral vascular resistance in the fetal brain, producing a brain-sparing effect.<sup>91</sup> Intrapartum Doppler ultrasonography and FPO have verified the brain-sparing response in the presence of intrapartum arterial hypoxemia (FSaO<sub>2</sub> less than 30% for 5 minutes or more), as reflected by increased mean flow velocity in the fetal middle cerebral artery.<sup>92</sup> Preliminary studies of the middle cerebral artery pulsatility index in minimally invasive procedures, such as fetal blood sampling, transfusion, shunt insertion, tissue biopsy, and ovarian cyst aspiration, have demonstrated significant cerebral hemodynamic responses (decreases in the middle cerebral artery pulsatility index) in fetuses that underwent procedures involving transgression of the fetal body. This response was not noted in the fetuses undergoing procedures at the noninnervated placental cord insertion.<sup>93</sup>

Although not yet advocated for routine intrapartum management, it has been suggested that the combination of reduced arterial oxygen saturation and increased cerebral blood flow may indicate an ominous phase during labor. The redistribution of the fetal circulation is not an unlimited protective mechanism, and with persistent cerebral hypoxia, the active vasodilation of the cerebral vessels may fail, leading to disastrous consequences for the fetus.<sup>94</sup>

## Physiologic Consequences of Pregnancy

### RESPIRATORY AND AIRWAY CONSIDERATIONS

There is an increase in metabolic demand of both the mother and the fetus, and this, along with anatomic and hormonal influences, accounts for the changes in maternal pulmonary physiology (Table 37-2). Pregnancy results in progressive increases in oxygen consumption and minute ventilation, along with a decreased residual volume and functional residual capacity.<sup>95</sup> The

increased metabolic demands and anatomic changes can make adequate oxygenation and perfusion of the parturient and the fetoplacental unit a constant challenge during maternal general anesthesia. During periods of apnea or hypoventilation, the parturient is prone to rapid development of hypoxia and hypercapnia. Even after adequate preoxygenation, the PaO<sub>2</sub> in an apneic anesthetized parturient decreases by about 8 mm Hg more per minute than in nonpregnant women.<sup>96</sup> Acidosis rapidly develops from hypoxia during difficult airway situations because of a decreased buffering capacity during pregnancy. The decreased pulmonary oxygen stores and increased oxygen consumption make parturients more susceptible than nonpregnant women to the consequences of airway mismanagement.

Not all physiologic changes of pregnancy are deleterious to the performance of anesthesia. For example, both the induction of and emergence from anesthesia with inhalational anesthetics occur faster in parturients than in nonpregnant women because the combination of increased alveolar ventilation and decreased functional residual capacity speeds the rate at which denitrogenation occurs and at which inspired and alveolar concentrations of inhalational agents reach equilibrium<sup>97</sup>; a faster induction, coupled with a decreased MAC, make parturients susceptible to relative anesthetic overdose and severe hypotension.<sup>98</sup>

### CARDIOVASCULAR CONSIDERATIONS

Cardiovascular function is appropriately increased during pregnancy to meet the increased metabolic demands and oxygen requirements of the mother (Table 37-3). Cardiac output increases by 35% to 40% by the end of the first trimester and continues to increase throughout the second trimester until it reaches a level 50% greater than that in nonpregnant women.<sup>99</sup> Heart rate increases 15% to 25% above prepregnancy rates and remains stable after the second trimester, and stroke volume progressively increases 25% to 30% by the end of the second trimester and remains stable until term.<sup>100,101</sup> Aortocaval compression by the gravid uterus can cause a 30% to 50% decrease in cardiac output; lesser decreases occur in the sitting or semirecumbent positions. Maternal position is a major factor contributing to hypotension and fetal well-being.<sup>102</sup>

Maternal blood flow and pressure are directly linked to fetal perfusion via the placenta, and uterine blood flow represents about 10% of maternal cardiac output. The avoidance of aortocaval compression by left or right uterine displacement is imperative to prevent a decrease in the maternal blood pressure. Because large doses of inhalational agent are often necessary for uterine relaxation during fetal intervention, prompt treatment of hypotension is vital. Because uteroplacental blood flow is not autoregulated, a decrease in maternal blood pressure will eventually

**TABLE 37-2** Anesthetic Considerations of Respiratory Changes of Pregnancy

Decreased functional residual capacity
Faster denitrogenation
Rapidly prone to hypoxia during apnea
Faster induction and emergence of anesthesia with inhaled agents
Increased oxygen consumption
Rapidly prone to hypoxia during apnea
Capillary engorgement of the respiratory mucosa
Predisposes upper airway to trauma, bleeding, and obstruction
Laryngeal edema increases the frequency of difficult intubation
Decreased PaCO <sub>2</sub> and no PETCO <sub>2</sub> -PaCO <sub>2</sub> gradient
Capnograph reading similar to PaCO <sub>2</sub>
Hyperventilation may lead to a reduction in uterine blood flow

PETCO<sub>2</sub>, End-tidal carbon dioxide pressure.

**TABLE 37-3** Anesthetic Considerations of Cardiovascular Changes of Pregnancy

Aortocaval compression
Supine position leads to a decline in cardiac output
May lead to supine hypotensive syndrome
Mostly prevented by left or right uterine displacement
Decreased colloid oncotic pressure
Parturient is at greater risk for developing pulmonary edema
Increased maternal blood volume
Parturient tolerates more blood loss than nonparturients
Hypotension and acidosis may develop with significant blood loss

decrease placental blood flow and, therefore, blood flow to the fetus. IV ephedrine (5 to 10 mg) or phenylephrine (50 to 100 µg) per dose should be used to treat maternal hypotension unless contraindicated.<sup>103</sup>

Careful attention to the volume status of the parturient is imperative; aggressive volume hydration, the normal decrease in colloid oncotic pressure that occurs during pregnancy, the decrease in colloid oncotic pressure post partum, and the use of tocolytic agents (e.g., magnesium or  $\beta$ -adrenoceptor agonists) may all predispose the parturient to pulmonary edema.

### CENTRAL AND PERIPHERAL NERVOUS SYSTEMS

Pregnancy-mediated analgesia is affected by changes in spinal opioid antinociceptive pathways and peripheral processes, including the effect of ovarian sex steroids (estrogen and progesterone) and uterine afferent neurotransmission. It is thought that pregnancy-mediated analgesia increases the woman's threshold for pain during the latter stages of pregnancy before labor.<sup>104,105</sup> Pregnant women are more sensitive to the action of many anesthetic agents and require less local anesthetic for spinal and epidural anesthesia and less inhalational anesthetics than their nonpregnant counterparts. The MAC of inhalational anesthetics in pregnancy is approximately 30% less than in nonpregnant females; and for this reason the concentration of inhalational anesthetic needs to be carefully titrated.<sup>106</sup>

### PHARMACOLOGIC CONSEQUENCES OF PREGNANCY

Physiologic changes of pregnancy alter the pharmacokinetics and pharmacodynamics of many anesthetic drugs. An increase in total body water and adipose tissue, and a decrease in plasma protein concentrations alter the volume of distribution. An increased renal blood flow and glomerular filtration rate can enhance the elimination of renally excreted drugs; hepatic metabolism of some drugs may be inhibited by competition with steroid hormones during pregnancy, whereas others may have a greater clearance associated with the increased basal metabolic rate. Therefore drug administration must consider the pharmacokinetics within the maternal-placental-fetal unit. Most drugs cross the placenta to some extent and the proportion transferred increases with the duration of gestation. The fetus has reduced plasma protein binding, producing relatively greater concentrations of free drug (i.e., unbound and available to cross biologic membranes).<sup>107</sup> Despite detection of oxidation and reduction reactions in the fetal liver from as early as 16 weeks, enzyme concentrations and reaction rates are minimal, exposing the fetus to more prolonged drug effects than occur in the mother.<sup>108</sup> Early in gestation, the primary mode of drug excretion is via blood flow to the placenta, but later, as the fetal kidneys mature, they become a route of drug excretion into the amniotic fluid for water-soluble drugs and metabolites. Amniotic fluid, however, can act as a reservoir for drugs, from which they can be reabsorbed.<sup>107</sup>

### Induction

Pregnancy increases the parturient's sensitivity to induction agents.<sup>109</sup> Propofol has been safely used for induction of anesthesia for cesarean delivery, in doses of 2 mg/kg, with minimal effects on the neonate.<sup>110</sup> Ketamine has also been used as the sole induction agent for parturients undergoing elective cesarean section; ketamine (1.5 mg/kg) has not been associated with maternal awareness or neonatal depression at delivery and parturients required fewer analgesics in the first 24 hours after delivery.<sup>111</sup> It is speculated that ketamine's analgesic properties may

reduce the sensitization of pain pathways and subsequently confer extended benefit into the postoperative period. Induction agents decrease spontaneous uterine contractions of isolated pregnant rat myometrium, but only in concentrations greater than those seen in clinical obstetric practice.<sup>112</sup>

### Neuromuscular Blocking Drugs

Although serum cholinesterase activity decreases 30% during pregnancy, recovery from a dose of 1 mg/kg of succinylcholine is not prolonged.<sup>113</sup> Succinylcholine has a very low placental transfer, owing to its low lipid solubility and high degree of ionization.<sup>114</sup> Similarly, cisatracurium has been safely used for cesarean section without routine neostigmine antagonism, despite decreased plasma cholinesterase activity.<sup>115</sup> Pregnant women may be more sensitive to the action of nondepolarizing muscle relaxants, with the administration of vecuronium resulting in a more rapid onset and delayed recovery of neuromuscular block when compared with nonpregnant control patients. The prolonged action of vecuronium persists into the postpartum period for at least 4 days<sup>116</sup>; the clinical duration of vecuronium in term and postpartum women is twice that of nonpregnant women.<sup>117</sup> However, in a study comparing cisatracurium 0.2 mg/kg for intubation in immediate postpartum and nonpregnant women, both the mean onset and recovery times in the postpartum period were significantly smaller.<sup>118</sup> Nondepolarizing muscle relaxants have no effect on uterine relaxation and, as quaternary amines, do not cross the placenta.

### Inhalational Anesthetics

Pregnant women are more sensitive to the anesthetic action of the inhalational anesthetics (MAC is reduced approximately 30% from nonpregnant females).<sup>119</sup> This may lead to a deeper level of anesthesia than predicted during fetal surgery, and a relative overdose associated with maternal cardiac depression and hypotension. All inhalational anesthetics rapidly cross the placenta, but their uptake occurs more slowly in the fetus than in the mother.<sup>120,121</sup> At light (1.0 MAC) isoflurane or halothane anesthesia, neither maternal pulse rate, cardiac output, and acid-base status, nor fetal pulse rate, acid-base status, and oxygen saturation changed significantly.<sup>122</sup> During moderately deep (1.5 MAC) isoflurane or halothane anesthesia, maternal arterial pressure and cardiac output decreased. Uterine vasodilation occurred, but uteroplacental perfusion was maintained; fetal oxygenation and base excess were also maintained. However, at concentrations of inhalational anesthetics that exceeded 2.0 MAC, maternal hypotension decreased uteroplacental perfusion despite uterine vasodilation, leading to fetal hypoxia and acidosis. Inhalational anesthetics produced a dose-related uterine relaxation.<sup>123</sup> At 0.5 MAC of enflurane, isoflurane, or halothane, uterine contractility decreases 20% whereas at 1.5 MAC, contractility decreases 60%.<sup>124</sup> Sevoflurane produces a dose-dependent depression in uterine muscle contractility, with complete abolition of uterine activity at greater than 3.5 MAC.<sup>125</sup> The large concentrations of inhalation anesthetic needed for profound uterine relaxation generally requires tracheal intubation and aggressive use of vasopressors.

### Fetal Preoperative Evaluation

Prenatal imaging of all fetal anomalies, including anatomic areas of involvement, the relationship to normal structures, and tracheal location, is needed to plan the most appropriate surgical

and anesthetic interventions. The accuracy and quality of preoperative fetal ultrasonography and magnetic resonance imaging (MRI) are of the utmost importance because some lesions, especially pulmonary lesions, may spontaneously regress in utero; an inaccurate diagnosis could lead to suboptimal or inappropriate intervention. In addition, extremely valuable information can be obtained that would aid in the decision-making process for a given treatment, namely, the presence of ascites, hydrops, mediastinal shift, degree of lung hypoplasia and lesion involvement, airway involvement and potential tracheal distortion, or compression from intrathoracic masses. Preoperative imaging can also determine other anticipated alterations in anatomy that may acutely alter fetal cardiopulmonary physiology (e.g., mediastinal shift and the known associated potential alterations in fetal preload). Serial radiologic examinations can also monitor the growth of certain masses, the development of hydrops, and the response to treatment medications (e.g., transplacental digoxin). Significant fetal ventricular dysfunction or heart failure should alert the anesthesiologist to the possibility of fetal cardiac arrest during a fetal intervention. Other congenital abnormalities may be detected that may render a potential fetal intervention useless.

In addition, a fetal karyotype must be obtained to rule out the presence of any genetic disorders that are associated with significant fetal morbidity or mortality, making further intervention pointless. An estimated fetal weight, obtained by ultrasonography immediately before surgical intervention, allows for preparation of unit doses of fetal medications. Any previous attempts at fetal intervention should be evaluated, including the number of interventions, fetal tolerance of the procedures, transient reversal in fetal symptoms, the presence of fetal cardiac dysfunction, and the reason or reasons for failed intervention. Assuming that fetal hydrops is present, any attempts to treat this condition should also be documented, including the effectiveness of digoxin therapy, total dose administered, method of administration, and response to treatment.

## Maternal Evaluation

A complete medical history and physical examination, especially a focused airway evaluation, are of the utmost importance. Details regarding fetal pathophysiology and its effects on secondary maternal morbidity should be addressed. Any patient with significant polyhydramnios and associated preterm contractions is at great risk for preterm labor and rupture of membranes with uterine manipulation. Patients with significant polyhydramnios despite multiple amnioreductions have required greater amounts of intraoperative tocolysis and greater inhalational anesthetic concentrations to obtain uterine relaxation and acceptable surgical conditions.

The presence of fetal hydrops should alert the practitioner to the possibility of maternal mirror syndrome. *Mirror syndrome* refers to characteristic maternal pathophysiologic changes associated with a variety of fetal disorders, including nonimmune hydrops, molar pregnancies, congenital cystic adenomatoid malformation of the lung, and sacrococcygeal teratoma. Polyhydramnios and placentomegaly are usually present. Although the etiology of this condition is unclear, the end result is a maternal hyperdynamic state with associated hypertension and total body edema.<sup>126</sup> Respiratory insufficiency or pulmonary edema may develop, requiring prompt and aggressive treatment. If preterm uterine contractions develop, treatment options may be limited because tocolytic agents can greatly exacerbate respiratory decompensation.

Treatment is aimed at maternal supportive care; even correction of the underlying fetal pathology will not completely resolve the maternal abnormalities. Delivery of the fetus is the only sure method to completely reverse this maternal pathologic process.

The anesthesiologist should specifically investigate for the presence of placentomegaly; increased placental blood flow may alter pharmacologic treatment in both the mother and the fetus because increased drug metabolism may occur. The presence of placentomegaly may also increase risk for acute intraoperative bleeding, and preparation must be made to rapidly transfuse the mother. Several reports describe inadvertent inclusion of the placental edge during the hysterotomy incision, causing a sudden, massive loss of blood with a completely relaxed uterus<sup>127,128</sup>; immediate surgical control, resuscitation with blood products, and vasopressors that do not increase placental vascular resistance must be administered.

## Tocolysis and Tocolytic Agents

The occurrence of contractions and preterm labor is an expectation for the first few postoperative days. Fortunately, in many cases, delivery can be postponed until after 32 weeks, giving the fetus time to heal from the procedure and allowing the lungs to mature. However, for many women, the onset of surgically induced preterm contractions heralds premature labor and delivery that, at best, eliminates the positive results of the procedure, and, at worst, ends in the loss of the pregnancy. Although most women who require fetal surgery can be successfully prevented from delivering immediately after surgery, the current generation of medications used for tocolysis have been ineffective in preventing premature labor and delivery. Preterm labor remains the single most common complication that limits the success of fetal surgery.

### HORMONAL RECEPTORS IN LABOR

The adrenergic hormonal system plays a very influential part in the activity of the myometrium; several types of adrenergic receptors are found in the uterus (Fig. 37-4). Stimulation of the  $\alpha$ -adrenergic receptor causes an increase in the rate and intensity of uterine contractions, whereas activation of the  $\beta_2$ -adrenergic receptors produce myometrial relaxation.<sup>129</sup> In addition, the term uterus is heavily populated with receptors for endogenously released oxytocin responsible for initiating uterine contractions. Prostaglandins also play a significant role in modulating myometrial tone. In general, prostaglandins are produced in or near the local environment where they exert their effect; both uterotonic and tocolytic prostaglandins have been identified. The balance of intrauterine and maternal uterotonic prostaglandins is thought to play an essential part in the preparation for both term and preterm labor. Prostaglandins, especially prostaglandin  $E_2$ , are an essential component of every aspect of natural labor.<sup>130</sup>

### TREATMENT OF ACUTE PRETERM LABOR

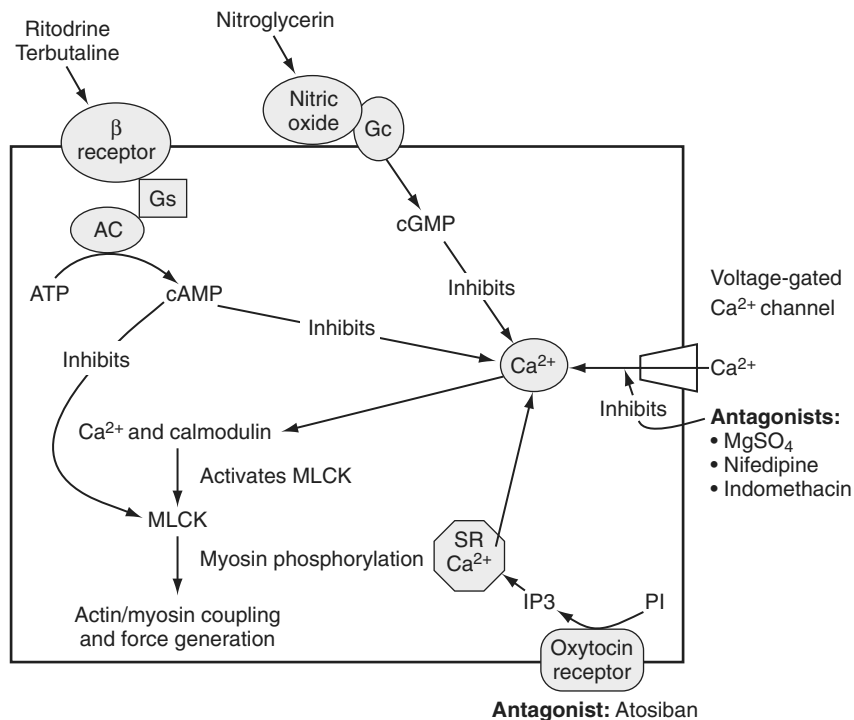

#### Nonsteroidal Antiinflammatory Drugs

Nonsteroidal antiinflammatory drugs (NSAIDs) block the action of cyclooxygenase, preventing the formation of prostaglandins. In-vitro studies of indomethacin have found consistent inhibition or complete arrest of overall myometrial activity.

#### $\beta$ -Adrenergic-Mimetic Agents

Currently, only  $\beta_2$ -adrenoceptor-selective medications are routinely used for acute preterm labor. Most adverse effects result

**FIGURE 37-4** Biochemistry of uterine contraction and its inhibition. AC, Adenylate cyclase; ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; cGMP, cyclic guanosine monophosphate; Gc, G-protein c; Gs, G-protein s; IP3, inositol triphosphate; MLCK, myosin light-chain kinase; PI, phosphatidylinositol; SR, sarcoplasmic reticulum.

from their lack of pure specificity, that is, simultaneous stimulation of  $\beta_1$ - and  $\beta_2$ -adrenergic receptors. Adverse effects include fetal tachycardia, maternal tremors, palpitations, tachycardia, a decreased or increased blood pressure, lethargy, sleepiness, ketoacidosis, and pulmonary edema. Pulmonary edema occurs in up to 5% of patients, especially when used with other tocolytics (e.g., magnesium).<sup>131</sup> Because the  $\beta$ -adrenergic-mimetic agents are nonspecific receptor agonists, in large concentrations these agents can stimulate  $\alpha$ -adrenergic receptors, which promotes uterine contractions, leading to treatment failure.

### Magnesium

Magnesium competes with calcium for transmembrane channel entry into cells.<sup>132</sup> Because the myometrium depends on stores of calcium for adequate contraction, a decrease in intracellular transport prevents the activation of the actin and myosin complex, resulting in uterine relaxation.

### Nitric Oxide Donors

Nitroglycerin is an effective uterine relaxant used in select situations to produce rapid uterine relaxation (e.g., extraction of a retained placenta and uterine inversion). In pregnant sheep, nitroglycerin causes a decrease in mean maternal arterial pressure and increase in heart rate, without compromising uterine blood flow.<sup>133</sup> During fetal surgery, nitroglycerin has been used to relax the myometrium and halt breakthrough contractions. Adverse effects include maternal hypotension, tachycardia, headache, development of tachyphylaxis, and a high incidence of maternal pulmonary edema.<sup>134</sup>

### Calcium-Channel Blockers

Calcium-channel blockers are better tolerated than  $\beta$ -adrenergic-mimetic agents. Nifedipine may be more effective than  $\beta_2$ -adrenergic agonists in postponing delivery, especially in those women with intact membranes.<sup>135</sup> Neonates born to women

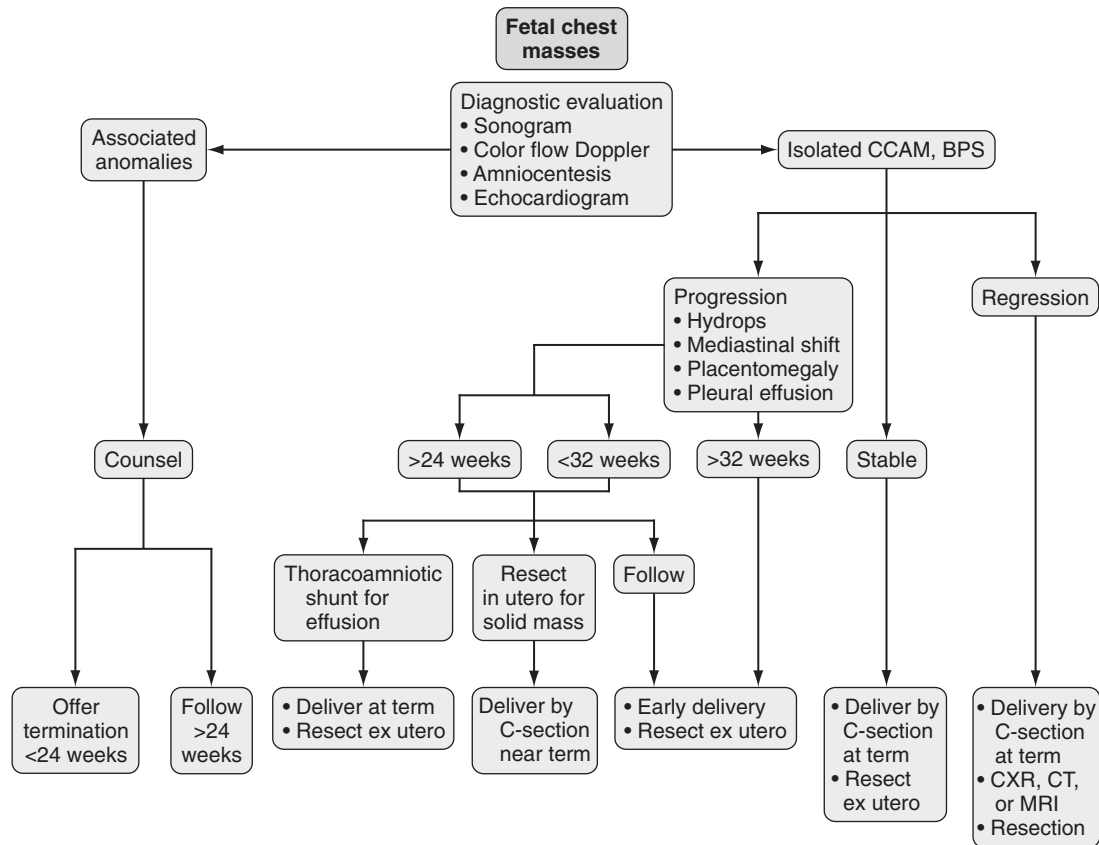

treated with calcium-channel blockers have a reduced frequency of respiratory distress, necrotizing enterocolitis, and intra-ventricular hemorrhage.<sup>136</sup> The most serious adverse effect is maternal hypotension; the combination of calcium-channel blockers and magnesium sulfate should generally be avoided.

### PAIN CONTROL

Pain control after fetal surgery is an essential component of tocolytic therapy, because it is thought that adequate pain control prevents the stress-induced hormonal impetus for preterm labor. Surgical stress elicits the release of adrenocorticotrophic hormone that increases production of cortisol; cortisol production, in turn, leads to the deleterious changes in the placenta that increase fetal estrogen and prostaglandin production, promoting increased uterine activity.

### FETAL COMPLICATIONS OF TOCOLYTIC THERAPY

The adverse effects of tocolytics in the fetus present a number of problems, albeit usually less so than in the mother. Sympathomimetics that act through  $\beta$ -adrenoceptors cause fetal tachycardia.<sup>137</sup> Whereas cyclooxygenase inhibitors have been shown to be more effective than other tocolytics in delaying labor,<sup>138</sup> the adverse effects of fetal oliguria and ductus arteriosus constriction have limited their long-term use.<sup>139</sup> However, after short-term use, these adverse effects are fully reversible within 72 hours from cessation of treatment.<sup>139</sup> Longer-term use of indomethacin has been associated with renal dysfunction and increased rates of necrotizing enterocolitis, intracranial hemorrhage, and patent ductus arteriosus in infants delivered at less than 30 weeks gestation.<sup>140</sup> Magnesium sulfate reduces FHR variability<sup>141</sup> and depresses fetal right ventricular function.<sup>142</sup> Because this drug rapidly crosses the placenta but is excreted more slowly by the fetal kidneys than by the maternal kidneys, there are concerns about fetal toxicity, resulting in respiratory and central nervous

system depression.<sup>143</sup> Nitric oxide donors, such as nitroglycerin, appear to have minimal fetal side effects.<sup>144</sup>

### POSTOPERATIVE PULMONARY EDEMA

Noncardiogenic pulmonary edema is a known complication of tocolysis. Most often, obstetric pulmonary edema is a result of increased hydrostatic pressures and resolves rapidly with diuretics, cessation of tocolytics, and fluid restriction. One study observed a prevalence of pulmonary edema of 0.5%, but that rate increased to 23% in fetal surgical patients; 93% of those with pulmonary edema required intensive care and 20% required tracheal intubation.<sup>134</sup> It has been hypothesized that extensive uterine manipulation during surgery may result in release of mediators that increase the permeability of lung vasculature. The class of medications most strongly associated with pulmonary edema is  $\beta$ -adrenergic-mimetic agents. An additional important observation is that patients receiving nitroglycerin for tocolysis have demonstrated more pronounced pulmonary edema (more severe hypoxemia, greater time to resolution, worse chest radiograph, and a greater composite lung injury scores) than those who received other tocolytics.<sup>134</sup>

## Congenital Cystic Adenomatoid Malformation: The Open Procedure

Congenital cystic adenomatoid malformation (CCAM) serves as a prime example of a fetal condition requiring open intervention.

Fetuses with lung masses presenting before extrauterine viability represent a complex group of congenital disorders. Before the advent of preterm fetal intervention, management of fetal lung masses consisted of limited options, which included (1) delivery with hydrops once fetal viability was determined with regard to lung maturity while acknowledging the potential need for emergent postpartum resuscitation, (2) transplacental digoxin therapy in an effort to treat severe forms of cardiac dysfunction,<sup>145,146</sup> and (3) termination of the pregnancy if the fetus was considered nonviable (Fig. 37-5). Fetuses demonstrating in-utero tumor regressions as documented by serial sonograms are allowed to progress to term gestation. Most infants with smaller lung masses or those with masses demonstrating in-utero regression do well with standard delivery and neonatal resection.<sup>147</sup> However, a subset of fetuses experience significant fetal lung mass growth, ultimately compromising normal lung development. Treatment options for these fetuses have expanded to include cyst aspiration, thoracocentesis, double-J stents for permanent thoracic drainage, and in-utero resection of the lung mass.<sup>147-149</sup> All treatment options aim to reduce the size of the lung mass to allow the remaining fetal lung to develop.

### CONGENITAL CYSTIC ADENOMATOID MALFORMATION OF THE LUNG

CCAM of the lung consists of cystic masses of pulmonary tissue and bronchial structures, neither of which participate in gas exchange,<sup>150,151</sup> that may represent a form of pulmonary hypoplasia.<sup>152</sup> CCAMs can compress surrounding lung tissue

and impede normal lung development, resulting in pulmonary hypoplasia.<sup>153</sup> Of all the fetal lung masses, CCAM is the lesion most frequently associated with hydrops fetalis that often indicates a premorbid fetal state. Although the exact mechanisms for the development of hydrops are unclear, it has been suggested that it is secondary to either cardiac compression or vena caval obstruction from the intrathoracic mass.<sup>154,155</sup> This condition is associated with a significant imbalance of fetal fluid, resulting in accumulation of fetal fluid causing increases in fetal interstitial and total body water, pericardial and pleural effusions, ascites, anasarca, polyhydramnios, or placental thickening.<sup>156,157</sup>

Fetal lung abnormalities themselves may lead to excessive fluid accumulation because the fetal lung is an important organ for amniotic fluid balance. The average fetal lung fluid production is estimated to be approximately 300 mL/day or about 4 mL/kg/hr.<sup>158</sup> Fetal urine output is approximately 700 mL/day, and fetal swallowing is about 700 mL/day. The remaining 300 mL/day is postulated to exit the amnion through the chorioamniotic membrane. CCAMs may impair fetal swallowing via esophageal obstruction and therefore disrupt normal fluid balance; fetal swallowing is the major method by which amniotic fluid water is returned to the fetal vascular compartment. A second possibility is hypersecretion or transudation of fluid from the CCAM itself.

### Management

Experts have formulated guidelines for the fetal surgical management of fetuses diagnosed with CCAM lesions; overall prognosis depends on the size of the lung mass and the presence of secondary physiologic derangements.<sup>147</sup> Special consideration is given to fetuses exhibiting signs of hydrops fetalis, especially those who are less than 32 weeks gestation.<sup>159</sup> Although these conclusions were based primarily on the experience with CCAM infants, it might be appropriate to extend this experience to the management of fetuses with other lung lesions. The primary goal of treatment is to reduce lesion size so that the fetal lung has an improved chance of normal development.

### Operating Room Preparation

Like all other types of fetal intervention, ultrasonography should be performed before the induction of anesthesia to assess fetal well-being and to obtain an estimated fetal weight. In addition to the normal preanesthesia preparation checklist, additional maternal airway equipment, resuscitation drugs, and tocolytic agents should be prepared and immediately available. The availability of type-specific packed red blood cells for the mother and O-negative irradiated packed red blood cells, divided into 50 mL aliquots for the fetus must be confirmed. The operating room (OR) temperature should be warmed to at least 80° F (26.7° C) to prevent hypothermia of the partially exposed fetus during thoracotomy. Resuscitation drugs for the fetus (atropine 10 to 20 µg/kg, epinephrine 1 to 10 µg/kg), as well as a neuromuscular blocking drug (NMBD; e.g., vecuronium 0.2 mg/kg or pancuronium 0.1 mg/kg), and fentanyl (10 µg/kg) are prepared under sterile conditions, thus making them available during the procedure.<sup>160</sup> A rapid infusion system with warmed isotonic saline is used to replace amniotic fluid loss during fetal lung resection, and is ready to administer onto the surgical field via a sterile tubing system. A pulse oximeter with a sterile extension cord should be available for application to the upper extremity of the fetus.

### Induction

The preferred method of maternal anesthesia for these cases is general anesthesia with endotracheal intubation and neuromuscular blockade. Before entering the OR, an IV line is started and sedation is administered as needed. If the mother has not received indomethacin (50 mg rectal suppository) for tocolysis before arrival, it is administered after induction of general anesthesia. Indomethacin is used in conjunction with magnesium in the postoperative period for tocolysis but does not play a significant tocolytic role in the intraoperative period. After placement of standard monitors, a lumbar epidural catheter may be inserted for postoperative pain management. With the exception of a test dose, most practitioners avoid local anesthetic administration through the epidural catheter until the fetal intervention is completed. This is done to avoid possible decreases in maternal mean arterial pressure from an epidural-associated sympathectomy. The mother is then positioned in a uterine displacement position, preoxygenated, and a rapid-sequence induction is performed with an induction agent, succinylcholine (and subsequently followed with a short-acting nondepolarizing agent), and a rapid-acting opioid. Anesthesia is maintained with 1 MAC of the inhaled anesthetic of choice (usually sevoflurane or desflurane, should a rapid reinstatement of uterine tone be required) in 100% oxygen, while an ultrasonographic examination maps out surface anatomy with respect to the placenta and fetus, as well as reassuring fetal well-being after anesthetic induction. A second large-bore peripheral IV catheter, radial arterial catheter, urinary catheter, and nasogastric tube are then inserted. Because the maternal anesthesia induction is the same as a standard cesarean section, invasive blood pressure monitoring is not necessary until the inhalational anesthetic is increased to 2 to 3 MAC. Fetal hemodynamics (heart rate, right ventricular contractility) are monitored intraoperatively by continuous fetal echocardiography.<sup>160</sup>

Alternatively, in cases where a long period of time is expected to transpire between maternal induction and hysterotomy, a substitution or combination with an IV anesthetic (typically propofol and remifentanyl) may reduce fetal cardiac acidosis seen with greater concentrations of inhalational anesthetics (most notably desflurane).<sup>161</sup> In such cases, large concentrations of inhalational anesthetics should be reinstituted before uterine incision to assure adequate uterine relaxation. Alternatively, recent reports have described total IV anesthesia techniques employing remifentanyl, nitrous oxide, midazolam as general anesthetic agents with IV nitroglycerin used for uterine relaxation.<sup>162</sup> Remifentanyl, which moves across the placenta freely, has also been described as an agent for fetal immobilization under combined spinal epidural anesthesia.<sup>163</sup>

### Maintenance

Before hysterotomy the concentration of inhalational anesthetic is increased to 2 MAC to ensure myometrial relaxation and tocolysis.<sup>160,164</sup> Satisfactory uterine relaxation can be achieved, but these concentrations may decrease maternal arterial pressure, uteroplacental perfusion, and fetal oxygenation, and may require pressor support.<sup>160,165</sup> Although only small increases in fetal PaO<sub>2</sub> occur with maternal inspired oxygen concentrations of 100%, this small increase may be advantageous. Additionally, the increased concentration of inhalational anesthetic needed for uterine relaxation dictates that only medications that augment uterine relaxation be administered.<sup>166</sup> Given that nitrous oxide does not affect the uterine tone to any measurable degree and

thus provides no direct surgical benefit, it is best omitted and 100% oxygen is used. Maternal eucapnia ( $\text{PaCO}_2$  of 31–33 mm Hg) is the physiologic goal,<sup>156</sup> because maternal hyperventilation may lead to decreases in fetal  $\text{PaO}_2$ .<sup>167,168</sup> Some have suggested that maternal hypercarbia can, in fact, increase fetal  $\text{PO}_2$ .<sup>169</sup> At this time, however, extrapolation of these conclusions to fetal intervention cases should be done with caution.

When recovery from the short-acting nondepolarizing agent has been achieved, additional doses of muscle relaxant should be titrated as needed. If preoperative tocolytic agents were administered, combined with the anticipated administration of magnesium sulfate during the abdominal closure, long-acting NMBDs are best avoided, to ensure that neuromuscular blockade can be antagonized at the end of the surgery.

Meticulous attention to maternal blood pressure is essential to ensure adequate uterine blood flow and uterine perfusion; maternal systolic pressure is maintained at 110% of mean awake values with IV ephedrine or phenylephrine. Total IV fluids are limited unless blood loss is excessive, so as to minimize the risk of postoperative maternal pulmonary edema.<sup>170</sup>

Once the uterus has been completely exposed, the surgeons assess uterine tone. Because there is no objective method to assess the degree of uterine relaxation, surgical palpation remains the standard. The concentration of inhalational anesthetic is adjusted as needed, with bolus doses of nitroglycerin administered, followed by an infusion to diminish uterine tone. Any attempted surgical manipulation before complete uterine relaxation may increase uterine vascular resistance, reduce uterine perfusion, and place the fetus at risk for hypoxia.

After adequate uterine relaxation, the hysterotomy site is prepared by placement of two sutures parallel to the proposed incision site and through the full thickness of the uterine wall. A hemostatic uterine stapling device is inserted. Once the stapler is deployed, the amniotic membranes are secured to the uterine wall, effectively minimizing excessive maternal bleeding. However, if the stapling device misfires or if the placental edge is mistakenly incorporated into the hysterotomy, significant hemorrhage may occur.

### Intervention

The fetal hemithorax and upper extremity are delivered through the hysterotomy. Warm fluids are continuously infused into the uterine cavity from a high-volume fluid warmer to replace amniotic fluid losses, provide a thermoneutral environment for the fetus, and prevent umbilical cord kinking or stretching. Limiting the size of the uterine incision helps prevent fetal evaporative fluid loss, uterine hemorrhage, and postoperative uterine contractions. Once the fetal hemithorax and upper extremity have been delivered into the operative field, fentanyl (5 to 20  $\mu\text{g}/\text{kg}$ ), atropine (20  $\mu\text{g}/\text{kg}$ ), and an NMBD (usually vecuronium 0.2 mg/kg or pancuronium 0.1 mg/kg) are given IM as a single injection into the exposed shoulder of the fetus.<sup>160</sup> Fentanyl is administered for intraoperative and postoperative fetal analgesia and to suppress the fetal stress response, atropine ablates the expected bradycardic response with fetal surgical manipulation, and an NMBD will ensure an immobile fetus during surgery. Although the fetus receives anesthesia from transplacental transfer of maternal inhaled anesthetic, these additional IM medications augment fetal anesthesia and ensure fetal analgesia before thoracotomy.

A pulse oximetry probe can be applied to the exposed fetal extremity. Fetal echocardiography provides information about

**FIGURE 37-6** In-utero thoracotomy in a 22-week fetus after excision of congenital cystic adenomatoid malformation. (Courtesy N. Scott Adzick, MD, Children's Hospital of Philadelphia.)

FHR and ventricular filling, which is particularly useful in those procedures in which fetal blood loss is anticipated (Fig. 37-6). Fetal lung lesions, especially if composed of multiple tissue types, may have a very irregular vascular supply, and significant fetal hemorrhage is possible. Direct vascular access in the exposed upper extremity allows immediate resuscitation and blood administration as needed. Even surgical manipulations alone can lead to hemodynamic instability, requiring urgent resuscitation. This may be secondary to mediastinal torsion, resulting in a sudden loss of cardiac preload.

### Intraoperative Fetal Resuscitation

Fetal bradycardia (FHR less than 100 beats per minute) usually results from hypoperfusion with low cardiac output, umbilical cord kinking, or surgical manipulation, but it may also be a result of increased uterine vascular resistance or unrecognized bleeding from the tumor site. Other expected surgery-related complications include blood loss from the tumor, hypothermia, dehydration, and unintended delivery of the fetus. Despite identification and correction of precipitating factors, the fetus may remain severely bradycardic and require resuscitation. Efforts should be made to maximize fetal perfusion and ensure adequate fetal intravascular volume. Maneuvers include confirming maternal  $\text{FiO}_2$  of 100%, increasing maternal mean arterial pressure to 15% to 25% above awake values, increasing the concentration of the inhalational anesthetic to minimize the resistance of the uterine vessels, confirming adequate intrauterine volume with warmed replacement Ringer's lactate solution, and identifying the umbilical cord via ultrasonography to verify that twisting or kinking has not occurred are essential to avoiding untoward events. Pharmacologic support may also be needed. In cases with no fetal intravascular access, IM epinephrine (1 to 2  $\mu\text{g}/\text{kg}$ ) and atropine (20  $\mu\text{g}/\text{kg}$ ) can be administered and repeated if necessary. If intravascular access is available, pharmacologic resuscitation should be administered via this route to guarantee immediate effect. In addition, blood transfusions (5 to 10 mL/kg O-negative irradiated packed red blood cells [PRBCs]) can be administered in cases of severe fetal hypovolemia, by either an upper extremity intravascular route or by percutaneous access to the umbilical vein with ultrasound guidance.

**FIGURE 37-7** Hysterotomy closure. (Courtesy N. Scott Adzick, MD, Children's Hospital of Philadelphia.)

### Closure

Once the lung lesion has been resected and fetal well-being is confirmed, the fetus is returned to the intrauterine environment and the hysterotomy incision closed. Closure consists of two separate layers, thus minimizing the risk for postoperative amniotic fluid leak and uterine wall dehiscence (Fig. 37-7). It is important to maintain complete uterine relaxation during closure, because uterine manipulation can alter blood flow and place the fetus at risk of hypoperfusion. Before the last uterine stitches, intraamniotic volume is assessed via ultrasonography and any deficit is replaced with warmed Ringer's lactate solution.

Once the uterine incision is closed, the surgeon begins to close the maternal abdominal wall. At this time, a loading dose of magnesium sulfate (6 g) is administered IV over 20 minutes, followed by a 3-g/hr infusion that is continued postoperatively. The epidural catheter can be dosed with local anesthetic (15 to 20 mL of 0.25% bupivacaine) and an opioid (e.g., fentanyl 1 to 2  $\mu\text{g/kg}$ ) as the inhalational anesthetic is decreased or discontinued. Careful attention to the degree of neuromuscular blockade is needed, as magnesium sulfate potentiates the action of the muscle relaxants. Extubation occurs as soon as the usual criteria for extubation are met.

### Postoperative Management

As soon as the procedure is completed, the mother should be monitored by experienced staff with necessary equipment to immediately address any complications that might occur. Ultrasonography is performed in the immediate postoperative setting and frequently over the subsequent week to monitor fetal hemodynamic stability. Tocodynamometers to assess the degree of uterine activity and irritability are used to guide tocolytic therapy.

Serious postoperative complications include premature labor, pulmonary edema, amniotic fluid leak, wound seroma, infection, and fetal demise.<sup>156,160,171-175</sup> Virtually all patients experience premature uterine contractions in the immediate postoperative period, thereby necessitating a continuous magnesium sulfate infusion until premature labor is significantly diminished. In some instances, additional tocolytic agents may be necessary. Despite maximal tocolytic therapies, continued uterine irritability may result in premature delivery. Amniotic fluid leak can lead to oligohydramnios and significant reductions in amniotic fluid

volume that may necessitate replacement. In refractory cases, the mother may return to the OR for reclosure of the hysterotomy incision.

The etiology of fetal demise after open fetal surgery is usually secondary to a primary complication (see earlier discussion). As such, every effort is made to minimize and promptly treat potential postoperative complications to ensure a positive fetal intervention and to provide an environment for a successful term gestation. Surgical stress and pain can lead to release of cortisol and inflammatory cytokines in both the mother and the fetus, which, in turn, may lead to premature uterine maturation and contractions.<sup>176</sup> Maternal pain control can be provided by patient-controlled analgesia and epidural or spinal analgesia. One disadvantage of epidural analgesia is that the systemic opioid concentrations are reduced; therefore less is transferred to the fetus for postoperative analgesia. The benefit from a greater concentration of systemic opioids produced by IV analgesia is the possibility of improved fetal analgesia. However, IV analgesia does not reliably prevent a maternal stress response. To address this, the optimal choice for epidural analgesia may be a reduced concentration of the local anesthetic with a large concentration of a fat-soluble opioid, such as fentanyl (e.g., bupivacaine [0.05%] and fentanyl [10  $\mu\text{g/mL}$ ]).<sup>171</sup>

## Other Diseases Eligible for Open Procedures

### PULMONARY SEQUESTRATION

Pulmonary sequestration, also known as bronchopulmonary sequestration, accessory lung, or bronchopulmonary foregut malformation, represents 0.5% to 6% of congenital lung disease (0.15% and 1.7% of live births).<sup>30-32</sup> Pulmonary sequestrations consist of nonfunctional lung tissue that does not communicate with the normal tracheobronchial tree and hence does not participate in gas exchange.<sup>31</sup> Pulmonary sequestration may be differentiated from CCAM by investigation of its blood supply. Unlike pulmonary sequestrations, CCAMs derive their blood supply and venous drainage from the pulmonary circulation. A multitude of somatic anomalies have been associated with sequestration, most commonly diaphragmatic hernia. If not treated in utero, these lesions often present as respiratory distress in the neonatal period or as chronic respiratory infections in older children.

### BRONCHOGENIC CYSTS AND MIXED OR HYBRID PULMONARY LESIONS

Bronchogenic cysts are embryonic abnormalities considered to be a type of bronchopulmonary foregut malformation.<sup>177</sup> These cysts are thought to result from an abnormal budding of the primitive bronchial tree between weeks 4 and 8 of gestation, thus representing abnormal lung development at an early stage of ontogeny.<sup>178</sup> In most cases, bronchogenic cysts are asymptomatic in the first months of life. A notable exception is a mediastinal cyst that usually manifests as stridor.

Although in-utero complications are less likely than with the other fetal lung lesions previously described, the propensity of these lesions to cause life-threatening postnatal complications warrants close attention throughout the prenatal period. Fetal intervention with intermittent or continuous drainage of cysts can prevent the secondary morbidity; definitive fetal surgery with thoracotomy has also been successful.<sup>179</sup>

**FIGURE 37-8** Fetal sacrococcygeal teratoma before in-utero resection in a 22-week fetus. (Courtesy N. Scott Adzick, MD, Children's Hospital of Philadelphia.)

### SACROCCOCCYGEAL TERATOMA

Sacrococcygeal teratomas (SCTs, Fig. 37-8) are one of the most common congenital neonatal tumors (1 per 40,000 live births).<sup>180-182</sup> A variety of tissues from the three primary germ layers are usually found, and the size of the tumor is quite variable.<sup>183,184</sup> Most SCTs are external, usually protruding from the perineal region. The majority include both solid and cystic components, with only 15% being entirely cystic.<sup>185,186</sup> Although usually benign, SCTs can cause significant secondary morbidity in selected cases because of the tumor's mass effect and vast blood supply.<sup>187</sup> With smaller tumors, complete surgical resection usually occurs after delivery under elective, controlled conditions. In extreme cases, the tumor can cause fetal congestive heart failure (usually high output failure), and even fetal demise if no treatment is performed.<sup>188</sup> Death is usually secondary to an enlarged tumor mass and associated polyhydramnios, resulting in preterm labor and delivery, with ultimate survival dependent on fetal lung maturity. Massive hemorrhage into the tumor with fetal exsanguination may occur spontaneously in utero or be precipitated by labor and delivery. Prenatal intervention may be necessary, including intrauterine transfusion or fetal surgery for those fetuses that develop significant secondary morbidity (e.g., hydrops).

### Hypoplastic Left Heart Syndrome: Percutaneous and Fetoscopic Procedures

A variety of congenital heart defects (CHDs) may be considered for fetal intervention. To date, the most studied defects include severe aortic stenosis with evolving hypoplastic left heart syndrome (HLHS) and pulmonary valve atresia with an intact ventricular septum with evolving hypoplastic right heart syndrome.<sup>189-193</sup>

#### RATIONALE FOR FETAL CARDIAC INTERVENTION

Most CHDs can be safely repaired in infancy, with excellent surgical survival and long-term prognosis. For these defects, there would be no need for in-utero intervention; and for many defects, in-utero intervention would not be technically possible (e.g., arterial switch procedure for transposition of the great

arteries). For other defects, surgical correction itself may not be possible and the only option is staged surgical palliation, which is often associated with significant surgical morbidity and mortality.<sup>189,194,195</sup> As such, the risk of performing any fetal intervention must be balanced against the potential benefits of improving the anticipated outcome of surgery performed in the neonatal period to correct the specific cardiac defect. It is the intention of prenatal intervention for certain types of CHD to reverse the pathologic process in an attempt to preserve cardiac structure and function and, thus, it is hoped, prevent serious postnatal disease. A secondary aim of prenatal intervention is to modify the severity of the disease and improve postnatal surgical outcomes.

#### DEFECTS AMENABLE TO IN-UTERO REPAIR

Certain congenital heart defects cause aberrations in blood flow, which are usually secondary to valvular stenosis or regurgitation. Regardless of the etiology, the end result is often an abnormally developed ventricle.<sup>196</sup> Several case reports have characterized the progression of valvular stenosis to ventricular hypoplasia from reduced flow through the chamber during gestation.<sup>197-199</sup> It has been hypothesized that relief of valvular stenosis in utero could reverse the progression toward ventricular hypoplasia. In these cases, there may be a window of opportunity in which ventricular growth can be salvaged. Because most routine prenatal ultrasonographic screening is performed between 16 and 24 weeks gestation, the window of opportunity for prenatal intervention is likely between 20 and 26 weeks gestation.

To date, the defect most amenable to correction is severe aortic stenosis with evolving HLHS.<sup>197-200</sup> Without prenatal intervention, severe aortic stenosis can lead to marked left ventricular dysfunction, diminished flow through the left heart, arrest of left ventricular growth, ventricular fibroelastosis, and, consequently, HLHS. Aortic valve dilation may be performed percutaneously with ultrasound guidance. Optimal fetal positioning, placental location, or maternal habitus may require exposure of the uterus through an abdominal incision to obtain ideal access to the fetal thorax. These procedures have been performed under both maternal regional and general anesthesia, although general anesthesia is often preferred to obtain optimal uterine relaxation and an anesthetized fetus. Preliminary results are promising, but larger prospective investigations are warranted to determine long-term outcomes.<sup>201</sup>

#### TECHNICAL ASPECTS OF FETAL CARDIAC INTERVENTIONS

Open cardiac surgery on the fetus is not presently technically possible.<sup>202-206</sup> In humans, all of the reported procedures to date have been attempted using the transcatheter or transuterine approach with ultrasound-guided access into the fetal heart.<sup>191-193</sup> Although hysterotomy would provide means for more direct fetal access (e.g., femoral artery, transumbilical or carotid artery access), maternal morbidity would be significantly increased and postoperative premature labor certain. After valvuloplasty, the fetus requires time for the ventricle to recover. Therefore, any procedure that substantially increases the likelihood of early delivery would likely be counterproductive.

Although initial percutaneous techniques for fetal cardiac valvuloplasty were performed with only the mother receiving sedation,<sup>191,192</sup> recent advances in surgical techniques have led to provision of maternal and fetal analgesia and anesthesia.<sup>207</sup> The mother usually receives general anesthesia. After ultrasonographic confirmation of placental location, the maternal abdomen and uterus are punctured with a 22-gauge spinal needle. An IM

**Normal Heart****Hypoplastic Left Heart****Catheterization Procedure (top view)**

**FIGURE 37-9** Technique for balloon dilation of a stenotic aortic valve in a fetus with hypoplastic left heart syndrome. (Reproduced with permission from Dream Magazine, Spring/Summer 2002, Boston: Children's Hospital Boston; 2002. p. 20.)

injection of fentanyl, atropine, and a muscle relaxant is delivered to the fetus. A 19-gauge needle is subsequently directed into the fetal thorax, and access to the fetal heart is obtained. A small coronary balloon-tipped catheter is threaded over a guidewire through the needle, and passed through the stenotic valve or closed septum. The catheter balloon is then dilated, and blood flow is confirmed using Doppler ultrasonography (Fig. 37-9). The technique has been modified in certain cases, such that a laparotomy to expose the uterus is performed. Using this technique, better ultrasonography and ideal fetal positioning are possible to achieve optimal access to the fetal thorax.

**ANESTHETIC MANAGEMENT FOR THE MOTHER**

Most cases of fetal cardiac intervention are performed using a percutaneous technique or through a laparotomy incision with direct uterine exposure. The surgical approach will vary according to patient habitus, placental position (anterior vs. posterior), and fetal position. For the less invasive percutaneous approach, the choice of a regional anesthetic accompanied by IV sedation for the mother may be acceptable. However, it must be remembered that although the placental transfer of sedative drugs administered to the mother may sedate the fetus, an anesthetized or immobile fetus is not guaranteed. Excessive fetal movement makes most cardiac interventions impossible and even dangerous to both the fetus and mother.

Patients who received an epidural anesthetic technique required significantly more IV fluids but less IV opioid. The administration of large amounts of crystalloid and tocolytics during fetal surgery increases the risk of maternal pulmonary edema.<sup>208,209</sup> Neuraxial techniques (e.g., spinal, epidural, and combined spinal-epidural anesthesia) have been used in other percutaneous and fetoscopic procedures; a T4 sensory level blockade is required. It should be noted that neuraxial anesthesia provides no uterine relaxation and no analgesia or anesthesia to the fetus unless supplemented with IV maternal analgesics and sedatives (e.g., fentanyl, benzodiazepines, propofol). Because of these issues, it is generally recommended, even in anticipated percutaneous procedures, to deliver a general anesthetic to the mother. If there is a high suspicion of a laparotomy being performed, a dose of spinal Duramorph (morphine sulfate) may be delivered to the mother before the anesthetic induction for postoperative pain relief and resultant suppression of myometrial contractility after laparotomy.<sup>197,198</sup>

**ANESTHETIC MANAGEMENT FOR THE FETUS**

Anesthesia for percutaneous and fetoscopic interventions, of which fetal cardiac interventions are a significant subset, pose several unique challenges for the anesthesiologist. The combination of immature organ systems and the underlying cardiac anomaly places the fetus at considerable anesthetic risk. Unlike

adults and older children, fetal cardiac output depends more on heart rate than on stroke volume. Because fetal myocardial contractility is likely maximally stimulated, the fetus has a limited ability to increase stroke volume. Therefore, it is plausible that fetal patients with congenital heart disease and evidence of failure (i.e., hydrops) will exhibit more pronounced physiologic limitations. Notably, anesthetic-induced decreases in contractility, combined with intracardiac catheter manipulation in a structurally compromised heart, can result in fetal hypotension, bradycardia, and eventual cardiac collapse and death. It is generally accepted that neonates manifest a greater degree of hypotension in response to isoflurane and halothane at equipotent anesthetic concentrations when compared with older children.<sup>210,211</sup>

Because direct exposure of the fetus is not warranted during most cardiac interventions, intraoperative monitoring is limited to echocardiography. An ultrasonographer continually monitors the fetal heart during placement of the intracardiac needle and during catheter balloon inflation. A continuous echocardiogram is also useful for measuring FHR, contractility, and volume status.

### INTRAOPERATIVE FETAL RESUSCITATION DURING PERCUTANEOUS INTERVENTIONS

If fetal bradycardia (heart rate less than 100 beats per minute) or significantly reduced ventricular function develops, resuscitation proceeds immediately. Because direct vascular access to the fetus may not be immediately available, several other treatments can be employed. Intracardiac and IM administration of epinephrine (1 to 2  $\mu\text{g/kg}$ ) may be used to treat severe sustained bradycardia. Other maneuvers improve uterine perfusion and hence fetal oxygenation and include increasing maternal mean arterial pressure to 15% to 25% above awake values with volume loading and ephedrine or phenylephrine, and decreasing uterine vascular resistance by ensuring adequate uterine relaxation. Occasionally, pericardial tamponade may cause impaired cardiac function; needle drainage of the effusion may be necessary for fetal survival. If fetal echocardiography indicates a decreased ventricular volume, an intracardiac blood transfusion with O-negative irradiated blood (5 to 10 mL/kg) may be indicated.

### POSTOPERATIVE CONSIDERATIONS

The fetus is monitored postoperatively with intermittent ultrasonographic examinations. The incidence of premature contractions and labor is less after fetoscopic surgery than after open hysterotomy.<sup>212,213</sup> Fetoscopic intervention also appears to have reduced requirements for tocolysis and a reduced rate of premature delivery.<sup>213</sup> If early delivery should occur, many of these fetuses are considered nonviable owing to their young gestational age (usually less than 24 weeks gestation) and serious cardiac disease.

## Other Diseases Eligible for Fetoscopic Procedures

### TWIN-TWIN TRANSFUSION SYNDROME

Twin-twin transfusion syndrome (TTTS) is a serious complication occurring in 10% to 15% of monozygotic monochorionic twin pregnancies.<sup>214</sup> Although all monochorionic twin pregnancies demonstrate one or more placental vascular anastomoses, TTTS represents a pathologic form of circulatory imbalance between the monochorionic twin fetuses.<sup>215</sup> As a result of this

**FIGURE 37-10** Schematic representation of umbilical cord ligation in twin reversed arterial perfusion sequence. (Courtesy T.M. Crombleholme, MD.)

imbalance, a net fetofetal transfusion occurs, from one twin (the donor) to the other (the recipient) (Fig. 37-10). Symptoms develop rapidly and, in the donor twin, include hypovolemia, oliguria, oligohydramnios, and growth retardation. In turn, the recipient twin develops hypervolemia, polyuria, polyhydramnios, and signs of circulatory volume overload, resulting in congestive heart failure.<sup>214-218</sup> In severe cases, if untreated, TTTS may result in intrauterine fetal death and miscarriage. Even if twins with TTTS survive, there remains a high incidence of secondary neurologic and pulmonary morbidities.

Fetoscopic laser photocoagulation of the communicating vessels associated with TTTS is based on three fundamental assumptions: (1) the syndrome occurs in the presence of vascular communications between fetuses in a monochorionic gestation, (2) obliteration of these vessels can halt the pathophysiologic process, and (3) both deep and superficial communications can be interrupted at the surface of the placenta.<sup>219</sup> Fetoscopic laser surgical occlusion of superficial communicating vessels is associated with a reported survival rate of 55% to 83% and a reduced neurologic complication rate (5%) among survivors.<sup>214,216</sup>

There are few data on the reported anesthetic techniques used for fetoscopic laser ablation. The procedure has been performed with local, general, epidural, and combined general and epidural anesthesia.<sup>220-223</sup> Factors that may influence the anesthetic technique include (1) the planned surgical approach and probability of converting to open fetal surgery; (2) the likelihood of surgical perturbation of innervated fetal tissues; (3) maternal preference; and (4) a history of prior uterine activity. The surgical approach for fetoscopic laser photocoagulation is determined by (1) the location of the placenta (anterior vs. posterior), (2) the position of the fetuses, and (3) the potential window(s) for trocar insertion.<sup>224</sup>

### TWIN REVERSED ARTERIAL PERFUSION SEQUENCE

Twin reversed arterial perfusion (TRAP) sequence denotes a common pathophysiology of several different conditions, all of which describe a twin pregnancy in which one twin is normal and the second twin exhibits multisystem malformations, including anencephaly or acardia. The twin with the hemodynamic advantage is denoted as the “pump” twin, perfusing deoxygenated blood in a retrograde direction to the other twin, “the recipient twin.” The term *reversed perfusion* is used to describe this scenario because blood enters the acardiac or anencephalic twin through its umbilical artery and exits through the umbilical vein. This eventually places the normal or “pump” twin at a hemodynamic disadvantage because this normal twin provides cardiac output to both itself and the nonviable sibling. This anomaly places the pump twin at risk of cardiac overload and congestive heart failure, often with associated hepatosplenomegaly.

Perinatal complications with TRAP sequence range in severity, with reported death rates for the pump twin ranging from 39% to 59% in untreated pregnancies.<sup>225</sup> Treatment options include observation, medical therapy with digoxin and indomethacin, selective delivery, umbilical cord blockade with a coil, and fetoscopic cord ligation. Although all endoscopic procedures have the primary aim of interrupting umbilical cord blood flow to the nonviable twin, this invasive technique is generally employed after failed medical therapy or after signs of cardiac failure in the viable twin.<sup>226,227</sup>

### NEEDLE ASPIRATION AND PLACEMENT OF SHUNTS

A variety of fetal disorders may benefit from in-utero needle aspiration or shunt placement. These disorders include posterior urethral valves, aqueductal stenosis, fetal hydrothorax, ovarian cyst, and fetal ascites. Various shunts have been attempted to provide long-term decompression, with variable results.<sup>221</sup>

## The EXIT Procedure

Ex utero intrapartum treatment, or the EXIT procedure, was initially described as a method for reversal of tracheal occlusion in fetuses with prenatally diagnosed severe congenital diaphragmatic hernia that had undergone in-utero tracheal clip application.<sup>228</sup> Although these infants demonstrated no reduced morbidity compared with those who underwent conventional treatment, this novel technique provided a new therapeutic option for fetuses with a variety of potentially fatal diseases. Improvements in prenatal imaging and widespread use of prenatal ultrasonography have increased the identification of potentially lethal fetal structural malformations, which has had a direct impact on perinatal management and outcomes.

Also referred to as the OOPS procedure (operation on placental support),<sup>229</sup> the EXIT procedure allows for a controlled delivery and intrapartum assessment strategy to treat fetuses with certain life-threatening diseases. By maintaining uteroplacental circulation with only partial delivery of the infant, crucial time is provided to perform procedures critical to infant survival. These procedures include direct laryngoscopy, bronchoscopy, intubation, tracheostomy, tumor decompression and resection, and extracorporeal membrane oxygenation (ECMO) cannulation before clamping the umbilical cord (Fig. 37-11). In this way, continuous oxygenation is maintained at all times to the threatened infant, thereby improving the chances of overall survival. The EXIT procedure is now used for infants in whom prenatal imaging suggests a very low probability of survival

**FIGURE 37-11** Fetal rigid bronchoscopy during an ex-utero intrapartum treatment procedure. (Courtesy N. Scott Adzick, MD, Children's Hospital of Philadelphia.)

with conventional treatment methods. This group includes fetuses with known tracheal obstruction and other life-threatening airway abnormalities, as well as those who will likely require ECMO support (i.e., congenital cardiac disease and diaphragmatic hernia).

Unlike many other fetal interventions, however, a planned delivery of the infant is the end result of these interventions. This unique difference creates significant increases in maternal morbidity because these procedures require complete uterine relaxation and serious maternal hemorrhage could result.<sup>230</sup> An intimate understanding of the EXIT procedure, the fetal pathophysiology involved, and pregnancy-induced alterations directly affecting anesthesia care is required to minimize maternal and fetal morbidity and mortality.

### FETAL DISEASES ELIGIBLE FOR THE EXIT PROCEDURE

#### Cervical Teratoma

Cervical teratomas are rare (1 per 20,000 to 40,000 live births) and can extend from the mastoid process to the sternal notch inferiorly and to the trapezius muscle posteriorly. They can also invade the oral floor and extend into the anterior mediastinum. Many of the larger teratomas diagnosed prenatally cause maternal polyhydramnios, which is secondary to esophageal compression by the tumor and impaired fetal swallowing. Most of these tumors are benign but are associated with substantial mortality rates caused by airway compression and difficulty in establishing an adequate airway after delivery (Fig. 37-12).<sup>231</sup> Of neonates with cervical teratomas, 30% die of airway obstruction shortly after delivery<sup>232</sup>; for infants not diagnosed prenatally, mortality rates are even greater.<sup>233,234</sup> In addition, some larger tumors may interfere with normal delivery methods and necessitate emergent alterations in maternal care, placing the mother at increased risk.<sup>231,235</sup>

Until recently, treatment options for infants with cervical teratomas who survived the intrauterine period were limited. The standard of care incorporated scheduled cesarean section followed by various airway maneuvers, including the establishment of a surgical airway. Even with skilled help immediately available, dismal outcomes were common.<sup>231-233</sup> Despite securing the airway,

**FIGURE 37-12** Newborn with a massive oropharyngeal cervical teratoma immediately after ex utero intrapartum treatment was performed to secure the airway. Immediate resection of the teratoma followed in an adjacent operating room.

critical time is needed to perform this task, often at the expense of neonatal oxygenation. With the introduction of the EXIT procedure, precious time is provided to locate the trachea and provide a definitive airway before clamping the umbilical cord, thereby maintaining continuous fetal oxygenation and decreasing morbidity and mortality.

### Cystic Hygroma

Cystic hygromas arise from the failure of the jugular lymph sacs to join the lymphatic system early in fetal development, resulting in the development of endothelium-lined cystic spaces that eventually compress normal surrounding structures. This compression may result in fetal hydrops, including skin edema, ascites, and pleural or pericardial effusions (Fig. 37-13).<sup>233,234</sup> In infants with isolated cervical cystic hygroma and no evidence of hydrops, airway compromise at birth or shortly thereafter is the main therapeutic concern. These infants are considered candidates for EXIT procedures.

### Congenital High Airway Obstruction Syndrome

Congenital high airway obstruction syndrome (CHAOS) is a clinical syndrome consisting of extremely large echogenic lungs, flattened or inverted diaphragms, a dilated tracheobronchial tree, ascites, and evidence of nonimmune hydrops, including fetal ascites, placentomegaly, and pleural or pericardial effusions.<sup>236-238</sup> Airway obstruction may be because of laryngeal atresia, laryngeal cyst, or tracheal atresia. Diagnosis of prenatal CHAOS is confirmed by ultrasonographic evidence of complete or near-complete upper airway obstruction. Most diagnostic findings result from increased intratracheal pressure and distention of the tracheobronchial tree secondary to the accumulation of fluid in the lungs. Cardiac changes include the appearance of an elongated heart, septal shift, and small, compressed heart chambers.<sup>233</sup>

Management guidelines for fetuses with CHAOS are not definitive. In third trimester fetuses with a diagnosis of CHAOS

**FIGURE 37-13** Fetus (with a cystic hygroma) that underwent ex utero intrapartum treatment to establish a surgical airway before delivery. (Courtesy N. Scott Adzick, MD, Children's Hospital of Philadelphia.)

and no evidence of hydrops, there is most probably incomplete airway obstruction, and management is aimed at establishing an airway before complete delivery. This subset of fetuses would likely benefit from an EXIT procedure.<sup>233,239</sup> Those fetuses with a diagnosis of CHAOS made in the second trimester and those with evidence of complete airway obstruction and/or nonimmune hydrops present a dilemma, because insufficient data exist to determine their best treatment options.

### Congenital Goiter

Congenital goiter is associated with fetal hypothyroidism, euthyroidism, or hyperthyroidism. Goiter associated with fetal hypothyroidism is almost always associated with the transplacental passage of a thyroid-stimulating immunoglobulin G antibody from the mother. Such antibodies are present in 90% of women with Graves disease. These antibody levels may not reflect maternal thyroid status, making the fetus of any woman with Graves disease at increased risk for fetal goiter. Less common causes include iodine deficiency, iodine intoxication, congenital metabolic disorders of thyroid hormone synthesis, or hypothalamic-pituitary hypothyroidism. Ultrasonographic findings of fetal hyperthyroidism include cardiac hypertrophy, tachycardia, or nonimmune hydrops fetalis. Fetal hypothyroidism may be associated with fetal cardiomegaly and heart block. Fetal blood sampling is required to determine the fetal thyroid status.<sup>233,240,241</sup>

The possibility of significant airway compression immediately after delivery is similar for all fetuses with goiter. In severe cases, even the presence of experienced personnel in the delivery room may not ensure prompt ability to secure the airway. These infants may benefit from the EXIT procedure; it can provide the time that may be necessary to identify and secure the compromised fetal airway.

### EXIT TO ECMO

In addition to airway management, the EXIT procedure may be considered for other instances in which separation from uteroplacental support is expected to cause critical cardiac or pulmonary compromise. Fetuses with congenital heart disease who are expected to need emergent ECMO at birth and fetuses with poor-prognosis congenital diaphragmatic hernias may benefit from the "EXIT to ECMO" strategy.<sup>230,242</sup> Neonates undergoing

this procedure are partially delivered via the EXIT procedure, and arterial and venous cannulas are inserted while uteroplacental perfusion is maintained. Although CHD remains the most common disease entity considered for potential EXIT to ECMO therapy, this technique has been used for neonates with other disease processes associated with almost certain chance of immediate cardiorespiratory collapse after conventional delivery.

### Intraoperative Considerations

A multidisciplinary team consisting of an obstetrician, pediatric surgeon, ultrasonographer, anesthesiologist, neonatologist, scrub nurses, and technicians provides the expertise in each respective field to aid in the overall success of the procedure. In cases in which immediate surgical intervention is planned (e.g., resection of a neck mass), a prepared adjacent OR with separate personnel should be available. A meeting of the entire team is held before the start of the case to clearly identify individual roles and to discuss any concerns or questions. This is also a good opportunity to address any clinical changes, either in radiographic findings or in fetal position, or other factors that may alter the surgical plan.

### Uterine Relaxation and Perfusion

To preserve maternal-fetal gas exchange at the placental interface, ensure fetal oxygenation, and avoid life-threatening hypoxemia, it is of primary importance to ensure complete uterine relaxation throughout the duration of fetal uteroplacental support. Factors affecting uterine blood flow include, but are not limited to, anesthetic induction agents, maternal hyperventilation, maternal hypotension, maternal catecholamine release, and other causes of increased noradrenergic activity and uterine tone. Any increase in uterine vascular resistance will decrease uterine perfusion, as is seen with uterine contractions. Of all factors ensuring the overall success of the EXIT procedure, minimal uterine vascular resistance is the most important, because decreases in uterine blood flow will cause fetal hypoxemia, acidosis, and, potentially, fetal demise.<sup>243</sup>

### Surgical Procedure

After the hysterotomy site has been created and hemostasis achieved, the fetal head, neck, and shoulders are delivered. Because many of these procedures involve large neck masses, a generous hysterotomy incision is needed to partially deliver the fetus without injury to the mass or fetus. Furthermore, if a uterine contraction occurs at this time, inadvertent expulsion of the fetus could occur, interrupting the fetoplacental unit and thus critically jeopardizing the viability of the fetus. In some cases, a fetal extremity may be delivered to apply a pulse oximetry probe and to obtain IV access.<sup>244,245</sup> Although the fetus is anesthetized via placental transfer of maternally administered inhaled anesthetics in most cases, additional analgesia and paralytics are administered (e.g., fentanyl, atropine, muscle relaxant). The additional medications may be given as a single IM dose in an upper extremity, or can alternatively be delivered under ultrasound guidance before hysterotomy. An advantage to earlier administration is increased time for fetal absorption via the IM route. If peripheral IV access is obtained, additional medications can be given through this route.

### ACCESS TO THE FETAL AIRWAY

Most EXIT procedures are currently performed to access a compromised fetal airway before delivery; successful access depends

on meticulous preoperative evaluation and careful preparation.<sup>246,247</sup> Portions of the trachea can be completely compressed and distorted such that even successful intubation may result in an inability to achieve adequate ventilation. For this reason, most surgeons perform a direct laryngoscopy and rigid bronchoscopy to examine the status of the fetal airway. In one series, successful endotracheal intubation by conventional means was reported in 77% of cases.<sup>230</sup> In those cases in which tracheal intubation is impossible, a surgical tracheostomy can be performed as soon as the trachea is identified. The trachea can be located with the aid of preoperative radiographic studies, often identifying the tracheal location relative to fixed external anatomic landmarks. Gentle surgical palpation may also aid in the identification of cartilaginous tracheal rings. In cases in which the former options have failed, ultrasonography with the sterile probe inserted directly into the surgical incision may help to locate the trachea.<sup>248</sup> When tracheal rings are identified, the trachea may be accessed directly with an endotracheal tube by tunneling through the fetal soft tissue, or with the aid of a retrograde wire inserted by the Seldinger technique. The trachea, exposed through a neck incision, may be incised via a temporary tracheotomy to allow passage of a feeding tube or wire from the trachea to the mouth or nose. The guidewire is then attached to the endotracheal tube, which is then pulled down into the proper position. After suturing the endotracheal tube securely to the mouth, the tracheotomy can then be closed.

Regardless of the method used to secure the trachea, the anesthesiologist must be prepared to control ventilation in the fetus. In some institutions, an anesthesiologist may be scrubbed at the operative field to assume this responsibility. In other institutions, one of the surgeons or neonatologists assumes this role. Adequate ventilation may be difficult to achieve for several reasons. Certain types of tumors, specifically cervical teratomas, may secrete thick mucus into the trachea, and this must be aggressively removed before ventilation. As soon as the airway is satisfactorily cleared, surfactant should be administered via the tracheal tube to diminish expected airway resistance. Surfactant is provided for two principal reasons. First, the majority of infants treated for such lesions are delivered at some point before term and their pulmonary development (considered both by gestational age and underlying pathophysiology) cannot be assumed to be normal. Second, the thick mucoid secretions and the aggressive lavage necessary to clear them may interrupt the normal surfactant layering and functionality, suggesting that surfactant therapy may provide a benefit if administered before lung ventilation. These steps should result in increases in fetal oxygen saturation to levels greater than 90%. If this does not occur, the position of the tracheal tube should be rechecked and the lungs should be auscultated with the aid of a sterile stethoscope. In addition, ultrasound examination for the presence of air bronchograms may be used to confirm tracheal intubation. Ventilation occurs most commonly with the aid of a sterile Jackson-Rees circuit. When adequate ventilation has been established, the fetus can be delivered.

### Delivery of the Infant and Maternal Management

Before umbilical cord clamping and delivery, coordination between the surgery and anesthesia teams is crucial to prevent uterine atony and excessive maternal hemorrhage. Because a decrease in the tocolytic agent, whether an inhalational or an IV agent, would result in increased uterine vascular resistance and decreased fetal oxygenation, reversal of the tocolysis must not

occur before the umbilical cord is clamped. However, at clamping, a near-total reversal of tocolysis is required to limit uterine bleeding. This is best achieved with a low-solubility inhalational anesthetic (e.g., desflurane). As the cord is clamped, the anesthetic is immediately discontinued and oxytocin is administered as a bolus followed by a continuous infusion and titrated to uterine response (e.g., 40 units oxytocin in 500 mL of normal saline over 30 minutes, followed by 20 units over 8 hours). Additional uterotonic medications may be necessary and must be immediately available should uncontrolled maternal hemorrhage occur.<sup>249</sup> These medications include methylergonovine, carboprost, and calcium carbonate. Anticipation of massive and rapid maternal hemorrhage is essential. Appropriate IV access (e.g., rapid infusion catheters, introducer sheaths) with a rapid infusion device in place for blood product administration may be life saving, should uncontrolled and persistent bleeding occur. In cases of uncontrolled hemorrhage despite maximal drug therapy, a hysterectomy may be necessary. When maternal hemostasis has been achieved, uterine tone restored, and the placenta delivered, then a low-dose inhalational anesthetic and nitrous oxide can be administered, provided that the mother is hemodynamically stable.

A separate team of neonatologists, anesthesiologists, and nurses should be available for the neonate because additional medications, blood products, and vascular access may be needed. A brief physical examination, confirmation of bilateral breath sounds, and hemodynamic stability must be ensured soon after delivery. In some instances, immediate surgical intervention is planned, necessitating entirely separate anesthetic, surgical, and nursing teams in an adjacent OR as the maternal abdomen is closed.

### Postoperative Considerations

Mothers recovering from an EXIT procedure differ from those who undergo standard cesarean deliveries. Potential postoperative complications include wound dehiscence, infection, bleeding, and urinary retention.<sup>230</sup> Although every attempt is made to place the hysterotomy incision in the lower uterine segment during EXIT procedures, those patients with anterior placentas may require incisions in different areas of the uterus. As a result, these patients are at increased risk of uterine rupture in any subsequent pregnancy. Practitioners should also consider the fact that, unlike with a standard cesarean section, the parents cannot immediately interact with or even view their neonates after delivery. Because many of these neonates undergo immediate surgical intervention, the parents' first glimpse of their child will be of an intubated, sedated child with monitors, invasive catheters, and swollen, distorted facies. Continued emotional support, social services, and education will help ease this transition.

## Movement toward Intervention for Non-Life-Threatening Diseases: Myelomeningocele

At present, nearly all human fetal interventions are performed to prevent almost certain fetal demise secondary to a known congenital defect or pathophysiologic process. Myelomeningocele (MMC) is the first nonfatal birth defect to be treated in utero. MMC affects 0.5 to 1 per 1000 live births annually, with variations in both population and geography.<sup>250-252</sup> At least 75% of affected individuals reach early adulthood; most deaths occur

during infancy and the preschool years secondary to respiratory and neurologic complications.<sup>253</sup> There is significant risk associated with this early fetal intervention. Many infants with MMC may be delivered prematurely as a direct result of intrauterine intervention, further adding to the risks of an already compromised infant.<sup>252</sup> Some have argued that because MMC is a non-lethal defect, intrauterine intervention for potential reduced secondary morbidity may not justify the significant maternal morbidity or fetal mortality associated with this procedure. However, the severe morbidity associated with MMC, combined with the promising results of animal research, have led to consideration of prenatal intervention for this disorder. Initial human outcomes have demonstrated some improvement in secondary morbidity.<sup>252,254,255</sup> Recent publication of the results of the Management of Myelomeningocele Study (or the MOMS trial) demonstrated a reduced need for placement of cerebrospinal fluid shunts and improved motor outcomes (e.g., earlier ambulation) at 30 months in the fetal intervention group, compared to infants whose repairs were deferred until after delivery. Nevertheless, significant maternal and fetal morbidities were reported.<sup>256</sup>

## Future Considerations

With the advances in surgical and anesthetic techniques and technologies, significant progress may be made in mid-gestation fetal intervention, and in moving from treatment of only life-threatening fetal pathologic processes toward preemptive management of fetal disorders that are not necessarily life-threatening but have significant, disabling postpartum morbidities. However, these benefits may have to be balanced against the possibility of long-term neurocognitive disorders in anesthetized fetuses, particularly in those fetuses undergoing prenatal repair of anomalies that are not life threatening.<sup>257-259</sup>

The particular challenges for anesthesiologists are to develop methods to provide selective fetal anesthesia and analgesia, and techniques of targeted uterine relaxation such that safer, specifically tailored anesthesia may be provided to all patients involved in the fetal intervention. Furthermore, techniques and technologies that will enhance tocolysis and retard PPROM and preterm labor will allow increased time for fetuses to heal and mature in utero, while reducing the incidence of postoperative pulmonary edema in mothers. Finally, enhanced fetal monitoring will help the anesthesiologist provide better care for the fetus both in utero and in the postoperative period. With such advances, the provision of fetal anesthesia may become a more routine part of pediatric surgical and anesthetic practice, bringing with it new opportunities for practice and research, and new problems to be solved.

## ANNOTATED REFERENCES

- Boat A, Mahmoud M, Michelfelder EC, et al. Supplementing desflurane with intravenous anesthesia reduces fetal cardiac dysfunction during open fetal surgery. *Paediatr Anaesth* 2010;20:748-56.
- In a retrospective study, Boat and colleagues found that early institution of high concentrations of volatile agents for extended periods before hysterotomy resulted in the development of intraoperative fetal bradycardia, most notably when desflurane was used as the maintenance agent. Based on their findings, they suggest alternative utilization of supplemental IV anesthesia with propofol and remifentanyl until just before the hysterotomy incision is made, at which point high volatile-anesthetic concentrations may be used to achieve the desired uterine relaxation.*

Courtier J, Poder L, Wang ZJ, et al. Fetal tracheolaryngeal airway obstruction: prenatal evaluation by sonography and MRI. *Pediatr Radiol* 2010;40:1800-5.

*The authors reviewed the sonographic and MRI findings of tracheolaryngeal obstruction in the fetus, including extrinsic causes, such as lymphatic malformation, cervical teratoma, and vascular rings, and intrinsic causes, such as congenital high airway obstruction syndrome (CHAOS). The authors found that accurate radiologic distinction of these conditions by sonography or MRI may facilitate optimizing patient selection for ex utero intrapartum treatment (EXIT) procedure, as well as identifying associated procedural risks for surgeons, anesthesiologists, and neonatologists.*

Fink RJ, Allen TK, Habib AS. Remifentanyl for fetal immobilization and analgesia during the ex utero intrapartum treatment procedure under combined spinal-epidural anaesthesia. *Br J Anaesth* 2011;106:851-5.

*The authors report three cases of ex utero intrapartum treatment performed under neuraxial anesthesia, with maternal administration of remifentanyl used to provide fetal immobilization and analgesia via placental transfer. No clinically significant maternal sedation or respiratory depression were observed. In all cases, the authors argue, remifentanyl provided adequate fetal immobilization and obviated the need to administer other analgesics or NMBDs.*

Ngan Kee WD, Khaw KS, Tan PE, Ng FF, Karmakar MK. Placental transfer and fetal metabolic effects of phenylephrine and ephedrine during spinal anesthesia for cesarean delivery. *Anesthesiology* 2009; 111:506-12.

*The authors randomized 104 healthy parturients having elective Cesarean section under spinal anesthesia, to receive infusions of either phenylephrine or ephedrine, titrated to maintain approximate baseline systolic blood pressure. The authors found that, although ephedrine crosses the placenta to a greater extent and undergoes less early metabolism (or redistribution) in the fetus compared with phenylephrine, its associated increased fetal concentrations of lactate, glucose, and catecholamines may favor phenylephrine as the preferred vasopressor for such indications, despite historical evidence suggesting uteroplacental blood flow may be better maintained with ephedrine.*

Tran KM, Maxwell LG, Cohen DE, et al. Quantification of serum fentanyl concentrations from umbilical cord blood during ex utero intrapartum therapy. *Anesth Analg* 2012;114:1265-7.

*The authors quantified the concentration of fentanyl in umbilical vein blood drawn following IM injection from 13 human fetal subjects undergoing EXIT procedures. The median dose of fentanyl was 60 µg (range, 45 to 65 µg) for fetuses with a mean weight at delivery of 3000 g. The median time between IM administration of fentanyl and collection of the sample was 37 minutes (range, 5 to 86 minutes). Fentanyl was detected in all of the samples, with a median serum concentration of 14.0 ng/mL (range, 4.3 to 64.0 ng/mL).*

	<b>Summary</b>

**ANESTHESIOLOGISTS COMMONLY PROVIDE CARE TO CHILDREN** who have suffered traumatic injuries. These injuries vary in complexity, and patients range from the healthy older child with an isolated elbow fracture to the infant with a life-threatening epidural hematoma. The anesthesiologist should view the management of children with traumatic injuries as a continuum of care that may originate in the prehospital setting with emergency medical services (EMS), progress to the emergency department (ED), and continue through the operating room, the postanesthesia care unit, and the intensive care unit. Anesthesiologists may become involved in all phases of care of the traumatically injured child, with the possible exception of the prehospital setting. The care required is often complex but can be effectively accomplished in a collaborative environment incorporating a standardized process for initial evaluation and management.<sup>1</sup> Anesthesiologists should be familiar with these processes to effectively continue this care in the perioperative setting.

Anesthesiologists are essential participants in many capacities during the care of injured children. Operative interventions demand full involvement of the anesthesiologist. In many institutions, anesthesiologists also provide emergency airway and critical care management. From the perspectives of airway control, ventilation, hemodynamic resuscitation, metabolic management, and effective control of pain, anesthesiologists can play a central role in the care of the injured child. Common diseases of childhood are now better understood and more effectively treated, which has resulted in more cures, better outcomes, and an improved quality of life. Despite major reductions in the overall mortality rate for pediatric trauma in recent years, unintentional injuries remain the leading cause of death and disability in the pediatric population of the United States.<sup>2</sup> Injury has also emerged as the most common public health threat to children around the world.<sup>3</sup>

This chapter reviews the key principles of anesthesia management of traumatic injuries to children. This discussion is intended to augment the principles established in the widely accepted Advanced Trauma Life Support (ATLS) program, which is

produced by the American College of Surgeons Committee on Trauma.<sup>4</sup> Additional resources for the management of the pediatric trauma patient include the Advanced Pediatric Life Support (APLS) course administered by the American Academy of Pediatrics and the American College of Emergency Physicians.<sup>5</sup> Many of the topics discussed in this chapter are being investigated to determine the most effective strategy, including volume resuscitation, evaluation of the cervical spine, and prehospital tracheal intubation.

## Epidemiology of Pediatric Trauma

Traumatic injuries are the most common cause of death within the United States for children older than 1 year of age.<sup>6</sup> Approximately 20,000 deaths of children occur annually as a result of trauma. Most traumatic injuries in children are a result of motor vehicle accidents (the leading cause of death), falls, nonaccidental trauma (Fig. 38-1), drowning, or extremes of temperature.

The epidemiology of trauma reflects its continued growth as a significant health risk for children of the world. Table 38-1 illustrates the recent incidence of injury types per 100,000 U.S. children.<sup>2</sup> Motor vehicle trauma is a major threat to the health of children in the United States, which has spurred research to identify methods to improve their protection.<sup>7-9</sup>

Pediatric and adult injury patterns and treatment protocols are different.<sup>10</sup> Head injuries are the leading cause of death in children. One explanation for this is the proportionately large head of children compared with adults. Thoracic injuries are the second leading cause of death for pediatric trauma patients. Due to increased rib cage pliability from a lack of bony calcification and the flexible cartilaginous component, severe internal injury can occur in children without obvious external signs such as rib fractures. Blunt abdominal trauma frequently can be treated with close observation, avoiding operative intervention. Penetrating abdominal trauma usually requires surgical exploration. However, diagnostic laparoscopy is being used in lieu of exploratory

**FIGURE 38-1** Fatalities by age group from child abuse and neglect in 2010. Most of these children are 3 years of age or younger. (Data from the U.S. Department of Health and Human Services, Administration for Children and Families, Administration on Children, Youth, and Families, Children's Bureau; Child Maltreatment 2010. Available at <http://www.acf.hhs.gov/programs/cb/pubs/cm10/cm10.pdf#page=70> [accessed September 2012]).

laparotomy in hemodynamically stable children to evaluate and repair many types of abdominal injuries.<sup>11</sup>

## Nonaccidental Trauma

Nonaccidental trauma, also referred to as shaken baby syndrome or child abuse, is an epidemic that continues to grow in virtually all parts of the world. Although 3 million reports of nonaccidental trauma are filed every year in the United States, most experts believe that this represents less than one third of the actual cases.<sup>12,13</sup> Every state has stringent laws for reporting nonaccidental trauma. These laws are designed to assist the health care provider who suspects mistreatment and to punish health care providers who do not appropriately report potential neglect. It is the responsibility of every physician involved, including the anesthesiologist, to be aware of the potential for nonaccidental trauma in all infants and children and to report all suspicious observations accurately to the appropriate authorities.

Characteristics of nonaccidental trauma include a history inconsistent with the character and extent of the injuries and a delay in seeking medical assistance.<sup>14,15</sup> Nonaccidental trauma should be considered when the history appears improbable. Funduscopic examination may disclose retinal hemorrhages or papilledema, which may suggest forceful shaking of the head or increased intracranial pressure (ICP), respectively. Examination of the skin may show bruises, burns, or other injuries in several stages of healing (Fig. 38-2). A skeletal survey may reveal multiple fractures of various ages occurring typically at the metaphyses of long bones. Occasionally, a child who has

previously been silent in the company of the parents or caregiver tells operating room or recovery room personnel about the events surrounding his or her injuries. These reports should be carefully documented and relayed to the appropriate personnel. Maltreated children are often terrified of painful procedures, and the need for sensitivity and reassurance in these settings cannot be overemphasized.

The anesthesiologist encountering a potential victim of nonaccidental trauma may provide the first impartial assessment of the child's status.<sup>16</sup> Physicians, nurses, and other professionals who provide initial resuscitation may be preoccupied with the small child's acute and potentially life-threatening injuries. Historical data associated with the event may be inaccurate or fictitious at the time of initial presentation. An objective evaluation by the anesthesiologist in preparation for operative intervention may reveal the first objective evidence of nonaccidental trauma. Indications of mistreatment may be subtle, ranging from lack of parental availability for perioperative counseling and consent to irrational refusal of permission for a necessary operative intervention.<sup>17,18</sup>

## Prehospital Care of the Pediatric Trauma Patient

### TRAUMA SYSTEMS

The evolution of pediatric trauma systems has significantly improved outcomes and quality of life for trauma victims.<sup>19,20</sup> Countries such as the United States have a trauma system philosophy more in line with the military approach, in which prehospital personnel such as paramedics are the initial team to make rapid assessments, initiate efforts at stabilization, obtain radio contact with the medical facility, and transport the child to the trauma center as rapidly as possible.<sup>21</sup> This philosophy of minimizing the time on the scene and emphasizing prompt transport to the closest trauma center is called *scoop and run*.

In parts of Canada and several European countries, initial resuscitation of injured children is commonly performed by physicians who are charged with evaluating the child at the scene, securing the airway, initiating resuscitative measures to maintain hemodynamic stability, and transporting the child to an appropriate trauma center (Fig. 38-3). Instituting these management procedures may result in additional time on the scene. This approach has been called *stay and play*. Many aspects of this system are being integrated into existing American trauma systems as part of mass casualty disaster management plans.<sup>22,23</sup>

Developing a systematic approach to the care of the pediatric trauma patient is crucial. This includes acquiring age- and size-appropriate equipment. Luten and Broselow developed a system that provides immediate guidance for the identification of appropriate equipment and drug doses based on the child's length.<sup>24-27</sup> This system assigns a specific color based on the child's body length. A corresponding color-coded, length-based wristband can then be placed onto the child, which designates drug doses and devices that match the assigned color. The system is designed to minimize delays, medication miscalculations, and equipment errors.

Over the past 2 decades, there have been dramatic advances in the capability of prehospital providers to recognize the need for and initiate resuscitation of pediatric trauma patients. Part of this progression has been attributed to the development of

trauma systems and the commitment of trauma centers to provide more effective medical direction to prehospital providers. Effective management of the continuum of care for trauma patients is optimized if the prehospital personnel communicate the details regarding the child's injuries directly to the hospital personnel. This information may include details about the mechanism of injury, forces involved, time elapsed from the event, loss of consciousness, estimated blood loss, treatment given, and a summary of suspected injuries.

As trauma systems have evolved and EDs have become overwhelmed by larger patient volumes, effective triage for the pediatric trauma patient has become increasingly important. Care of

traumatically injured children requires the use of significant personnel and resources from many services, including the operating room and ancillary services such as diagnostic imaging and transfusion services.<sup>28</sup> Inappropriate triage may waste precious resources and potentially limit access to patients most in need if every patient with traumatic injuries, regardless of their severity, is sent to a trauma center. Conversely, not recognizing that a child must be brought to a trauma center may increase morbidity and result in preventable deaths.<sup>29,30</sup>

The Glasgow Coma Scale (GCS) (E-Table 38-1) and the modified GCS for children (Table 38-2) are the most common scales used to estimate the severity of neurologic injury. The GCS

**FIGURE 38-2** Common examples of child abuse, also referred to as nonaccidental trauma, are shown. **A**, Typical areas on children where bruising can be caused by daily living activities. The blue areas indicate regions where normal bruising may occur. The black areas are regions of unusual bruising. Any bruise in the black areas must be considered for possible child abuse. Cutaneous manifestations of child abuse vary. **B**, A child with obvious facial trauma. **C**, A whipping injury from a belt plus additional bruises.

assigns a total score with a range of 3 to 15 that quantifies eye opening, verbal, and motor functions. The Pediatric Trauma Score (PTS) was developed to facilitate the initial assessment and triage of injured children (Table 38-3). As trauma systems have matured and prehospital providers have become more experienced with assessment and field management, the GCS and PTS

have emerged as effective tools for determination of appropriate direct transfer to a trauma center.<sup>31,32</sup>

#### PREHOSPITAL AIRWAY MANAGEMENT

Effective airway management in the prehospital environment has many challenges, including poor access to the child, lack of use

**FIGURE 38-3** Management of pediatric trauma patients. The primary goals are delivery of oxygen, appropriate ventilation, perfusion to vital organs, maintenance of normothermia to mild hypothermia, stability of renal and neurologic function, correction of coagulopathies, avoidance of overhydration, and meticulous management of metabolic demands. (Modified from Todres ID, Fugate JH, editors. Critical care of infants and children. Boston: Little, Brown; 1996, p. 17.)

of pharmacologic agents, inclement weather conditions, trauma to the face, and providing care in challenging environments such as an ambulance. Several studies of adult patients undergoing tracheal intubation in the prehospital setting have reported an increased incidence of difficult tracheal intubation,<sup>33</sup> need for multiple attempts,<sup>34</sup> and undiagnosed esophageal intubation.

These events have been reported by all levels of providers, including anesthesiologists.<sup>35</sup> However, anesthesiologists have increased success rates and lower complication rates during tracheal intubation compared with other providers.<sup>36-38</sup>

Unsuccessful prehospital airway management in children may be due to a combination of training, experience, equipment, and

\*The Pediatric Trauma Score is the sum of all rows. Scoring: minor injury, 12 (maximum); severe injury, <7; uniformly fatal, -6 (minimum).

environmental issues. A significant proportion of the unsuccessful prehospital tracheal intubations result from ineffective operator training and lack of professional experience. Most prehospital providers, such as paramedics, receive minimal dedicated training in pediatric airway management, including tracheal intubation.<sup>39</sup> These providers may not have an opportunity to use their skills on a routine basis. Over time, the psychomotor skills required for pediatric tracheal intubation decay, which likely contributes to the increased complication and failure rates associated with tracheal intubation in children.

Guidelines have proposed that avoidance of airway instrumentation in the prehospital setting may be just as effective as tracheal intubation for pediatric trauma patients. For example, the American Heart Association Pediatric Advanced Life Support (PALS) guidelines state, "Bag-mask ventilation can be as effective as ventilation through an endotracheal tube for short periods and may be safer."<sup>40</sup> The 2010 PALS guidelines state, "In the prehospital setting, ventilate and oxygenate infants and children with a bag-mask device, especially if transport time is short."<sup>40</sup> As a result, many EMS personnel have developed policies containing a scoop and run philosophy for pediatric trauma patients that avoid definitive airway management if the transport time is brief and bag-mask ventilation is effective. Several investigators have also questioned whether prehospital tracheal intubation is the best approach in children who require positive-pressure ventilation. The infrequent need for tracheal intubation in pediatric trauma patients has created obstacles for members of the emergency medical teams to maintain their skills. Multiple studies have demonstrated an increased mortality rate or worsening neurologic outcomes for adult patients who received prehospital tracheal intubation compared with those who received standard bag-mask ventilation.<sup>41,42</sup> Several studies that focused on children also reported increased complication rates associated with prehospital tracheal intubation.<sup>43-46</sup>

There is a trend for using alternative airway devices in the field in adult and pediatric trauma patients. Among the devices that have found favor, supraglottic airway devices have proved easy to use and reliable in the field. Although these devices do not protect the airway from regurgitation and aspiration, they may prevent airway obstruction during transport. One meta-analysis of prehospital alternative airway devices in adults and children

indicated that LMAs were very successful in the hands of anesthesiologists and nonphysician flight crews (success rate of 96%) and slightly less successful in the hands of nonphysician clinicians (83%).<sup>47</sup> However, there is a dearth of evidence to support a role for the LMA in pediatric trauma.

## Emergency Department Evaluation and Management of the Pediatric Trauma Patient

Anesthesiologists should familiarize themselves with the initial management of pediatric trauma patients in the ED because they may be asked to assist in emergency airway management and intraoperative care. Rapid establishment of provisional diagnoses and priorities of care is essential in the ED management of trauma victims.<sup>48</sup> Most trauma centers use a multilayered assessment system consisting of a primary survey with resuscitation, a secondary survey, and definitive management.<sup>1</sup>

Anesthesiologists can provide more effective intraoperative management if they understand the care of pediatric trauma patients commonly used in the ED. During initial resuscitation, a team member should attempt to obtain a history from the parents, the prehospital personnel, and perhaps the child. It should include the usual questions about drug allergies, medications, and past illnesses and inquiries about loss of consciousness, estimated blood loss, and treatment rendered before arrival at the ED.

Based on the ATLS course, evaluation of the trauma patient occurs in three progressive steps: primary survey, secondary survey, and definitive care.<sup>4</sup> The initial evaluation of all trauma patients is the primary survey. The sequence of the primary survey can be remembered as "ABCDE": airway (A), breathing (B), circulation (C), disability (D), and exposure or environment (E). Many trauma centers have the personnel and resources to simultaneously perform several activities and have prepared trauma rooms, usually in the ED. A trauma cart should be maintained daily in the trauma room and be prepared with all necessary equipment to resuscitate a child (E-Fig. 38-1 and E-Table 38-2). In this circumstance, it would be acceptable for the primary and secondary surveys to occur simultaneously—that is, the primary survey (e.g., volume resuscitation) can occur as a part of the secondary survey (e.g., drawing blood samples).

The airway (A) should be evaluated for patency and opened using a jaw-thrust technique if obstruction is encountered. Immobilization of the cervical spine should be maintained. The child's breathing (B) and ventilation should be evaluated, and immediate intervention should take place if they are inadequate. Circulation (C) is evaluated by palpation of peripheral pulses, blood pressure, sensorium, and skin turgor. Control of external hemorrhage by the application of direct pressure is also part of the circulation phase. Disability (D) is evaluated by examining the child for neurologic injuries. A GCS score of 8 or less implies severe neurologic injury (see Table 38-2), and immediate intubation (with in-line neck stabilization if indicated) is strongly recommended. Exposure (E) of the whole child is essential for a complete examination. The environment (E) should consist of a heated treatment area that is ideally prepared in advance of the child's arrival.

The importance of an adequate and secure airway cannot be overemphasized. All trauma patients should initially receive 100% supplemental oxygen. Tracheal intubation of most children

**E-FIGURE 38-1** Trauma cart. This shelving system, devised in 1984 by Robert Luten, MD, remains the most effective and efficient way to store age- and weight-based resuscitation equipment and to ensure that all compartments are always stocked.

**E-TABLE 38-2** Recommended Equipment for a Trauma Resuscitation Room

#### Airway Equipment

Appropriate sizes (neonate to adult) of facemasks, endotracheal tubes, oral airways, nasal airways, and laryngeal mask airways

Appropriate size stylettes for the endotracheal tubes

Self-inflating ventilating devices capable of administering at least 90% oxygen

Anesthesia type bag and mask

Difficult airway and cricothyrotomy kits of appropriate sizes

Jet ventilator

#### Monitoring Equipment

Noninvasive blood pressure, with appropriately sized cuffs

Pulse oximetry

Electrocardiogram

Capnograph or similar device to detect exhaled carbon dioxide (see E-Fig. 38-2)

Temperature

Transducers and monitors for direct arterial and central venous pressures

#### Surgical Instruments

Tracheostomy tray

Thoracostomy tray

Thoracotomy tray

Vascular tray

#### Resuscitation (Crash) Cart

##### Vascular Access Equipment

##### Emergency Treatment and Evaluation Charts

Visibly displayed charts allowing easy dosage of resuscitation medications (Broselow tape)

Pediatric Trauma Score (see Table 38-3)

Glasgow Coma Scale (see E-Table 38-1)

Pediatric Modified Glasgow Trauma Scale (see Table 38-2)

#### Other Equipment

Universal precautions equipment (e.g., gloves, masks, eye protection)

Infusion pumps capable of delivering small volumes

External warming devices

Blood-warming devices

with major trauma occurs by using a rapid-sequence induction (RSI) with appropriate medications or, in some situations, while the child remains awake. When increased ICP is suspected, measures to prevent further increases during tracheal intubation should be undertaken. Regardless of site or mode of tracheal intubation, proper position and patency of the tracheal tube must be confirmed as soon as the child arrives in the ED.<sup>49</sup> Techniques to verify correct tracheal tube position may initially include auscultation, direct laryngoscopy, and determination of the tracheal tube length from the lips and the detection of end-tidal carbon dioxide (E-Fig. 38-2). All children should be monitored with frequent blood pressure measurements and continuous electrocardiography and pulse oximetry.

In trauma patients, shock is most commonly the result of hypovolemia. Cardiogenic shock, although rare in children, may be associated with chest trauma or preexisting cardiovascular disease. Attempts should be made to place two large-bore intravenous lines that are appropriate for age. One strategy for a child who has hypotension is to administer an initial bolus of 20 mL/kg of an isotonic crystalloid solution such as lactated Ringer's solution or normal saline. Fluid administration may be repeated with additional boluses of isotonic crystalloid as required to stabilize the blood pressure into the normal range. Blood products should be considered when the volume of isotonic crystalloid surpasses 40 to 60 mL/kg and the blood pressure remains unstable. Glucose-containing solutions usually should not be administered because they may produce unacceptable hyperglycemia and worsen the neurologic outcome.

For traumatic injuries that are primarily located in the abdomen, attempts should be made to place intravenous access in the upper extremities. Traumatic injuries that are located in the chest should have vascular access placed in the upper and lower extremities to account for disruption of a major vessel above or below the right atrium. If vascular access cannot be obtained promptly, femoral venous or intraosseous access should be strongly considered (see Fig. 48-6, *A-D*, and E-Fig. 48-1, *A-E*).<sup>50</sup>

When the primary survey and initial resuscitation have been completed, a secondary survey is initiated. The secondary survey is a complete head-to-toe examination designed to identify additional injuries not recognized during the primary survey. Frequent reassessment of the vital signs is critical during this phase. If clinical deterioration occurs, the primary survey and initial resuscitation should be repeated. Head examination should include visual inspection, palpation, assessment of pupillary size and reactivity, and a funduscopic examination. The cervical spine, chest, and abdomen should be evaluated in detail. Chest examination should involve inspection for wounds, palpation for tenderness and crepitance, and auscultation for bilateral breath sounds. The abdomen should also be examined carefully. In children, the physical signs of intraabdominal injuries can be subtle, especially in sedated or neurologically depressed children. The extremities should be inspected for tenderness, bruising, deformities, and vascular insufficiency.

Diagnostic testing is completed during the secondary survey.<sup>51,52</sup> Imaging studies, including computed tomography (CT) scans of the brain, neck, chest, abdomen, and pelvis, may be obtained, along with a bedside focused abdominal sonography for trauma (FAST) examination, which is used to detect intraperitoneal free fluid. Standard radiographs of the chest and extremities may also be obtained during the secondary survey. Laboratory studies, including blood count, electrolytes, and

blood product crossmatching, are completed during the secondary survey. If the child remains unstable despite aggressive resuscitation, the patient should be considered for emergent transfer to the operating room for surgical intervention. After the child has been stabilized and all injuries have been identified, plans for definitive care can be made. This may include admission to the intensive care unit, an acute care bed, or an observation unit; discharge home with outpatient follow-up and consultation with specialists; or transfer to the operating room.

## Anesthesia Management of the Pediatric Trauma Patient

Anesthesiologists, surgeons, and other personnel should work as a coordinated team when managing children with trauma. This collaborative approach can optimize the prompt and reliable identification of suspected injuries so that the anesthesiologist can more effectively anticipate the magnitude of bleeding, physiologic effects, and nature of the surgical procedures. By understanding the appropriate evaluation and initial management of the pediatric trauma patient, the anesthesiologist can recognize injuries that might have been undiagnosed and anticipate the resultant effects intraoperatively.<sup>53</sup>

The approach to diagnosis and treatment for the pediatric trauma patient is dictated by the degree of urgency (see Fig. 38-3). For critically ill and hypotensive children who need immediate surgical intervention, resuscitation and the administration of anesthesia may need to be provided simultaneously. Basic principles are applied in this circumstance, including establishment and protection of the airway, maintenance of adequate ventilation, and support of hemodynamics with fluids, blood products, and vasoactive medications. Establishment of generous vascular access is recommended in the critically injured child; this may necessitate a vascular cutdown or placement of an intraosseous needle for volume resuscitation. Anesthetic medications should be cautiously administered in this situation by carefully titrating the dose of the medication to the child's hemodynamic status.

For the child who requires emergent transfer to the operating room, does not have a secure airway in place, and is not anticipated to have a difficult airway, induction of anesthesia should begin with preoxygenation and be followed by intravenous RSI. If the child is thought to be hypovolemic, a preoperative fluid bolus of balanced salt solution (20 mL/kg) should be administered before induction of anesthesia and drugs selected that maintain circulatory homeostasis. If concern exists regarding a possible cervical spine injury, which applies to most trauma patients, the practitioner should also incorporate in-line immobilization of the cervical spine during airway management and all transfers (Fig. 38-4).<sup>54</sup> Arterial and central venous line placements should be selected on a case-by-case basis. The anesthesiologist should be vigilant for the development of undiagnosed traumatic injuries that may manifest in the operating room. For a child who is critically ill, surgery should proceed without delay, and monitoring may initially include only a blood pressure cuff, pulse oximeter, and electrocardiogram.

As conditions permit, hemodynamic monitoring with arterial and central venous catheters may be established. Arterial catheters for trauma patients may be helpful in some situations, including concern about the adequacy of ventilation and need to frequently sample arterial blood gases, the need for frequent and repeated blood sampling (i.e., severe hemorrhage or

**E-FIGURE 38-2** Appropriate endotracheal intubation is best confirmed by a measurement of exhaled carbon dioxide. When a capnograph is unavailable, portable products, such as the Easy Cap II (Mallinckrodt, Inc., Pleasanton, Calif.), which has a dead space of 25 mL and usually is indicated for patients weighing less than 15 kg, or the PediCap, which has a dead space of 3 mL and is designed for children who weigh 1 to 15 kg, may be used.

**FIGURE 38-4** Cervical spine control must be maintained during intubation. The child with a cervical spine injury requiring a definitive airway should be intubated under controlled circumstances. A neurosurgeon or the primary trauma physician should stabilize the head and neck during intubation. Oral intubation is the preferred route. In-line stabilization before attempts at laryngoscopy should be made so that the head is stabilized and prevented from rotating from side to side and from flexion and extension. No traction should be placed on the cervical spine because it is associated with increased neurologic deficits in patients with proven cervical fractures.

metabolic derangements), hemodynamic instability; and the need to alter the blood pressure rapidly. In a setting with significant actual or anticipated blood loss, establishment of large-bore venous access is of much greater priority than obtaining arterial access. Establishment of central venous access may be delayed until hemodynamic stability is established, because peripheral venous lines typically can be obtained quickly and provide effective volume resuscitation. Rotating the neck to place an internal jugular central line in a trauma patient with a possible cervical spine injury should be avoided.

After oxygenation, ventilation, and circulation have been stabilized, the anesthesiologist may need to address other concerns. If it has not been possible to administer acceptable doses of anesthetic medications, they are administered in stepwise increments after hemodynamic stability has been achieved. Evidence from adult victims of major trauma indicates that recall is more common in these cases. It is reasonable to assume that a similar risk holds true in children.<sup>55-57</sup> An intravenous dose of midazolam is strongly recommended,<sup>58</sup> although a single agent may be insufficient to guarantee amnesia. If inhalational anesthetics cannot be tolerated, the anesthesiologist may include a ketamine infusion (1 to 5 mg/kg/hr, titrated to the child's hemodynamic responses; infants may require up to 15 mg/kg/hr).

An important principle is maintenance of body temperature. Hypothermia occurs commonly in victims of major trauma. Hypothermia may potentiate neuromuscular blockade, exacerbate coagulopathy, and contribute to delayed emergence, although moderate hypothermia (34.5° C) may be protective in children with traumatic brain injury.<sup>59</sup> Measures to warm the child should be instituted as early as possible. They include warming the blood products and intravenous fluids, using forced-air warming devices and heat lamps, wrapping the head and extremities in plastic bags, and increasing the temperature of the operating room. Ideally, the operating room should be warmed in advance of the child's arrival to minimize radiant heat loss.

The features and mechanisms of trauma are different in children and adults. In children, abdominal trauma is more common than thoracic trauma, and blunt traumatic injuries are more common than penetrating traumatic injuries. In thoracic trauma, hemothorax and pneumothorax are common; needle decompression followed by chest tube placement may be lifesaving for a tension pneumothorax. Strong consideration should be given to needle decompression or the placement of a chest tube before instituting positive-pressure ventilation in a child with a tension pneumothorax. The greater mobility of the mediastinum in children makes it more likely for tension pneumothorax to occur and to produce hemodynamic instability. Chest injuries in children may be overlooked because rib fractures are less common than in adults.<sup>60</sup>

Head injury is the most common cause of traumatic death in children.<sup>61</sup> Although the principles of managing head injuries in polytrauma patients are mostly similar in adults and children, there are some differences. In neonates and infants, unlike adults, intracranial bleeding can lead to hypovolemic shock because the head is a significantly larger fraction of the body. The open fontanelles in children may provide greater compliance and a potential space for a proportionately larger amount of blood to accumulate. However, the open fontanelles may also provide additional protection against initial increases in ICP. A key goal for children with neurosurgical emergencies is maintenance of hemodynamic stability to preserve cerebral perfusion pressure. A child with suspected intracranial hemorrhage is at risk for increased ICP. Acute treatment for increased ICP due to intracranial hemorrhage includes hyperventilation, intravenous administration of hyperosmolar medications such as hypertonic saline, administration of medications such as opioids, cerebrospinal fluid drainage, and surgical removal of an intracranial hematoma.

## PREOPERATIVE EVALUATION

Advances in health care have produced an increased patient population with significant preinjury comorbid conditions. For example, children with repaired congenital heart disease may become victims of a traumatic injury. It is common for an acutely injured child to have a preexisting diagnosis of a medical condition such as asthma, developmental delay, seizure disorder, and significant psychosocial issues exacerbated by an unstable home environment. Each of these issues must be carefully considered when planning appropriate anesthesia management.

Emergency surgery is a great source of fear and anxiety for children and their parents.<sup>62</sup> The unexpectedness of the event provides little time for the child and family to adjust to the crisis and often limits the time the anesthesiologist has to develop rapport with the child and parents. The anesthesiologist who appears calm and reassuring is of great benefit to all parties.

If the child's condition permits, the preoperative evaluation should include a complete assessment. Vital signs should be stable and appropriate for age. Sensorium, urine output, skin turgor, and vital signs can be used to evaluate and estimate the child's preoperative volume status. A comprehensive airway evaluation should be done, including assessing the cervical spine. The medical and surgical history is obtained when possible. A list of previous injuries and interventions should be acquired before entering the operating room. Special attention to fluid management helps to estimate preoperative volume status and assist with intraoperative fluid administration. Assessment should include review of available laboratory reports, such as

hemoglobin, electrolyte, and coagulation studies and arterial blood gas determinations, including CO-oximetry results. Diagnostic imaging studies, including plain radiographs and CT scans, should be obtained.

Evidence suggests that the gastric residual volume in children undergoing emergency surgery is greater than in those undergoing elective surgery.<sup>63,64</sup> There is evidence to suggest that in emergency cases, the size of the gastric residual volume (measured in milliliters per kilograms) depends in part on the time interval between the last food ingestion and the injury.<sup>64</sup> There is some reassurance in these numbers, but the anesthesiologist should consider these children to have a full stomach and take appropriate measures to reduce the risk of aspiration.<sup>65-68</sup> The possible value of H<sub>2</sub>-blocking agents, metoclopramide, and clear antacids may be considered but their use in these circumstances is not evidence based.

Premedication for emergency procedures, if indicated, usually is administered by the intravenous route. Benzodiazepines, such as midazolam, may help to reduce preoperative anxiety. If pain is present, opioids may be beneficial for children who are hemodynamically stable and have no airway compromise. Other than ketamine, anesthetics rarely cause profuse secretions, and the use of antisialagogues before induction should be reserved for specific indications. The administration of premedications to alleviate pain or control anxiety must be balanced against their disadvantages, including the potential for respiratory compromise, increased sedation, or hemodynamic instability.

### CERVICAL SPINE EVALUATION

Cervical spine injuries occur less often in children than in adults and typically occur in different locations.<sup>69</sup> Cervical spine injuries in children tend to be located at a more cephalad spinal level than in adults, usually at or above C3. In contrast to actual injuries, pseudosubluxation of the cervical spine is a common and benign finding in children. Pseudosubluxation of the cervical spine usually occurs as the anterior displacement of C2 on C3. In the pediatric trauma patient, the examiner may need to differentiate benign pseudosubluxation from a true cervical spine injury.<sup>70</sup> After consultation with the surgeon, pseudosubluxation can be excluded by placing the child's head in the sniffing position and repeating the radiograph; pseudosubluxation is reduced with this maneuver. In older children, an odontoid or open mouth view can also be considered to evaluate the superior cervical vertebrae. The physician must assume a cervical spine injury exists if the child complains of tenderness in response to palpating the spinous processes of the cervical spine, if the sensorium is decreased, or if neurologic deficits are found. Any of these findings demand a neurosurgical consultation and cervical spine immobilization.

Injury to the cervical spine is less common in children than in adults because the child's spine is more elastic and mobile, and their incompletely calcified vertebrae are less likely to fracture with minor trauma. Nevertheless, the risk of spine injury is increased when the child is subjected to a substantial force from a fall or the substantial forces associated with motor vehicle crashes.<sup>71</sup> Any child with a suspected neck injury should have cervical spine precautions implemented (e.g., placement of a cervical collar, backboard to provide immobilization). Cervical spine immobilization (see Fig. 38-4) should always be maintained when airway management is attempted (Fig. 38-5).

Challenges in obtaining plain radiographs of the cervical spine include difficulty in obtaining a complete view of the spine

**FIGURE 38-5** Intubation of a child with a cervical fracture may require up to four individuals: one person to provide in-line stabilization, a second person to perform the intubation, a third person to perform cricoid pressure and hold the endotracheal tube or retract the cheek for the individual performing the intubation, and a fourth person to administer the medications.

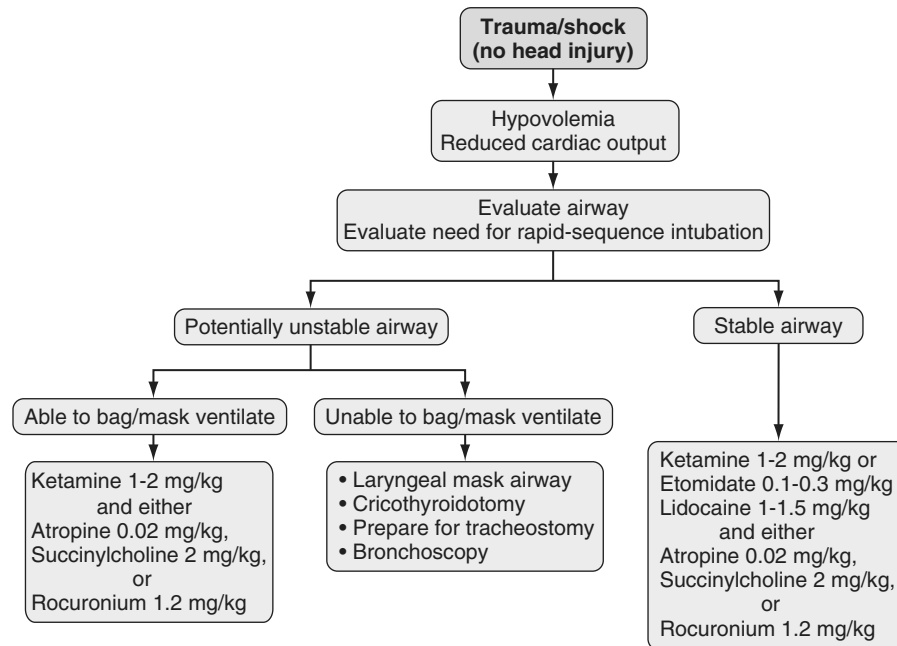

below C6 and the odontoid process. As CT technology has advanced to more rapid and precise imaging, many centers have replaced standard radiographic examinations with CT scans for evaluation of the cervical spine in the trauma patient. The American College of Surgeons updated the ATLS guidelines, stating that a CT scan of the neck can be substituted for a cervical spine radiograph.<sup>4</sup> Replacing plain films with CT scans resulted in a doubling of the rate of cervical spine fractures identified in one study.<sup>72</sup>

It is challenging to rule out spinal cord injuries in children by standard radiography alone because up to 50% of spinal cord injuries may exist without positive radiographic findings. However, spinal cord injury without radiographic abnormality (SCIWORA) has been estimated in as many as 25% to 50% of children with spinal cord injuries.<sup>73,74</sup> These occult cases may reflect ligamentous damage that cannot be detected with standard radiographic examinations or CT scans but can be visualized with magnetic resonance imaging (MRI).

Imaging must be used in conjunction with the physical examination to evaluate the cervical spine, but the cervical spine cannot be considered cleared of pathology only on the basis of diagnostic imaging studies.<sup>75,76</sup> Appropriate spine immobilization should continue during the intraoperative and postoperative periods if the cervical spine of the child cannot be confirmed to be uninjured by a negative imaging study and by unremarkable results of the physical examination. The cervical spine cannot be considered undamaged if the child is not alert, is nonconversant, has positive neurologic deficits, has midline cervical tenderness, or has a painful, distracting injury. If the cervical spine cannot be clinically cleared in the postoperative period, MRI should be considered after the child is stable.

### AIRWAY MANAGEMENT

Children undergoing emergency surgery are assumed to have a full stomach. They often have considerable gastric contents because of a recent meal,<sup>65</sup> increased acid secretion, and delayed gastric emptying caused by pain, trauma, and the administration of opioids. Many experts recommend using an RSI to secure the airway to protect against pulmonary aspiration of gastric contents

**FIGURE 38-6** Algorithm for the airway management of children with multiple trauma but without traumatic brain injury. These are commonly used doses and combinations of medications. The selection of sedatives, anxiolytics, opioids, and neuromuscular blocking agents depend on each child's condition and should be modified accordingly. (Modified from Todres ID, Fugate JH, editors. *Critical care of infants and children*. Boston: Little, Brown; 1996, p. 36.)

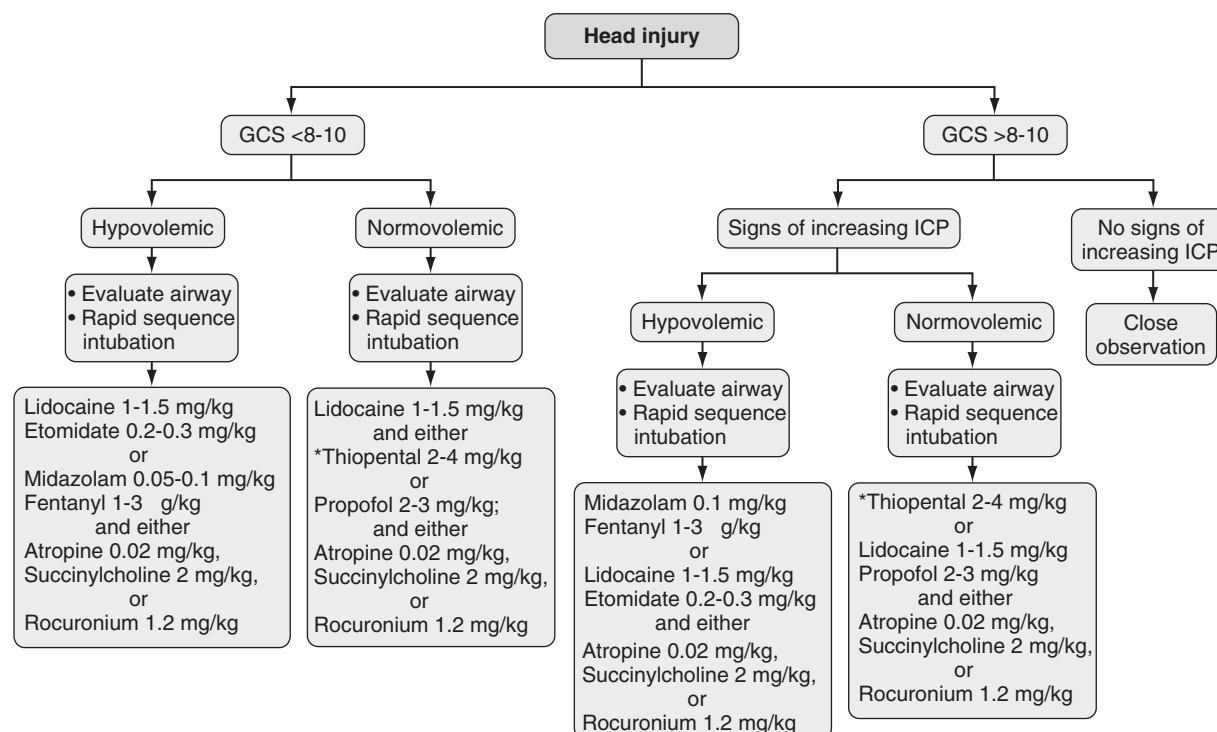

in the pediatric trauma patient. However, evidence-based data supporting this approach are lacking.<sup>77</sup> The anesthesiologist must balance the risks of an RSI with the risks of other airway management techniques. RSI is associated with an inability to intubate the trachea and rapid desaturation during periods of apnea. The risks of using this approach must be weighed against the benefit of reducing the risk for aspiration. The decision to use an RSI assumes that the anesthesiologist has completed an airway evaluation and predicts that the intubation will be uncomplicated and that mask ventilation while maintaining cricoid pressure will be possible as a backup temporizing measure.

In the operating room, induction of anesthesia depends on the child's injuries, condition at the time of presentation, whether the airway has been secured, and anticipated airway difficulty. The most common approach to the initial airway management is to follow a protocol for RSI.<sup>78,79</sup> Awake intubation is another approach for airway management and usually is reserved for those with severely depressed consciousness, cardiac arrest, or suspected difficult airway. The selection of medications depends on individual circumstances (e.g., head injury, hypovolemia, contraindication to succinylcholine) and preferences of the anesthesiologist. Table 38-4 lists dosages, advantages, and disadvantages of selected anesthetic medications for RSI. Figure 38-6 presents an algorithm for management of children with multiple traumatic injuries but without a suspected traumatic brain injury. Specific considerations for children with multiple trauma that include a traumatic brain injury are outlined in Figure 38-7.

Before an RSI is performed, the anesthesiologist must ensure that the proper equipment is present and functioning, including laryngoscope blades and handles, suction, a leak-free anesthesia circuit, an anesthesia machine, monitors, tracheal tubes of appropriate sizes, and a tracheal tube stylet. All monitors should be properly functioning, and at a minimum, the pulse oximeter and blood pressure cuff should be applied before induction, even though these monitors may not function properly in a crying,

uncooperative child until after induction of anesthesia. After intravenous access is confirmed, the child's lungs are denitrogenated with 100% oxygen for several breaths (as tolerated). Studies of adult patients demonstrate that oxygen saturation remains greater than 95% for 6 minutes after only four vital capacity breaths of 100% oxygen by mask.<sup>80</sup> Similar studies have not been performed in children, although the rates at which the  $\text{PaO}_2$  decreases<sup>81</sup> and the  $\text{SaO}_2$  decreases to 95%<sup>82</sup> in infants and younger children after breathing 100% oxygen through a tracheal tube and then performing an apnea maneuver was more rapid than in older children and adults. Even with an uncooperative child, it is possible to increase the  $\text{PaO}_2$  by enriching the immediate environment with high flows of oxygen. Preoxygenation should not involve forcefully holding the facemask on the awake child; this will likely result in increased anxiety, increased oxygen consumption, and decreased effectiveness of denitrogenation. Premedication (e.g., 0.05 to 0.1 mg/kg of intravenous midazolam) in divided doses may be considered to alleviate fear and anxiety before induction. All drugs intended for use during the RSI should be prepared and labeled along with the doses predetermined for the child's weight and hemodynamic status.

RSI consists of preoxygenation with 100% oxygen and application of cricoid pressure, followed by the bolus administration of an induction agent such as ketamine (2 mg/kg), etomidate (0.2 to 0.3 mg/kg), or propofol (2 to 3 mg/kg), as well as atropine (20  $\mu\text{g/kg}$ ) if succinylcholine is selected and along with a neuromuscular blocking agent such as succinylcholine (2 mg/kg) or high-dose rocuronium (1.2 mg/kg), depending on the age of the child. This is followed immediately by laryngoscopy and tracheal intubation (see Chapters 4 and 12). We recommend using a modified Bier block technique with 1 mg/kg of lidocaine applied using an occlusive tourniquet for 30 to 60 seconds to prevent pain from injection before the administration of propofol or etomidate through a small peripheral vein. Positive-pressure ventilation before tracheal intubation is avoided during an RSI.

**FIGURE 38-7** Algorithm for the airway management of children with multiple trauma, including traumatic brain injury. Specific considerations to avoid increased intracranial pressure in traumatized children are outlined. GCS, Glasgow Coma Scale score; ICP, intracranial pressure. (Modified from Todres ID, Fugate JH, editors. Critical care of infants and children. Boston: Little, Brown; 1996, p. 36.) \*Thiopental is no longer available in the United States.

**TABLE 38-4** Medications Used in Pediatric Trauma Patients for Rapid-Sequence Induction

Medication	Intravenous Dose (mg/kg)	Advantages	Disadvantages
Atropine	0.01-0.02	Attenuates vagal response	Flushed skin, tachycardia, mild hyperpyrexia; possible sedation/agitation
Glycopyrrolate	0.01	Attenuates vagal response and antisialogogue; lacks sedation/agitation	Longer acting
Lidocaine	1-1.5	Attenuates hemodynamic and intracranial responses to intubation	Can cause toxicity in large doses (e.g., >5 mg/kg)
Fentanyl	0.001-0.003	Analgesic and attenuates hemodynamic and intracranial responses to intubation	Can cause bradycardia, chest wall and glottic rigidity
Midazolam	0.05-0.2	Sedation, amnesia, anxiolysis	May cause hypotension when combined with opioids in hypovolemic patients
Thiopental*	3-5	Sedative-hypnotic, some neuroprotective properties	May decrease blood pressure, increase heart rate, decrease cardiac output; usually avoided in hypovolemic patients
Ketamine	1-2	Sympathomimetic, used when hypovolemia is suspected	Increases oral secretions (administer with atropine or glycopyrrolate to reduce secretions), may increase intracranial pressure
Propofol	1-3	Sedative-hypnotic, some neuroprotective properties	May cause hypotension
Etomidate	0.2-0.3	Hemodynamic stability with no cardiac depression, some neuroprotective properties, used in patients with hypovolemia and cardiac instability	Possible adrenal suppression
Rocuronium	0.6-1.2	Rapid onset (with high doses), vagolytic properties; is a substitute for succinylcholine; sugammadex rapidly reverses neuromuscular blockade if "cannot intubate, cannot ventilate" occurs	Intermediate to long duration depending on dose; in the absence of sugammadex, neuromuscular blockade cannot be quickly antagonized if the airway is lost
Succinylcholine	2 (precede with atropine or glycopyrrolate)	Rapid onset and ultra-short duration	May cause bradycardia if not preceded by an anticholinergic; may cause hyperkalemia in children with muscular dystrophy, crush injury, prolonged immobilization, burns, intraabdominal sepsis and upper and lower motor neuron lesions; may increase intracranial pressure and gastric pressures

\*Thiopental is no longer available in the United States.

Cervical spine immobilization is typically indicated for most trauma patients during RSI (see Fig. 38-4) and requires an assistant to perform manual in-line stabilization during laryngoscopy (see Fig. 38-5).

An RSI can be a considerable risk for children with cardiovascular problems such as hypovolemia or congenital heart disease. When performing an RSI, it may be difficult to select the appropriate anesthetic dose for the child's needs because it may lead to profound hypotension due to myocardial depression and vasodilation. Strategies for dosing intravenous induction agents in a child with presumed hypovolemia include reduced doses of propofol (e.g., 1 mg/kg) or using agents that are less likely to produce hypotension (e.g., etomidate, ketamine). Conversely, severe hypertension is also possible due to inadequate dosing during airway management procedures such as prolonged direct laryngoscopy.

Succinylcholine is the neuromuscular blocking agent of choice because of its rapid onset and short duration of action. A Cochrane Review concluded that succinylcholine created superior intubating conditions compared with rocuronium using doses of less than 1.2 mg/kg.<sup>83</sup> However, high-dose rocuronium may also be effectively used as an alternative to succinylcholine for an RSI in children.<sup>84</sup> If large doses of rocuronium (e.g., 1.2 mg/kg) are used in infants and children, the time to recovery of the train-of-four to 25% averages about 45 minutes, and it may take as long as 75 minutes.<sup>84</sup> It is possible that the duration of action may be longer than the planned procedure. Moreover, if the child's lungs are impossible to ventilate and the trachea cannot be intubated, the situation may become life-threatening. The use of high-dose sugammadex if available (see Chapter 6) can abbreviate the duration of the neuromuscular block in these situations. If rocuronium (or any nondepolarizing muscle relaxant) is combined with thiopental, the thiopental must be cleared from the intravenous tubing before administering the relaxant to prevent the former from precipitating.<sup>85</sup> The routine use of succinylcholine for elective tracheal intubation in children has lost popularity among pediatric anesthesiologists due to reports of hyperkalemia-induced cardiac dysrhythmias and cardiac arrest, which led the U.S. Food and Drug Administration to issue a black box warning about the use of succinylcholine in children undergoing elective surgery.<sup>86</sup> Many of the male children who developed hyperkalemic cardiac arrest were subsequently diagnosed with various forms of muscular dystrophy (mostly Duchenne's muscular dystrophy, which may manifest with few clinical signs in boys 8 years of age or younger).

Establishing a definitive airway may be required for children with a suspected difficult airway due to facial, laryngeal, or thoracic trauma. Alternative approaches for airway management should be considered when difficult intubation is anticipated.<sup>87,88</sup> In these situations, the urgency of securing the airway takes priority over the increased risk of tracheal aspiration of gastric contents. These cases can be managed by using an awake intubation approach, which commonly includes topical anesthesia and sedation combined with one of the following airway techniques:

- Awake intubation under direct laryngoscopy or rigid bronchoscopy
- A lighted stylet
- Indirect laryngoscopy using a fiberoptic bronchoscope (FOB) or video laryngoscope
- Supraglottic airway device–assisted tracheal intubation with or without an FOB
- Awake tracheostomy

In a nonemergent situation, the FOB is the gold standard approach to manage a difficult airway. An FOB can be very effective, especially in children with limited mouth opening, restricted neck movement (common in the trauma patient with a cervical collar in place), or associated congenital syndromes that make direct laryngoscopy difficult or impossible.<sup>89,90</sup> The alternative approaches are advantageous because their main goals are to maintain spontaneous ventilation, to maintain oropharyngeal reflexes to prevent aspiration if regurgitation occurs, and to allow the option of aborting the procedure if the airway cannot be secured. However, these airway techniques can be challenging in small children, in those whose airway anatomy is severely distorted, and those with copious secretions or blood in the pharynx. Large amounts of sedation to achieve effective patient cooperation during airway interventions may approach levels of general anesthesia and produce significant respiratory depression.

Another strategy for airway management in the child with a suspected difficult airway is to anesthetize the child using a face-mask with an inhalational anesthetic such as sevoflurane in 100% oxygen combined with gentle cricoid pressure. After the child is effectively anesthetized, airway management can be performed using any of the previously mentioned techniques with the child breathing spontaneously. In addition to or instead of using an inhalational anesthetic, total intravenous anesthesia (TIVA) can be used with medications such as propofol or dexmedetomidine while maintaining spontaneous respirations during instrumentation of the airway. An infusion of ketamine can provide sedation and analgesia while maintaining spontaneous respirations, although glycopyrrolate may be required to attenuate increased production of oral secretions.

In emergency situations, blind placement of a supraglottic airway device such as an LMA is recommended as part of the American Society of Anesthesiologists' difficult airway algorithm.<sup>91</sup> The LMA does not protect the airway from tracheal aspiration of gastric contents, but it may be used as a conduit to facilitate blind or fiberoptic intubation of the trachea.<sup>92</sup> The development of an LMA (LMA North America, San Diego, Calif.) with a modified cuff and drainage tube (ProSeal) and that is available in sizes 1 to 5 may make this process even safer by allowing evacuation of gastric contents and providing a better airway seal than earlier LMA devices.<sup>93,94</sup> The Fastrach LMA (LMA North America) provides an additional supraglottic device that is useful when direct visualization of the laryngeal inlet is not possible. This device has been designed to blindly place a tracheal tube into the trachea from within the supraglottic airway.<sup>95</sup> However, this is only of benefit in children larger than 30 kg because pediatric sizes (1 to 2) are not available.

### CRICOID PRESSURE

Cricoid pressure was popularized for RSI by Sellick in his seminal report in 1961,<sup>96</sup> which carefully described the position of the head and neck during the maneuver. The patient assumes the supine position with the neck fully extended in a slight head-down tilt, and the nasogastric tube, if present, is removed. The concavity of the cervical neck is maintained during cricoid pressure using a firm support placed under the cervical spine. Cricoid pressure is applied by an assistant using the thumb and second finger; the first finger stabilizes the thumb and finger on the cricoid ring. Pressure is applied firmly as consciousness is lost and released only after the tracheal tube cuff has been inflated.

In current practice, the head and neck are often not positioned as described by Sellick. Although Sellick's preliminary

evidence suggested that his technique was very effective for occluding the esophagus, there have been no randomized, controlled trials that document its effectiveness or its superiority over other techniques in preventing aspiration during RSI.<sup>97,98</sup> Radiologic evidence suggests that cricoid pressure may not completely occlude the lumen of the esophagus because the contours of the vertebral bodies are asymmetric and the esophagus is not aligned directly over the vertebral bodies.<sup>99</sup> The application of cricoid pressure in children may result in even further lateral displacement of the esophagus than it does in adults.<sup>100</sup> Sellick never described the amount of force required to occlude the lumen of the esophagus, although in adults, a force of 30 to 40 N (equivalent to a 3- to 4-kg mass) is considered sufficient to occlude the esophagus. In a study of the force required to occlude the esophagus in infants, investigators determined that a force of only 5 N distorts the airway in infants weighing less than 5 kg and that a force of only 12 N produces the same distortion in 15-year-old adolescents.<sup>101</sup> This begs the question of how much force is required to reliably occlude the esophagus without distorting the airway in infants and children. The answer is unknown.

Many assistants who perform cricoid pressure apply insufficient force,<sup>102</sup> apply force at an incorrect location<sup>103</sup> or use excessive force that may distort the larynx and make tracheal intubation more difficult. One study found that correctly applied cricoid pressure in children 2 weeks to 8 years of age with or without paralysis resulted in no leak of air into the stomach with up to 40 cm H<sub>2</sub>O of peak inflation pressure.<sup>104</sup>

In children, the application of cricoid pressure has been viewed with some skepticism because the force required has been considered excessive in younger children. However, in the current medicolegal climate, many have perceived an obligation on their part to apply it to prevent regurgitation. In support of this perception, the results of a survey documented that even though 71% do not believe cricoid pressure occludes the esophagus, 90% use it when there is an increased risk for aspiration.<sup>105</sup>

## VOLUME ADMINISTRATION

Better understanding of the mechanisms of the stress response and particularly of the factors that contribute to sepsis and ongoing proliferation of proinflammatory cytokines has helped redefine the immediate and long-term goals of acute resuscitation and definitive management of the unstable trauma patient.<sup>106</sup> The original concept of resuscitation was restoration of adequate circulating volume with appropriate red cell mass and adequate oxygenation, but this has evolved to become a continuum of critical care focused on restoration of total body homeostasis. The initial priority is focused on hemodynamic stabilization and should progress seamlessly to the aggressive management of metabolic derangements. The anesthesiologist who is involved in immediate resuscitation of the severely injured child should focus on these initial hemodynamic goals.

The preservation of intravascular volume is a primary priority during resuscitation of the severely injured child. When immediate surgical intervention in the operating room is not necessary, it is advisable to replace fluid deficits before induction of anesthesia. Mild to moderate deficits can be replaced with isotonic crystalloid solutions. In severe hypovolemia with ongoing blood loss, colloids such as 5% albumin can be considered for use as an intravascular volume expander along with packed red blood cells. If time permits and if clinically indicated, crossmatched blood products should be administered, starting with an initial dose of 10 mL/kg. Type-specific uncrossmatched blood has a

very low incidence of transfusion reactions and is typically available before crossmatched blood.<sup>107</sup> In an emergency situation requiring the immediate transfusion of blood products, type O negative packed red blood cells should be administered if the ABO blood type of the child has not been determined.

Life-threatening exsanguination is most commonly caused by a massive disruption of the solid viscera or major vascular structures within the abdomen and chest. The most important part of this resuscitation process is restoration of adequate red cell mass and circulating volume to promote effective tissue perfusion and oxygenation. Evaluation of 103,434 cases in phases II and III of the National Pediatric Trauma Registry (NPTR) study suggests that massive exsanguination is relatively uncommon.<sup>108</sup> Children who sustain massive exsanguinating injuries typically die at the scene.

If volume resuscitation is vigorous and large volumes of crystalloid solutions are administered, hemorrhage-induced red blood cell loss may be further exacerbated by dilution with crystalloids. Overzealous fluid resuscitation may worsen bleeding by abrupt elevation of the systolic blood pressure from circulatory expansion that disrupts clots from injured vessels. Clinical evidence of this has been limited to assessment of penetrating injury in adults and elective cardiac surgery, emphasizing the necessity of a proper balance between restoration of adequate peripheral perfusion and avoidance of gross fluid overload.<sup>109-110</sup> Effective circulatory resuscitation of the injured child requires a combination of clinical data, anticipation of pending physiologic challenges, and coordination of planned operative interventions by all specialists involved in the child's acute care. Large-volume transfusions without consideration of coagulation status, electrolyte shifts, or critical serum protein depletion may produce coagulopathy. Injudicious or inadequate crystalloid infusions may worsen capillary leak locally in injured organs and remotely in the interstitium of lung and brain. It is postulated that the concentrations of systemic inflammatory mediators increase after traumatic injuries. Increased serum secretory phospholipase A<sub>2</sub> levels have been associated with increased injury magnitudes in patients after traumatic injuries,<sup>111</sup> and increased plasma high-mobility group box 1 (HMGB1) levels have been identified after traumatic injuries, although clear correlations with patient outcomes were not established.<sup>112</sup>

Injured children tend to be reasonably free of the acquired cardiovascular diseases that complicate the care of injured adults. However, transient myocardial ischemia can quickly undermine contractility of even the healthiest heart. In the presence of cardiovascular collapse from massive or ongoing hemorrhage, this can rapidly lead to cardiac failure and peripheral hypoperfusion. Children who are being resuscitated from major hemorrhage and who have been exposed to prolonged low flow states may require inotropic support to maintain adequate peripheral perfusion. Because an accurate definition for what was previously referred to as myocardial contusion is not easily quantifiable, a high index of suspicion based on an understanding of the child's mechanism of injury is the best guide to preemptive management, especially if rhythm disturbances are observed.<sup>113,114</sup>

Studies are being conducted to determine the ideal products and dosing schedules for fluid resuscitation of injured children. Several studies have evaluated hypertonic saline for use as a resuscitation solution and for the management of traumatic brain injury.<sup>115-117</sup> Investigators from several studies suggest that no definitive recommendations can be made because no fluid product is superior.<sup>118-120</sup> However, children with evidence of

significant hypovolemia who are bleeding significantly and receiving isotonic crystalloids probably should be initially resuscitated with lactated Ringer's solution due to its pH of 6.6, compared with a pH of 5.5 for normal saline, although Plasma-lyte has a more normal physiologic pH. The critical objectives are immediate control of the sources of hemorrhage, restoration of red cell mass to ensure adequate oxygen delivery, and appropriate rheology to enhance tissue microperfusion.

### VASCULAR ACCESS

Vascular access can be overlooked as one of the more important priorities in the initial care of injured children. In some circumstances, placement of two large-bore intravenous lines may be very challenging in the hypovolemic child. In some cases, the child arrives in the ED with no vascular access. In the setting of the ED or operating room, adequate vascular access can usually be readily obtained by a standard percutaneous approach through a peripheral vein or by direct percutaneous cannulation of the femoral vein. These two methods are consistently successful in achieving immediate vascular access without resorting to invasive cutdown techniques. The success rate for percutaneous femoral catheterizations using a Seldinger technique is so high that using a cutdown approach is rarely required (see also Fig. 48-2). If the child is severely exsanguinated and percutaneous femoral vascular access is unsuccessful, surgical exposure through an incision 1 cm below the inguinal ligament can expose the saphenous vein at the saphenofemoral junction. This provides immediate access to a large-caliber vessel and facilitates the placement of a femoral arterial line for ongoing management. Ultrasound-guided vascular access techniques may also be used to place peripheral and central lines in the venous and arterial systems.<sup>121,122</sup> Many trauma centers do not routinely use subclavian or internal jugular veins for vascular access during acute resuscitation. Personnel responsible for airway management usually obstruct access to the neck, as does the cervical collar that should be in place as part of standard prehospital management protocols. In an orchestrated approach, one individual or group of individuals should concentrate fully on management and support of the airway while a second group addresses access to the vascular system.

Intraosseous infusion devices are being increasingly used in adults and children for whom percutaneous vascular access is unavailable or unsuccessful.<sup>123</sup> In the pediatric population, intraosseous needles are usually placed in the tibial plateau medial to the tibial tuberosity approximately 3 to 5 cm below the knee. These devices can be lifesaving and usually are inserted after several attempts at venous access have failed. If appropriately placed, they are useful conduits for infusion of all medications, crystalloids, and dilute blood products.<sup>124</sup> Intraosseous needles should be replaced by effective and reliable venous access as soon as possible (see also Fig 48-6, A-D). Pneumatic-driven devices for placement of intraosseous needles have also been described. Some of these devices have been extraordinarily difficult to remove and require specific training from the product manufacturer; their overall usefulness remains to be evaluated. One type of intraosseous infusion device, the EZ-IO (Vidacare Corporation; San Antonio, Tex.) operates like a battery-powered drill and is relatively simple to train providers in its use (see E-Fig. 48-1, A-E).<sup>125</sup>

### DAMAGE CONTROL SURGERY

Children with massive anatomic derangements associated with uncontrollable hemorrhage usually require emergent operative

intervention. In many trauma centers, these hemodynamically unstable children are treated by *damage control surgery*,<sup>126</sup> which is based on the premise that rapid control of abdominal bleeding by placing abdominal packing and immediate coverage of the open abdomen enables more effective resuscitation before exposing the child to a more prolonged definitive repair.

Over the past decade, the use of damage control surgery for the initial stabilization rather than definitive repair has moved the focus of resuscitation away from simple circulatory volume management to a need for immediate correction of whole-body metabolic derangements associated with the stress response.<sup>127</sup> Acute abdominal packing and coverage avoids development of abdominal compartment syndrome, allows reevaluation of the injured tissue, and provides access for repeated lavage of contaminated spaces. Although there have been concerns that this approach may be used more often than necessary, the risks of leaving an abdomen open are minimal compared with the ventilatory and circulatory consequences that may develop from an abdominal compartment syndrome. Damage control surgery has proved to be a lifesaving technique in isolated circumstances by allowing an unstable child to receive comprehensive resuscitation in a more controlled environment.

### PAIN MANAGEMENT

Acute pain occurring as a result of traumatic injuries is one of the most common adverse stimuli experienced by children.<sup>128</sup> There has been fear that treating pain due to trauma may mask the symptoms of progressive injury. Historically, adults have received significantly more analgesia after injuries than children.<sup>129</sup> As a result, many physicians withhold significant pain relief, especially opioids, because they fear serious side effects such as respiratory depression or hypotension may develop. All medications used for analgesia and sedation in children can have significant side effects; however, careful titration to the desired effect along with appropriate monitoring should ensure safe administration.

The management of acute pain in the injured child can be accomplished by using nonpharmacologic interventions and pharmacologic therapies. Nonpharmacologic interventions include positive reinforcement, distraction, hypnotherapy, acupuncture, massage and touch relaxation, and guided imagery.<sup>130</sup> Pharmacologic therapies include oral and intravenous acetaminophen and nonsteroidal antiinflammatory drugs (NSAIDs) for mild to moderate pain and oral and intravenous opioids for moderate to severe pain.<sup>131</sup> Regional anesthesia can be very useful in the acutely injured child, especially for orthopedic injuries.

Injured children are often in pain at the time of arrival in the ED. For unstable children and those with evolving neurologic dysfunction, opioids must be used with caution. In many circumstances, injured children are sufficiently stable to allow judicious administration of opioids. Opioids free of histamine release (e.g., fentanyl) are preferable to those that release histamine (e.g., morphine), especially for children who are potentially hypovolemic. Fentanyl should be titrated in small increments (e.g., 0.5 to 1.0 µg/kg) to reduce the risk for respiratory depression and side effects such as chest wall or glottic rigidity.

In certain cases, regional nerve blocks can be used to provide analgesia in the ED; as primary anesthesia in a cooperative or older child to avoid some of the risks associated with general anesthesia, including aspiration; and as a supplement to general anesthesia for postoperative analgesia.<sup>132,133</sup> For example, analgesia for children with midshaft fractures of the femur can be

provided by a traditional femoral nerve block or fascia iliaca compartment block, diminishing pain from the femur and quadriceps muscle spasm. Similarly, an axillary or supraclavicular nerve block may be used in children with forearm fractures. Central neuraxial techniques, such as epidural analgesia, can be useful for children with major thoracoabdominal trauma, including rib fractures. Close communication with orthopedic and general surgical colleagues is advised so that there are no misunderstandings about the ability to perform sensory and motor examinations and about coordination of additional analgesic medications.

## Future Directions in Pediatric Trauma

As traumatic injuries have become recognized as a significant public health threat, numerous initiatives have emerged to improve prevention of this hazard, management of its victims, and measurement of system performance and outcomes. Exciting areas of investigation continue to emerge in aspects of clinical management, systems development, patient safety, and injury prevention.<sup>134-136</sup>

Prevention and public education are important areas of ongoing research in pediatric trauma. There has been great progress in educating the public that many injuries are avoidable, but there are still many factors that undermine the best intentions to produce a safe and nurturing environment for children. A significant advance in effective prevention and public education has occurred through the Injury Free Coalition for Children sponsored by the Robert Wood Johnson Foundation.<sup>137-139</sup> This coalition has evolved into a network of 40 institutions throughout the country, and each focuses on specific areas of enhanced public education to define opportunities for improvement within the environment of children. Although there is no such thing as a completely risk-free environment, ongoing and effective public awareness campaigns can enhance the likelihood that risks to children throughout the world will diminish.

As the transition from fluid resuscitation to metabolic management has evolved, there has been increasing interest in identifying tissue-specific biomarkers that reflect the severity and prognosis of injury.<sup>140,141</sup> The efficacy of resuscitation could be enhanced by routine assay of biomarkers that accurately reflect levels of physiologic derangements or effective restoration of homeostasis. Numerous studies are focusing on identification of various components of neuronal tissue markers that reflect the presence and severity of brain injury.

The combination of hypovolemia, coagulopathy, hypothermia, and acidosis is associated with increased morbidity and mortality. There have been many efforts to control these issues, and most significant has been the evolution of damage control surgery. There is growing laboratory animal evidence that hypothermia, if induced in a rapid and controlled fashion, is cytoprotective.<sup>59,142-144</sup> In the near future, the use of hypothermia in the minutes after traumatic injury may widen the margin of safety for injured children, especially those with significant cerebral injury. This is an area that must make the transition from animal observations in the basic science laboratory to well-designed, randomized, controlled trials involving prehospital providers and established trauma programs. Emerging evidence suggests that premature death in bleeding patients with severe trauma may be attenuated by administering antifibrinolytics, such as tranexamic acid.<sup>145-147</sup> Institution of tranexamic acid within 3 hours of the insult, particularly in countries with low to middle incomes, is

likely to have the greatest impact on outcome. However, there is insufficient evidence to recommend antifibrinolytics in patients with traumatic brain injury.<sup>148</sup> Randomized, controlled trials enrolling traumatized children are warranted to identify a possible role for antifibrinolytics to prevent premature death.

## Summary

Trauma remains the most common cause of death for children older than 1 year of age. Pediatric patients develop unique traumatic injuries compared with adults, resulting in the need for specific knowledge and specialized anesthesia management. Anesthesiologists may function in several essential roles in the perioperative management of the pediatric trauma patient. They may provide urgent airway management in the ED, intraoperative care in the operating room, and anesthesia and pain control in the intensive care unit. The transition from acute resuscitation to definitive care should be a seamless continuum focusing on immediate recognition of threats to life, rapid restoration of homeostasis, definitive treatment of injuries, and effective rehabilitation and convalescence.

Care of the trauma patient is a perfect example of a team-driven approach that requires thoughtful coordination and adherence to established protocols. The investment of time necessary to prepare for this level of multidisciplinary, comprehensive care produces returns in diminished mortality and enhanced quality of life for all children.

## ACKNOWLEDGMENT

We thank J. Tepas, MD, and H. DeSoto, MD, for their prior contributions to this chapter.

# Cardiopulmonary Resuscitation

POOJA KULKARNI, MARILYN C. MORRIS, AND CHARLES L. SCHLEIEN

Historical Background	$\alpha$ - and $\beta$ -Adrenergic Agonists
Epidemiology and Outcome of In-hospital Cardiopulmonary Arrest	Epinephrine
Diagnosis of Cardiac Arrest	Vasopressin
Mechanics of Cardiopulmonary Resuscitation	Atropine
Airway	Sodium Bicarbonate
Breathing	Calcium
Circulation	Glucose
Defibrillation and Cardioversion	Amiodarone
Electric Countershock	Lidocaine
Practical Aspects of Defibrillation in Children	<b>Special Cardiac Arrest Situations</b>
Open-Chest Defibrillation	Perioperative Cardiac Arrest
Automated External Defibrillation	Hyperkalemia
Transcutaneous Cardiac Pacing	Anaphylaxis
Vascular Access and Monitoring during Cardiopulmonary Resuscitation	Supraventricular Tachycardia
Vascular Access and Fluid Administration	Pulseless Electrical Activity
Endotracheal Medication Administration	<b>Adjunctive Cardiopulmonary Resuscitation Techniques</b>
Monitoring during Cardiopulmonary Resuscitation	Open-Chest Cardiopulmonary Resuscitation
Medications Used during Cardiopulmonary Resuscitation	Extracorporeal Membrane Oxygenation
	Active Compression-Decompression
	<b>Postresuscitation Stabilization (Post-Cardiac Arrest Care)</b>

THE PEDIATRIC ANESTHESIOLOGIST must be prepared to resuscitate a child who suffers a cardiac arrest in the course of a routine elective anesthetic, during a high-risk surgery, or outside the operating room (OR) during the delivery of an anesthetic or as a vital part of the "code team." The goal of this chapter is to provide pediatric anesthesiologists with an in-depth understanding of cardiopulmonary-cerebral resuscitation physiology and recommended resuscitative techniques.

## Historical Background

In 1814, a description in poetical form of the Rules of the Humane Society for recovering drowned persons included the following description of mouth-to-mouth resuscitation<sup>1</sup>:

*Let one the mouth, and either nostril close  
While through the other the bellows gently blows.  
Thus the pure air with steady force convey,  
To put the flaccid lungs again in play.  
Should bellows not be found, or found too late,  
Let some kind soul with willing mouth inflate;  
Then downward, though but lightly, press the chest.  
And let the inflated air be upward prest.*

External cardiac massage was successfully conducted more than 100 years ago in two children (ages 8 and 13 years) after circulatory arrest precipitated by chloroform anesthesia during

a surgical procedure.<sup>2</sup> In 1904, Crile described the effectiveness of external cardiac compressions in maintaining the circulation of dogs.<sup>3</sup>

After multiple reports that attested to the effectiveness of mouth-to-mouth resuscitation,<sup>4,6</sup> in 1958 the National Academy of Sciences National Research Council recommended mouth-to-mouth resuscitation with maximum backward tilt of the head as the preferred technique for all individuals requiring emergency artificial ventilation. In 1960, external cardiac compression was revived as a resuscitation technique when Kouwenhoven, Jude, and Knickerbocker<sup>7</sup> demonstrated its effectiveness when combined with artificial respirations. Many of their patients, including the first, were in cardiac arrest as a result of anesthesia. Before this study, internal cardiac compression was the accepted technique, with its effectiveness demonstrated by experience in cardiac bypass surgery. In 1947, Beck and associates<sup>8</sup> successfully internally defibrillated the human heart; and in 1956, Zoll and colleagues<sup>9</sup> performed the first successful external defibrillation of a human heart.

## Epidemiology and Outcome of In-Hospital Cardiopulmonary Arrest

A 2009 review of cardiac arrest events submitted to the National Registry of Cardiopulmonary Circulation included 3342 pediatric

events, excluding events in a delivery room or neonatal intensive care unit (NICU).<sup>10</sup> Seventy-three percent of the inpatient cardiac arrests reported occurred in an ICU, 7% in a general inpatient area, 11% in an emergency department, and 3% in an operating room or postanesthesia care unit. Return of spontaneous circulation (ROSC) was achieved in 65%, 24-hour survival occurred in 47%, and 30% of children survived until hospital discharge. Other large series of in-hospital pediatric cardiac arrest report survival until hospital discharge ranging from 14% to 44%,<sup>11-14</sup> with the 44% survival representing cardiac arrests that occurred in a pediatric cardiac ICU. In another multicenter cohort study of in-hospital pediatric cardiac arrest,<sup>15</sup> 48.7% of the 353 children survived until hospital discharge. Survivors had greater body temperatures, greater pH values, and reduced serum lactate concentrations compared with nonsurvivors. Nonsurvivors were more likely to have a tracheal tube before the arrest, and to receive sodium bicarbonate, calcium, and vasopressin during the arrest. In this study, postoperative cardiopulmonary resuscitation (CPR) was associated with decreased mortality.

## Diagnosis of Cardiac Arrest

For the child who suffers a cardiac arrest in the OR, electronic monitoring will generally alert the anesthesiologist to an actual or impending cardiac arrest. The electrocardiogram (ECG) may indicate nonperfusing rhythms such as ventricular fibrillation and asystole, end-tidal carbon dioxide (ETCO<sub>2</sub>) may decrease precipitously reflecting a decrease in cardiac output as a result of a decreased delivery of carbon dioxide (CO<sub>2</sub>) to the lungs, and a pulse oximeter may lose its regular waveform in the absence of pulsatile blood flow. Granting the importance of these monitors, the diagnosis of cardiopulmonary arrest still rests on the absence of a pulse in a major artery (e.g., carotid, femoral, or brachial artery) as determined by palpation in the presence of unconsciousness and apnea.

Attention must be paid in the early minutes of resuscitation to determining the cause of the arrest. Many children will not be successfully resuscitated without correction of the underlying cause. A focused physical examination should be conducted and a brief history elicited if it is not already known. If not present, a cardiorespiratory monitor should be placed and the ECG examined. In an intraoperative arrest, the surgeon may be able to provide clues to the diagnosis, such as excessive blood loss, compression of major blood vessels, decreasing venous return to the heart, or manipulation of anatomic structures (e.g., manipulation of the peritoneum resulting in a severe vagal bradycardia or asystole). Equipment malfunction must always be considered as a potential cause of arrest. Early in the course of an attempted resuscitation, a blood gas analysis should be performed and key electrolytes measured (ideally as point-of-care testing).

## Mechanics of Cardiopulmonary Resuscitation

Management proceeds along the well-known airway, breathing, circulation (ABC) algorithm with the exception that the child with ventricular fibrillation or pulseless ventricular tachycardia should receive electrical defibrillation without delay. Airway access in children with ventricular fibrillation or pulseless ventricular tachycardia should be performed secondarily. CPR should be continued without interruption until a shock can be delivered.

### AIRWAY

Before tracheal intubation, the child's airway can usually be managed effectively with bag-valve-mask (BVM) ventilation with proper head positioning and jaw thrust. Although tracheal intubation ensures optimal control of the airway for effective ventilation, multiple attempts at tracheal intubation by an inexperienced operator may seriously compromise the airway and increases the cumulative duration of "no flow" (i.e., no CPR) time.

In the child without an artificial airway, the use of BVM devices may result in a significant risk of gastric inflation, followed by pulmonary aspiration of gastric contents. Abdominal distention (gastric and bowel) can significantly compromise oxygenation; therefore the stomach should be vented when excessive gastric inflation occurs. One study found a 28% incidence of pulmonary aspiration in a series of failed resuscitations.<sup>16</sup> For this reason as well as for the risk of barotrauma and volutrauma, excessive inflation pressures should be avoided. However, effective bilateral ventilation is best judged by visualizing bilateral chest excursions and listening to the quality of the breath sounds rather than setting a preset maximal inflation pressure.

Tracheal intubation should be performed as soon as appropriate personnel and equipment are available. The ETCO<sub>2</sub> is a valuable method of confirming correct placement of the tracheal tube. In the absence of capnography, a disposable colorimetric ETCO<sub>2</sub> device serves the same purpose. However, it is important to appreciate that ETCO<sub>2</sub> measurements are meaningful only in the presence of effective pulmonary circulation, such that a lack of color change may reflect either improper placement of the tube or a lack of pulmonary blood flow resulting from ineffective chest compressions or a massive pulmonary embolism. It is also essential to use the proper size colorimetric device for the child's weight because the adult size may not detect the presence of CO<sub>2</sub> and may lead the user to misdiagnose a successful intubation.

### BREATHING

In the inpatient environment, equipment necessary to ventilate the lungs emergently should be readily available. Because the equipment provided for emergency ventilatory support may differ from standard equipment, depending on the location within a hospital, the anesthesiologist needs to be familiar with all of the equipment in the hospital in which he or she practices. Anesthesiologists are skilled providers of ventilatory support, but in the context of a cardiac arrest, must return to the basics and remember that *if there is no chest movement, there is no ventilation*. If no chest movement occurs during BVM ventilation despite an apparently good seal between the mask and the child's face, the underlying cause, be it upper airway obstruction, whether anatomic or presence of a foreign body, bilateral tension pneumothoraces, or severe bronchospasm must be considered.

Overventilation is common during CPR, resulting in greater mean intrathoracic pressures than required, which decreases venous return and reduces cardiac output.<sup>17</sup> In cardiopulmonary arrest, a less than normal minute ventilation may be appropriate, because cardiac output and delivery of CO<sub>2</sub> to the lungs are diminished. If an artificial airway is not in place for single person rescue, two breaths should be given for each 30 chest compressions. If an artificial airway is not in place for two person rescue, two breaths should be given after each 15 chest compressions. Once an artificial airway is in place, a ventilator rate of 8 to 10 per minute *without* pausing during rapid chest compressions should be used (Table 39-1).

**TABLE 39-1** Ventilation and Chest Compressions during Pediatric Cardiopulmonary Pulmonary Resuscitation (all ages)

	Respirations	Chest Compressions	Notes
Bag-mask ventilation	2 respirations after each 15 chest compressions (if one rescuer only, 2 respirations after each 30 compressions)	100/minute	Aspirate (vent) the stomach if gastric inflation interferes with ventilation.
Endotracheal intubation	8 to 10/minute	100/minute	Do not pause compressions during ventilation.

### CIRCULATION

During cardiac arrest, chest compressions provide the sole perfusion to a child's vital organs; therefore optimal performance of CPR is critical. Key elements to providing quality chest compressions include (1) ensuring an adequate rate (100 compressions per minute), (2) ensuring adequate chest wall depression (one third to half of the anteroposterior chest diameter), (3) releasing completely between compressions to allow full chest wall recoil, (4) minimizing interruptions in chest compressions, and (5) ensuring that the child is on a sufficiently hard surface to allow effective chest compressions.<sup>18</sup> In short, push hard and push fast, release completely, and do not interrupt compressions unnecessarily. Incomplete recoil during CPR is associated with higher intrathoracic pressures and significantly decreased venous return, and coronary and cerebral perfusion.<sup>19</sup>

If a child is small enough (e.g., younger than 6 months) that the person providing chest compressions can comfortably encircle the chest with his or her hands, chest compressions should be performed using the circumferential technique, with thumbs depressing the sternum and the fingers supporting the infant's back and circumferentially squeezing the thorax (Fig. 39-1). In larger infants, the sternum can be compressed using two fingers; and in the child, either one or two hands can be used, depending on the size of the child and of the rescuer.<sup>19</sup> Whichever method is used, focused attention must remain on delivering effective compressions with *minimal interruptions*.<sup>20</sup> In all cases other than circumferential CPR, a backboard must be used. Properly delivered chest compressions are tiring to the provider, and providers should rotate approximately every 2 minutes to prevent compressor fatigue and deterioration in the quality and rate of chest compressions.<sup>19</sup>

### Mechanisms of Blood Flow

External chest compressions provide cardiac output through two mechanisms: the cardiac pump mechanism and the thoracic pump mechanism. By the cardiac pump mechanism of blood flow, blood is squeezed from the heart by compression of the heart between the sternum and the vertebral column, exiting the heart only anterograde because of closure of the atrioventricular valves. Between compressions, ventricular pressure decreases below atrial pressure, allowing the atrioventricular valves to open and the ventricles to fill. This sequence of events resembles the normal cardiac cycle. Although the cardiac pump is likely not the dominant blood flow mechanism during most closed-chest

**FIGURE 39-1** Chest-encircling method for cardiac compressions in a neonate: thumbs are placed one finger's breadth below the nipple line. (Modified from Todres ID, Rogers MC. Methods of external cardiac massage in the newborn infant. J Pediatr 1975;86:781-2.)

**FIGURE 39-2** A, Cardiac pump mechanism by which the heart is directly squeezed between the sternum and vertebral column, representing artificial systole. B, Artificial diastole occurs with relaxation of the compressions. (From Babbs CF. New versus old theories of blood flow during CPR. Crit Care Med 1980;8:191-5, © by Williams & Wilkins.)

CPR, specific clinical situations have been identified in which the cardiac pump mechanism is more prominent. For example, a smaller, more compliant chest may allow for more direct cardiac compression (Fig. 39-2). Increasing the applied force during chest compressions also increases the likelihood of direct cardiac compression.

Several observations do not support the cardiac pump as the primary mechanism of blood flow during CPR. Angiographic studies show that blood passes from the vena cava through the

right heart into the pulmonary artery and from the pulmonary veins through the left heart into the aorta during a single chest compression.<sup>21,22</sup> Echocardiographic studies show that the atrioventricular valves are open during blood ejection.<sup>21,23,24</sup> Without closure of atrioventricular valves during chest compression, the cardiac pump mechanisms cannot account for forward movement of blood during CPR.

In 1976, Criley and colleagues<sup>25</sup> made the dramatic observation that several patients who developed ventricular fibrillation during cardiac catheterization produced enough blood flow to maintain consciousness by repetitive coughing.<sup>25</sup> The production of blood flow by increasing thoracic pressure without direct cardiac compression describes the thoracic pump mechanism, in which the heart is a passive conduit for blood flow. The intrathoracic pressure is greater than the extrathoracic pressure during the compression phase of CPR, at which time blood flows out of the thorax, with venous valves preventing excessive retrograde blood flow (Fig. 39-3). Experimental and clinical data support both mechanisms of blood flow during CPR in human infants.

### Rate and Duty Cycle

The recommended rate of chest compressions for all patients is 100 per minute, with great care taken to minimize interruptions in chest compressions and to ensure adequate compression depth.<sup>20</sup> This rate represents a compromise that attempts to maximize contributions from both the thoracic pump and cardiac pump mechanism of blood flow.

Duty cycle is defined as the percent of the compression-relaxation cycle that is devoted to compression. If blood flow is generated by direct cardiac compression, then primarily the force of compression determines the stroke volume. Prolonging the compression (increasing the duty cycle) beyond the time necessary for full ventricular ejection should have no additional effect on stroke volume. Increasing the rate of compressions should increase cardiac output, because a fixed volume of blood is

ejected with each cardiac compression. In contrast, if blood flow is produced by the thoracic pump mechanism, the volume of blood that is ejected comes from a large reservoir of blood contained within the capacitance vessels in the chest. With the thoracic pump mechanism, flow is enhanced by increasing either the force of compression or the duty cycle but is not affected by changes in compression rate over a wide range of rates, given a set duty cycle.<sup>26</sup>

Different animal models yield conflicting results as to the optimal compression rate and duty cycle. However, a rate of compression during conventional CPR of 100 per minute satisfies both those who prefer the faster rates and those who support a longer duty cycle. This is true because it is easier to produce a longer duty cycle when compressions are administered at a faster rate.<sup>27,28</sup>

## Defibrillation and Cardioversion

In children with ventricular fibrillation or pulseless ventricular tachycardia, the immediate management should be defibrillation, without delay to secure an airway.

### ELECTRIC COUNTERSHOCK

Electric countershock, or defibrillation, is the treatment of choice for ventricular fibrillation and pulseless ventricular tachycardia. Defibrillation should not be delayed to secure an airway, because the likelihood of restoring an organized rhythm decreases with increased duration of fibrillation. Ventricular fibrillation is terminated by simultaneous depolarization and sustained contraction of a critical mass of myocardium,<sup>29</sup> allowing return of spontaneous, coordinated cardiac contractions, assuming the myocardium is well oxygenated and the acid-base status is relatively normal. Drug treatment may be required as an adjunct to defibrillation, but by itself cannot be relied on to terminate ventricular fibrillation.

An older generation of defibrillators that is still present in many hospitals delivers energy in a monophasic damped sinusoidal waveform (Fig. 39-4, A). This type of instrument delivers a single, unidirectional current with a gradual decrease to zero current. By contrast, the newer generation of biphasic defibrillators delivers a current in a positive direction for a set period, followed by a reversal in current (see Fig. 39-4, B). Biphasic defibrillators are more effective than monophasic defibrillators in terminating ventricular fibrillation in adults; therefore their use is recommended where possible.

In the majority of adult cases, energy levels of 100 to 200 joules are successful when shocks are delivered with minimal delay.<sup>30,31</sup> The goal of defibrillation is to deliver a minimum of electrical energy to a critical mass of ventricular muscle while avoiding excessive current that could further damage the heart. The most reliable predictor of success of defibrillation is the duration of fibrillation before the first countershock.<sup>32</sup> Acidosis and hypoxemia also decrease the success of defibrillation.<sup>32</sup>

### PRACTICAL ASPECTS OF DEFIBRILLATION IN CHILDREN

Correct paddle size and position are critical to the success of defibrillation. The largest paddle size appropriate for the child should be used because a larger size reduces the density of current flow, which in turn reduces myocardial damage. In general, adult paddles should be used in children weighing more than 10 kg and infant paddles should be used in infants weighing less than 10 kg. Paddle force is important as well. If the entire paddle does

**FIGURE 39-3** A, Thoracic pump mechanism by which blood flow occurs through a general increase in intrathoracic pressure with external compressions (i.e., the heart is a passive conduit). B, Artificial diastole occurs with release of external compressions. (From Babbs CF, New versus old theories of blood flow during CPR. *Crit Care Med* 1980;8:191-5, © by Williams & Wilkins.)

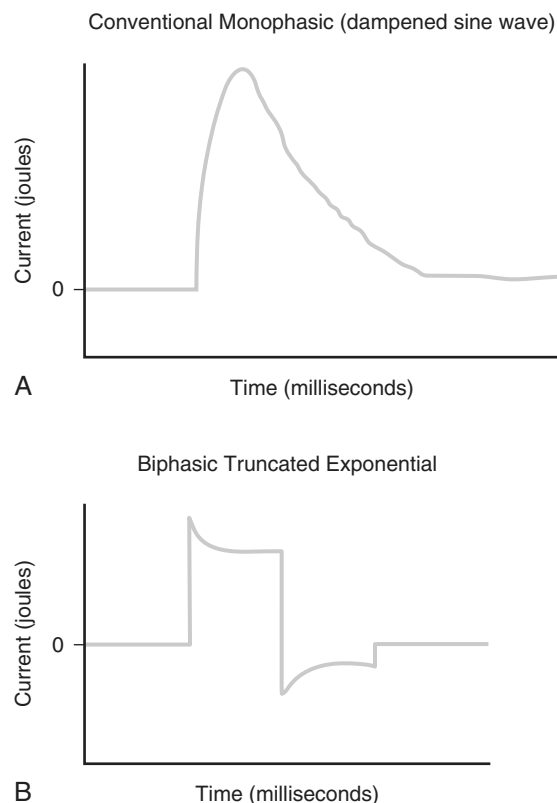

FIGURE 39-4 Energy delivery during conventional monophasic (A) and biphasic truncated exponential (B) defibrillation.

not rest *firmly* on the chest wall, a current of increased density will be delivered to a small contact point. Paddles should be positioned on the chest wall so that the bulk of myocardium lies directly between them. One paddle is placed to the right of the upper sternum below the clavicle; the other is positioned just caudad and to the left of the left nipple. For children with dextrocardia, the position of the paddles should be a mirror image. An alternative approach is to place one paddle anteriorly over the left precordium and the other paddle posteriorly between the scapulae.

The interface between the paddle and chest wall can be gel pads, electrode cream, or electrode paste. The electrode cream produces less impedance than the paste. *Electric current follows the path of least resistance, so care should be taken that the interface material from one paddle does not touch that of the other paddle. This is especially important in infants, in whom the distance between paddles is small.* If the gel is continuous between paddles, a short circuit is created and an insufficient amount of current will traverse the heart. Use of bare metal paddles increases the risk of arcing and worsens cutaneous burns from defibrillation. The use of self-adhesive pads is preferable when feasible.

In an oxygen (O<sub>2</sub>)-enriched atmosphere, sparking from poorly applied defibrillator paddles can cause a fire. Therefore any sources of free-flowing O<sub>2</sub> should be removed to a distance of at least 1 meter from the child. These potentially hazardous O<sub>2</sub> sources include nasal cannula O<sub>2</sub>, “blow-by” O<sub>2</sub>, and nebulizers powered by O<sub>2</sub>. By contrast, O<sub>2</sub> in a closed circuit may remain on the child. For example, it is not necessary to disconnect the ventilator from the child’s tracheal tube (if a ventilator is disconnected, the fresh gas flow should be turned off because large volumes of O<sub>2</sub> flow through disconnected ventilators).

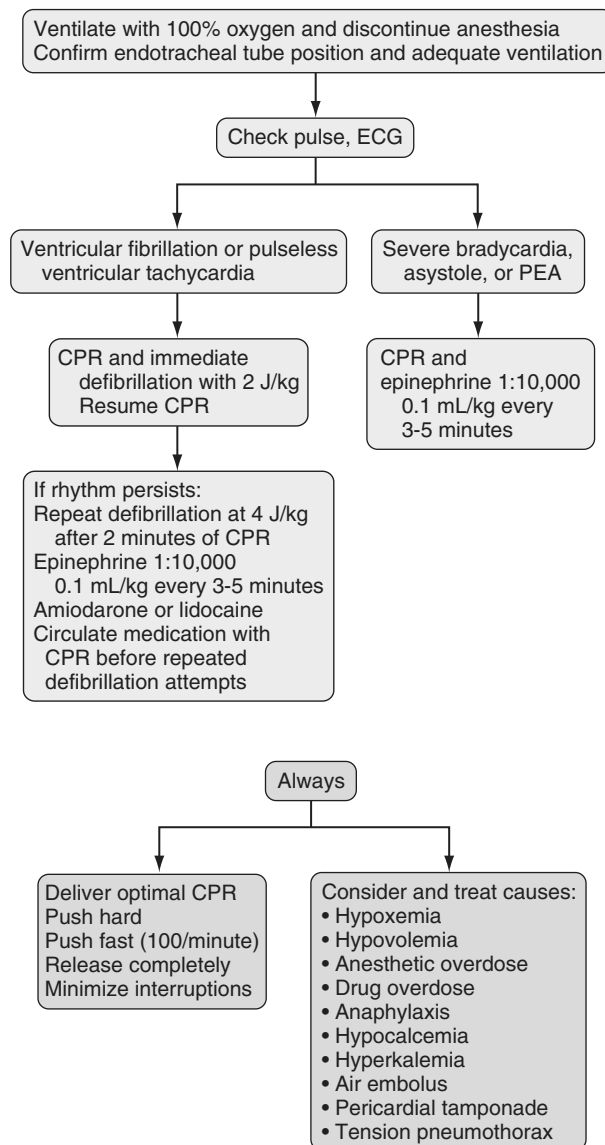

FIGURE 39-5 Algorithm for diagnosis and treatment of acute cardiac dysfunction in the operating room. CPR, Cardiopulmonary resuscitation; ECG, electrocardiogram; PEA, pulseless electrical activity.

For children with in-hospital ventricular fibrillation or pulseless ventricular tachycardia, defibrillation should be attempted as soon as possible, with optimal CPR until the defibrillator is ready to deliver a shock. For the first defibrillation attempt, 2 joules/kg of delivered energy should be administered (Fig. 39-5). After shock delivery, CPR should resume immediately with chest compressions for five duty cycles (2 minutes). If one shock fails to eliminate ventricular fibrillation, the incremental benefit of another immediate shock is small. Resumption of CPR is likely to confer a greater benefit than another shock. CPR may provide coronary perfusion, increasing the likelihood of defibrillation with a subsequent shock. It is important to minimize the time between chest compressions and shock delivery and between shock delivery and resumption of postshock compressions.<sup>20</sup> Approximately 2 minutes of CPR should be delivered before a second attempt at defibrillation at twice the original energy level (4 joules/kg).<sup>20</sup>

If ventricular fibrillation or pulseless ventricular tachycardia persists beyond the second defibrillation attempt, standard doses of epinephrine should be administered (with subsequent doses every 3 to 5 minutes during persistent cardiac arrest). After 2 minutes of chest compressions, defibrillation should be attempted again, followed by administration of amiodarone (5 mg/kg) or lidocaine (1 mg/kg) with subsequent defibrillation attempts. It is not necessary to increase the energy level on each successive shock during defibrillation after the second dose. However, successful defibrillation has been reported with currents in excess of 4 joules/kg without adverse sequelae, up to a maximum dose not exceeding 10 joules/kg or the adult level, whichever is less.<sup>20</sup> This sometimes occurs when a fixed energy level, adult automated external defibrillator (AED) is used in a small child.

### OPEN-CHEST DEFIBRILLATION

If the chest is already open in the OR or easily opened as in a fresh postoperative cardiac patient, ventricular fibrillation should be treated with open-chest defibrillation, using internal paddles applied directly to the heart. These should have a diameter of 6 cm for adults, 4 cm for children, and 2 cm for infants. Handles should be insulated. Saline-soaked pads or gauzes should be placed between the paddles and the heart. One electrode is placed behind the left ventricle and the other over the right ventricle on the anterior surface of the heart. The energy level used should begin at 5 joules in infants and 20 joules in adults.

### AUTOMATED EXTERNAL DEFIBRILLATION

Use of AEDs is now standard therapy in out-of-hospital resuscitation of adults.<sup>19,30</sup> AEDs are now deemed appropriate for use in children older than 1 year. If available, use of pediatric attenuator pads or a pediatric mode on the AED should be used in children 1 to 8 years of age, but if unavailable (and a standard defibrillator is similarly unavailable), an unmodified AED should be used.

### TRANSCUTANEOUS CARDIAC PACING

In the absence of in situ pacing wires or an indwelling transvenous or esophageal pacing catheter, transcutaneous cardiac pacing (TCP) is the preferred method for temporary electrical cardiac pacing in children with asystole or severe bradycardia. TCP is indicated for children whose primary problem is impulse formation or conduction, with preserved myocardial function. It is most effective in those with sinus bradycardia or high-grade atrioventricular block, with slow ventricular response but adequate stroke volume. TCP is not indicated for children during prolonged arrest, because in this situation it usually results in electrical but not mechanical cardiac capture and its use may delay or interfere with other resuscitative efforts.

To set up pacing, one electrode is placed anteriorly at the left sternal border and the other posteriorly just below the left scapula. Smaller electrodes are available for infants and children, but adult-sized electrodes can be used in children weighing more than 15 kg. ECG leads should be connected to the pacemaker, the demand or asynchronous mode selected, and an age-appropriate heart rate used. The stimulus output should be set at zero when the pacemaker is turned on and then increased gradually until electrical capture is identified on the monitor. After electrical capture is achieved, whether an effective arterial pulse is generated must be determined. If not, additional resuscitative efforts should be initiated.

The most serious complication of TCP is the induction of a ventricular arrhythmia. Fortunately, this is rare and may be

prevented by pacing only in the demand mode. Mild transient erythema beneath the electrodes is common. Skeletal muscle contraction can be minimized by using large electrodes, a 40-msec pulse duration, and the smallest stimulus required for capture. If defibrillation or cardioversion is necessary, a distance of 2 to 3 cm must be allowed between the electrode and paddles to prevent arcing of the current.

## Vascular Access and Monitoring during Cardiopulmonary Resuscitation

### VASCULAR ACCESS AND FLUID ADMINISTRATION

One of the key aspects of successful CPR is early establishment of a route for administration of fluids and medications. If intravenous access cannot be established rapidly, the intraosseous or endotracheal route should be used (see Chapter 48).

#### Intravenous Access

Many children who suffer an in-hospital cardiac arrest will already have established vascular access. For children with impending cardiac arrest and no vascular access, a brief attempt should be made to establish peripheral intravenous access. If access is not achieved quickly, an intraosseous needle should be placed. For young children in cardiac arrest without vascular access, an intraosseous needle should be placed immediately, to avoid any delay from repeated attempts at establishing intravenous access.

#### Intraosseous Access

The intraosseous route can be used to administer all medications and fluids used during CPR, including whole blood. An intraosseous needle also may be used to obtain initial blood samples, although acid-base analysis will be inaccurate after administration of sodium bicarbonate via the intraosseous needle. Intraosseous access should be considered a temporary measure during emergencies when other access is not available. The placement of an intraosseous needle in the older child (older than 10 years) and adult, although possible, is difficult owing to the thick bony cortex; however, a 50% success rate has been reported in these age-groups.<sup>33</sup>
