#### Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

*We dedicate this edition of A Practice of Anesthesia for Infants and Children to all physicians around the world who have the pleasure of caring for children in the operating room, ICU, or other venues where anesthesia services are vital. In particular, we especially thank all who take care of children and deliver the best possible care with the resources available. Our specialty has grown exponentially in the past 20 years. As a result of new licensing laws, medications are now more thoroughly investigated before they are released for use in children. Ultrasound technology has made regional anesthesia and invasive line insertion far safer than in the past. The quality of airway devices continues to improve. Noninvasive continuous cardiac output devices may provide the next generation of monitors to safeguard the care of our children. Depth-of-anesthesia monitors also continue to evolve, but currently are unreliable in young infants and children younger than 5 years. We hope that in the near future advances will ensure that these devices are reliable in the infant and young child to both assess the depth of anesthesia as well as differentiate moderate from deep sedation and deep sedation from general anesthesia.*

*We also dedicate this book to the children we work for every day. We would like to assure the families we work with that their children are safe from harm.*

*Consequently, it is imperative that we investigate the possible harmful effects of anesthetics on the developing brain in infants and children and determine if this is a laboratory phenomenon or an issue that is potentially harmful to humans. If it is the latter, then we must develop methods or new medications to block these adverse effects so that children can continue to undergo anesthesia safely. Our challenge in this next decade is to determine if the laboratory studies concerning anesthetic agent toxicity are a tempest in a teacup or a real threat to our children.*

*This edition of A Practice of Anesthesia for Infants and Children highlights key advances and questions in our specialty that we hope will continue to inspire anesthesiologists worldwide.*

Charles J. Coté  
Jerrold Lerman

# PREFACE

*A Practice of Anesthesia for Infants and Children, Fifth Edition*, has evolved from its predecessors. Jerrold Lerman joined as co-editor in the previous edition, and we have greatly strengthened our editorial team with the addition of Brian J. Anderson in this edition. Dr. Anderson brings not only a further international perspective to the editorship that reflects the mission of our text, but also a specific expertise in pharmacology.

This book has blossomed from its humble beginnings as a synopsis of local practice to an international authoritative and evidence-based tome. In addition to pediatric anesthesiologists, the list of contributors includes pediatric subspecialists, internists, two surgeons, and a lawyer. More than 20 of the pediatric anesthesiologists are also board-certified pediatricians, and several have subspecialty board certification in cardiology and neonatology. The inclusion of 110 authors from 10 countries and six continents speaks to the global nature of this edition.

In the fifth edition, we have exploited the advances in state-of-the-art publishing, including Internet access. The book has the same feel and style as the previous edition, divided into 10 color-coded sections: Introduction, Drug and Fluid Therapy, The Chest, The Heart, The Brain and Glands, The Abdomen, Other Surgeries, Emergencies, Pain, and Special Topics. This format enables the reader to find chapters and topics of interest easily and quickly. To maintain a size similar to that of the previous edition, we have again shifted all but a few select references from each chapter to the accompanying Expert Consult website, with hypertext links to the original publications. We also have combined a few chapters. Color illustrations, photographs, and graphics maximize clarity and enhance visual appeal; many new video clips, figures, tables, and appendices also are available online.

In keeping with our mission to create a comprehensive text, we have again sought contributions from a number of pediatric subspecialists, who have shared their perspectives on and insights into basic pediatric physiology and the pathophysiologic implications of diseases in children. In each case, these specialists have been paired with a pediatric anesthesiologist to ensure the basic science is intertwined with a practical clinical perspective.

The largest chapter of the book covers pharmacology and includes more than 1900 references. As in previous editions, the chapter has benefited from very significant contributions from Dr. Anderson, who now has assumed the role of first author. Written by all three editors, the chapter's usefulness is enhanced by including three different perspectives in pediatric pharmacology. It includes older and less frequently used medications to address the wide range of practices used around the world. Given the rapidly increasing interest in total intravenous anesthesia (TIVA) in children, the TIVA chapter also now provides online computer simulations.

The pediatric airway chapter includes a more extensive discussion of the numerous supraglottic devices as well as emergency airway management strategies and equipment currently available

for use in infants and children. This chapter has been enhanced with online video clips. The transfusion chapter has been updated with contributions from a pediatric hematologist specializing in hemophilia and the director of the Blood Transfusion Service at the Massachusetts General Hospital.

All of the chapters on specialized topics—including thoracic anesthesia, orthopedics, plastic surgery, general and urologic surgeries; the cardiac chapters, including cardiopulmonary bypass, medications used for hemostasis, cardiac assist devices, and the cardiac catheterization laboratory; as well as the practice of anesthesia in medically disadvantaged countries—have been extensively updated. In the section on the abdomen, the chapter on organ transplantation remains the centerpiece.

Perhaps the most important addition is a chapter on anesthesia and the developing brain. This topic remains a major concern for pediatric anesthesiologists at the time of printing. The chapters that address the extremely premature infant, the ex-utero intrapartum treatment procedure and trauma, medical-legal issues, and infectious diseases have been extensively revised.

The increasing importance of training residents to diagnose and treat pain in children is highlighted in several chapters that include an extensive discussion on pain scoring systems for both “normal” and cognitively impaired children. Likewise, these topics are covered at length in chapters devoted to landmark- and ultrasound-guided regional anesthesia, also supplemented with online video clips. A wholly new chapter addresses medical simulation in children, with several demonstrative video clips on the website. Further sophistication of medical simulation may ultimately improve the safety of anesthesia.

Finally, the accompanying website has been greatly expanded in audio-visual content to include myriad illustrations, figures, video clips, and sample order forms. The addition of videos, in particular, affords users the opportunity to view a hands-on approach to procedures such as ultrasound- and landmark-guided nerve blocks, catheter insertions, radiologic investigations, ultrasound procedures, and echocardiograms, as well as various levels of sedation and analgesia. A pocket reference card also provides general recommendations for dosages of commonly used medications by weight and other useful guides such as LMA sizes, ETT sizes, and other quick references.

Undertaking this revision has been quite a journey, often appearing to be a microcosm of the world and life in general. Once again many of our contributors have experienced various challenges, such as the loss of loved ones, personal crises, and illnesses, during the writing of their chapters. Despite these obstacles, the authors have succeeded in crafting masterful chapters to create what we think is a state-of-the-art text on pediatric anesthesia. Furthermore, the entire text and e-only content is also available for purchase as an eBook.

In assembling this edition, we have spent many days and nights debating controversial issues. We think we have arrived

at a middle ground that addresses the diversity of pediatric anesthesia practice. It is our hope that these discussions, combined with the global perspective offered by our contributing authors, strengthen the quality of our text while showcasing the diversity of our specialty.

We believe *A Practice of Anesthesia for Infants and Children, Fifth Edition*, will continue to provide the basis for residency and

fellowship training in pediatric anesthesia, and be a valuable resource to practicing pediatric anesthesiologists and other pediatric care providers around the world.

**Charles J. Coté, MD, FAAP, MA(Hon)**

**Jerrold Lerman, MD, FRCPC, FANZCA**

**Brian J. Anderson, MB, ChB, PhD, FANZCA, FCICM**

# ACKNOWLEDGMENTS

We wish to thank the chairpersons of the departments of anesthesiology, pediatrics, surgery, and internal medicine around the world who supported the academic endeavors of their staff and thus made it possible for them to contribute to *A Practice of Anesthesia for Infants and Children, Fifth Edition*. In particular, we thank all of the wives, husbands, significant others, children,

friends, secretaries, and staff members who lent their support to this wonderful international family of experts that has come together to produce this edition.

**Charles J. Coté, MD, FAAP, MA(Hon)**

**Jerrold Lerman, MD, FRCPC, FANZCA**

**Brian J. Anderson, MB, ChB, PhD, FANZCA, FCICM**

A Practice of Anesthesia for Infants and Children

CJ Coté MD, J Lerman MD, BJ Anderson MB ChB

Pocket Reference Guide

Note that the drug doses and management decisions presented are those that are commonly recommended; each child's care must be individualized according to the child's underlying medical and surgical conditions. All drug doses should be double checked before administration so as to avoid errors.

RESUSCITATION	
Oxygen	ventilate with 100% oxygen
Epinephrine (Adrenaline)	1 µg/kg to treat hypotension IV; 10 µg/kg IV for cardiac arrest; repeat every 3-5 minutes as needed
Atropine	20 µg/kg IV (for symptomatic bradycardia); maximum dose 1 mg for child and 2 mg for adolescent
Bicarbonate	1-2 mEq/kg IV to be guided by blood gas analysis
Calcium Chloride	10-20 mg/kg IV (0.1-0.2 mL/kg of a 10% solution)
Calcium Gluconate	30-60 mg/kg IV (0.3-0.6 mL/kg of a 10% solution)
Adenosine (Adenocard)	100 µg/kg rapid IV bolus and flush (maximum 6 mg ); second dose 200 µg/kg (maximum 12 mg)*
Lidocaine	1 mg/kg IV then followed by 20-50 µg/kg/min by infusion pump
Amiodarone (Cordarone)	5 mg/kg IV, maximum 300 mg for ventricular fibrillation and/or ventricular tachycardia
Procainamide (Pronestyl)	5 to 15 mg/kg IV loading dose over 30-60 minutes, then 20-80 µg/kg/min by infusion pump. ECG monitoring required. Caution: hypotension and prolonged QT interval may occur particularly when combined with amiodarone
Magnesium	25-50 mg/kg IV for Torsades de Pointes (maximum dose 2 grams)

\*Reduce by half if administering through a central line or for patients who have had a heart transplant.

VASOACTIVE DRUGS	
Note that all are administered by IV infusion pump; consider invasive arterial pressure monitoring	
Dopamine	1-20 µg/kg/min; titrate to effect
Dobutamine	1-20 µg/kg/min; titrate to effect
Epinephrine (Adrenalin)	0.1-1 µg/kg/min; titrate to effect
Isoproterenol (Isuprel)	0.1-1 µg/kg/min; titrate to effect
Norepinephrine (Levophed)	0.1-1 µg/kg/min; titrate to effect
Phenylephrine (Neo-Synephrine)	0.1-1 µg/kg/min; titrate to effect
Milrinone (Primacor)	50-100 µg/kg loading dose followed by 0.25-1 µg/kg/min infusion
Nitroprusside (Nipride)	0.5-10 µg/kg/min; titrate to effect; observe for signs of cyanide toxicity
Nitroglycerine (NitroQuick)	1-10 µg/kg/min; titrate to effect
Prostaglandin E <sub>1</sub>	0.01-0.1 µg/kg/min (Note that apnea may occur and intubation is often required with doses >0.05 µg/kg/min)
Vasopressin (Pitressin)	0.0001 to 0.001 units/kg/min

CARDIOVERSION/DEFIBRILLATION (EXTERNAL)	
cardioversion	For supraventricular/ventricular tachycardia 0.5 joules/kg <b>SYNCHRONOUS</b> ; repeat up to 2 joules/kg
defibrillation	For ventricular fibrillation/ventricular tachycardia 2 joules/kg <b>ASYNCHRONOUS</b> ; repeat up to 4 joules/kg

RULE OF SIXES	
0.1 µg/kg/min = 0.6 mg/100 mL administered as body weight (kg) <b>in mL/hr</b>	
1 µg/kg/min = 6 mg/100 mL administered as body weight (kg) <b>in mL/hr</b>	
10 µg/kg/min = 60 mg/100 mL administered as body weight (kg) <b>in mL/hr</b>	
20 µg/kg/min = 120 mg/100 mL administered as body weight (kg) <b>in mL/hr</b>	

ANAPHYLAXIS	
Search for cause, especially latex allergy; remove source if possible	
Oxygen	Ventilate with 100% oxygen
Epinephrine (Adrenaline)	1 µg/kg IV to treat hypotension/bronchospasm; repeat with increasing doses every 3-5 minutes as needed; may need continuous infusion
Fluid bolus	20 mL/kg balanced salt solution; repeat as necessary
Phenylephrine (Neo-Synephrine)	0.1 µg/kg/min IV; titrate to effect if inadequate response to epinephrine
Hydrocortisone	2-3 mg/kg IV
Diphenhydramine	1-2 mg/kg IV
Ranitidine (Zantac)	1.5 mg/kg IV

HYPERKALEMIA TREATMENT	
Intervention	Dose
Calcium chloride	5-10 mg/kg/dose IV; repeat until normal sinus rhythm
Calcium gluconate	15-30 mg/kg/dose IV; repeat until normal sinus rhythm
Hyperventilation	
Albuterol (Ventolin, Proventil)	by inhalation administered with a spacer
Salbutamol	5 µg/kg IV over 15 minutes
Glucose + insulin	glucose (0.5-1 g/kg) with insulin (0.1 U/ kg) given IV over 30-60 minutes
Kayexalate	1 g/kg (up to 40 g) q4hr (PO, PR, per gastric tube)

LARYNGEAL MARK AIRWAY (CLASSIC)			
Weight (kg)	Size	Cuff Volume (mL)	Largest ETT that will fit through LMA
<5	1	4	3.5 uncuffed
5-10	1.5	7	4 uncuffed
10-20	2	10	4.5 uncuffed
20-30	2.5	14	5 uncuffed
30-50	3	20	6 cuffed
50-70	4	30	6 cuffed
70-100	5	40	7 cuffed
>100	6	50	7 cuffed

ETT SIZE (mm ID)		
	Uncuffed	Cuffed
Preterm (<1.5 kg)	2.5	
Preterm (1.5-3 kg)	3	
Full-term neonate	3	
1 year	4	3-3.5
2 years	5	4-4.5
>2 years	Age/4 + 4 (or 4.5)	0.5-1.0 smaller than uncuffed ETT*

\*Assure leak with deflated cuff at 20-40 cm H<sub>2</sub>O PIP.

DISTANCE OF INSERTION (cm) EVEN WITH GUMS	
Preterm (<1000 grams)	6-7
Preterm (<2000 grams)	7-9
Full-term neonate	~10
1 year	~11
2 years	~12
16 years	~18
≥20 years	~20-21

LARYNGOSCOPE BLADES (APPROXIMATE SIZE)			
Age	Miller	Wis-Hipple	Macintosh
Preterm	0		
Full-term neonate	0		
Term-2 years	1	1	
2-6 years		1.5	1-2
6-10 years	2	NA	2
>10 years	2 or 3	NA	2 or 3

INDUCTION AGENTS			
	IV (mg/kg)	IM (mg/kg)	Rectal (mg/kg)
Propofol (Diprivan)	2-3 mg/kg IV		
Ketamine (Ketalar)	1-2	3-12	5-10
Etomidate (Amidate)	0.2-0.3		
Thiopental	4-6		20-30
Methohexital	1-3		20-30

DURATION OF E-CYLINDER OXYGEN SUPPLY	
Non-SI units	SI units
Time (in minutes) = 1/3 × tank pressure (pounds/ square inch)/ oxygen flow rate (L/min)	Time (in minutes) = tank pressure (kPa)/(23 × oxygen flow rate (L/min))

NEUROMUSCULAR BLOCKING DRUGS	
Succinylcholine (Anectine)*	2-3 mg/kg IV for <1 year; 1-2 mg/ kg IV; 4-5 mg/kg IM or 1-3 mg/kg intralingual (submental) for >1 year
Rocuronium (Zemuron)	0.3 mg/kg in neonates = ~30-45 min, 0.6 mg/kg in children = ~30-45 min duration, 1.2 mg/kg in children for rapid sequence intubation = ~75 min duration
Vecuronium (Norcuron)	0.1 mg/kg IV
Pancuronium (Pavulon)	0.05-0.1 mg/kg IV
Cisatracurium (Nimbex)	0.1 mg/kg IV neonates; 0.1-0.2 mg/ kg older children
Atracurium (Tracrium)	0.5 mg/kg IV

\*Pretreatment with anticholinergic recommended.

REVERSAL AGENTS/ANTAGONISTS	
Neostigmine (Prostigmin)	0.02-0.05 mg/kg + atropine 0.02 mg/kg or glycopyrrolate 0.01 mg/kg
Edrophonium (Enlon)	0.3-1 mg/kg + atropine 0.02 mg/kg or glycopyrrolate 0.01 mg/kg
Sugammadex	2 mg/kg for reversal of rocuronium
Physostigmine (Antilirium)	0.01-0.03 mg/kg followed by infusion 0.03 mg/kg/hr to treat cholinergic syndrome
Naloxone (Narcan)	0.25-0.5 µg/kg, additional doses titrated to effect; up to 100 µg/kg (maximum 2 mg) may be needed for respiratory arrest; must observe child for recrudescence. May also give the effective dose IM to prevent recrudescence
Flumazenil (Romazicon)	10 µg/kg/dose, titrate to effect; must observe child for minimum of 2 hours after antagonism

ANALGESICS	
Non-Opioids	
Acetaminophen oral/rectal (Tylenol) Acetaminophen IV (OFIRMEV) (Pro-Dafalgan)	Non-IV routes (Tylenol): 10-15 mg/kg PO every 4-6 hours or 30-40 mg/kg PR loading dose, then 20 mg/kg PR every 6 hours ( <b>maximum 75 mg/kg/24 hr</b> ) IV routes: 15 mg/kg paracetamol IV every 6 hours or 30 mg/kg propacetamol every 6 hours (with only 15 mg/kg of the prodrug in neonates)
Ibuprofen (Advil)	10 mg/kg PO every- 6 hours (max 800 mg)
Ketorolac (Toradol)	0.5 mg/kg up to 15 mg <50 kg; 0.5 mg/kg up to 30 mg >50 kg, IV, IM, PO every 6 hours
Ketamine (Ketalar)	0.25-1 mg/kg every 8-10 minutes IV as needed
Opioids	
Codeine	0.5-1.5 mg/kg PO/IM every 6 hours
Fentanyl (Sublimaze)	0.5-2 µg/kg; greater doses up to 100 µg/kg for cardiac or other major cases
Hydromorphone (Dilaudid)	0.015 mg/kg IV every 3-4 hours
Morphine	0.05-0.1 mg/kg IV every 3-4 hours (postoperative analgesia infusion 5-20 µg/kg/hr)
Remifentanyl (Ultiva)	0.05-0.15 µg/kg/min (may need larger doses for brief periods); continuous infusion may cause hypotension and bradycardia

OPIOID CONVERSION APPROXIMATIONS		
Morphine (1 mg) is equivalent to:		
	IV (mg)	PO (mg)
Codeine	~12-13	~20
Fentanyl (Sublimaze)	~0.01 (10 µg)	~0.02 (20 µg)
Hydromorphone (Dilaudid)	~0.15	~0.75
Oxycodone (OxyContin)		~2-3
Methadone	~1	~1.5
Tramadol (Ultram)	~10	~15

SEDATIVES	
Chloral hydrate	50-100 mg/kg maximum 2 grams in divided doses (PO or PR)
Dexmedetomidine (Precedex)	0.3-2 µg/kg loading dose infused over 10 minutes followed by 0.7 to 1 µg/kg/hr
Pentobarbital	2 mg/kg IV every 10 minutes up to 6 mg/kg

ANTIBIOTICS			
Antibiotic (IV)*	1st week postnatal (>2000 grams)	1-4 weeks postnatal	>4 weeks postnatal
Ampicillin (Omnipen)	50 mg/kg every 8 hours	25-50 mg/kg every 6 hours	25-50 mg/kg every 4-6 hours
Ampicillin/ Sulbactam (UNASYN)			25-37.5 mg/kg every 6 hours
Cefotaxime (Claforan)	50 mg/kg every 8-12 hours	50 mg/kg every 6-8 hours	50 mg/kg every 6-8 hours
Cefazolin (Ancef)	20 mg/kg every 12 hours	20 mg/kg every 8 hours	16-33 mg/kg every 8 hours (up to 3 grams)
Ceftriaxone (Rocephin)	50 mg/kg every 24 hours	50-75 mg/kg every 24 hours	50-75 mg/kg every 12-24 hours
Cefuroxime (Zinacef)	25-50 mg/kg every 12 hours	25-50 mg/kg every 12 hours	25-50 mg/kg every 8 hours
Clindamycin (Cleocin)	5 mg/kg every 8 hours	10 mg/kg every 8 hours	10 mg/kg every 6-8 hours
Gentamicin <sup>†‡</sup>	4 mg/kg every 24 hours	4 mg/kg every 24 hours	2-2.5 mg/kg every 8 hours
Metronidazole (Flagyl)	7.5 mg/kg every 12 hours	15 mg/kg every 12 hours	7.5 mg/kg every 6 hours
Nafcillin (Unipen)	25 mg/kg every 8 hours	25 mg/kg every 6 hours	25-50 mg/kg every 6 hours
Piperacillin/ Tazobactam (Zosyn)			37.5-75 mg/kg every 6 hours
Ticarcillin (Timentin)	75 mg every 8 hours	50-75 mg/kg every 6 hours	33-50 mg/kg every 4 hours
Vancomycin (Vancocin) <sup>‡§</sup>	15 mg/kg every 12 hours	15 mg/kg every 8 hours	10-15 mg/kg every 8 hours

\*For preterm infants, check with pharmacy.  
†Monitoring blood levels recommended.  
‡0-4 weeks, <1200 g, 2.5 mg/kg every 18-24 hours; <1000 g 3.5 mg/kg every 24 hours.  
§Should generally be administered by infusion pump over 60 minutes.

ANTIHISTAMINES		
	IV (mg/kg)	PO (mg/kg)
Diphenhydramine (Benadryl)	1-1.25	1-1.5
Ranitidine (Zantac)	1.5	2-5
Famotidine (Pepcid)	0.5	0.5

ANTIEMETICS		
	IV (mg/kg)	PO (mg/kg)
Dexamethasone	0.0625-0.15 (max 10-15 mg)	
Metoclopramide (Reglan)	0.15	0.15
Ondansetron (Zofran)	0.05-0.1 up to a maximum total dose of 4 mg	0.1 up to 4 mg
Tropisetron (Navoban)	0.1-0.2	

ANTICHOLINERGICS		
	IV (mg/kg)	PO (mg/kg)
Atropine	0.02 (20 µg/kg)	0.02-0.03
Scopolamine	0.01 (10 µg/kg)	
Glycopyrrolate	0.01 (10 µg/kg)	

DIURETICS	
Chlorothiazide (Diuril)	10-15 mg/kg PO every 12 hours
Furosemide (Lasix)	1-2 mg/kg/dose PO/IM/IV
Spironolactone (Aldactone)	1 mg/kg PO every 8-12 hours
Mannitol	0.25-0.5 g/kg IV (slowly to avoid hypotension)

ANTIHYPERTENSIVES		
	Adrenergic receptor	Dose
Captopril (Capoten)		0.05-0.25 mg/kg every 6 hours PO or NG
Hydralazine		0.1-0.2 mg/kg IM/IV every 4-6 hours
Esmolol (Brevibloc)	β 1	100-500 µg/kg IV over 1-5 minutes; 50-100 µg/kg by infusion pump up to 300 µg/kg/min
Labetalol (Trandate)	α 1, β 1, and β 2	0.1-0.4 mg/kg IV every 5-10 minutes until desired effect
Atenolol (Tenormin)	β 1	1-2 mg/kg/day PO up to 3 mg/kg in single or divided doses until desired effect
Propranolol (Inderal)	β 1 and β 2	0.05-0.1 mg/kg/ dose IV every 10 minutes; titrate to effect; maximum single dose 10 mg; hypotension may occur in infants; (1-2 mg/kg PO every 6 hours)
Nitroprusside (Nipride)& Nitroglycerin (NitroQuick) (See above)		0.5-10 µg/kg/min by infusion pump; titrate to effect; may cause precipitous decrease in blood pressure; arterial line recommended

LOCAL ANESTHETICS (VOLUME ADJUSTED FOR NERVE BLOCKS)		
Conversion from percent to mg/mL: concentration (percent) × 10 = mg/mL		
Maximum doses	Plain mg/kg	With epinephrine (1 : 200,000) mg/kg
Lidocaine	5	7
Bupivacaine	2.5	3
Levobupivacaine	2.5	3
Ropivacaine	2.5	3

MIDAZOLAM DOSING ACCORDING TO ROUTE OF ADMINISTRATION (APPROXIMATE EQUIVALENCE)			
MIDAZOLAM			
Route	mg/kg	Onset (minutes)	Peak effect (minutes)
Intravenous	0.05-0.15	immediate	3-5
Intramuscular	0.1-0.2	3-5	10-20
Orogastric	0.25-0.75	5-15	10-30
Nasal	0.1-0.2	3-5	10-15
Rectal	0.75-1	5-10	10-30

KETAMINE DOSING ACCORDING TO ROUTE OF ADMINISTRATION	
Route	mg/kg
Intravenous	1-2
Intramuscular	2-10
Oral	3-6
Nasal	2-4
Rectal	5-10

FLUID AND BLOOD
Maintenance Fluids (balanced salt solution)
For neonates and infants <6 months: 4 mL/kg/hour first 10 kg, 2 mL/kg/hour 10-20 kg, 1 mL/hour for each kg above 20
Perioperatively for infants and children >6 months: 10-40 mL/kg over 1-4 hours

BLOOD PRODUCTS	
MABL = $\frac{EBV}{Child's\ hematocrit}$ (child's hematocrit – minimum accepted hematocrit) e.g., 10-kg child with a hematocrit of 42% who could be hemodiluted to a hematocrit of ~25% (assuming EBV = ~ 70 mL/kg)	MABL = $\frac{700}{42} \frac{(42 - 25)}{42} = \frac{700}{42} \frac{17}{42} = 285\text{ mL}$

EBV, Estimated blood volume; MABL, maximal allowable blood loss.

PRBC TRANSFUSION	
Volume of PRBCs = $\frac{(\text{desired Hct} - \text{present Hct})}{\text{Hematocrit of PRBCs}} \times \text{estimated blood volume (70 mL/kg 10 kg)}$ $= \frac{(35 - 23)}{60} \frac{(70)}{10}$ = 140 mL PRBCs	Volume of PRBCs to be transfused = $\frac{(35 - 23)}{60} \frac{(70)}{10} = \frac{12}{60} \frac{700}{60}$ = ~140 mL PRBCs e.g., a 10-kg child with a hematocrit of 23 who you wish to transfuse to a hematocrit of 35

Summary

IN THIS CHAPTER WE outline the basis of our collective practice of pediatric anesthesia. These basic principles of practice can be applied regardless of the circumstances; they provide the foundation for safe anesthesia.

## Preoperative Evaluation and Management

## PARENTS AND CHILD

Anesthesiologists must assume an active role in the preoperative assessment of children. Ideally, the anesthesiologist performing the preoperative evaluation will also anesthetize the child. A complete medical and surgical history; family history; medical record review; evaluation and review of laboratory, radiologic, and other investigations; and physical examination are performed on every child who is to be anesthetized (see Chapter 4). When appropriate, the child should receive preoperative medical therapy to optimize his or her medical condition or conditions (e.g., children with seizure disorders or reactive airway disease) before receiving anesthesia. In addition, the emotional state of the child and family must be considered and appropriate psychological and, if necessary, pharmacologic support provided. The anesthesia team, working in concert with surgical colleagues, nursing, and child-life specialists, should find appropriate and creative techniques (e.g., use of videotapes, booklets, hospital tours, and trained paramedical personnel) to prepare the child and family. The marked increase in the number of outpatient surgical procedures has reduced the time available for interaction among the anesthesiologist, the family, and the child. Despite this reduced contact time, these support techniques should not be neglected.

Familiarity with a child's clinical and psychological status as well as the parental concerns is essential to delivering quality anesthesia care. To achieve the very best outcome for each child, it is essential to meet with the child and the parents (or caregiver or legal guardian) together and establish rapport preoperatively. There are many developmental issues that surround the hospital experience: for example, teenagers fear loss of control, awareness, and pain; younger children fear mutilation from their surgery; and toddlers fear separation from their parents (see Chapter 3). However, for children who are old enough to understand (usually age 5 years and older), it is reasonable to explain in simple terms what anesthesia involves and what will transpire on entering the operating room. It is vital to speak directly to the child because he or she is the person having the surgery. Children at the age of reason have the same fears as adults, but have greater difficulty articulating them. It is important to explain the differences between "sleep" from anesthesia medicine and the sleep they get at home. Even if they undergo anesthesia for hours, they will feel as if they were unconscious for only the time it takes to blink the eyelids once. Many children are also fearful of awakening during the surgery and others are fearful of not awakening at the end of surgery. Children require reassurance that *they will not feel anything during surgery, that they will not wake up during the procedure, and that they will awaken at the conclusion of the surgery.*

The possibility of postoperative pain and the relief the child will receive in the form of nerve blocks and analgesics must be clearly presented to the child and the parents. It is also important to explain to the child and the family what they can anticipate on entering the operating room and to explain the special monitoring you, as the anesthesiologist, will provide for the child. A

simple explanation of the monitors can be very reassuring to parents and interesting for many children. For example, the pulse oximeter can be described as a “*Band-Aid-like device*” that lights up red and measures the oxygen in the bloodstream during anesthesia and recovery; the blood pressure cuff can be characterized as an “*arm hugger*” or “*muscle tester*”; and the electrocardiogram leads can be called “*little sticky things that don’t hurt so we can watch the heart beat*.” Simple descriptions of the measurements may also be soothing. For example, you can say: “*We measure the oxygen you (your child) are (is) breathing, we measure the amount of the anesthesia medicines you (your child) are (is) breathing, and we measure the carbon dioxide you (your child) are (is) breathing so as to ensure that your (your child’s) breathing is just right throughout the anesthesia.*” Sometimes asking teenagers if they have studied carbon dioxide in school science class helps them to better understand the monitors and provides reassurance, as well as making it more interesting. The detail with which this is presented will vary from family to family and child to child as well as with the anesthesiologist’s understanding of the needs of the child and family. By the end of the interview, however, the child and the parents should understand that you will be providing the quality of care that ensures the child’s safety during anesthesia, thus reducing the child’s and parents’ anxiety. Explanation is also needed to describe how anesthesia will be induced, although the degree of detail used will again depend on the developmental level of the child. For young children, one can describe a plan to breathe “laughing gas” through a flavored mask, with a flavor that he or she chooses. Older children can be given the option of an intravenous (IV) induction, with nitrous oxide by mask to establish IV access painlessly; or if they are afraid of needles, they might be given the option of an inhalational induction.

If parents are to be present during induction, it is essential to describe to them how they can assist in comforting the child and prepare them for what they might observe and experience to avoid any misconceptions. Parents should not be pressured into feeling that they must be present for induction. It must be clear that, if at any time during the induction there is a new or additional risk to the child, they may be asked to leave the operating room and will be escorted to the parent waiting room. Remind them that their presence at induction is for their child’s benefit and is a privilege, not a right. Thus, if there are issues with a difficult airway, if a rapid induction of anesthesia is needed, or if the child is very young, it would be inappropriate for the parents to be present and not in the child’s best interest for physicians and nurses to be distracted at a time when everyone’s attention needs to be focused on the child.

It is helpful and essential to explain to the parents specific changes in the child that might be observed at the time of anesthetic induction:

1. As your child is anesthetized, the eyes may roll up: “*You might see your child’s eyes roll up and this is completely normal and happens to all of us when we fall asleep; it is just that we are not looking for it.*”
2. “*As people fall asleep they often make snoring noises and other noises from their throat; if your child does this it is completely normal.*”
3. “*As the anesthetic reaches the brain, the brain sometimes gets excited and causes movement of the arms and legs that are without purpose, or it may cause them to turn their head from side to side. This means the anesthetic is having its effect and even though your child appears to be partly awake, he (or she) has received enough anesthesia to ensure that he (or she) does not remember this.*”
4. “*If your child becomes frightened, we will increase the amount of the anesthesia medicine rapidly and calm your child as quickly as possible.*”
5. If the child is to have an IV induction, then informing the parents that the child might suddenly look pale and that the start of anesthesia will be very rapid is also helpful so as to avoid confusion about what the parents will observe.

These preemptive explanations are important to undermine the parents’ anxiety at a time when you need to focus on the child. It is common for parents to decline to be present during induction once they hear these explanations. Finally, it is prudent to reassure the parents that for surgeries that are emetogenic and in children who have been or are prone to emesis, that appropriate prophylactic therapy will be administered before the child recovers. Similarly, explain to them that if pain is anticipated, it will be managed aggressively in the operating room and in the recovery room. Anesthesiologists can provide valuable assistance in this respect because of their knowledge of the pharmacology of sedative and opioid medications (see Chapter 6), as well as their ability to perform neuraxial and peripheral nerve blocks (see Chapters 41 to 43). The possible need for postoperative intensive care, including assisted ventilation, should be anticipated and fully discussed with the parents and child (if the child is of an appropriate age). If special monitoring is required in the operating room or postoperatively, this should be explained and the child assured that the IV catheters, airway devices, and all invasive monitoring devices will be placed after induction of anesthesia to avoid causing discomfort and will be removed as soon as the child’s postoperative condition permits.

The anesthesiologist who sits down, who speaks slowly and clearly while answering questions, and who is neither distracted nor in a rush to leave, presents a very different image to the child and parents from the anesthesiologist who stands tapping his or her toes, speaks quickly, and has one foot pointed toward the door. Details regarding the anesthetic should not be recited in a cold and technical manner, but rather with communication that addresses the parents’ and the child’s questions and concerns. This dialogue is frequently afforded too little time, leaving the parents and child insecure and apprehensive, their questions unanswered. Body language is especially important during this preoperative interview. If the family speaks a different language than the anesthesiologist, then a medical interpreter should be sought.

## THE ANESTHESIOLOGIST

Anesthesiologists must fully understand the proposed surgical or investigative procedure to facilitate the planning of an appropriate level of monitoring and selection of anesthetic drugs and technique. The anesthesiologist must anticipate the needs of the surgeon or proceduralist in terms of positioning the child, the need for or avoidance of muscle relaxants, considerations regarding specific procedures (e.g., the surgeon’s need for motor and sensory evoked potentials may influence choices of anesthetic technique), IV fluid and blood product management (see Chapters 8 and 10), as well as the need for strategies to alleviate perioperative pain and anxiety. For complex cases, the anesthesiologist and surgeon should formulate a plan preoperatively and explain the plan to the parents and child. All important medical issues that require clarification should be investigated during the preoperative evaluation and planning process. It is useful to discuss your concerns with the appropriate medical consultants (e.g., the neurologist for the management of seizure medications

in the perioperative period, the hematologist for the child with hemophilia, and others as indicated). To maximize the benefit from these consultations, it is important to focus on the specific anesthetic or medical issue of concern. Consultant recommendations must be carefully reviewed and should reflect the consultant's understanding of the anesthesia process and what it is that you require regarding the child's medical condition that will assist you in the delivery of anesthesia (see Chapters 11, 14, 22, 25, 26, and 28).

All children should be fasted preoperatively. Infants must receive special consideration; prolonged abstinence may lead to dehydration or hypoglycemia (see Chapters 4 and 8). Children may surreptitiously circumvent the preoperative fasting orders, especially if the period of fasting is prolonged or other children in the vicinity are in possession of food. One must always be prepared for the possibility of a full stomach and its sequelae. For example, the risk of pulmonary aspiration of gastric contents is increased in some children (e.g., who are obese and who had previous esophageal surgery, difficult intubation, or hiatal hernia). In these children, the anesthetic management should be modified to minimize the risk of regurgitation and aspiration. Preoperative consideration must be given to proper psychological support, appropriate premedication, and the timing of the premedication (see Chapters 3 and 4). Psychological support of the child and parents must never be neglected, no matter how calm they might appear. Premedication may be administered on the ward or in the waiting area; however, once any medication is administered, the child must be observed for compromise in cardiopulmonary function. If the child is premedicated on the ward, transport to the operating room must be undertaken with caution and with appropriate monitoring. A critically ill child must be accompanied by skilled staff who will ensure continued infusion of vasoactive medications and who are skilled in the management of any emergencies that could arise during transport (see Chapter 38). In some, premedication may be omitted because of the critical nature of a child's illness or because a child is especially cooperative.

## Informed Consent

The benefits and risks of the anesthetic procedure must be presented in clear, easily understood terms. At the same time, it is important not to present this in a manner that unduly frightens the child or parents. The details of such a presentation will depend, in part, on the severity of the underlying medical and surgical conditions and how these affect anesthetic management and the planned procedure. Thus, risk can be presented in general terms, such as:

- *"The risks of anesthesia are generally proportional to the health of the child. For example, if a child has a heart, lung, or kidney disorder, etc., then the risk from anesthesia is increased. In your child's case these are our concerns"* (and then elaborate the particular patient's issues, such as reactive airway disease, apnea of prematurity, etc.). *"Knowing these problems ahead of time may reduce the anesthetic risk for your child because we can modify our anesthetic prescription according to your child's specific needs. However, there is always the possibility of allergic or unusual responses to anesthetic medications that we cannot predict, and that is why I shall carefully observe and monitor your child as I have described."*

We are designing the "anesthetic prescription" specifically for the particular needs of their child, and this notion should be described exactly this way to the parents. We are physicians and

not technicians, and just as the pediatrician writes a prescription for antibiotics, anesthesiologists write the treatment prescription for anesthesia and administer it.

If a child is critically ill or has a disease process that is an immediate threat to his or her life, then this must be explained to the family. If a parent asks about the mortality risk, then all one can say is that the mortality related to anesthesia in most advanced countries is very small, less risky than crossing a busy thoroughfare on foot. Statistically, the incidence varies from one in several hundred thousand for healthy children undergoing routine procedures to a much greater rate for those who are critically ill. Nonetheless, the mortality for any specific child cannot be predicted with certainty. Recent concerns regarding possible anesthetic agent-induced neurotoxicity (see Chapter 23) has become a common question from parents of neonates or toddlers. Again, reassurance regarding the lack of substantive human data, the importance of our monitors, and our experience will help allay their concerns.

## Operating Room and Monitoring

For the anesthesiologist to successfully carry out a proposed anesthetic plan, the child's medical record must be examined for pertinent information before induction of anesthesia. For children who have already been assessed preoperatively, the record should be reviewed again for new information that may have been added since the initial evaluation. It is most important that the child's identification bracelet is checked, especially if the anesthetizing team is different from the preoperative evaluation team. A "time-out" and checklist for nurses, surgeon, and anesthesiologist to confirm the child's name, the planned surgical procedure, and the site of the surgical procedure (right or left side or bilateral); airway concerns; the need for prophylactic antibiotics; allergies and anaphylaxis; and availability of special equipment and large IV access are also reviewed. This review constitutes a vital safety net that we provide in the operating room (Fig. 1-1). All equipment for induction and maintenance of anesthesia, including suction and all necessary monitoring devices, must be functioning and reliable (see Chapter 51). *Equipment must be checked by the anesthesia team before induction of anesthesia.*

The monitoring should be appropriate for the child's clinical condition and surgical procedure. In every situation, basic monitoring is essential; to this are added special monitoring devices as they become necessary. The basic monitors are the anesthesiologist's eyes, ears, and hands, which confer the ability to observe a child's color and chest movements, to listen for heart tones and breath sounds, and to palpate the arterial pulse and temperature of the skin. A precordial or esophageal stethoscope is a very useful and simple device that allows constant assessment of heart tones and the quality of breath sounds even when our attention is focused away from physiologic monitors. All children, except those undergoing the briefest noninvasive procedures, should have IV access to allow for fluid administration and to provide a route for rapid and predictable drug administration. If IV access is already in place, it is essential to ensure its functionality and size before anesthesia is induced. Fluid replacement with balanced salt solution is particularly important in children who have undergone prolonged fasting or who have ongoing third-space losses, although glucose-containing solutions may be preferable under specific circumstances (see Chapter 8). Continuous monitoring of the electrocardiogram,

Surgical Safety Checklist

**FIGURE 1-1** WHO Surgical Safety Checklist. (From World Health Organization, Geneva, 2009. Available from: <http://www.who.int/patientsafety/safesurgery/en/>)

temperature, inspired oxygen concentration, oxygen saturation, expired carbon dioxide, and intermittent blood pressure determination are considered routine. Expired carbon dioxide monitors (especially those that display the waveform) and pulse oximetry are extremely important in the early detection of potential anesthetic-related events that, if undetected, could result in serious morbidity or mortality. Identifying the anesthetic agent and monitoring its concentration breath by breath is also helpful but not mandatory. The role of wakefulness-monitoring devices in children remains unestablished, especially in children who are younger than 2 years of age (see Chapters 6 and 51). Near infrared spectroscopy is being used increasingly during cardiac surgery; it provides a useful monitor of cerebral (i.e., organ) oxygenation.

Invasive hemodynamic monitoring (e.g., direct arterial blood pressure, central venous pressure) may be required for major surgery if extensive blood loss or major fluid shifts are anticipated, or if a child is medically unstable. Urine output provides indirect data of the intravascular volume and organ perfusion in the presence of normal renal function. Monitoring urinary output is particularly useful for prolonged operations, for procedures involving major blood loss, when there is the potential for rapid or massive blood loss, when wide variations in blood pressure and fluid balance can be anticipated, or during induced hypotensive anesthesia. *In general, if a particular variable would be monitored in an adult, then the same approach should be adopted for a child.*

Invasive monitoring procedures are sometimes forsaken in a child because inexperience with pediatric techniques causes the anesthesiologist to dismiss these procedures as being “excessive.” These monitors, however, allow the accurate measurement of blood pressure, cardiac output, filling pressures, and cardiac and pulmonary function. In turn, they provide a safe mechanism for assessing the response to pharmacologic interventions, as well as the responses to administration of blood products, fluids, and vasoactive medications (see Chapter 48).

*A cautionary note:* With increased sophistication in monitoring, anesthesiologists have become more distanced than ever from their patients. Relying totally on mechanical monitoring devices to detect clinical abnormalities is dangerous. *The focus must always be on the child and the surgical field. Monitors may fail, and if the anesthesiologist focuses attention on the monitor in an effort to interpret it, rather than attending directly to the child, the child may suffer.* This is the reason that a precordial stethoscope is so useful; strong heart sounds in the face of failed monitors provides some degree of assurance that the child is not in severe trouble. *Disabling monitor alarms for an extended period of time is a serious breach of safety and practice standards.* One of the editors knows of a child for whom all monitor alarms and sounds were disabled during anesthesia, who was discovered dead at the conclusion of the procedure after an unrecognized, unintended tracheal extubation. Most importantly, the tone of the pulse oximeter should be audible by everyone in the operating room to detect decreasing oxygen saturation.

## Induction and Maintenance of Anesthesia

Significant differences in the physiology and behavior of a child, especially a neonate, in comparison with an adult, mandate that the anesthesiologist not consider a child merely a small adult. In an infant, the rate of uptake of inhalation anesthetic agents is more rapid than in an adult. An infant's response to most oral and IV medications is also different; therefore, if changes need to be made, the inspired concentration of an inhalation agent should be adjusted more gradually and the doses of medication diluted and titrated more carefully than in older children and adults (see Chapter 6).

In principle, the approach to an anesthetic procedure in a child is similar to that in an adult. In practice, however, it is often advisable to modify the sequence of application of monitoring devices. In a relatively stable child, induction of anesthesia may proceed with only a pulse oximeter and possibly a precordial stethoscope, while the remaining monitors are applied after induction. This sequence often avoids a prolonged preparation phase during which a child may have more time to become anxious and distressed. In critically ill children, however, omitting some monitors in order to avoid upsetting them is imprudent, especially if it compromises the child's well-being during anesthesia. In a struggling, upset child, some monitors may display accurate measurements before induction of anesthesia, whereas others do not. The pulse oximeter may not provide reliable measurements in a struggling child until the finger or toe is relaxed.

## Clinical Monitors

In children as in adults, monitoring begins with the basic observations of a child's general condition: the heart rate, blood pressure, respirations, and temperature. The most important aspect of basic monitoring consists of using the senses of sight, hearing, and touch to integrate all the data provided by patient observations and the monitors.

### SIGHT

Constantly observing a child's chest excursions (depth and symmetry), the color of the nail beds, oral mucosa, and capillary refill provides vital information about the adequacy of ventilation and perfusion. Observation of the surgical field provides an immediate indication of the extent of fluid shifts and blood loss, the color of the blood in the surgical field, evidence of muscle relaxation, depth of anesthesia, and various physiologic problems that may occur during the surgery (e.g., surgical retraction causing venous obstruction).

### HEARING

Constantly listening to the pitch of the pulse oximeter as well as the heart tones and breath sounds through a precordial or esophageal stethoscope provides instant and continuous feedback about oxygenation (pulse oximeter), heart rate and rhythm, an impression of the cardiac output (changes in intensity of heart sounds), and the adequacy of ventilation (wheezing, stridor, laryngeal spasm, no air exchange). This information is particularly helpful in diagnosing arrhythmias, hypovolemia, anesthetic overdose, and airway obstruction. It may also be helpful to listen to the sounds of surgery, such as the sudden change in the noise of the suction device with rapid blood loss or the surgeon's comments regarding technical difficulties with the procedure.

### TOUCH

Intermittently examining a child—especially palpating peripheral pulses and the skin—provides information that may confirm the auditory input about heart rate, cardiac output, blood pressure, perfusion, and temperature.

## Airway and Ventilation

The most important consideration in the safe practice of pediatric anesthesia is attention to the adequacy of the airway. Airway obstruction occurs readily because of the unique characteristics of the infant and child airway (see Chapter 12). Thus the anesthesiologist must maintain constant vigilance of the airway to ensure that it remains clear at all times. Airway obstruction may lead to hypoventilation, although the causes of hypoventilation may be central (opioids or inhalation agents) or peripheral (muscle relaxants) in origin. Thus anesthesiologists must always place emphasis and attention on constantly monitoring the adequacy of ventilation, particularly when administering anesthesia via a facemask. This is necessary because the expired carbon dioxide tension may underestimate the true carbon dioxide tension as a result of a poor mask fit with air leaks, in combination with an obstructed airway. The capnogram is usually very accurate during mask anesthesia with a circle breathing circuit. Failure to detect an appropriate end-tidal carbon dioxide tension suggests inadequate ventilation, a mask leak, or reduced pulmonary blood flow, with the result that the child's condition may deteriorate from lack of an adequate airway or dilution of the anesthetic gas concentrations.

Although it is desirable to optimize ventilation by maintaining an arterial carbon dioxide pressure within the normal range (35 to 45 mm Hg), most healthy infants and children are not harmed by mild to moderate overventilation; however, severe underventilation has more serious implications.

Constantly monitoring the inspired concentration of oxygen, the expired concentration of carbon dioxide, and the oxygen saturation is a valuable adjunct to the senses of sight, hearing, and touch. *Failure to ventilate adequately is probably the most important factor in the morbidity and mortality of children undergoing anesthesia.*

## Fluids and Perfusion

Appropriate intraoperative fluid management is especially important in infants and children. Because of the relatively small blood volumes of infants and children, hypovolemia may develop rapidly after what may appear to be a trivial amount of blood loss. Fluid shifts may occur in infants because they were fasted for a prolonged period preoperatively. Replacement of lost blood and basic fluid administration must be carefully titrated (using rate-limiting devices), because overhydration readily occurs. The anesthesiologist should have a clear plan for the type and volume of fluid for perioperative administration. Preoperative calculation of maintenance, deficit, and potential third-space losses helps in formulating this fluid management plan, although for children beyond 1 year of age, the fluid replacement strategy has been greatly simplified. A well-planned outline results in a rational and safe approach both to fluid maintenance and to correction of fluid deficit and losses (see Chapters 8 and 10). The anesthesiologist should have immediate access to indwelling IV cannulae; obstructions in the line, loose connections, disconnections, or interstitial cannulae result in children not receiving intended fluid therapy or medications, sometimes with disastrous consequences.

## Conduct of the Anesthesia Team

The anesthesiologist must concentrate exclusively on the child and the monitors throughout the procedure. The child's safety is in his or her hands, and any inattention may place the child's life in jeopardy. Should members of the anesthesia team need to replace each other during the anesthetic procedure, it is essential that the "baton of responsibility" be passed in a smooth and coordinated manner. A clear dialogue between team members must be established about the nature of the surgery, the child's underlying conditions, anesthetic agents and other medications, fluid and blood product management, and any problems that have developed during the anesthetic procedure. Drugs on the anesthesia machine must be clearly labeled by name and dosage. For infants, dilution of drugs or the use of tuberculin syringes may improve the safety of drug administration by limiting the amount of drug in each syringe and allowing more accurate dose administration, although a disproportionate amount of the small volumes of a drug—as in the case of undiluted drugs administered from a tuberculin syringe—may be trapped in the dead space of claves and/or stopcocks, resulting in an underdosing of the drug.

Ongoing communication between the anesthesiologist and surgeon is important if the anesthesiologist is to anticipate potential changes in a child's physiologic status due to surgical manipulations, and deal with them immediately, appropriately, and effectively.

The conclusion of an anesthetic procedure is fraught with potential problems. The anesthesiologist should not be left alone in the operating room without a nurse or other physician, nor should he or she relax vigilance while a child is awakening and being transferred to the recovery room or intensive care unit. It is during this stage that airway obstruction, desaturation, vomiting and aspiration, and excitement are likely to occur.

Records of an anesthetic procedure must be accurate and complete; however, anesthesiologists must avoid the compulsion to complete these during the procedure if a child's condition warrants special attention.

## The Postanesthesia Care Unit

The anesthesiologist's responsibility to a child continues into the postanesthesia care unit (PACU). Transport to the PACU must be carried out with appropriate monitoring, attention to a clear airway, and adequate ventilation, oxygenation, and perfusion. If necessary, battery-powered infusion pumps should be used to maintain accurate infusions of vasoactive drugs. If needed, oxygen should be administered by facemask. Alternately, oxygen saturation may be monitored during transport; administering oxygen and monitoring pulse oximetry may give misleading information regarding the adequacy of ventilation. Oxygen should be available during transport. For children who are not yet fully awake, transport in the "tonsil position" or "recovery position" (lateral decubitus position) rather than the common

practice of transport in the supine position is recommended so that, should vomiting occur, it will flow away from the larynx and will be seen immediately. In general, oxygen should be administered to children who have not yet awakened. The mask should be observed for condensation with each breath to assess the respiratory rate as well as gas movement with respiration.

On arrival in the PACU, a clear summary of the medical and surgical problems of the child; important intraoperative events; timing of antibiotics, analgesics, local anesthetics, or nerve blocks; and details of the anesthetic procedure are given to the PACU personnel. The PACU must be equipped with age- and size-appropriate resuscitation equipment. Vital signs (oxygen saturation, heart rate, blood pressure, respirations, temperature, and pain score) should be recorded on admission to the PACU and at appropriate intervals during the child's stay (see Chapter 46). If appropriate, specific instructions should be given relating to fluid management; the administration of oxygen, analgesics, antiemetics, and other medications; blood tests (e.g., hematocrit, blood gases, electrolytes, and coagulation profile); and radiographs. Once the anesthesiologist is certain that the child is stable from a cardiopulmonary standpoint and that all vital information has been provided to the PACU staff, the anesthesiologist should inform the parents that the child has arrived safely in the PACU, provide them with a summary of the anesthetic procedure, and then proceed to the next case. If the child requires special attention (airway issues, hypotension, possible ongoing blood loss, etc.) in the PACU, then the anesthesiologist should reassess the child personally before the child is discharged.

## Postoperative Visit

If the child has been admitted to the hospital for more than an overnight observation, it is good practice to visit the child and family postoperatively to assess the postanesthetic clinical course and discuss the child's reaction to the anesthetic. A note documenting the visit should also be inserted into the child's record. All too often the anesthesiologist appears only preoperatively and is never seen again by the family, especially if there was a poor outcome. If the public is to understand and respect the profession of anesthesiology as a vital medical specialty, close interaction and trust among parents, child, and anesthesiologist are essential. A follow-up telephone call from the nursing staff is also useful in identifying and managing anesthesia-related postoperative issues.

## Summary

This introductory chapter has outlined the fundamentals of safe pediatric anesthesia practice. The chapters that follow elaborate on these principles; our collective experience has been used to guide practicing anesthesiologists. We reiterate specific points throughout to emphasize their importance and to present several different perspectives on those issues.

Neurologic Development

Developmental Issues

AS AN INFANT GROWS and matures, vital changes occur that affect the child's response to disease, drugs, and the environment. Growth is an increase in physical size, and development is an increase in complexity and function. An overview of the subject is presented so that anesthesiologists can appreciate the uniqueness of developing children from both physical and psychological perspectives.

The physician should understand the main developmental changes that occur over time, as well as how these changes affect both responses to diseases and to drug pharmacokinetics and pharmacodynamics.

## Normal and Abnormal Growth and Maturation

Growth is the quantitative development of the body and maturation is the acquisition of new functionalities; both phenomena occur during pregnancy and after birth. Prenatal growth is the most important phase in development, comprising organogenesis in the first 8 weeks (embryonic growth), followed by the functional development of organ systems and maturation of the fetus to full term (fetal growth). Rapid growth occurs particularly in the second trimester; a major increase in weight from subcutaneous tissue and muscle mass occurs in the third trimester. Environmental agents may affect the human embryo in a negative way. The duration of gestation and the weight of an infant have an important relationship (Table 2-1).

The term *prematurity* has conventionally been applied to infants weighing less than 2500 g at birth, but the designation *preterm infant* is more appropriate and is defined as one born before 37 completed weeks of gestation. A *term or full-term infant* is one born between 37 and 42 completed weeks of gestation. A *postterm infant* is one born after 42 completed weeks of gestation.

Preterm infants are further classified according to their actual birth weight. A low-birth-weight (LBW) infant is one weighing less than 2500 g regardless of the duration of the pregnancy. A very low-birth-weight (VLBW) infant weighs less than 1500 g, and an extremely low-birth-weight infant weighs less than 1000 g. In addition, infants weighing less than 750 g are now being called "*micropremies*"; there is very little published information regarding the anesthetic management of this vulnerable subpopulation of neonates (see Chapter 35). Common neonatal problems as they relate to age and birth weight are presented in Table 2-2.

After birth, physical growth continues at a rapid pace during the first 6 months of extrauterine life but slows by about 2 years of age. Physical growth accelerates a second time during the pubertal period. A simple way to remember how rapidly the infant grows is that birth weight doubles by 6 months of age and triples by 1 year. Length doubles by 4 years of age. This scale, however, does not affect all organs or functions in the same way. It is important to be able to assess correctly and precisely the stage of development of the child, because any abnormal slowdown requires investigation to find the cause.

**TABLE 2-1** The Relationship of Gestational Age to Weight

Gestation (weeks)	Mean Weight (grams)
28	1165 ± 109
32	1760 ± 128
36	2621 ± 274
40 (full term)	3351 ± 448

Data from Naeye RL, Dixon JB. Distortions in fetal growth. *Pediatr Res* 1978;12: 987-91.

### GESTATIONAL AGE ASSESSMENT

The gestational age of an infant may be assessed in one of three ways. The most accurate means of assessing gestational age is by measuring the crown-rump length of the fetus during a first-trimester ultrasonographic examination. Another method involves calculating gestational age from the first day of the mother's last menstrual period, but this is commonly inaccurate, leading to errors in estimation. Finally, the Dubowitz scoring system is a well-accepted method combining neurologic and physical criteria of the infant to provide an accurate assessment of gestational age.<sup>1,2</sup> A summary of the more significant neurologic and physical signs of maturity is presented in Table 2-3.

### WEIGHT AND LENGTH

Assessment of growth is measured by changes in weight, length, and head circumference. Percentile charts are valuable for monitoring the child's growth and development. Deviation from growth within the same percentile for a child of any age is of greater significance than any single measurement (Figs. 2-1 and 2-2). Weight is a more sensitive index of well-being, illness, or poor nutrition than length or head circumference and is the most commonly used measurement of growth. Change in weight reflects changes in muscle mass, adipose tissue, skeleton, and body water and thus is a nonspecific measure of growth. Measurement of length provides the best indicator of skeletal growth because it is not affected by changes in adipose tissue or water content.

Term infants may lose 5% to 10% of their body weight during the first 24 to 72 hours of life from loss of body water. Birth weight is usually regained in 7 to 10 days. A daily increase of 30 g (210 g/week) is satisfactory for the first 3 months. Thereafter, weight gain slows so that at 10 to 12 months of age it is 70 g each week (Table 2-4).

*When plotting the weight of a preterm infant on a growth chart, it is common to use the infant's corrected gestational age (postmenstrual age; postconceptual age is taken from conception and is approximately 2 weeks shorter) instead of his or her chronologic age (postnatal age, i.e., from birth) during the first 2 years of the infant's life in order to correct for prematurity.*

Weight and length are important but changes affect the composition of the body itself, especially total body water, which decreases at the expense of the extracellular compartment, with adult levels attained at 1 year of age.<sup>3,4</sup> This finding has implications for drug dosing and distribution in the infant. Males have a greater percentage of water, whereas females have a slightly greater percentage of fat. The percentage decrease in extracellular water is greater than the decrease in total body water because of the simultaneous increase in intracellular water (Table 2-5).<sup>5</sup>

Another, more precise way to assess development is to calculate the body surface area (BSA).<sup>6</sup>

**TABLE 2-2** Common Neonatal Problems with Respect to Weight and Gestation

Gestation	Relative Weight	Neonatal Problems at Increased Incidence

Age	Body Water (percent)	Extracellular	Intracellular
Fetus	90	60	25
Preterm	80	55	30
Full-term	70	50	35
6-12 months	60	30	40

**FIGURE 2-1** Postnatal growth curve (weight) for term male infants. This figure represents normal growth curves. *Triangles* indicate a normal child. *Circles* demonstrate failure to thrive in a child with severe renal failure.**FIGURE 2-2** Postnatal growth curve (weight) for preterm infants. This figure represents normal growth curves for preterm infants. *Triangles* indicate a normal preterm infant. *Circles* demonstrate failure to thrive in an infant with bronchopulmonary dysplasia.

$$BSA (m^2) = \sqrt{\text{Body length (cm)} \times \text{Body weight (kg)} / 3600}$$

BSA can also be described using an allometric equation with an exponent of  $\frac{2}{3}$  (see Chapter 6):

$$BSA \propto \text{weight}^{2/3}$$

## HEAD CIRCUMFERENCE

Head size reflects growth of the brain and correlates with intracranial volume and brain weight. Changing head circumference reflects head growth and is a part of the total body growth process; it may or may not indicate underlying involvement of

the brain. An abnormally large or small head may indicate abnormal brain development, which must alert the anesthesiologist to possible underlying neurologic problems. A large head may indicate a normal variation, familial feature, or pathologic condition (e.g., hydrocephalus or increased intracranial pressure), whereas a small head may indicate a normal variant, familial feature, or pathologic condition such as craniosynostosis or abnormal brain development.

During the first year of life, head circumference normally increases 10 cm, and it increases 2.5 cm in the second year. By 9 months of age, head circumference reaches 50% of adult size, and by 2 years it is 75%. Head circumference is closely followed on standard percentile growth curves. As with weight, deviations of growth of the head within the same percentile are more significant than a single measurement.

The anterior fontanel should be palpated to assess whether it is sunken (dehydration) or bulging abnormally (suggesting increased intracranial pressure as in hydrocephalus, infection, hemorrhage, or increased partial pressure of carbon dioxide in the arterial blood [ $\text{PaCO}_2$ ]). If it is bulging, the sutures should be palpated for abnormal separation as a result of increased intracranial pressure. The anterior fontanel closes between 9 and 18 months of age; the posterior fontanel closes by 2 to 4 months of age (Fig. 2-3). Cranial molding occurs particularly in LBW infants and is usually of no clinical importance.

## FACE

Although the cranial vault increases rapidly in size, the face and base of the skull develop at a slower rate. At birth, the mandible is small; but as a child develops, forward growth occurs, reducing the obliquity of the mandibular angle. Failure of prenatal development of the mandible may be associated with severe congenital defects (e.g., Pierre Robin, Treacher Collins, or Goldenhar syndromes). These syndromes often have other associated anomalies. After 2 years of age, the cranial vault increases only marginally in size, whereas the facial configuration undergoes substantive changes. The upper jaw grows rapidly to accommodate the developing teeth. In addition, the frontal sinuses develop by 2 to 6 years of age, and the maxillary, ethmoidal, and sphenoidal sinuses appear after 6 years of age.

## TEETH

The first tooth, usually a lower incisor, erupts at approximately 6 months after birth (deciduous dentition). Eruption of all deciduous teeth is usually complete by 28 months of age. Permanent teeth appear at 6 years, with the shedding of the deciduous teeth; this process takes place during the next 6 to 8 years. Abnormally developed teeth occur with hereditary disorders, Down syndrome, cerebral palsy, medications (eg., tetracycline) and nutritional defects. Preterm infants may show severe enamel hypoplasia in their primary dentition.<sup>7,8</sup>

**FIGURE 2-3** Cranial development. **A** and **B** depict the skull of a neonate with wide-open suture. **C** and **D** depict the skull of a 7-year-old boy with fused sutures.

## COMPORTMENT AND BEHAVIOR

The neurologic status and social acquisition of the child are part of the development assessment and will be described later in this chapter.

## Airway and Respiratory System

Airway development includes a large number of structures including cranial vault and base, craniovertebral development, face, branchial apparatus, larynx and oral cavity.

These structures are involved in the respiratory function (to provide enough oxygen and to remove carbon dioxide) but also to separate the circulation of air from the circulation of liquid and food. A variety of processes, including ventilation, perfusion, and diffusion, are involved in fulfilling these functions. Specifically, the anesthesiologist has to consider these developmental changes because of their implication in airway management and ventilation.

### UPPER AIRWAY DEVELOPMENT

During the course of development, the infant upper airways undergo deep anatomic modifications that include changes in size, shape, and interrelationship; this is particularly prominent during the first few years of life.

The face and the nasal chamber, the oropharynx with the tongue, and the laryngotracheal lumen are the three main parts of the upper airway involved. The development of the neurocranium will lead to the maturation of the cranial vault and skull

base, and the development of the viscerocranium to the skeletal part of the face. The primordial areas involved in forming the covering of the tongue appear early in the second month of development.

The larynx is developed embryologically from ectodermal, endodermal, and mesodermal tissues that are derived from the third, fourth, and sixth branchial arch and pouch apparatus. The development of the larynx and airway in the neonate is outlined in detail in Chapter 12. The laryngeal opening (epiglottis and vocal cords) in a neonate and 2-year-old boy are shown in Figure 2-4. Note the omega-shaped long epiglottis and the pearly white vocal cords in the neonate.

The skull base grows rapidly until age 6 years, with relatively slower growth thereafter. The cranial base flexes postnatally in a rapid growth trajectory that is complete by 2 years of age.

The depth of the nasopharynx increases due to remodeling of the palate as well as changes in the angulation of the skull base. During childhood, the soft tissues of the pharyngeal structures surrounding the upper airway grow proportionally to the skeletal structures. After birth, the dimensions of the nasal cavity increase very rapidly. During the first year of life, the total minimal cross-sectional area is increased by 67%, and the volume of the anterior 4 cm of the nasal airways by 36%.<sup>9</sup>

The volume of the oral cavity in the neonate is proportionally less than that in the adult, owing to a significantly shorter mandibular ramus. The volume of the oral cavity significantly increases during the first 12 months because of rapid growth in the height of the mandibular ramus.

**FIGURE 2-4** Larynx development from neonate to 2 years old. The larynx in the neonate (**A** and **B**), with the long epiglottis (**A**) and the vocal cords (**B**, close-up). The larynx in a 2-year-old (**C** and **D**), with a shorter epiglottis (**C**) and the vocal cords (**D**, close up).

Compared with the adult, the tongue in the neonate contains considerably less fat and soft tissue, but overall is large in size relative to the dimensions of the mouth, with relatively larger extrinsic musculature and a less developed superior longitudinal muscle resulting in a flat dorsal surface with poor lateral mobility (see also Chapter 12).

### RESPIRATORY SYSTEM DEVELOPMENT

The development of the respiratory system begins during week 4 of gestation. Three “laws” that describe the temporal development of the conducting airways, alveoli, and pulmonary vessels govern normal lung growth.

**Airways:** The bronchial tree down to and including the terminal bronchioles forms by week 16 of gestation. The acinus, consisting of all the airway structures distal to the terminal bronchiole and the entire gas-exchanging apparatus, develops throughout the remainder of gestation.

**Alveoli:** Alveoli develop mainly after birth, increasing in number until approximately 8 years of life and in size until growth of the chest wall ceases.

**Pulmonary vessels:** Arteries and veins accompanying the bronchial tree form by week 16 of gestation. Those vessels lying within the acinus follow the development of the alveoli. The appearance and growth of arterial smooth muscle lags behind the sprouting of new vessels and is not completed until late adolescence.

### TRANSITION TO AIR BREATHING

Fetal breathing movements have been detected as early as 11 weeks of gestational age; they are interspersed with long periods of apnea and produce little tidal movement of lung fluid.<sup>10,11</sup> The critical event in the change from placental to pulmonary gas exchange is the first inspiration, which initiates pulmonary ventilation, promotes the clearance of lung fluid, and triggers the change from the fetal to the neonatal pattern of circulation.

The first breath is a gasp that generates a transpulmonary distending pressure of 40 to 80 cm H<sub>2</sub>O.<sup>12</sup> This moves the tracheal fluid (100 times more viscous than air), overcomes surface forces that develop as the air–fluid interface reaches the small airways, and overcomes tissue resistance. In some children, the removal of lung fluid may be delayed, producing the syndrome called *transient tachypnea of the newborn*.<sup>13</sup> Tachypnea lasts for 24 to 72 hours and is associated with a characteristic chest radiographic appearance consisting of increased perihilar markings, fluid in the interlobar fissures, and streaky linear opacities in the parenchyma.

With the onset of pulmonary ventilation, pulmonary blood flow sharply increases. Decreased pulmonary vascular resistance (PVR) and increased peripheral systemic vascular resistance (loss of the umbilical circulation) are the two crucial events involved in the immediate transition from the fetal circulation to the normal postnatal pattern. The increase in systemic afterload causes an immediate closure of the flap valve mechanism of the foramen ovale and reverses the direction of shunt through the ductus arteriosus. Until these fetal shunt pathways close anatomically, the pattern of circulation is unstable. Increased pulmonary vascular reactivity in response to hypoxia and acidosis may precipitate a reversal to right-to-left shunting (“flip-flop” circulation).

In the first few minutes of life, a state of “normal” asphyxia exists as a result of impairment of placental blood flow during labor. The partial pressure of oxygen in arterial blood (PaO<sub>2</sub>) and pH are low, whereas the PaCO<sub>2</sub> is increased immediately after

birth, but these parameters change rapidly in the first hour of life. Extrapulmonary shunting through fetal channels and intrapulmonary shunting, probably through unexpanded regions of the lung, persist for some time after birth, so that in neonates the physiologic right-to-left shunt is about three times that in adults.<sup>14</sup>

### MECHANICS OF BREATHING

#### Chest Wall and Respiratory Muscles

The accessory muscles of inspiration are relatively ineffective in infants because of an unfavorable anatomic rib configuration. In infancy, the ribs extend horizontally from the vertebral column, moving little with inspiration.<sup>15</sup> These factors increase the workload on the diaphragm. Consequently, and in contrast to an adult, thoracic cross-sectional area is fairly constant throughout the breathing cycle, and inspiration occurs almost entirely as a result of diaphragmatic descent.

The chest wall of a neonate is floppy because it comprises noncalcified cartilage, its musculature is poorly developed, and the ribs are incompletely calcified.<sup>16,17</sup> As the work of breathing increases, diaphragmatic displacement must also increase to maintain the tidal volume. The increased workload may lead to diaphragmatic fatigue and respiratory failure or apnea, especially in preterm infants.<sup>18,19</sup>

The tendency to respiratory muscle fatigue is the result of the metabolic characteristics of the diaphragm, which has very little type I (slow twitch, high oxidative capacity) muscle fibers (see Fig. 12-11).

#### Elastic Properties of the Lung

Changes in the static pressure–volume relationship of the lungs during growth are caused by increases in volume and changes in the elastic properties of lung tissue. Volume is the principal factor that determines lung compliance, which increases throughout childhood. Specific lung compliance remains relatively constant throughout childhood.<sup>20</sup> In contrast, specific compliance of the chest wall declines throughout childhood and adolescence, reflecting the progressive calcification of the ribs and the increasing bulk of the thoracic muscles.

#### Static Lung Volumes

Detailed information expressing static lung volumes on the basis of body weight are detailed in Table 2-6.

#### Total Lung Capacity

Adults have a markedly greater total lung capacity (TLC) than infants (Fig. 2-5). This difference reflects the fact that TLC is an effort-dependent parameter, depending on the strength and efficiency of the inspiratory muscles, which can be estimated by the maximum inspiratory pressure at functional residual capacity (FRC). An adult can generate negative pressures in excess of 100 cm H<sub>2</sub>O; negative inspiratory pressures as high as 70 cm H<sub>2</sub>O have been recorded for neonates, a surprisingly high value in view of their underdeveloped musculature and highly compliant chest wall. This may be a consequence of the small radius of curvature of an infant’s rib cage, which by the Laplace relationship converts a small tension into a large pressure difference.<sup>21</sup>

#### Functional Residual Capacity

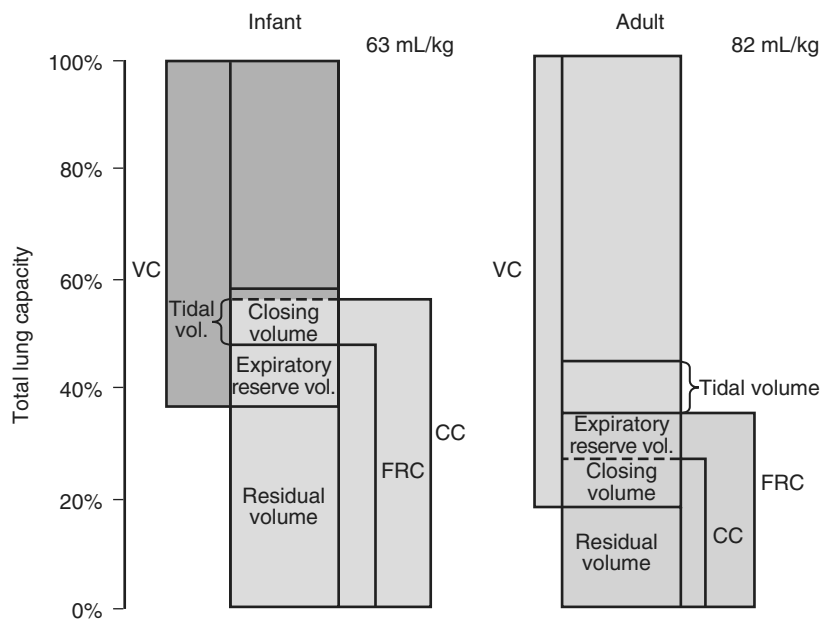

FRC is similar on a per-kilogram basis at all ages, but the mechanical factors on which it is based are different in infants and adults.<sup>22</sup> In adults, FRC is the same as the volume at which the elastic forces generated by the passive recoil of the chest wall are

**TABLE 2-6** Age-Dependent Respiratory Variables

	Newborn	6 months	12 months	3 years	5 years	12 years	Adult	Units

**FIGURE 2-5** Lung volumes in infants and adults. Note that, in infants, tidal volume breathing occurs at the same volume as closing volume. CC, Closing capacity; FRC, functional residual capacity; VC, vital capacity. (Modified from Nelson NM. Respiration and circulation after birth. In: Smith CA, Nelson NM editors. The physiology of the newborn infant. Springfield, Ill.: Charles C Thomas; 1976. p. 207.)

balanced by the recoil of the lung (Fig. 2-6); this is the volume attained at end-expiration with an open glottis.

An important clinical implication of the dynamic control of FRC is that an apneic infant has a disproportionately smaller reserve of intrapulmonary oxygen on which to draw than a similarly affected adult. This, combined with their increased metabolic rate, contributes to the rapid development of hypoxemia if the airway is lost in the anesthetized infant.

### Closing Capacity

As exhalation proceeds to completion, small airways in dependent regions of the lung close, leading to air trapping in the affected areas. Closing capacity is closely related to age, declining

throughout childhood and adolescence and increasing thereafter throughout adult life (see Fig. 2-5). This pattern of change has been related to the development and deterioration of lung elastic tissue and its effect on recoil pressure. The latter is the principal determinant of transmural pressure and therefore patency of the smallest airways, which lack intrinsic stability because they contain no cartilage.

Closing volume is within the range of tidal breathing in some adults older than 40 years and some children younger than 10 years (see Fig. 2-5). It is not possible to measure closing volume in children younger than 5 years, but because elastic recoil pressure decreases to very low levels in infancy (see Fig. 2-6); it is likely that some airways remain closed throughout tidal

**FIGURE 2-6** Compliance curves for the chest wall, lungs, and thorax (combination of chest wall and lungs) in infants and adults. (Modified and reproduced with permission from Pérez Fontán JJ, Haddad GG. Respiratory physiology. In: Behrman RE, Kliegman RM, Jenson HB, editors. Nelson textbook of pediatrics. 17th ed. Philadelphia: WB Saunders; 2003. p. 1363.)

breathing. This conclusion is supported by the finding that infants have a large “trapped gas volume” that is not in free communication with the conducting airways. Age-related changes in  $\text{PaO}_2$ , which parallel the changes in the difference between FRC and closing volume, may also be related to airway closure.<sup>21</sup>

## AIRWAY DYNAMICS

### Resistance and Conductance

Airway resistance declines markedly with growth from 19 to 28 cm  $\text{H}_2\text{O}/\text{L}/\text{sec}$  in neonates to less than 2 cm  $\text{H}_2\text{O}/\text{L}/\text{sec}$  in adults.<sup>22,23</sup> Airway resistance is greater in preterm than in full-term infants. On the other hand, specific airway conductance (reciprocal of resistance) is greater in preterm infants, and it continues to decline throughout the first 5 years of life.<sup>24,25</sup>

### Distribution of Resistance

The distribution of airway resistance changes markedly around the age of 5 years. Airway resistance per gram of lung tissue is constant at all ages in the “central airways” (trachea to the twelfth to fifteenth bronchial generation), whereas it decreases markedly around the age of 5 years in the “peripheral airways” (twelfth to fifteenth generation to the alveoli).

### Inspiratory and Expiratory Flow Limitation

Tracheal compliance in neonates is twice that of adults; it is even greater in preterm infants and appears to be a consequence of

cartilaginous immaturity. The functional importance of this finding is that dynamic collapse of the trachea may occur with inspiration and expiration (see Fig. 12-10).

## Regulation of Breathing

In neonates as in adults,  $\text{PaO}_2$ ,  $\text{PaCO}_2$ , and pH control pulmonary ventilation, with  $\text{PaO}_2$  acting mainly through peripheral chemoreceptors in the carotid and aortic bodies and  $\text{PaCO}_2$  and pH acting on central chemoreceptors in the medulla. Unlike an adult, an infant’s response to hypercapnia is not potentiated by hypoxia. In fact, hypoxia may depress the hypercapnic ventilatory response in term and preterm infants.<sup>26</sup>

High concentrations of oxygen depress the neonate’s respirations, whereas low concentrations stimulate it. The hypoxic response is not sustained. However, sustained hypoxia leads first to a return to baseline ventilation and then to ventilatory depression. This pattern of response persists in normal term infants for the first week of life, after which the response to sustained hypoxia is replaced by a sustained increase in ventilation.<sup>27</sup> This pattern persists longer in preterm infants.

Periodic breathing commonly occurs in neonates and should be distinguished from clinical apnea, which occurs in as many as 25% of all preterm infants but especially in the most premature. Apnea of prematurity may be a life-threatening condition. Ventilatory pauses are prolonged and are associated with desaturation of arterial oxygen, bradycardia, and loss of muscle tone.

Prematurity is an important risk factor for life-threatening apnea in infants undergoing general anesthesia.<sup>28</sup> The risk of postanesthetic respiratory depression is inversely related to gestational age and postconceptual age at the time of anesthesia.<sup>29</sup> It has been stated that infants may be at risk up to 60 weeks after conception.<sup>29-31</sup>

The reduced  $\text{PaO}_2$  of neonates is compensated by a greater oxygen-carrying capacity due to increased hemoglobin concentrations, which decline during the first several weeks of life. At birth, the hemoglobin content of the blood is made up of 50% fetal hemoglobin, which has an in vivo oxygen-dissociation curve that is shifted to the left in comparison with normal adult hemoglobin. The shift in position of the oxygen-dissociation curve depends on the ratio of adult to fetal hemoglobin. It shifts to the right during the course of the first week of life, reflecting a switch from fetal to adult hemoglobin formation.<sup>20</sup> Normal  $\text{PaCO}_2$  and pH are somewhat lower in the neonatal period than in later infancy (see Table 2-6).

## Cardiovascular System

An understanding of cardiovascular development is important for anesthesiologists. This section briefly considers developmental changes in heart rate, blood pressure, cardiac output, and the electrocardiogram; more detailed descriptions are found in Chapters 14 and 16.

### HEART RATE

Autonomic control of the heart in utero is mediated predominantly through the parasympathetic nervous system. It is only shortly after birth that sympathetic control appears. In neonates, the heart rate may have a wide variation that is within normal limits.

In older children, a significant number of arrhythmias and conduction abnormalities are also encountered, with marked fluctuations in heart rate due to variations in autonomic tone.

The mean heart rate in neonates in the first 24 hours of life is 120 beats per minute. It increases to a mean of 160 beats per minute at 1 month, after which it gradually decreases to 75 beats per minute at adolescence (Table 2-7).<sup>32</sup>

### BLOOD PRESSURE

Mean systolic blood pressure in neonates and infants increases from 65 mm Hg in the first 12 hours of life to 75 mm Hg at 4 days and 95 mm Hg at 6 weeks. There is little change in mean systolic pressure between 6 weeks and 1 year of age; between 1 year and 6 years, there is only a slight change, followed by a gradual increase.<sup>33,34</sup> These measurements apply to infants and children who are awake and quiet. The blood pressure in preterm infants in the first 12 hours is less than that in full-term infants; a gradual increase in blood pressure occurs after birth—68/43 mm Hg on day 1 of life compared with 90/55 mm Hg on day 90 of life (Table 2-8).<sup>35,36</sup> It has also been noted that infants with birth asphyxia and those who require mechanical ventilation have reduced blood pressures.<sup>37</sup> Blood pressure measured in the lower leg is less than in the upper arm.<sup>38</sup>

Blood pressure in adolescents and adults who were born preterm is greater than in those who were born full-term. However, the slower fetal growth in preterm, LBW infants was not identified as an independent predictor of this greater blood pressure later in life.<sup>39</sup>

**TABLE 2-7 The Relationship of Age to Heart Rate\***

Age	Mean Heart Rate in Beats per Minute (range)
Premature	120-170
0-3 months	100-150
3-6 months	90-120
6-12 months	80-120
1-3 years	70-110
3-6 years	65-110
6-12 years	60-95
>12 years	55-85

\*Note that the blood pressure will be lower during sleep or during anesthesia.

### CARDIAC OUTPUT

Determination of cardiac output and blood pressure allows calculation of systemic vascular resistance. It provides important information relating to the left ventricular afterload and allows rational application of vasoactive (e.g., vasoconstrictor, vasodilator) and inotropic drugs. Measurement of cardiac output may be carried out by the Fick method (using oxygen extraction) or thermodilution using a pulmonary artery flow-directed catheter. In neonates, the latter technique is rarely used because shunts at the atrial and ductal level introduce errors when interpreting the results.

Pulsed Doppler determinations of cardiac output provide reasonable noninvasive estimates of cardiac output for clinical application in neonates. Cardiac output, normalized for body weight, in neonates between 780 and 4740 g at birth, remains fairly constant, changing approximately 10% over the weight range.<sup>40</sup> The range of cardiac output in both full-term and preterm neonates is 220 to 350 mL/kg/min, two- to threefold greater than in adults.<sup>40,41</sup> Between birth and the end of the first year, mean cardiac output normalized for body weight (or surface area), remains fairly constant at  $204 \pm 45$  mL/kg/min.<sup>42</sup> The relatively large cardiac output (mL/min/kg) in neonates reflects their greater metabolic rate (expressed per kilogram) and oxygen consumption compared with adults. Basal metabolic rate has been shown to increase as size decreases in all species<sup>43</sup> (see Chapter 6).

Pulsed Doppler estimation of cardiac output has also been found useful in assessing left ventricular myocardial dysfunction in neonates after perinatal asphyxia and acidosis, as well as its response to therapy.<sup>35,44,45</sup> In older children, measurements of cardiac output are necessary in circulatory shock.<sup>46</sup> New noninvasive techniques using changes in impedance may be useful in the future (see Chapter 51).

### NORMAL ELECTROCARDIOGRAPHIC FINDINGS FROM INFANCY TO ADOLESCENCE

The P wave reflects atrial depolarization and varies little with age. The PR interval increases with age (mean value for the first year is 0.10 second, increasing to 0.14 second at 12 to 16 years).<sup>47</sup> The duration of the QRS complex increases with age, but prolongation greater than 0.10 second is abnormal at any age.

At birth, the QRS axis is right sided, reflecting the predominant right ventricular intrauterine development. It moves leftward in the first month as left ventricular muscle hypertrophies. Thereafter, the QRS follows a gradual change away from the initial marked right-sided axis.

In addition, T waves are upright in all chest leads. Within hours, they become isoelectric or inverted over the left chest; by the seventh day, the T waves are inverted in  $V_{4R}$  ( $V_4$  position under the right clavicle),  $V_1$ , and across to  $V_4$ ; from then on, the T waves remain inverted over the right chest until adolescence, when they become upright over the right side of the chest again. Failure of T waves to become inverted in  $V_{4R}$  and  $V_1$  to  $V_4$  by 7 days may be the earliest electrocardiographic evidence of right ventricular hypertrophy.<sup>48,49</sup>

### Renal System

The complex development of the human kidney begins in week 4 of gestation and continues into adulthood. Serious renal malfunctioning is usually associated with growth retardation.

Urine production begins in utero at 10 to 12 weeks of gestation and is excreted into the amniotic cavity, helping to maintain amniotic fluid volume. The fetus maintains its metabolic

homeostasis through the placenta. It is only after birth that the kidney assumes this responsibility. More than 90% of neonates will have voided urine within the first 24 hours after birth. All normal infants should have voided by 48 hours after birth.<sup>50</sup>

Tubular function begins to develop after 34 weeks of gestation and increases during the first two years of life.<sup>51</sup> The number and function of the  $\text{Na}^+/\text{K}^+$ -ATPase transporters, are reduced at birth (activity increases 5- to 10-fold during the postnatal period). All transporters reliant on the  $\text{Na}^+$  gradient are also reduced in function. The renal tubular threshold is decreased for sodium (identifying the risk for hyponatremia), for glucose (increased risk for osmotic polyuria), and for bicarbonates (increased risk for metabolic acidosis).

Nephrogenesis is complete by 36 weeks of gestation. Renal blood flow and glomerular filtration rate (GFR) are reduced and correlate with gestational age. GFR is 20% to 25% of adult levels at term. They increase rapidly in the postnatal period due to an increase in cardiac output and a decrease in renal vascular resistance.<sup>52</sup> Adult rates are achieved by approximately two years of age<sup>53</sup> (see Fig. 6-11). A reduced GFR significantly affects the neonate's ability to excrete saline and water loads, as well as drugs. At birth, the serum creatinine concentration reflects the maternal concentration, but decreases during the first days of life. Over the course of early childhood, creatinine clearance slowly increases, reaching adult values between 2 and 3 years of age. Due to the rapid growth and increase in muscular mass, normal serum creatinine values increase with age and are greater in males.

In utero, the fetus maintains a mild respiratory acidosis, with a similar plasma bicarbonate concentration, but a greater  $\text{PaCO}_2$  than its mother. After birth, infants have a reduced plasma bicarbonate concentration and  $\text{PaCO}_2$  than older children and adults. They have a comparatively greater basal acid production and are less able to respond to an acid load. Endogenous acid production in small children is between 50% and 100% greater per kilogram when compared with adults. This is primarily due to the deposition of  $\text{Ca}^{2+}$  in bone, a process that produces 0.5 to 1 mEq per liter of acid per day. Bicarbonate absorption from the gastrointestinal tract is an important source of base to neutralize this nonvolatile acid, and in part, explains the tendency of infants to become profoundly acidotic when suffering from gastroenteritis. The infant or small child is living near its limit of acid compensation and is therefore prone to develop acidosis during the course of an acute illness or starvation.

Neonates and preterm infants are obligate salt losers; they cannot excrete a large salt load or concentrate urine effectively. Immaturity of distal tubular function and relative hypoaldosteronism explain the risk of hyperkalemia in preterm infants.

## Digestive and Endocrine System

### HEPATIC SYSTEM

Development of the liver and bile ducts begins as an outgrowth of the foregut; by 10 weeks of gestation, the biliary tract has completed its development. The vitelline veins give rise to the portal and hepatic veins. Hepatic sinusoids form the ductus venosus, the bridge between the hepatic vein and the inferior vena cava. Most umbilical venous blood from the placenta passes through the ductus venosus to the inferior vena cava. The remainder passes via the portal vein through the liver to the hepatic veins. The portal venous drainage to the left lobe is less than to the right lobe, leading to a relative underdevelopment of the left lobe. The ductus venosus closes soon after birth.

At 12 weeks of gestation there is evidence of gluconeogenesis and protein synthesis; at 14 weeks, glycogen is found in liver cells. Although by late gestation liver cell morphology is similar to that of adults, the functional development of the liver is immature in neonates and more so in preterm infants. The liver has a major role in metabolism, controlling carbohydrate, protein, and lipid delivery to the tissues. Toward the end of pregnancy, large amounts of glycogen appear in the liver, and, as a result, preterm and small-for-gestational-age (SGA) infants with smaller stores of glycogen may develop hypoglycemia. Bile acid secretion in neonates is reduced, and malabsorption of fat occurs.

The liver is the site for the synthesis of proteins; this process is active in fetal and neonatal life. In fetal life, the main serum protein is alpha-fetoprotein. This protein first appears at 6 weeks of gestation and reaches a peak at 13 weeks. Albumin synthesis starts at 3 to 4 months of gestation and approaches adult values at birth; in preterm infants, the level is reduced. Proteins involved in clotting are also formed in the liver but their concentrations in preterm and full-term neonates are less than normal for the first few days after birth. Hematopoiesis occurs in the fetal liver, with peak activity at 7 months of gestation. After 6 weeks of age, hematopoiesis is confined to the bone marrow except under pathologic conditions, such as hemolytic anemia (see Chapter 28).

The capacity to enzymatically break down proteins is reduced at birth. This is particularly important in preterm infants, when the intake of a large protein load can result in dangerous levels of serum amino acid concentrations. In the first weeks of life, drug metabolism is less efficient than in later life. In addition to less effective hepatic metabolism, altered drug binding by serum proteins and immature renal function contribute to the problem (see Chapter 6).

### Physiologic Jaundice

Hyperbilirubinemia (defined as a total serum bilirubin level  $>5$  mg/dL) is an especially important problem in neonates. About 60% of term and 80% of preterm neonates develop jaundice in the first week of life, with a total bilirubin concentration greater than 5 mg/dL.<sup>54</sup> The mechanisms for producing jaundice are outlined in Table 2-9.<sup>55,56</sup> In term neonates, the normal total bilirubin concentration is usually less than 5 mg/dL (86  $\mu\text{mol/L}$ ), rarely  $>12$  mg/dL without a risk factor and peaks at 3 to 4 days. In preterm infants, the bilirubin concentration peaks at 10 to 12 mg/dL on the fifth to seventh postnatal day. After this period, the concentration gradually decreases reaching adult values (less than 2 mg/dL) by 1 to 2 months in both term and preterm infants. The concentration of indirect bilirubin is also increased in the first few days after birth. The cause of nonhemolytic physiologic hyperbilirubinemia is excessive bilirubin production from breakdown of red blood cells and increased enterohepatic circulation of bilirubin with deficient hepatic conjugation due to depressed glucuronyl transferase activity. The relationship between breast feeding and hyperbilirubinemia has been well documented. It is usually delayed in onset (after the third day of life), its cause remains unclear, and it occurs in about 1% of

**TABLE 2-9 Causes of Jaundice in Neonates**

Excess bilirubin production
Impaired uptake of bilirubin
Impaired conjugation of bilirubin
Defective bilirubin excretion
Increased enterohepatic circulation of bilirubin

**TABLE 2-10 Pathologic Causes of Jaundice in Neonates**

Antibody-induced hemolysis (Rh and ABO)
Hereditary red blood cell disorders (e.g., glucose-6-phosphate dehydrogenase deficiency, which gives rise to hemolysis from drugs or infection)
Infections (e.g., neonatal hepatitis, sepsis, severe urinary tract infections)
Hemorrhage into the body (e.g., intracerebral)
Biliary atresia
Metabolic (e.g., hypothyroidism, galactosemia)

breastfeeding infants. An earlier hypothesis ascribing it to inhibition of glucuronyl transferase by  $3\alpha$ ,  $20\beta$ -pregnanediol activity has not been substantiated.

Important pathologic causes of jaundice in neonates are presented in Table 2-10. The relative rarity of cholestasis is in sharp contrast with the very common finding of jaundice during the first weeks of life, and therefore, a false diagnosis of physiologic or breast milk jaundice is easily made. Symptoms indicative of cholestasis such as dark urine and pale stools are often unrecognized.<sup>57</sup>

Once the distinction between physiologic and hemolytic hyperbilirubinemia has been made, the underlying cause can then be treated and efforts can be directed at preventing bilirubin encephalopathy (kernicterus) by the use of phototherapy and, in selected cases, exchange transfusions. Phototherapy reduces serum bilirubin concentrations by converting bilirubin through structural photoisomerization and photooxidation into excretable products.<sup>58</sup> A possible relationship between neonatal blue-light phototherapy and the development of benign or malignant melanocyte lesions has been suggested<sup>59</sup>; further studies are required to clarify this concern.

Sick preterm infants are especially at risk for kernicterus and are more aggressively treated at reduced bilirubin concentrations than full-term infants. Increasingly common is a form of cholestatic jaundice in LBW infants receiving prolonged hyperalimentation. Its mechanism is unclear, but it may be due to inhibition of bile flow by amino acids.<sup>60-63</sup> Future therapy for hyperbilirubinemia in LBW infants may include the use of tin-mesoporphyrin, which inhibits the production of bilirubin.<sup>64,65</sup>

## GASTROINTESTINAL TRACT

In an embryo, the digestive tract consists of the developing foregut and hindgut. These rapidly elongate so that a loop of gut is forced into the yolk sac. At 5 to 7 weeks, this loop twists around the axis of the superior mesenteric artery and returns to the abdominal cavity. Maturation occurs gradually from the proximal to the distal end. Blood vessels and nerves (Auerbach and Meissner plexuses) are developed by 13 weeks of gestation, and peristalsis begins. The pancreas arises from two outgrowths of the foregut; a diverticulum of the foregut gives rise to the liver.

Enzyme levels of enterokinase and lipase increase with gestational age but are lower at birth compared with older children. Full-term neonates and preterm infants handle protein loads reasonably well, although preterm infants may have difficulty with large loads. Fat digestion is limited, particularly in preterm infants, who absorb only 65% of adult levels. Neonatal duodenal motility undergoes marked maturational changes between 29 and 32 weeks of gestation. This is one factor limiting tolerance of enteral feeding before 29 to 30 weeks of gestation. Central nervous system abnormalities will delay these maturational changes.<sup>66</sup>

Swallowing is a complex process that is under central and peripheral control. The reflex is initiated in the medulla, through cranial nerves to the muscles that control the passage of food through the pharyngoesophageal sphincter. In the process, the tongue, soft palate, pharynx, and larynx all are smoothly coordinated. Any pathologic condition of these structures can interfere with normal swallowing. Neuromuscular incoordination, however, is more likely to be responsible for any dysfunction. This is particularly evident when the central nervous system has sustained damage either before or during delivery.

Lower esophageal pressures are reduced at birth but increase steadily reaching adult values 3 to 6 weeks postnatally. Daily vomiting or "spitting up" may be seen in half of all infants between 0 and 3 months of age and up to two-thirds of 4- to 6-month-old infants.<sup>67</sup> Most of these infants suffer no ill effect ("happy spitters") and grow well.<sup>68</sup> This condition usually begins in the first weeks of life and resolves spontaneously by 9 to 24 months of age as solid food is introduced and the child assumes the upright position. Between 1:300 and 1:1000 infants have reflux that is significant enough to warrant treatment to prevent complications.<sup>69</sup>

Meconium is the material contained in the intestinal tract before birth. It consists of desquamated epithelial cells from the intestinal tract, bile, pancreatic and intestinal secretions, and water (70%). Meconium is usually passed in the first few hours after birth; virtually all term neonates pass their first stool by 48 hours. However, passage of the first stool is usually delayed in LBW neonates, probably because of immaturity of bowel motility and lack of gut hormones due to delayed enteral feeding. Meconium ileus occurs in cystic fibrosis or Hirschsprung disease.

The gastrointestinal transit time in the infant is less than that of an adult and increases with age. The normal physiologic range of stool frequency varies greatly (from 10 times a day to 1-2 times a week<sup>70</sup> and more often in breastfed infants. The frequency of bowel movements gradually declines over the first years of life, reaching adult habits at about 4 years of age.

Necrotizing enterocolitis is an acquired gastrointestinal disease associated with significant morbidity and mortality in prematurely born neonates. The disease affects about 10% of preterm neonates weighing less than 1500 g or 1% to 5% of all neonatal intensive care unit admissions (see also Chapters 35 and 36). Combined with enteral feeds and bacterial colonization, inflammatory mediators are released, leading to a propagated inflammatory response with both pro- and antiinflammatory influences.<sup>71</sup>

## PANCREAS

The placenta is impermeable to both insulin and glucagon. The islets of Langerhans in the fetal pancreas, however, secrete insulin from week 11 of fetal life; the amount of insulin secretion increases with age. After birth, insulin response is related to gestational and postnatal age and is more mature in term infants.

Maternal hyperglycemia, particularly when uncontrolled, results in hypertrophy and hyperplasia of the fetal islets of Langerhans. This leads to increased levels of insulin in the fetus, affecting lipid metabolism and giving rise to a large, overweight infant characteristic of a mother with poorly controlled diabetes (infant of a diabetic mother, IDM). Hyperglycemia alone is not instrumental in this effect; IDM may also be the result of an increase in serum amino acids found in diabetic mothers. Hyperinsulinemia of the fetus persists after birth and may lead to rapid development of serious hypoglycemia. In addition to

severe hypoglycemia, these infants have an increased incidence of congenital anomalies.

Infants who are SGA are frequently hypoglycemic, and this may be the result of malnutrition in utero. In addition, hepatic glycogen stores are inadequate, and deficient gluconeogenesis exists. Preterm infants may be hypoglycemic without demonstrable symptoms, necessitating close monitoring of blood glucose levels.

Full-term neonates undergo a metabolic adjustment postnatally with regard to glucose. Studies have defined values for glucose levels that should be cause for concern: plasma glucose levels less than 35 mg/dL in the first 3 hours of life; less than 40 mg/dL between 3 and 24 hours; and less than 45 mg/dL after 24 hours.<sup>72</sup> Others have defined hypoglycemia in full-term infants as a plasma glucose concentration of less than 30 mg/dL in the first day of life or less than 40 mg/dL in the second day of life.<sup>73</sup> It is important to recognize that infants may develop serious hypoglycemia that could lead to irreversible central nervous system damage, even though they demonstrate no symptoms. Other infants may present with convulsions, but signs may also be subtle (e.g., lethargy, somnolence, and jitteriness).

Hyperglycemia (plasma glucose 150 mg/dL or greater) occurs in stressed neonates, particularly LBW infants infused with glucose-containing solutions. Hyperglycemia commonly occurs in infants undergoing elective surgery under general anesthesia; infusion of glucose-containing solutions may increase the risk of hyperglycemia. Thus it is advisable that intraoperative glucose levels be monitored. A study in infants undergoing surgery under general anesthesia showed that postsurgical plasma glucose values were significantly greater than postinduction values; insulin changes were minimal.<sup>74</sup> The risk of hyperglycemia is considerably greater in infants weighing less than 1000 g compared with infants of 2000 g or more.<sup>73</sup> Hyperglycemia may also lead to osmotic diuresis and dehydration and has been associated with an increased incidence of intraventricular hemorrhage and a neurologic handicap.

## Hematopoietic and Immunologic System

The blood volume of a full-term neonate depends on the time of cord clamping, which modifies the volume of placental transfusion. The blood volume is 93 mL/kg when cord clamping is delayed after delivery, compared with 82 mL/kg with immediate cord clamping.<sup>75,76</sup> Within the first 4 hours after delivery, however, fluid is lost from the blood and the plasma volume contracts by as much as 25%. The larger the placental transfusion, the larger this loss of fluid in the first few hours after birth, with resultant hemoconcentration. The blood volume in preterm infants is greater (90 to 105 mL/kg) than it is in full-term infants because of increased plasma volume.

### HEMOGLOBIN

The normal hemoglobin range in the neonate is between 14 and 20 g/dL. The site of sampling must be considered when interpreting these values for the diagnosis of neonatal anemia or hyperviscosity syndrome. Capillary sampling (e.g., heel stick) generally overestimates the true hemoglobin concentration because of stasis in peripheral vessels that results in a loss of plasma and produces hemoconcentration. The net effect may be an increase in hemoglobin by as much as 6 g/dL. As a result, venipuncture is preferred over capillary sampling. In 1% of infants,

fetal-maternal transfusion before the umbilical cord is cut may explain many of the "lower normal" hemoglobin values reported.

Erythropoietic activity from the bone marrow decreases immediately after birth in both full-term and preterm infants. The cord blood reticulocyte count of 5% persists for a few days and declines below 1% by 1 week. This is followed by a slight increase to 1% to 2% by the 12th week, where it remains throughout childhood. Preterm infants have greater reticulocyte counts (up to 10%) at birth. Abnormal reticulocyte values reflect hemorrhage or hemolysis.

In term infants, the hemoglobin concentration decreases during the 9th to 12th week to reach a nadir of 10 to 11 g/dL (hematocrit 30% to 33%) and then increases. This decrease in hemoglobin concentration is due to a decrease in erythropoiesis and to some extent due to a shortened life span of the red blood cells. In preterm infants, the decrease in the hemoglobin level is greater and is directly related to the degree of prematurity; also, the nadir is reached earlier (4 to 8 weeks).<sup>77</sup> In infants weighing 800 to 1000 g, the decrement may reach a very small concentration, 8 g/dL. This "anemia" (physiologic anemia of the newborn) is a normal physiologic adjustment to extrauterine life. Despite the reduction in hemoglobin, the oxygen delivery to the tissues may not be compromised because of a shift of the oxygen-hemoglobin dissociation curve (to the right), secondary to an increase of 2,3-diphosphoglycerate.<sup>78</sup> In addition, fetal hemoglobin is replaced by adult-type hemoglobin, which also results in a shift in the same direction. In neonates, especially preterm infants, reduced hemoglobin concentrations may be associated with apnea and tachycardia.<sup>79</sup> Vitamin E administration does not prevent anemia of prematurity; no significant difference was noted between vitamin E-supplemented and unsupplemented groups in terms of hemoglobin concentration, reticulocyte and platelet counts, or erythrocyte morphology in infants at 6 weeks of age.<sup>80</sup> Infants with anemia of prematurity have been found to have an inadequate production of erythropoietin (the primary regulator in erythropoiesis). Some centers are now using recombinant human erythropoietin in VLBW infants to stimulate erythropoiesis and decrease the need for transfusions.<sup>81,82</sup>

After the third month, the hemoglobin concentration stabilizes at 11.5 to 12 g/dL, until about 2 years of age. The hemoglobin values of full-term and preterm infants are comparable after the first year. Thereafter, there is a gradual increase in the hemoglobin concentration to mean values at puberty of 14 g/dL for females and 15.5 g/dL for males.

### LEUKOCYTE AND IMMUNOLOGY

The white blood cell count may normally reach 21,000/mm<sup>3</sup> in the first 24 hours of life and 12,000/mm<sup>3</sup> at the end of the first week, with the number of neutrophils equaling the number of lymphocytes. It then decreases gradually, reaching adult values at puberty. At birth, neutrophil granulocytes predominate but rapidly decrease in number so that during the first week of life and through 4 years of age the lymphocyte is the predominant cell. After the fourth year, the values approximate an adult's. Neonates have an increased susceptibility to bacterial infection, which is related in part to immaturity of leukocyte function. Sepsis may be associated with a minimal leukocyte response or even with leukopenia. Spurious increases in the white blood cell content may be due to drugs (e.g., epinephrine). The incidence of neonatal sepsis correlates inversely with gestational age and may be as great as 58% in VLBW infants.<sup>83</sup>

## PLATELETS

Thrombocytopenia is a common hematologic finding in neonates, occurring in 1% to 2% of healthy term neonates.<sup>84</sup> Mechanical ventilation has been associated with a significant decrease in the platelet count in neonates.<sup>85</sup> There appears to be an inverse correlation between gestational age or birth weight and the severity of platelet reduction. A study of neonatal thrombocytopenia and its impact on hemostatic integrity showed that thrombocytopenic infants are at greater risk for bleeding than equally sick nonthrombocytopenic infants (see Chapter 18).

## COAGULATION

At birth, vitamin K-dependent factors (i.e., II, VII, IX, and X) are 20% to 60% of adult values; in preterm infants, the values are even less. The result is prolonged prothrombin times, normally encountered in full-term and preterm infants. Synthesis of vitamin K-dependent factors occurs in the liver, which, being immature, leads to relatively lower levels of the coagulation factors, even with the administration of vitamin K. It takes several weeks for the levels of coagulation factors to reach adult values; the deficit is even more pronounced in preterm infants. Vitamin K prophylaxis has been evaluated,<sup>86</sup> and the findings show that the majority of cases of neonatal vitamin K deficiency occur in normal neonates. Thus, all neonates should receive prophylactic vitamin K soon after birth to prevent hemorrhagic disease of the neonate. Its omission could lead to serious and life-threatening consequences, especially if surgery is undertaken. However, in theory, the increasing risk of bleeding is balanced by the protective effects of physiologic deficiencies of coagulation inhibitors, as well as by the decreased fibrinolytic capacity. Developmental hemostasis should be considered, as well as laboratory variations of coagulation tests that may render any diagnosis of bleeding disorder in infants difficult to establish.<sup>87</sup>

Infants of mothers who have received anticonvulsant drugs during pregnancy may develop a serious coagulopathy similar to that encountered with vitamin K deficiency.<sup>88</sup> Vitamin K<sub>1</sub> administered to neonates usually reverses this bleeding tendency, but deaths have occurred despite therapy. Other risk factors include maternal use of drugs such as warfarin, rifampin, and isoniazid. Breastfeeding may also be associated with severe vitamin K deficiency.

## POLYCYTHEMIA

Neonatal polycythemia (central hematocrit greater than 65%) occurs in 3% to 5% of full-term neonates.<sup>89</sup> Using M-mode echocardiography, a study of neonates demonstrated an increase in PVR with hyperviscosity.<sup>90</sup> Partial exchange transfusion to reduce the hematocrit and decrease the blood viscosity improves systemic and pulmonary blood flow and oxygen transport, although one review questioned the efficacy when the exchange transfusion was conducted after 6 hours of life in asymptomatic infants.<sup>91</sup> The increased organ blood flow should prevent the cardiovascular and neurologic symptoms associated with the hyperviscosity syndrome.

# Neurologic Development and Cognitive Development Issues

## NEUROLOGIC DEVELOPMENT

Reduction of perinatal mortality during the past decade has not resulted in the expected reduction in the prevalence of cerebral

palsy (1 : 500 live births). The most common etiologies of cerebral palsy are perinatal ischemic stroke, white matter disorder, and intrauterine inflammation.<sup>92</sup> Less than 5% of cerebral palsy results from perinatal asphyxia. The strongest predictors of cerebral palsy appear to be congenital anomaly, low birth weight, low placental weight, multiple fetuses, or abnormal fetal position before labor and delivery.<sup>93</sup>

The nervous system is anatomically complete at birth; functionally it remains immature with the continuation of myelination and synaptogenesis. Myelination is usually complete by 7 years of age. An infant's normal mental development depends on the maturation of the central nervous system. This development may be affected by physical illness, inadequate psychosocial support, or bad nutrition conditions in preterm babies. In a randomized trial of diet in preterm babies, a suboptimal diet resulted in reduced intelligence quotients 7 to 8 years later.<sup>94</sup>

Recent controversies concerning the potential adverse effects of anesthesia on the developing brain show how delicate this organ is and how its development may be affected by environmental agents<sup>95,96</sup> (see Chapter 23).

The rate of brain growth is different from the growth rate of other body systems. The brain has two growth spurts, neuronal cell multiplication between 15 and 20 weeks of gestation, and glial cell multiplication commencing at 25 weeks and extending into the second year of life. Myelination continues into the third year. Malnutrition during this phase of neural development may have profound handicapping effects.

Plasma membrane transport selectively promotes the passage of essential substrates such as glucose, organic acids, and amino acids across the blood-brain barrier. Hypoxemia and ischemia may lead to a breakdown in this barrier, with resulting edema and increased intracranial pressure. Injury to the blood-brain barrier may result from abnormal entry of calcium or formation of free radicals. Further studies of the mechanism of this breakdown will lead to rational approaches to therapy. In preterm infants stressed by hypoxia, the blood-brain barrier may become particularly permeable to the water-soluble unbound bilirubin, with possible damage to the brain.<sup>97</sup>

Normal neonates show various primitive reflexes, which include the Moro response and grasp reflex. Milestones of development are useful indicators of mental development and possible deviations from normal. It should be appreciated, however, that these milestones represent the *average*, and infants can vary in their rates of maturation of different body functions and still be within the normal range.<sup>98</sup> The Denver Developmental Screening Test is useful for assessing these milestones. The test focuses on four areas: (1) gross motor function, (2) fine motor and adaptive skills, (3) language, and (4) personal and social skills. Developing infants rapidly acquire motor skills. For effective movement, an infant needs postural control, which develops in a cephalocaudal direction. It starts with head control and progresses to sitting, standing, walking, and finally running (Table 2-11).

**TABLE 2-11** Relationship of Motor Milestones to Age

Motor Milestone	Age
Supports head	3 months
Sits alone	6 months
Stands alone	12 months
Balances on one foot	3 years

**TABLE 2-12** Relationship of Fine Motor/Adaptive Milestones to Age

Fine Motor/Adaptive Milestones	Age
Grasps rattle	3 months
Passes cube hand to hand	6 months
Pincer grip	1 year
Imitates vertical line	2 years
Copies circle	3 years

Adaptive skills are performed through well-coordinated fine motor movements (Table 2-12). Abnormal development may be reflected in a delay in appearance of a particular milestone or in its pathologic persistence with maturation in a child. For example, at 20 weeks, a child reaches and retrieves objects, frequently placing them in his or her mouth. As an infant matures, however, this behavior pattern usually ceases at 12 to 13 months of age; in infants with a developmental delay, this practice may continue much longer.

Language development correlates closely with cognitive skills (Table 2-13). Personal and social skills are modified by environmental factors and cultural patterns (Table 2-14). Development of walking, speech, and sphincter control are most important. For appropriate evaluation consider familial patterns, level of intelligence, and physical illness. Deafness may cause delayed speech.

#### DEVELOPMENTAL ISSUES

Children with developmental issues are delayed in *many* aspects of both cognitive and motor development. Smiling, vocalization, sitting, walking, speech, and sphincter control are delayed. When there is a delay in the eye following an object and the head turning in response to sound, blindness and deafness may erroneously be diagnosed. Drooling, common in young infants, is frequently prolonged for years in neurologically delayed children. Initially, a mentally handicapped infant appears to be inactive

**TABLE 2-13** Relationship of Language Milestones to Age

Language Milestones	Age
Squeals	1.5-3 months
Turns to voice	6 months
Combines two words	1.5 years
Composes short sentences	2 years
Gives entire name	3 years

**TABLE 2-14** Relationship of Personal-Social Milestones to Age

Personal-Social Milestones	Age
Smiles spontaneously	3 months
Feeds self crackers	6 months
Drinks from cup	1 year
Plays interactive games	2 years

and may be seen as a “good child.” The child later demonstrates constant and sometimes uncontrollable overactivity. In diagnosing a developmental abnormality, anesthesiologists must be aware of possible pitfalls: Infants born prematurely will be delayed and should be assessed in terms of their conceptional age. Infants with cerebral palsy or sensory deficits (auditory and visual) may have normal mental development, but the handicap may interfere with assessment of mental status. The effects of drugs should be considered (e.g., barbiturates for epilepsy).

## Intraoperative Clinical Outcomes

Summary

INTEREST IN CHILDREN'S PERIOPERATIVE behavior has increased dramatically over the past 20 years. Specifically, the recognition of the importance of developmental factors in perioperative research has created a dramatic growth of investigation in this area. In this chapter, we discuss developmental considerations that are relevant to the child's perioperative experience (cognitive development, attachment and separation, temperament). We then offer a review and synthesis of recent data on preoperative anxiety and maladaptive behavioral and cognitive outcomes associated with surgery and anesthesia.

## Developmental Issues

### COGNITIVE DEVELOPMENT AND UNDERSTANDING OF ILLNESS

The perioperative period is stressful for many individuals undergoing surgery, and this is especially true for children. Children's stress during the perioperative period results from multiple sources, one of which is a limited understanding of illness and the need for surgery. Early developmental theorists (e.g., Piaget,<sup>1,2</sup> Werner<sup>3</sup>) suggested that a child's understanding of illness changes qualitatively as cognitive maturation occurs. The most widely cited model for understanding a child's perspective on illness posits that the child's understanding of illness evolves from prelogical explanations, such as phenomenism (e.g., magical thinking), to concrete-logical explanations, such as contamination (e.g., eating bad food), to formal-logical explanations (e.g., physiologic causes), and differences in understanding occur according to the child's differentiation between the self and others.<sup>4</sup>

Children's understanding of the treatments for illnesses is thought to follow a similar developmental pattern. In terms of surgery, a child's concepts are particularly underdeveloped. Young children have difficulty defining "an operation," suggesting that it is the same as being sick, going for a doctor's checkup, or taking a nap.<sup>5</sup> Given these developmental considerations, it is not surprising that young children are more likely to have misconceptions about hospitalization and surgery than are older children and adults,<sup>6</sup> and therefore are at unique and disparate risk for perioperative stress.

### ATTACHMENT

Attachment style is another developmental consideration unique to children in the perioperative setting. Although adults also undergo separation from family, the separation of children from their parents is particularly stressful and affected by the parent-child relationship.

Coping with separation is a lifelong challenge that is inevitable and necessary for a child's normal, healthy development.<sup>7</sup> Separation experiences, such as saying good-bye at school or sleeping overnight at a friend's house, facilitate normal childhood psychological growth and personality organization by mobilizing opportunities for learning and adaptation. Other separation experiences, especially those occurring in the context of loss, illness, or other stressors, can precipitate states of confusion, anger, and anxiety. Brief separations, such as those associated with surgery, are most stressful for infants, toddlers, and preschool-aged children. Indeed, for school-aged children, responses to separation may reflect, in part, response patterns established early in the preschool years.<sup>7</sup> For children with biologically based vulnerabilities, such as a sensitivity to novelty and changes in routines, even expected separations may impose a greater degree of stress than for less sensitive children.<sup>7</sup> Similarly, for children with developmental delay, separation may be experienced with a degree of anxiety and developmental stress more like that experienced by a younger child.

Attachment affects a child's response to separation and is shaped through early experiences with the primary caregiver. Through these interactions, an infant has the opportunity to develop a sense of trust and security in the reliability and predictability of his or her relationship and the world.<sup>8</sup> The style of attachment exhibited by infants is evident in their responses to brief separations from the primary caregiver and is conceptualized as *secure*, *insecure*, or *anxious*.

Children who are more "securely attached" to their parents deal more adaptively with the stress of brief separation and with the novelty of the hospital experience. Such children are more willing to explore their world and respond positively to their caregivers' return, using the caregivers as a secure, stable base from which to approach strangers and new situations.<sup>9,10</sup> In contrast, children classified as "anxiously attached" to their parents

tend to be distressed in unfamiliar situations, like the perioperative environment, even in the presence of their caregivers. When their parents return after brief separations, these infants exhibit anger and distress and avoid physical contact. Another form of “insecure attachment” is avoidance. Avoidant children do not explore their surroundings as much as securely attached infants, rarely show distress at separation, and tend to ignore their parents on reuniting. Conversely, “insecurely attached” infants are more easily distressed by even brief separations and spend more time trying to stay close to their parents. They are less likely to explore and adapt positively to new situations.

## TEMPERAMENT

Responses of young children to the stress of the perioperative period also reflect the child’s temperament. Temperament refers to stable emotional and behavioral responses (e.g., emotionality, activity, attention, reactivity, sociability, etc.) that appear in infancy and are thought to be primarily genetic in nature.<sup>11</sup> Three main dimensions have been proposed to classify infant temperament: emotionality, activity, and sociability.<sup>12</sup> *Emotionality* refers to the ease with which an infant becomes aroused or anxious, especially in situations that might lead to fear, such as perioperative settings. *Activity* refers to the infant’s customary level of energy and intensity of behavior. *Sociability* reflects the infant’s tendency to approach or avoid others. These behavioral dimensions of temperament are also reflected in physiologic responses related to anxiety.<sup>13,14</sup> In long-term studies, infants who are inhibited in the face of novelty continue to be so through early school age.<sup>15</sup> Thus, temperament as a behavioral descriptor appears to characterize an enduring cluster of traits reflecting reactivity and anxiety regulation in the face of novelty.

In light of these issues, the child’s developmental level is an important consideration in the perioperative period, especially as it relates to the child’s perioperative behavior. The remainder of this chapter addresses specific behavioral issues related to surgery in children, including anxiety in the preoperative period as well as postoperative behavioral outcomes, such as emergence delirium, sleep, and other maladaptive behavioral changes.

## Preoperative Anxiety

Anxiety in children undergoing anesthesia and surgery is characterized by feelings of tension, apprehension, and nervousness.<sup>16</sup> This response is attributed to separating from parents, loss of control, uncertainty about anesthesia, and uncertainty about the surgery and its outcome.<sup>16</sup> It is estimated that 40% to 60% of children develop significant fear and anxiety before their surgery.<sup>17</sup> Furthermore, separation from parents and induction of anesthesia have been found to be the most stressful times during the surgical and anesthesia experience. Some children verbalize their fears explicitly, whereas others express their anxiety only by behavioral changes. Children may appear scared or agitated, breathe deeply, tremble, stop talking or playing, and start to cry. Some may wet or soil themselves, display increased motor tone, and actively attempt to escape from medical personnel.<sup>18</sup> These behaviors may give children some sense of control in the situation and thereby diminish the damaging effects of a sense of helplessness.<sup>16,18</sup> In addition to the behavioral manifestations detailed here, several studies have documented that anxiety before surgery is associated with neuroendocrine changes, such as increased serum cortisol, epinephrine, growth hormone, and

adrenocorticotrophic hormone levels, as well as increased natural killer cell activity.<sup>19,20</sup> Significant correlations between heart rate, blood pressure, and behavioral ratings of anxiety have also been reported.<sup>21,22</sup>

## RISK FACTORS

Preoperative anxiety is a clinically important phenomenon that should be treated as any other clinical phenomenon or disease. In epidemiologic terms, *all* diseases are characterized operationally by risk factors, interventions, and outcomes; preoperative anxiety is no exception. We review the phenomenon of preoperative anxiety using the classic epidemiologic model of a disease (Fig. 3-1).

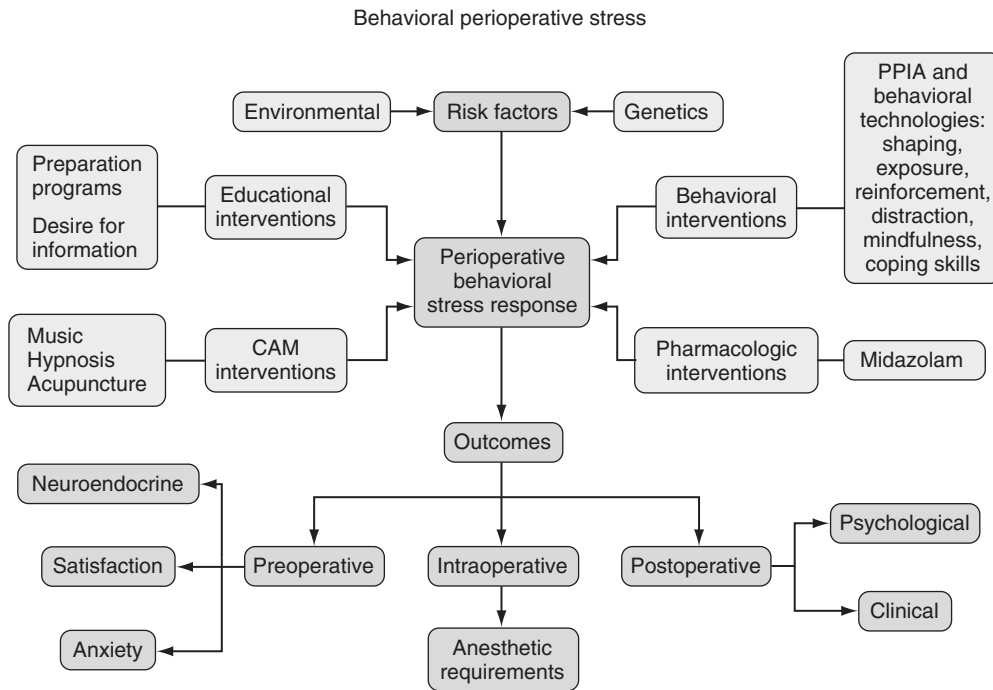

Identifying the risk factors for preoperative anxiety is important because the routine use of pharmacologic and behavioral interventions is associated with both advantages and disadvantages. Routine administration of sedative premedication may increase indirect pharmacy costs, the need for nursing staff, and appropriately monitored bed space in the preoperative holding area. Children undergoing extremely short outpatient procedures may also experience delayed discharge. Similarly, behavioral preparation programs administered preoperatively are associated with increased hospital operational costs. Likewise, anxious children can use hospital resources that would be reduced with appropriate pharmacologic preparation. Thus, identifying children who are at a particularly high risk for developing extreme anxiety and distress before surgery would help guide the most effective use of limited resources.

Variation in children’s behavioral responses to the perioperative experience has its origin in at least four domains:

- Age and developmental maturity
- Previous experience with medical procedures and illness
- Individual capacity for affect regulation and trait (baseline) anxiety
- Parental state (situational) and trait anxiety

Previous studies that examined the behavioral responses to induction of anesthesia in children did so in terms of these four domains.<sup>23-27</sup> Children between the ages of 1 and 5 years are at greatest risk for developing extreme anxiety and distress. This is not surprising because separation anxiety often does not peak until 1 year of age and children older than the age of 5 years can more easily cope with new and unpredictable situations. A history of previous stressful medical encounters, such as with previous hospitalization, affects how a child reacts to new medical encounters; these are important risk factors for preoperative anxiety. Children who are shy and inhibited, as identified by temperament tests, and those who lack good social adaptive abilities, are also at increased risk for developing anxiety and distress before surgery.<sup>27</sup>

Parental characteristics also have a strong influence on a child’s behavior during the perioperative experience. Children of parents who are more anxious, children of parents who use avoidance coping mechanisms, and children of separated or divorced parents all appear to be at high risk for developing preoperative anxiety.<sup>28</sup> Because children of anxious parents are more likely to experience high levels of preoperative anxiety, it is important to identify the predictors of increased *parental* preoperative anxiety. Parent gender (mothers are more anxious than fathers<sup>29</sup>), the child’s age (under 1 year), children with repeated hospital admissions, and the child’s temperament are all predictors of increased parental preoperative anxiety.<sup>28,30,31,32</sup> Identification of children and parents who are at the greatest risk for preoperative anxiety

**FIGURE 3-1** Operational overview of perioperative anxiety. CAM, Complementary alternative medicine; PPIA, parental presence during induction of anesthesia.

and distress allows for appropriate intervention for this “at risk” population.

### BEHAVIORAL INTERVENTIONS

Pharmacologic (e.g., administration of premedications) and behavioral (e.g., psychological preparation programs) interventions are used to treat preoperative anxiety and distress in children and their parents.<sup>17,33</sup>

#### Preoperative Preparation Programs

Psychological preparation for children undergoing anesthesia and surgery has been widely advocated. These preparation programs may provide narrative information, an orientation tour of the operative facility, role rehearsal using dolls, modeling using videotapes or a puppet show, child life preparation, or coping education and relaxation skills.<sup>34,35,36</sup>

Although there is general agreement in the medical community about the benefit of preparation programs, recommendations regarding the content of behavioral preoperative preparation differ widely. Early programs were information oriented and often incorporated modeling techniques using videos or a puppet show.<sup>37,38</sup> These techniques were augmented in the late 1980s with child life preparation and coping skills education.<sup>35</sup> Child life specialists are trained individuals who facilitate development of coping skills and the adjustment of children and parents to the perioperative environment by providing play experiences, presenting information about events and procedures, and establishing supportive relationships with children and parents.<sup>36</sup> Currently, the development of coping skills is considered the most effective preoperative intervention, followed by modeling, play therapy, operating room (OR) tour, and printed material.<sup>39</sup> Interestingly, coping skills preparation with child life specialists was associated with less anxiety on the day of surgery when compared to lesser rated techniques; however, no differences were found

immediately or up to 2 weeks after surgery.<sup>40</sup> Thus, from a cost-effectiveness point of view, one must decide whether the additional cost associated with child life specialists is justified by reduction of anxiety *only* during the preoperative period.

It is important that preparation programs are tailored to the individual, age-appropriate needs of each child. Several variables have been identified as influencing the response of children to preparation programs.<sup>28</sup> For example, children who are 6 years of age or older benefit most if they participate in a preparation program more than 5 days before the scheduled surgery and benefit least if the program is given only 1 day before surgery. In fact, older children prepared a week in advance showed an *increase* in anxiety level during and immediately after the preparation program, but demonstrated a gradual decrease in anxiety during the 5 days before the time of surgery.<sup>41</sup> To avoid increasing excessive anticipatory anxiety, older children should be given enough time to process the new information and to rehearse newly acquired coping skills. It is also important to realize that there may be a *negative* effect of a preparation program on children younger than 3 years of age. This may be a result of their inability to distinguish fantasy from reality.<sup>1</sup> A reality-based preparation program may do little to calm young children and may even exacerbate anxiety or sensitize the young child to the surgery. From age 3 to 6 years, children demonstrate an increasing ability to distinguish fantasy from reality and by the age of 6 this distinction is usually accomplished.<sup>1</sup> Therefore, to provide the most benefit, both the age of the child and timing must be factored into delivery of the program.

In addition to age and timing, previous experience in a hospital setting also influences the effectiveness of a preparation program. A child who was previously hospitalized is more likely to develop an exaggerated emotional response to a behavioral preoperative preparation program and the perioperative experience.<sup>28,41-43</sup> Information about what will occur, as demonstrated

by sensory expectation and doll play, does *not* provide new information for these children. Furthermore, if the child has had a previous negative medical experience, the routine preparation may increase anxiety by triggering negative memories. In this case, alternative behavioral interventions, such as extensive individualized coping-skills training combined with desensitization and actual practice, may be better suited and indicated.<sup>42</sup>

Because increased parental preoperative anxiety has been shown to result in increased preoperative anxiety in their children, preparation programs for surgery should also be directed at parents.<sup>23</sup> Although various interventions are routinely used to reduce a child's anxiety, there is a paucity of information regarding interventions directed toward reducing parental anxiety.<sup>44</sup> One study demonstrated that parental preoperative anxiety decreased after viewing an educational videotape.<sup>45</sup> Most studies to date suggest that preoperative preparation programs for children reduce preoperative anxiety and enhance coping.<sup>35,41,46</sup>

Children whose parents have been taught to be active in distracting their child during stressful medical events may evidence lower anxiety compared to parents who receive no intervention.<sup>47</sup> Indeed, this was the case in a randomized controlled trial evaluating a family-centered behavioral preparation program (ADVANCE) (Table 3-1). Parents and children who received

ADVANCE were less anxious before and during induction of anesthesia than parents and children who did not receive this program. In fact, ADVANCE was as successful as midazolam in managing children's compliance with and anxiety at induction of anesthesia (Table 3-2).<sup>48</sup> It is important to note that ADVANCE also decreased the time spent in the postanesthesia care unit and decreased the analgesic requirements during the postoperative period. A major disadvantage of ADVANCE, however, is its high cost and personnel requirements. Accordingly, efforts to dismantle this multimodal intervention indicate that behavioral shaping through exposing children to the anesthesia mask before surgery and distraction on the day of surgery proved to be the most effective components of the program.<sup>49</sup>

### Parental Presence during Induction of Anesthesia

It is well established that most parents and children prefer to remain together during procedures such as immunization, bone marrow aspiration, and dental treatment.<sup>50,51</sup> Several survey studies have also indicated that most parents prefer to be present during induction of anesthesia regardless of the child's age or previous surgical experience.<sup>52,53</sup> This is even the case for those parents who have had previous experience with pharmacologic interventions. Indeed, parents of children undergoing repeated surgery were likely to request parental presence regardless of their experience with prior parental presence or premedication with midazolam.<sup>54</sup> That is, even if children were calm after midazolam during their first surgery, parents still preferred to be present during induction of anesthesia during subsequent surgeries.

It is important to note, however, that parental presence during induction of anesthesia (PPIA) does not necessarily equate with appropriate choice of interventions. For example, mothers who were most highly motivated to be present at induction of anesthesia also reported high levels of anxiety and their children were more distressed at induction.<sup>55</sup> Indeed, more than 90% of parents report some degree of anxiety during the anesthesia induction process.<sup>56</sup> The most upsetting factors include seeing their child become flaccid during induction and separation from their child.<sup>56</sup> This observation was confirmed by a study that examined heart rate, blood pressure, and skin conductance levels in mothers as they observed their child's induction of anesthesia.<sup>57</sup> Mothers

Asterisks indicate time points at which differences between groups are statistically significant ( $P < 0.05$ ). BPM, Beats per minute; OR, operating room; PPIA, parental presence during induction of anesthesia. (From Kain ZN, Caldwell-Andrews AA, Mayes LC, et al. Parental presence during induction of anesthesia: physiological effects on parents. *Anesthesiology* 2003;98:58-64.)

who were present during induction of anesthesia showed a moderate increase in heart rate and blood pressure (Fig. 3-2). However, no cardiac arrhythmias or ischemic episodes were noted. Another study examined whether parental auricular acupuncture would reduce parental preoperative anxiety and thus allow children to benefit from parental presence during induction of anesthesia.<sup>58</sup> A multivariate model demonstrated that children whose mothers had received the acupuncture intervention were significantly less anxious on entrance to the OR and during placement of the anesthesia mask on their child's face.

Potential benefits from PPIA include minimizing the need for premedication and avoiding the screaming and struggling of the child that may result on separation from the parents. Whether PPIA decreases child anxiety during induction and affects the long-term behavior effects of surgery and anesthesia remain controversial. Common objections to PPIA include concern about disruption of the OR routine, compromising operative sterility, crowded ORs, and a possible adverse reaction of the parent. For some children, their behavioral response to stress may be more negative when a parent is present than when the parent is absent.<sup>59</sup> In several reports, PPIA resulted in disruptive behavior, parents refusing to leave the room when requested, and even removal of a child from the OR by a grandmother during the second stage of anesthesia.<sup>60,61</sup> However, one report has described a 4-year experience with 3086 children in a freestanding ambulatory surgery center in which no parent needed to be escorted from the OR because of undue anxiety and only two parents developed syncope, with prompt recovery.<sup>62</sup> Despite objections, the prevalence of PPIA is becoming more common in the United States. In fact, there has been an increase in the overall prevalence in PPIA from 1995 to 2002, and geographic differences in PPIA use decreased during the 7-year period (Fig. 3-3).<sup>63,64</sup>

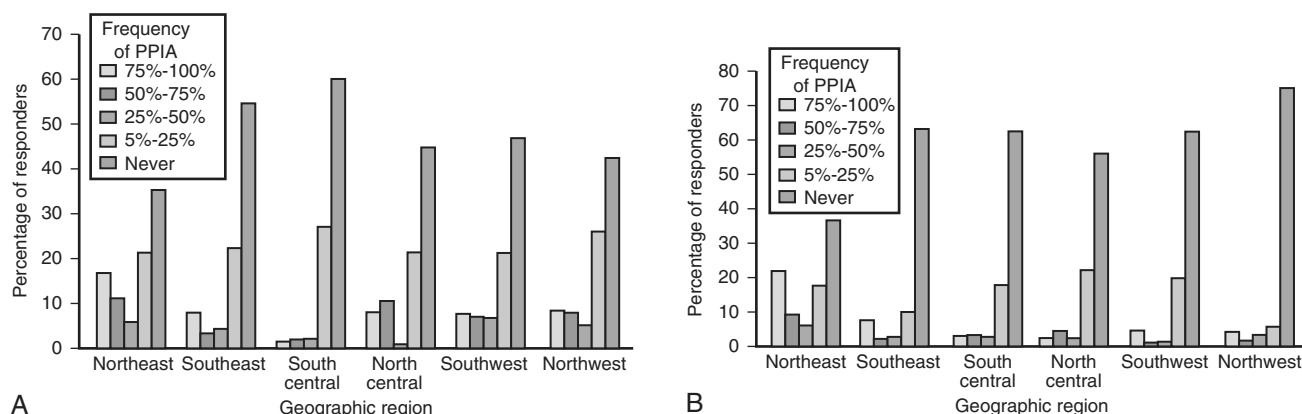

The experimental evidence to date does not clearly support the routine use of PPIA.<sup>65-67</sup> Although early studies suggested reduced anxiety and increased cooperation if parents were present during induction,<sup>68,69</sup> more recent investigations indicate that routine PPIA may *not* always be beneficial.<sup>65-67</sup> Characteristics of

the parent and child have an impact on the effectiveness of parental presence. For example, older children (over 4 years), children with a "calm" and less active baseline temperament, parents with less situational anxiety, and parents with lower external locus of control benefit most from PPIA.<sup>30,65</sup> The match between parent and child anxiety level also appears to be important. Calm children with anxious parents do more poorly during induction when compared with calm children with calm parents or anxious children with either calm or anxious parents.<sup>30</sup> When interpreting the results of these studies, however, several factors should be considered. First, the design of a randomized controlled study, while considered a gold standard in research, may *not* reflect the practice of *all* anesthesiologists. That is, although a randomized controlled study is applicable to centers that offer PPIA for *all* parents, it may not be applicable to centers in which each request for PPIA is considered individually based on personality characteristics of each child and parent. Such centers may have different results with PPIA than were demonstrated in experimental studies. Second, allowing PPIA without adequate preparation of the parent may be counterproductive. Some parent behaviors, such as criticism, excessive reassurance, and commands, are associated with greater distress.<sup>70</sup>

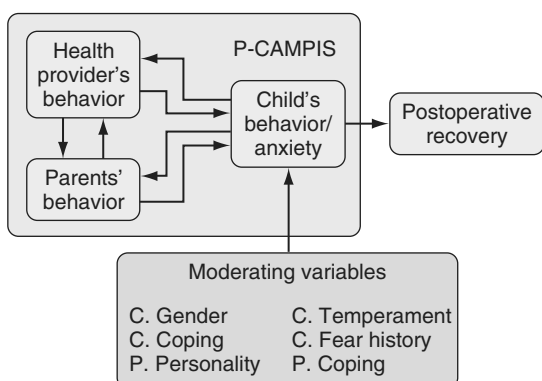

Given these drawbacks, interest in this area has begun to shift toward an emphasis on what parents actually do during induction of anesthesia. The development of a new tool for assessing child and adult behavior in the perioperative setting (Perioperative Child-Adult Medical Procedure Interaction Scale [P-CAMPIS]) has been developed to facilitate such research (Fig. 3-4).<sup>71</sup> Preliminary validation of this measure indicates that parental behavior affects the child's anxiety during induction much as it affects a child's distress during immunizations.

### The Preoperative Interview

Although not obvious, the preoperative interview is a behavioral intervention that is routinely administered to *all* children undergoing anesthesia and surgery.<sup>72</sup> It is clear that anesthesiologists have an ethical and legal responsibility to disclose to children

**FIGURE 3-3 A**, Frequency of parental presence during induction of anesthesia (PPIA) practice in the United States as of 2002. **B**, Frequency of PPIA practice in the United States as of 1995/1996. Data reported are medians (range, 0%-100%). (From Kain ZN, Caldwell-Andrews AA, Krivutza DM, et al. Trends in the practice of parental presence during induction of anesthesia and the use of preoperative sedative premedication in the United States, 1995-2002: Results of a follow-up national survey. *Anesth Analg* 2004;98:1252-9.)

**FIGURE 3-4** The conceptual framework that underlies the relation between a child's preoperative anxiety, parental behaviors, health care provider's behaviors, moderating variables, and postoperative recovery. C, Child; P, parent; P-CAMPIS, Perioperative Child-Adult Medical Procedure Interaction Scale. (From Caldwell-Andrews AA, Blount RL, Mayes LC, Kain ZN. Behavioral interactions in the perioperative environment: a new conceptual framework and the development of the perioperative child-adult medical procedure interaction scale. *Anesthesiology* 2005;103:1130-5.)

and parents detailed anesthetic risk information when obtaining informed consent, but how far this disclosure must extend remains controversial. A common reason given for not providing detailed anesthetic risk information is that it may increase the child's or parents' anxiety. Comparative studies investigating anxiety levels in adult patients given a limited amount of information, versus more detailed information concerning procedural and anesthetic risks, report conflicting results. Although early studies provided mixed data regarding whether detailed information delivered preoperatively increased anxiety,<sup>73-75</sup> several studies in the United States and Australia have demonstrated that patients and parents who received detailed information, including numerical estimates of anesthesia-related complications, were no more anxious than those given minimal information regarding risks.<sup>76-78</sup> Furthermore, parents have expressed their desire to have as much perioperative information about their child's

surgery as possible,<sup>77</sup> and even children have expressed a desire for detailed perioperative information, including information about pain, anesthesia, and potential complications.<sup>79</sup> Thus, the presentation of very detailed anesthetic information of what might go wrong should not increase parental or patient anxiety and has the advantage of allowing for fully informed choices. It should be emphasized, however, that anesthesiologists should note the particular coping style of the parents. Parents use different strategies to cope with or handle difficult, unclear, or unpleasant life experiences, such as a child undergoing surgery. Whereas some parents try to avoid information about unpleasant or unclear situations ("avoidance behavior"), others may seek any available information ("monitoring behavior").<sup>80</sup> Although a "monitoring" parent will benefit from a large amount of perioperative information, an "avoiding" parent may react to the information with increased anxiety and distress. Thus, the amount of information provided should be tailored to the needs of the individual parent.

### HEALTH CARE PROVIDER INTERVENTIONS

In addition to behavioral interventions targeting children and their parents, a promising new line of research supports the use of behavioral interventions targeting health care providers—both anesthesiologists and nurses. Specifically, an empirically derived intervention titled Provider-Tailored Intervention for Perioperative Stress (P-TIPS) was shown to be successful in changing anesthesiologist and nurse behaviors in the perioperative setting and represents a new clinical avenue for decreasing perioperative anxiety in children.<sup>81</sup> The development of P-TIPS was based on research documenting that adult behaviors (parents and health care providers) affect children's distress during invasive medical procedures, including surgery. Specifically, the use of distraction, nonprocedural talk, and humor are conceptualized as "coping promoting" behaviors and have been shown to decrease children's distress.<sup>82-88</sup> Conversely, adults' use of reassurance, apology, empathy, criticism, or allowing the child too much control over the medical procedure are conceptualized as "distress promoting" behaviors and lead to increased distress in children.<sup>82,87-90</sup> With P-TIPS, a new behavior that affected child distress also emerged: medical reinterpretation (i.e., reconceptualizing medical experiences and equipment as nonthreatening) and was found to

increase a child's coping when used with medical experiences that were in the child's immediate environment, but increase distress when used in reference to objects outside of the immediate environment.<sup>87</sup>

Preliminary investigation revealed that P-TIPS was successful at both increasing desired behaviors (coping promoting) and decreasing undesired (distress promoting) behaviors among health care providers.<sup>81</sup> Both resident and attending anesthesiologists were included in this study and evidenced behavior change, as did OR nurses, who were charged with not only changing their own behaviors, but with changing parent behaviors in the perioperative setting as well. In fact, nurses demonstrated appropriate behavior change and, in turn, parents demonstrated increases in desired and decreases in undesired behaviors. One important benefit to the type of approach offered by P-TIPS is that it is not necessary to conduct individual training with parents of children undergoing surgery, rather health care providers who interact with multiple children and parents are targeted, which reduces both logistical and financial constraints of behavioral interventions.

### PHARMACOLOGIC INTERVENTIONS

The primary goals of administering a premedication to children are to facilitate an anxiety-free separation from their parents and a smooth, stress-free induction of anesthesia. Other effects that may be achieved by pharmacologic preparation of the child include amnesia, anxiolysis, prevention of physiologic stress (e.g., avoiding tachycardia in patients with cyanotic congenital heart disease), and analgesia (see Chapter 4).

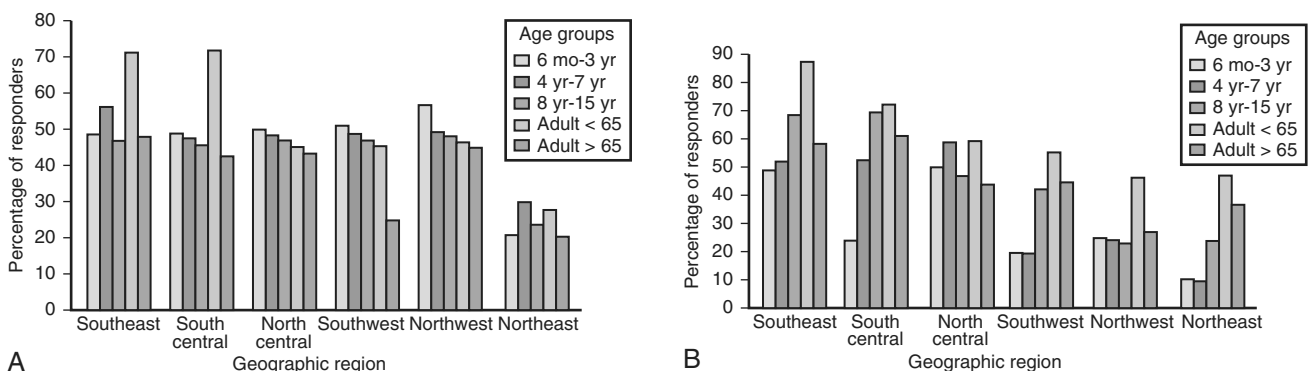

The pattern of use of sedative premedications in the United States has changed over the past decade. Premedication use varied widely among age groups and geographic locations in 1996.<sup>63</sup> Premedication sedative drugs were least often prescribed for children younger than 3 years of age and most often prescribed for adults younger than 65 years of age (25% vs. 75%). When analyzed by geographic location, sedative premedications were used least often in the southwest and northeast regions and most often in the southeast region. A follow-up study revealed several interesting changes (Fig. 3-5).<sup>64</sup> Most notably, the overall number of children undergoing surgery with premedication increased from 30% to 50%. There was also significantly less geographic variability in premedication use in 2002 than there was in 1996. In both years, the most commonly used sedative premedication in the

preoperative holding area was midazolam, followed by ketamine, transmucosal fentanyl, and meperidine. When data from several survey studies were reviewed, it was noted that anesthesiologists from the United States who allowed PPIA *least* used sedative premedication most frequently.<sup>63,91</sup> Thus, most anesthesiologists in the United States use either parental presence or sedative premedication to treat preoperative anxiety in children.

### PHARMACOLOGIC INTERVENTIONS VERSUS BEHAVIORAL INTERVENTIONS

When pharmacologic interventions are directly compared with behavioral interventions, children receiving a sedative are less anxious and more compliant than those who are accompanied to the OR by a parent.<sup>67</sup> Interestingly, parental anxiety is also decreased when the child receives a premedication. Examining both sedative premedication and PPIA revealed that a combination of PPIA and sedative premedication was more effective than medication alone for reducing parent anxiety and improving parent satisfaction.<sup>92</sup> However, PPIA offered no additional anxiolysis for children who received a sedative preoperatively. Nonetheless, parents who accompanied their sedated children into the operating rooms were themselves significantly less anxious and more satisfied both with the separation process and with the overall anesthetic, nursing, and surgical care provided. It is important to note that these parents had no preparation for their presence at anesthesia induction. Premedication combined with an advanced behavioral preparation resulted in similar outcomes on child and parent anxiety at induction and child compliance with induction.<sup>48</sup> Furthermore, children who received behavioral preparation evidenced significantly less emergence delirium and required less analgesia in the recovery room compared with children who received only premedication.

In conclusion, although sedative premedications are effective for treatment of preoperative anxiety, they should *not* be used routinely in all children undergoing surgery. Their use should be directed to children who are at a significant risk for the development of preoperative anxiety. Variables, such as age, duration of surgery, and potential recovery delays, should also be considered. However, it is important to not withhold premedication if that premedication would likely be of benefit to a selected child. For example, a child undergoing a very brief procedure who is very anxious would likely benefit from a premedication regardless of the negative effects on recovery and discharge.

**FIGURE 3-5 A,** Frequency of sedative premedication practice in the United States as of 2002. **B,** Frequency of sedative premedication practice in the United States as of 1996. Data reported are medians (range, 0%-100%). (From Kain ZN, Caldwell-Andrews AA, Krivutza DM, et al. Trends in the practice of parental presence during induction of anesthesia and the use of preoperative sedative premedication in the United States, 1995-2002: Results of a follow-up national survey. *Anesth Analg* 2004;98:1252-9.)

## Postoperative Outcomes

Four decades ago, it was proposed that moderate levels of preoperative anxiety in adult patients were associated with good postoperative behavioral recovery, whereas low and high levels of preoperative anxiety were associated with poor behavioral recovery.<sup>93</sup> Although this theory is intriguing, these studies were based on descriptive data from nonrandom, limited samples and retrospective reports of questionable validity. Subsequent studies have reported a linear rather than a curvilinear relationship between anxiety level and postoperative behavioral recovery.<sup>94,95,96,97</sup> In addition, increased preoperative anxiety in adult patients correlates with increased postoperative pain, increased postoperative analgesic requirements, prolonged recovery and hospital stay, and behavioral changes after surgery.<sup>23,98-101</sup> Anxious children have been shown to experience significantly more pain both during the hospital stay and over the first 3 days at home<sup>102</sup> (Fig. 3-6). During home recovery, anxious children also consumed significantly more codeine and acetaminophen compared with nonanxious children. Anxious children also had a greater incidence of emergence delirium (9.7% vs. 1.5%), postoperative anxiety, and sleep problems compared with nonanxious children. The investigators concluded that preoperative anxiety in young children undergoing surgery is associated with a more painful postoperative recovery and a greater incidence of disrupted sleep and other problems.<sup>102</sup> Moreover, a recent study suggests that perioperative anxiety—not just preoperative anxiety—is associated with poorer surgical outcomes.<sup>103</sup> That is, children have traditionally been conceptualized as anxious or nonanxious via assessment of anxiety in children before surgery, such as in the presurgical holding area or at the point of induction in the OR. By contrast, this study examined anxiety in children throughout the perioperative continuum (pre- and postoperatively) and replicated findings of associations between perioperative anxiety and both postoperative pain and new-onset behavioral changes.<sup>103</sup>

The assumption that minimal preoperative anxiety predicts good postoperative outcomes underlies many interventions in which the aim is to reduce preoperative anxiety. To date, preoperative preparation studies in adult patients have used diverse postoperative outcome measures, including intensity of pain, analgesic requirements, postsurgical complications, length of hospital stay, patient satisfaction, blood cortisol levels, changes in blood pressure and heart rate, and behavioral indices of recovery.<sup>96,104-111</sup> Reviews of this research, while critical of the methodology, concluded that psychologically prepared adult patients

**FIGURE 3-6** Children's self-reported postoperative pain as a function of preoperative anxiety. (From Kain ZN, Mayes LC, Caldwell-Andrews AA, et al. Preoperative anxiety, postoperative pain, and behavioral recovery in young children undergoing surgery. *Pediatrics* 2006;118:651-8.)

may have improved postoperative recovery.<sup>99,104,112,113</sup> As noted previously, children who received the ADVANCE preoperative program were less anxious preoperatively and experienced a reduced incidence of emergence delirium, had a briefer stay in the recovery area, reported less postoperative pain, and required fewer analgesics as compared with a control group.<sup>48</sup>

## EMERGENCE DELIRIUM

The first maladaptive behavioral change in children that may be evident after surgery is emergence delirium. This phenomenon is characterized by nonpurposeful restlessness and agitation, thrashing, crying or moaning, and disorientation. Published studies have reported up to 18% of all children undergoing surgery and anesthesia develop emergence delirium.<sup>114</sup> Factors such as young age, previous surgery, type of procedure, and type of anesthetic all affect the incidence of emergence delirium.<sup>114,115</sup> Preoperative anxiety has also been shown to be related to emergence delirium.<sup>115,116</sup> Furthermore, preoperative anxiety, emergence delirium, and postoperative maladaptive behavior changes have been shown to be closely related phenomena. One study found that the odds of children experiencing marked symptoms of emergence delirium increased in proportion with their preoperative anxiety scores, and that the odds of the onset of new maladaptive behavioral changes also increased with the presence of emergence delirium.<sup>102</sup> This finding is highly significant to practicing clinicians, who can now predict the development of adverse postoperative phenomena, such as emergence delirium and postoperative behavioral changes, based on levels of preoperative anxiety.

## SLEEP CHANGES

Changes in sleep patterns in the postoperative period have been well documented in adults and children. One study reported that 47% of children experienced sleep disturbances after anesthesia<sup>117</sup> and approximately 14% of children showed significant decreases in percentage of time spent asleep (in both REM and non-REM sleep) after surgery. The most common predictor of sleep difficulties after surgery has been postoperative pain,<sup>118</sup> but psychological variables have also been shown to be important. Specifically, parental personality measures of anxiety and child measures of externalizing behavior have both been found to predict sleep efficiency in children after surgery.

## OTHER BEHAVIORAL CHANGES

In addition to sleep, changes in daytime behavior in children after surgery and anesthesia have also been documented. A number of studies have indicated that up to 60% of children undergoing outpatient surgery may develop negative *postoperative* behavioral changes within 2 weeks after surgery.<sup>119-121</sup> These negative postoperative behaviors include sleep and eating disturbances, separation anxiety, apathy, withdrawal, and new-onset enuresis.<sup>23,103,121</sup> In fact, some children may develop long-lasting psychological effects that could have an impact on their responses to subsequent medical care. Interference with normal development has also been described.<sup>122</sup> A significant number of children demonstrate new negative behaviors postoperatively, such as new onset of general anxiety, nighttime crying, enuresis, separation anxiety, temper tantrums, and sleep or eating disturbances. These behaviors may occur in up to 44% of children 2 weeks after surgery; about 20% of these children continue to demonstrate negative behaviors up to 6 months postoperatively.<sup>23</sup> The postoperative negative behavioral changes are likely the result of an interaction between the distress the child experiences during the

perioperative period and the individual personality characteristics of the child. Previously, variables such as the age and temperament of the child and the state and trait anxiety of the parent have been identified as predictors for the occurrence of negative postoperative behavioral changes.<sup>23</sup> There is a paucity of data, however, regarding a possible association between the distress the child experiences during induction of anesthesia and the occurrence of these negative postoperative behavioral changes. One investigation concluded that extreme anxiety, such as that which occurs with a “stormy induction” of anesthesia, was associated with an increased incidence of postoperative negative behavioral changes.<sup>123</sup> The investigators recommend that anesthesiologists advise parents of children who are anxious during induction of anesthesia of the increased likelihood that their children will develop postoperative negative behavioral changes, such as nightmares, separation anxiety, and aggression toward authority.<sup>123</sup>

Because the anxiety level of the child and mother in the preoperative holding area predicts the occurrence of negative postoperative behavioral problems,<sup>23</sup> it can be hypothesized that if sedative premedications reduce anxiety of the child and the parents in the preoperative holding area, they may also have an effect on negative postoperative behavioral outcomes.<sup>70</sup> One investigation of premedicated children found a significantly reduced incidence of negative behavioral changes during week 1 after surgery.<sup>124</sup> This study suggests that reducing anxiety in the holding area has a beneficial effect on the behavior of the child preoperatively, as well as in the immediate postoperative period.<sup>124</sup>

## Intraoperative Clinical Outcomes

It is commonly believed that increased anxiety before surgery is associated with increased intraoperative anesthetic requirements.<sup>95,125</sup> This belief, however, is based on early studies of questionable scientific validity,<sup>126,127</sup> many of which did not use validated scales to measure anxiety or control for potential confounding variables, such as sedative premedication and the surgical procedure.<sup>22</sup> One investigation indicated that an increased baseline (i.e., trait) anxiety is associated with increased intraoperative anesthetic requirements in adults. The investigators in that study controlled for the surgical procedure, used bispectral electroencephalographic analysis (bispectral index) monitoring to ensure the same anesthetic depth in all patients, and used a total intravenous anesthetic technique to ease the calculation of the anesthetics used.<sup>128</sup> As such, it does seem clear that an increased baseline, or trait, anxiety is associated with increased intraoperative anesthetic requirements.

Although several review articles suggest that increased anxiety before surgery and anesthesia is associated with postoperative nausea and vomiting,<sup>129</sup> experimental data suggest that a child's anxiety in the preoperative holding area is not predictive of postoperative nausea and vomiting either in the postanesthesia care unit or at home.<sup>130</sup>

## Summary

Approximately 3 million children undergo anesthesia and surgery in the United States every year. It is reported that 40% to 60% of these children develop behavioral stress before their surgery. Multiple interventions have been proposed to treat the preoperative behavioral stress response in children. Currently, however, there is a trend toward a *reduction* in both behavioral and

pharmacologic preoperative interventions aimed at children. One possible reason for this trend may be that some physicians believe that reducing parental anxiety during the preoperative period is a surrogate outcome. Rather than evaluating the effects of various preoperative interventions on the transient preoperative behavior, some believe that we should concentrate on research directed at demonstrating that a reduction in preoperative anxiety can dramatically change postoperative outcomes. It is well established that low levels of preoperative anxiety are associated with good postoperative behavioral recovery, whereas moderate and high levels of preoperative anxiety are associated with poor postoperative behavioral recovery. A far more intriguing question is the possible association between preoperative anxiety and postoperative clinical recovery; quality research needs to be developed regarding the relationship between preoperative anxiety and postoperative recovery. Further, shifting research focus toward development of economically and clinically feasible interventions that can be delivered to the large numbers of children undergoing surgery each year is vital. Accordingly, incorporating web-based technologies and changes in institutional practice (i.e., changing health care provider behaviors) represent two promising new avenues of intervention.

Kain ZN, Caldwell-Andrews AA, Mayes LC. Parental intervention choices for children undergoing repeated surgeries. *Anesth Analg* 2003;96:970-5.

*Children were assigned to parental presence at induction (PPLA), premedication with midazolam, PPLA + premedication, or no intervention at initial surgery. Children were then followed up at subsequent surgery and parental preference for intervention was assessed. Of parents whose children were assigned to PPLA, 70% would choose PPLA as intervention again. Of those assigned to premedication, only 23% would choose premedication again. Regardless of prior intervention, parents at subsequent surgery favored PPLA. Children's and parents' anxiety also affected parental preference for intervention.*

Kain ZN, Caldwell-Andrews AA, Mayes LC, et al. Family-centered preparation for surgery improves perioperative outcomes in children: a randomized controlled trial. *Anesthesiology* 2007;106:65-74.

*This study evaluated the efficacy of a family-centered behavioral preparation program (ADVANCE) for children undergoing outpatient surgery (n = 408). Children were randomly assigned to no intervention, ADVANCE + PPLA, PPLA without advance, and midazolam premedication. Children in ADVANCE + PPLA displayed significantly less anxiety at induction than no intervention or PPLA alone. Anxiety and compliance in the ADVANCE + PPLA group were comparable to premedication. ADVANCE + PPLA was superior to all other groups on postoperative recovery variables.*

Kain ZN, Hofstadter MB, Mayes LC, et al. Midazolam: Effects on amnesia and anxiety in children. *Anesthesiology* 2000;93:676-84.

*These researchers assessed children's memory at baseline and in four randomly assigned groups (5, 10, and 20 minutes post midazolam administration, and no midazolam [control]) of children (n = 118). Compared with controls, recall memory was impaired for children in the 10- and 20-minute post-midazolam groups. All midazolam groups demonstrated recognition deficits when compared with controls. In terms of perioperative anxiety, significant effects of midazolam were evidenced at approximately 15 minutes.*

Kain ZN, Mayes LC, Caldwell-Andrews AA, et al. Preoperative anxiety and postoperative pain and behavioral recovery in young children undergoing surgery. *Pediatrics* 2006;118:651-8.

*This study assessed preoperative anxiety and postoperative pain and behavioral outcomes after surgery in 241 children. Children who displayed more preoperative anxiety were rated as having higher pain after surgery by their parents. Anxious children also consumed more analgesics at home after surgery and were more likely to experience emergence delirium and postoperative sleep disturbances.*

Kain ZN, Mayes LC, Wang SM, et al. Parental presence during induction of anesthesia vs. sedative premedication: which intervention is more effective? *Anesthesiology* 1998;89:1147-56.

*Eighty-eight children undergoing outpatient surgery were randomly assigned to parental presence at anesthesia induction, midazolam premedication, or no intervention. Children in the midazolam group exhibited significantly less perioperative anxiety than children in the parental presence or no intervention groups.*

## Preparation of Children for Anesthesia

### FASTING

Infants and children are fasted before sedation and anesthesia to minimize the risk of pulmonary aspiration of gastric contents. In a fasted child, only the basal secretions of gastric juice should be present in the stomach. In 1948, Digby Leigh recommended a 1-hour preoperative fast after clear fluids. Subsequently, Mendelson reported a number of maternal deaths that were attributed to aspiration at induction of anesthesia.<sup>1</sup> During the intervening 20 years, the fasting interval before elective surgery increased to 8 hours after all solids and fluids. In the late 1980s and early 1990s, an evidence-based approach to the effects of fasting intervals on gastric fluid pH and volume concluded that fasting more than 2 hours after clear fluids neither increased nor decreased the risk of pneumonitis should aspiration occur.<sup>2-10</sup> In the past, the risk for pneumonitis was reported to be based on two parameters: gastric fluid volume greater than 0.4 mL/kg and pH less than 2.5; however, these data were never published in a peer-reviewed journal.<sup>1,11</sup> In a monkey, 0.4 mL/kg of acid instilled endobronchially, equivalent to 0.8 mL/kg aspirated tracheally, resulted in pneumonitis.<sup>12</sup> Using these corrected criteria for acute pneumonitis (gastric residual fluid volume greater than 0.8 mL/kg and pH less than 2.5), studies in children demonstrated no additional risk for pneumonitis when children were fasted for only 2 hours after clear fluids.<sup>2-9</sup>

The incidence of pulmonary aspiration in modern routine elective pediatric or adult cases without known risk factors is

small.<sup>13-16</sup> This small risk is the result of a number of factors including the preoperative fasting schedule. The half-life to empty clear fluids from the stomach is approximately 15 minutes (Fig. 4-1); as a result, 98% of clear fluids exit the stomach in children by 1 hour. Clear liquids include water, fruit juices without pulp, carbonated beverages, clear tea, and black coffee. Although fasting for 2 hours after clear fluids ensures nearly complete emptying of the residual volume, extending the fasting interval to 3 hours introduces flexibility in the operative schedule. The potential benefits of a 2-hour fasting interval after clear fluids include a reduced risk of hypoglycemia, which is a real possibility in children who are debilitated, have chronic disease, are poorly nourished, have metabolic dysfunction, or are preterm or formerly preterm infants.<sup>17-20</sup> Additional benefits include decreased thirst, decreased hunger (and thus reduced temptation that the fasting child will “steal” another child’s food), decreased risk for hypotension during induction, and improved child cooperation.<sup>2,11,21</sup>

A scheduled operation on a preterm infant or neonate may occasionally be delayed, thus extending the period of fasting to a point that could be potentially dangerous (i.e., from hypoglycemia or hypovolemia). In this circumstance, the infants should be given glucose-containing intravenous maintenance fluids before induction of anesthesia. Alternatively, if the period may be protracted, the infant should be offered clear fluids orally until 2 hours before induction.

Breast milk, which can cause significant pulmonary injury if aspirated,<sup>22</sup> has a very high and variable fat content (determined by maternal diet), which will delay gastric emptying.<sup>21</sup> *Breast milk*

**FIGURE 4-1** Clear liquids are rapidly absorbed from the stomach with a half-life of approximately 15 minutes. In this figure, for example, 200 mL of apple juice would be reduced to 12.5 mL after 60 minutes. (Data abstracted from Hunt JN, MacDonald M. The influence of volume on gastric emptying. *J Physiol* 1954;126:459-74.)

*should not be considered a clear liquid.*<sup>23</sup> Two studies estimated the gastric emptying times after clear fluids, breast milk, or formula in full-term and preterm neonates.<sup>24,25</sup> The emptying times for breast milk in both age groups were substantively greater than for clear fluids, and the gastric emptying times for formula were even greater than those for breast milk. With half-life emptying times for breast milk of 50 minutes and for formula of 75 minutes, fasting intervals of at least 3.3 hours for breast milk and 5 hours for formula are required. More importantly, perhaps, was the large (15%) variability in gastric emptying times for breast milk and formula in full-term infants (E-Fig. 4-1). Based in part on these data, the Task Force on Fasting of the American Society of Anesthesiologists (ASA) issued the following guidelines: for breast milk, 4 hours; and for formula, 6 hours (Table 4-1).<sup>10</sup>

Children who have been chewing gum must dispose of the gum by expectorating it, not swallowing it. Chewing gum increases both gastric fluid volume and gastric pH in children, leaving no clear evidence that it affects the risk of pneumonitis should aspiration occur.<sup>26</sup> Consequently, we recommend that if the gum is discarded, then elective anesthesia can proceed without additional delay. If, however, the child swallows the gum, then surgery should be cancelled, because aspirated gum at body temperature may be very difficult to extract from a bronchus or trachea.

Children can never be trusted to fast. Therefore, anesthesiologists must always be suspicious and question children just before induction as to whether they have eaten or drunk anything (although the veracity of the answer may always be questioned as well). It is not unusual to find bubble gum, candy, or other food in a child's mouth. This is another reason to ask children to open their mouth fully and stick out their tongue during the preoperative examination of the airway.

When the anesthesiologist suspects that the child has a full stomach, induction of anesthesia should be adjusted appropriately. The incidence of pulmonary aspiration of gastric contents during elective surgery in children ranges from 1:1163 to 1:10,000, depending on the study.<sup>13-15,27</sup> In contrast, the frequency of pulmonary aspiration in children undergoing emergency procedures is several times greater, 1:373 to 1:4544.<sup>27</sup> Risk factors for perianesthetic aspiration included neurologic or esophagogastric abnormality, emergency surgery (especially at

**TABLE 4-1** Preoperative Fasting Recommendations in Infants and Children

Clear liquids*	2 hours
Breast milk	4 hours
Infant formula	6 hours†
Solids (fatty or fried foods)	8 hours

From Warner MA, Caplan RA, Epstein B. Practice guidelines for preoperative fasting and the use of pharmacologic agents to reduce the risk of pulmonary aspiration: application to healthy patients undergoing elective procedures. A report by the American Society of Anesthesiologists Task Force on Preoperative Fasting. *Anesthesiology* 1999;90:896-905.

\*Include only fluids without pulp, clear tea, or coffee without milk products.

†Some centers allow plain toast (no dairy products) up to 6 hours prior to induction.

night), ASA physical status 3 to 5, intestinal obstruction, increased intracranial pressure, increased abdominal pressure, obesity, and the skill and experience of the anesthesiologist.<sup>14</sup>

The majority of aspirations in children occur during induction of anesthesia, with only 13% occurring during emergence and extubation. In contrast, 30% of the aspirations in adults occur during emergence. Bowel obstruction or ileus was present in the majority of infants and children who aspirated during the perioperative period in one study, with the risk increasing in children younger than 3 years of age.<sup>27</sup> A combination of factors predispose the infant and young child to regurgitation and aspiration, including decreased competence of the lower esophageal sphincter, excessive air swallowing while crying during the preinduction period, strenuous diaphragmatic breathing, and a shorter esophagus. In one study, almost all cases of pulmonary aspiration occurred either when the child gagged or coughed during airway manipulation or during induction of anesthesia when neuromuscular blocking drugs were not provided or before the child was completely paralyzed.<sup>27</sup>

When children do aspirate, the morbidity and mortality are exceedingly small for elective surgical procedures and generally reflect their ASA physical status. In general, most ASA 1 or 2 patients who aspirate clear gastric contents have minimal to no sequelae.<sup>13,27</sup> If clinical signs of sequelae from an aspiration in a child are going to occur, they will be apparent within 2 hours after the regurgitation.<sup>27</sup> The mortality rate from aspiration in children is exceedingly low, between zero and 1:50,000.<sup>13,14,27</sup>

## PIERCINGS

Body piercing is common practice in adolescents and young adults. Single or multiple piercings may appear anywhere on the body. To minimize the liability and risk of complications from metal piercings, they must be removed before surgery. Complications that may occur if they are left in situ during anesthesia are listed in E-Table 4-1.<sup>28-30</sup>

## PRIMARY AND SECONDARY SMOKING

### Primary Smoking

Unfortunately, cigarette smoking is not only limited to adults. Each day, about 6000 American adolescents smoke their first cigarette. Of these, 50% will become regular smokers. Even though two thirds of these adolescents will regret taking up the habit and will want to quit, three quarters of them will not succeed because they are addicted to the nicotine. Sadly, about one third of those who cannot quit will die prematurely due to

**E-FIGURE 4-1** Percentage of gastric feeding remaining in the stomach after water, breast milk, or formula versus time after ingestion by infants. Data are expressed as mean  $\pm$  standard deviation. The time to 50% gastric emptying of water was 15 minutes, of breast milk 50 minutes, and of formula 80 minutes. On the basis of these data, about 95% emptying (i.e., four half-lives) of gastric feedings should occur in about 1 hour after water, about 3.5 hours after breast milk, and about 5.5 hours after infant formula. However, note the wide standard deviations for the emptying times for breast milk and formula. (From Cavell B. Gastric emptying in preterm infants. *Acta Paediatr Scand* 1979;68:725-30; Cavell B. Gastric emptying in infants fed human milk or infant formula. *Acta Paediatr Scand* 1981;70:639-41.)

**E-TABLE 4-1** Complications from Metal Piercings

#### Electrocautery Burns

All tissues adjacent to metal piercings are at risk; to avoid burns, use bipolar cautery or an harmonic knife; the cautery grounding pad should be remote from the piercing.

#### Airway Difficulty with Intubation

Laryngospasm and hypoxia  
Pulmonary aspiration

#### Tissue Damage

Necrosis  
Bleeding

Modified from Rosenberg AD, Young M, Bernstein RL, Albert DB. Tongue rings: just say no. *Anesthesiology* 1998;89:1279-80; Wise H. Hypoxia caused by body piercing. *Anaesthesia* 1999;54:1129.

smoking.<sup>31</sup> Even though the rate of new smokers in North America has waned in the past 2 decades, this has been offset by the increasing rate of new smokers in other continents. Media, peer influence, and secondhand smoke exposure play a significant role in influencing initiation of smokers in this age group.<sup>32</sup>

Smoking is known to increase blood carboxyhemoglobin concentrations, decrease ciliary function, decrease functional vital capacity (FVC) and the forced expiratory flow in midphase (FEF<sub>25%-75%</sub>), and increase sputum production. There is extensive evidence that smokers undergoing surgery are more likely to develop wound infections and postoperative respiratory complications.<sup>33</sup> Although stopping smoking for 2 days decreases carboxyhemoglobin levels and shifts the oxyhemoglobin dissociation curve to the right, stopping for at least 6 to 8 weeks is necessary to reduce the rate of postoperative pulmonary complications.<sup>34,35</sup>

We seldom interview our patients 8 weeks before surgery, but because the perioperative period is the ideal time to abandon the smoking habit permanently, anesthesiologists can perhaps play a more active role in facilitating this process. Physician communication with adolescents regarding smoking cessation has been shown to positively impact their attitudes, knowledge, intentions to smoke, and quitting behaviors.<sup>36</sup> In summary, during the preoperative visit with adolescents, anesthesiologists should inquire about cigarette smoking and emphasize the need to stop the habit by offering measures to ameliorate the withdrawal (e.g., nictoine patch).

### Secondary Smoking

The World Health Organization has estimated that approximately 700 million children, or almost half of the children in the world, are exposed to environmental tobacco smoke (ETS).<sup>37</sup> Children exposed to ETS are more likely to have asthma, otitis media,<sup>38</sup> atopic eczema, hay fever,<sup>39</sup> and dental caries.<sup>40</sup> There is also an increased rate of lower respiratory tract illness in infants with ETS exposure.<sup>41,42</sup>

Several authors have demonstrated that ETS results in increased perioperative airway complications in children. In one study<sup>43</sup> of children receiving general anesthesia, urinary cotinine, the major metabolite of nicotine, was used as a surrogate of ETS. A strong association was found between passive inhalation of tobacco smoke and airway complications on induction and emergence from anesthesia. Other investigators confirmed that ETS exposure was associated with an increased frequency of respiratory complications during emergence and recovery from anesthesia.<sup>44</sup>

The evidence against ETS is clearly overwhelming. During the preoperative visit, the anesthesiologist must question the child's exposure to ETS by asking parents or guardians about smoking within the household. This is an opportune time to educate parents and guardians about the dangers of ETS for their children.

### PSYCHOLOGICAL PREPARATION OF CHILDREN FOR SURGERY

The perioperative period is stressful and anxiety-provoking for the child and family; many parents express more concern about the risks of anesthesia than those of the surgery. The factors that influence the ability of the child and family to cope with the stress of surgery include family dynamics, the child's developmental and behavioral status and cultural biases, and our ability to explain away misperceptions and misinformation.

Because of logistics and today's practice constraints, there is limited time to evaluate family dynamics and establish rapport. It is therefore vital for the anesthesiologist to interact directly with the child in a manner that is consistent with the child's level of development. A specific child-oriented approach by the anesthesiologist, surgeon, nurses, and hospital staff is required. Preoperative evaluation is usually simplified once the basic concepts of how to evaluate a child are understood.

Although the preoperative evaluation and preparation of children are similar to those of adults from a physiologic standpoint, the psychological preparation of infants and children is very different (see also Chapter 3). Many hospitals have an open house or a brochure to describe the preoperative programs available to parents before the day of admission.<sup>45</sup> However, printed material should not replace verbal communication with nursing and medical staff.<sup>46</sup> Anesthesiologists are encouraged to participate in the design of these programs so that they accurately reflect the anesthetic practice of the institution. The preoperative anesthetic experience begins at the time parents are first informed that the child is to have surgery or a procedure that requires general anesthesia. Parental satisfaction correlates with the comfort of the environment and the trust established between the anesthesiologist, the child, and the parents.<sup>47</sup> If parental presence during induction is deemed to be in the child's best interest, a parental educational program that describes what the parent can expect to happen if he or she accompanies the child to the operating room can significantly decrease parents' anxiety and increase their satisfaction.<sup>48</sup> The greater the understanding and amount of information the parents have, the less anxious they will be, and this attitude, in turn, will be reflected in the child.<sup>49,50</sup>

Informed consent should include a detailed description of what the family can anticipate and our role to protect the welfare of the child. Before surgery, the anesthetic risks should be discussed in clear terms but in a reassuring manner by describing the measures that will be taken to carefully and closely monitor the safety of the child. Mentioning specific details and the purpose of the various monitoring devices may help diminish the parents' anxiety by demonstrating to them that the child will be anesthetized with the utmost safety and care. A blood pressure cuff will "*check the blood pressure*," an electrocardiographic monitor will "*watch the heartbeat*," a stethoscope will help us "*to continuously listen to the heart sounds*," a pulse oximeter will "*measure the oxygen in the bloodstream*," a carbon dioxide analyzer will "*monitor the breathing*," an anesthetic agent monitor will "*accurately measure the level of anesthesia*," and an intravenous catheter will be placed "*to administer fluid and medications as needed*." Children who are capable and their parents should be given ample opportunity to ask questions preoperatively. Finally, they should be assured that our "anesthetic prescription" will be designed specifically for their child's needs, taking into account the child's underlying medical conditions and the needs of surgery to ensure optimal conditions for surgery, the safety of the child, and analgesia.

It has been shown that parents desire comprehensive preoperative information, and that discussion of highly detailed anesthetic risk information does not increase parent's anxiety level.<sup>51</sup> Inadequate preparation of children and their families may lead to a traumatic anesthetic induction and difficulty for both the child and the anesthesiologist, with the possibility of postoperative psychological disturbances.<sup>52</sup> Numerous preoperative educational programs for children and adults have evolved to alleviate some of these fears and anxiety. They include preoperative tours of the operating rooms, educational videos, play

therapy, magical distractions, puppet shows, anesthesia consultations, and child life preparation.<sup>53</sup> The timing of the preoperative preparation has been found to be an important determinant of whether the intervention will be effective. For example, children older than 6 years of age who participated in a preparation program more than 5 to 7 days before surgery were least anxious during separation from their parents, those who participated in no preoperative preparation were moderately anxious, and those who received the information 1 day before surgery were the most anxious. The predictors of anxiety correlated also with the child's baseline temperament and history of previous hospitalizations.<sup>54</sup> Children of different ages vary in their response to the anesthetic experience (see also Chapter 3).<sup>55</sup> Even more important may be the child's trait anxiety when confronted with a stressful medical procedure.<sup>56</sup>

### Child Development and Behavior

Understanding age-appropriate behavior in response to external situations is essential (E-Table 4-2). Infants younger than 10 months of age tolerate short periods of separation from their parents. Many do not object to an inhalation induction and frequently respond to the smell of the inhalation agents by sucking or licking the mask. These infants usually do not need a sedative premedication.

Children between 11 months and 6 years of age frequently cling to their parents. In an unfamiliar environment such as a hospital, preschool children tend to become very anxious, especially if the situation appears threatening. Their anxiety may be exacerbated if they sense that their parents are anxious. Efforts to educate the parents to allay their anxiety can also reduce the child's anxiety.<sup>45,57,58</sup> A heightened anxiety response may lead to immediate postoperative maladaptive behavior, such as nightmares, eating disturbances, and new-onset enuresis. Compared with other patients, children 2 to 6 years of age are more likely to exhibit problematic behavior when separated from their parents (see also Chapter 3).<sup>55</sup> Children who display one or more of the predictive risk factors would probably benefit from a sedative premedication.<sup>59-62</sup> They are generally more content if their parents accompany them during induction or if they are sedated in the presence of their parents in a nonthreatening environment before entering the operating room (see later discussion).

Children older than 6 years of age and those who attend preschool or kindergarten are more willing to accept brief periods of separation from their parents. They tend to be more independent because of their school experience. They are better able to communicate and have a greater understanding of their environment. Their sense of curiosity and interest in new things and their trust of adults can be used to elicit their cooperation for a mask induction of anesthesia without the need for premedication.

Children ages 4 to 10 years may exhibit psychological factors that are predictive of postoperative behavior (e.g., abnormal sleep patterns, parental anxiety, aggressive behavior).<sup>63,64</sup> In addition, children who have pain on the day of the operation have behavioral problems that continue well after the pain has been relieved.<sup>65</sup> Therefore, preventing postoperative pain decreases and limits the duration of postoperative behavioral problems.

Special aspects of a child's perception of anesthesia should be anticipated; children often have the same fears as adults but are unable to articulate them. The reason and need for a surgical procedure should also be carefully explained to the child. It is important to reassure children that anesthesia is not the same as the usual nightly sleep but rather a special sleep caused by the

medicines we give during which they cannot be awakened and no matter what the surgeon does, they cannot feel pain. Many children fear the possibility that they will wake up in the middle of the anesthetic and during surgery. They should be reassured that they will awaken only after the surgery is completed.

The words the anesthesiologist uses to describe to the child what can be anticipated must be carefully chosen, because children think concretely and tend to interpret the facts literally. Examples of this are presented by the following anecdotes:

*Example 1:* A 4-year-old child was informed that in the morning she would receive a "shot" that would "put her to sleep." That night, a frantic call was received from the mother, describing a very upset child; the child thought she was going to be "put to sleep" like the veterinarian had permanently "put to sleep" her sick pet.

*Example 2:* A 5-year-old child admitted for elective inguinal herniorrhaphy received a heavy premedication and was deeply sedated on arrival in the operating room. After discharge, the parents frequently discovered him wandering about the house at night. On questioning, the child stated that he was "protecting" his family. He stated: "I don't want anyone sneaking up on you and operating while you are sleeping."

In the first example, the child's concrete thought processes misunderstood the anesthesiologist's choice of words. The second case represents a problem of communication: the child was never told he would have an operation.

The importance of proper psychological preparation for surgery should not be underestimated. Often, little has been explained to both patient and parents before the day of surgery. Anesthesiologists have a key role in defusing fear of the unknown if they understand a child's age-related perception of anesthesia and surgery (see Chapter 3). They can convey their understanding by presenting a calm and friendly face (smiling, looking at the child and making eye contact), offering a warm introduction, touching the patient in a reassuring manner (holding a child's or parent's hand), and being completely honest. Children respond positively to an honest description of exactly what they can anticipate. This includes informing them of the slight discomfort of starting an intravenous line or giving an intramuscular premedication, the possible bitter taste of an oral premedication, or breathing our magic laughing gas through the flavored mask.

The postoperative process, from the operating room to the recovery room, and the onset of postoperative pain should be described. Encourage the child and family to ask questions. Strategies to maintain analgesia should be discussed, including the use of long-acting local anesthetics; nerve blocks; neuraxial blocks; patient-controlled, nurse-controlled, or parent-controlled analgesia or epidural analgesia; or intermittent opioids (see also Chapters 41, 42, and 43).

As children age, they become more aware of their bodies and may develop a fear of mutilation. Adolescents frequently appear quite independent and self-confident, but as a group, they have unique problems. In a moment their mood can change from an intelligent, mature adult to a very immature child who needs support and reassurance. Coping with a disability or illness is often very difficult for adolescents. Because they are often comparing their physical appearance with that of their peers, they may become especially anxious when they have a physical problem. In general, they want to know exactly

**E-TABLE 4-2** Age-Specific Anxieties of Pediatric Patients

Age	Specific Type of Perioperative Anxiety
0-6 months	<ul style="list-style-type: none"> <li>• Maximum stress for parent</li> <li>• Minimum stress for infants—not old enough to be frightened of strangers</li> </ul>
6 months-4 years	<ul style="list-style-type: none"> <li>• Maximum fear of separation</li> <li>• Not able to understand processes and explanations</li> <li>• Significant postoperative emotional upset and behavior regression</li> <li>• Begins to have magical thinking</li> <li>• Cognitive development and increased temper tantrums</li> </ul>
4-8 years	<ul style="list-style-type: none"> <li>• Begins to understand processes and explanations</li> <li>• Fear of separation remains</li> <li>• Concerned about body integrity</li> </ul>
8 years-Adolescence	<ul style="list-style-type: none"> <li>• Tolerates separation well</li> <li>• Understands processes and explanations</li> <li>• May interpret everything literally</li> <li>• May fear waking up during surgery or not waking up at all</li> </ul>
Adolescence	<ul style="list-style-type: none"> <li>• Independent</li> <li>• Issues regarding self-esteem and body image</li> <li>• Developing sexual characteristics and fear loss of dignity</li> <li>• Fear of unknown</li> </ul>

Modified with permission from Cruickshank BM, Cooper LJ. Common behavioral problems. In: Greydanus DE, Wolraich ML, editors: Behavioral pediatrics. New York: Springer; 1992.

what will transpire during the course of anesthesia. Adolescents are usually cooperative, preferring to be in control and unpremedicated preoperatively. The occasional overly anxious or rambunctious adolescent, however, may benefit from preanesthetic medication.

Monitoring the attitude and behavior of a child is very useful. A child who clings to the parents, avoids eye contact, and will not speak is very anxious. A self-assured, cocky child who “knows it all” may also be apprehensive or frightened. This know-it-all behavior may mask the child’s true emotions, and he or she may decompensate just when cooperation is most needed. In some cases, nonpharmacologic supportive measures may be effective. In the extremely anxious child, supportive measures alone may be insufficient to reduce anxiety, and premedication is indicated.

Identifying a difficult parent or child preoperatively is not always easy, especially if the anesthesiologist first meets the child or family on the day of surgery and has limited time to assess the situation. Occasionally, we receive a warning regarding a difficult parent or child from the surgeon or nursing staff, based on their encounters with the family. With experience, some anesthesiologists are able to identify difficult parents and children during the short preoperative assessment and make appropriate adjustments to the anesthetic management plan.

The “veterans” or “frequent flyers” of anesthesia can also be difficult in the perioperative period. They have played the anesthesia and surgical game before and are not interested in participating again, especially if their previous experiences were negative. These children may benefit the most from a relatively heavy premedication; reviewing previous responses to premedication will aid in the adjustment of the current planned premedication (e.g., adding ketamine and atropine to oral midazolam so as to achieve a greater depth of sedation).

It is important to observe the family dynamics to better understand the child and determine who is in control, the parent or the child. Families many times are in a state of stress, particularly if the child has a chronic illness; these parents are often angry, guilt ridden, or simply exhausted. Ultimately, the manner in which a family copes with an illness largely determines how the child will cope.<sup>66</sup> The well-organized, open, and communicative family tends to be supportive and resourceful, whereas the disorganized, noncommunicative, and dysfunctional family tends to be angry and frustrated. Dealing with a family and child from the latter category can be challenging. There is the occasional parent who is overbearing and demands total control of the situation. It is important to be empathetic and understanding but to set limits and clearly define the parent’s role. He or she must be told that the anesthesiologist determines when the parent must leave the operating room; this is particularly true if an unexpected development occurs during the induction.

### Parental Presence during Induction

One controversial area in pediatric anesthesia is parental presence during induction. Some anesthesiologists encourage parents to be present at induction, whereas others are uncomfortable with the process and do not allow parents to be present. Inviting a parent to accompany the child to the operating room has been interpreted by some courts as an implicit contract on the part of the caregiver who invited the parent to participate in the child’s care; in one case, the institution was found to have assumed responsibility for a mother who suffered an injury when she

fainted.<sup>67</sup> Each child and family must be evaluated individually; what is good for one child and family may not be good for the next.<sup>68-71</sup> (See Chapter 3 for a full discussion of this and other anxiolytic strategies in children.)

If the practice of having parents present at induction is to work well, then the anesthesiologist must be comfortable with such an arrangement. No parent should ever be forced to be present for the induction of anesthesia, nor should any anesthesiologist be forced into a situation that compromises the quality of care he or she affords a child in need.

Parents must be informed about what to anticipate in terms of the operating room itself (e.g., equipment, surgical devices), in terms of what they may observe during induction (e.g., eyes rolling back, laryngeal noises, anesthetic monitor alarms, excitation), and when they will be asked to leave. They must also be instructed regarding their ability to assist during the induction process, such as by comforting the child, encouraging the child to trust the anesthesiologist, distracting the child, and consoling the child (Video 4-1). Personnel should be immediately available to escort parents back to the waiting area at the appropriate time. Someone should also be available to care for a parent who wishes to leave the induction area or who becomes lightheaded or faints. An anesthesiologist’s anxiety about parents’ presence during induction decreases significantly with experience.<sup>72</sup>

Explaining what parents might see or hear is essential. We generally tell parents the following:

*As you see your child fall asleep today, there are several things you might observe that you are not used to seeing. First, when anyone falls asleep, the eyes roll up, but since we are sleeping we do not generally see it. You may see your child do that today, and I do not want you to be frightened by that—it is expected and normal. The second thing is that as children go to sleep from the anesthesia medications, the tone of the structures in the neck decreases, so that some children will begin to snore or make vibrating noises. Again, I do not want you to be frightened or think that something is wrong. We expect this, and it is normal. The third thing you might see is what we call “excitement.” As the brain begins to go to sleep, it can actually get excited first. About 30 to 60 seconds after breathing the anesthesia medications, your child might suddenly look around or suddenly move his or her arms and legs. To you it appears that he is awakening from anesthesia or that he or she is upset. In reality, this is a good sign, because it indicates to us that your child is falling asleep and that 15 to 30 seconds later he or she will be completely anesthetized. Also you should know that even though your child appears to be awake to you, in reality he or she will not remember any of that. As soon as your child loses consciousness, we will ask you to give your child a kiss and step out of the operating room.*

This kind of careful preparation provides to the parents the confidence that the anesthesiologist really knows what he or she is talking about, and it avoids frightening the parents. In general, the more information provided, the lower the parental anxiety levels.

Occasionally, the best efforts to relieve a child’s anxiety by parental presence or administration of a sedative premedication (or both) are not successful, and an anticipated smooth induction may not go as planned. There are three options that may be used depending on the age of the child: (1) renegotiate (which is seldom successful), (2) hold the mask farther away from the child’s face, or (3) suggest an intravenous or intramuscular induction. Sedation can be considered if it was not already used and may be intramuscular, oral, inhalational (nitrous oxide), or given by another route. If an intramuscular shot or intravenous induction is proposed, the child will usually choose the mask. If the

**TABLE 4-2** Review of Systems: Anesthetic Implications

System	Factors to Assess	Possible Anesthetic Implications
Respiratory	Cough, asthma, recent cold Croup Apnea/bradycardia	Irritable airway, bronchospasm, medication history, atelectasis, infiltrate Subglottic narrowing Postoperative apnea/bradycardia
Cardiovascular	Murmur Cyanosis History of squatting Hypertension Rheumatic fever Exercise intolerance	Septal defect, avoid air bubbles in intravenous line Right-to-left shunt Tetralogy of Fallot Coarctation, renal disease Valvular heart disease Congestive heart failure, cyanosis
Neurologic	Seizures Head trauma Swallowing incoordination Neuromuscular disease	Medications, metabolic derangement Intracranial hypertension Aspiration, esophageal reflux, hiatus hernia Neuromuscular relaxant drug sensitivity, malignant hyperpyrexia
Gastrointestinal/hepatic	Vomiting, diarrhea Malabsorption Black stools Reflux Jaundice	Electrolyte imbalance, dehydration, full stomach Anemia Anemia, hypovolemia Possible need for full-stomach precautions Drug metabolism/hypoglycemia
Genitourinary	Frequency Time of last urination Frequent urinary tract infections	Urinary tract infection, diabetes, hypercalcemia State of hydration Evaluate renal function
Endocrine/metabolic	Abnormal development Hypoglycemia, steroid therapy	Endocrinopathy, hypothyroid, diabetes Hypoglycemia, adrenal insufficiency
Hematologic	Anemia Bruising, excessive bleeding Sickle cell disease	Need for transfusion Coagulopathy, thrombocytopenia, thrombocytopathy Hydration, possible transfusion
Allergies	Medications	Possible drug interaction
Dental	Loose or carious teeth	Aspiration of loose teeth, bacterial endocarditis prophylaxis

situation is totally out of control, either elective surgery can be rescheduled or intramuscular ketamine can be used if the parents choose to proceed. These situations are particularly difficult for the parents and the caregivers but must be handled on an individual basis.

### HISTORY OF PRESENT ILLNESS

The medical history of a child obtained during the preanesthetic visit allows the anesthesiologist to determine whether the child is optimized for the planned surgery, to anticipate potential problems due to coexisting disease, to determine whether appropriate laboratory or other tests are available or needed, to select optimal premedication, to formulate the appropriate anesthetic plan including perioperative monitoring, and to anticipate postoperative concerns including pain management and postoperative ventilatory needs. The history of the present illness is described to the physicians by the parents and verified by the referring or consultant surgeon's notes. If the child is old enough, it is helpful to obtain the child's input. The history should focus on the following aspects:

- A review of all organ systems (Table 4-2) with special emphasis on the organ system involved in the surgery
- Medications (over-the-counter and prescribed) related to and taken before the present illness, including herbals and vitamins, and when the last dose was taken
- Medication allergies with specific details of the nature of the allergy and whether immunologic testing was performed
- Previous surgical and hospital experiences, including those related to the current problem

- Timing of the last oral intake, last urination (wet diaper), and vomiting and diarrhea. It is essential to recognize that decreased gastrointestinal motility often occurs with an illness or injury.

In the case of a neonate, problems that may have been present during gestation and birth may still be relevant in the neonatal period and beyond (E-Table 4-3). The maternal medical and pharmacologic history (both therapeutic and drug abuse) may also provide valuable information for the management of a neonate requiring surgery.

### PAST/OTHER MEDICAL HISTORY

The past medical history should include a history of all past medical illnesses with a review of organ systems, previous hospitalizations (medical or surgical), childhood syndromes with associated anomalies, medication list, herbal remedies, and any allergies, especially to antibiotics and latex. Whether the child was full-term or preterm at birth should be discerned; if preterm, any associated problems should be noted, including admission to a neonatal intensive care unit, duration of tracheal intubation, history of apnea or bradycardia (including oxygen treatment, home apnea monitor, intraventricular hemorrhage), and congenital defects.

Examination of previous surgical and anesthesia records greatly assists in planning the anesthesia. Particular attention should be paid to any difficulties encountered with airway management, venous access, or emergence. The response to or need for premedication and the route of administration utilized should be noted.

**E-TABLE 4-3** Maternal History with Commonly Associated Neonatal Problems

Maternal History	Commonly Expected Problems with Neonate
Rh-ABO incompatibility	• Hemolytic anemia, hyperbilirubinemia, kernicterus
Toxemia	• SGA and its associated problems,* muscle relaxant interaction with magnesium therapy
Hypertension	• SGA and its associated problems*
Drug addiction	• Withdrawal, SGA
Infection	• Sepsis, thrombocytopenia, viral infection
Hemorrhage	• Anemia, shock
Diabetes	• Hypoglycemia, birth trauma, LGA, SGA, and associated problems*
Polyhydramnios	• Tracheoesophageal fistula, anencephaly, multiple anomalies
Oligohydramnios	• Renal hypoplasia, pulmonary hypoplasia
Cephalopelvic disproportion	• Birth trauma, hyperbilirubinemia, fractures
Alcoholism	• Hypoglycemia, congenital malformation, fetal alcohol syndrome, SGA, and associated problems*

SGA, Small for gestational age; LGA, large for gestational age.  
\*See Table 2-2.

### Herbal Remedies

Increasing numbers of children are ingesting herbal medicine products. During the preoperative interview, anesthesiologists should include specific inquiries regarding the use of these medications because of their potential adverse effects and drug interactions. Hospital surveys suggest that the use of herbal remedies ranges from 17% to 32%<sup>73-75</sup> of presurgical patients, and 70% of these patients do not inform their anesthesiologist of such use.

In Hong Kong, 80% of patients undergoing major elective surgery use prepacked over-the-counter traditional Chinese herbal medicines, and 8% use medicines prescribed by traditional Chinese medicine practitioners.<sup>76</sup> The prescription users of traditional Chinese medicines experienced a greater incidence of adverse perioperative events. In particular, this group was twice as likely to have hypokalemia or impaired hemostasis (i.e., prolonged international normalized prothrombin ratio [INR] and activated partial thromboplastin time [aPTT]) than nonusers, although there was no significant difference in the incidence of perioperative events between self-prescribed users and nonusers. To further complicate this subject, there is an important difference between Chinese and Western herbs. Traditional Chinese herbal medicines consist of multiple herbs that are combined for their effects, whereas Western herbs are usually ingested as a single substance.<sup>77</sup>

Herbal medicines are associated with cardiovascular instability, coagulation disturbances, prolongation of anesthesia, and immunosuppression.<sup>78</sup> The most commonly used herbal medications reported are garlic, ginseng, *Ginkgo biloba*, St. John's wort, and echinacea.<sup>79</sup> The three "g" herbals, together with feverfew (*Tanacetum parthenium*), potentially increase the risk of bleeding during surgery. The amount of active ingredient in each preparation may vary, the dose taken by a child may also vary, and detection of a change in platelet function and other subtle coagulation disturbances may be difficult. St. John's wort is the herb that most commonly interacts with anesthetics and other medications, usually via a change in drug metabolism, because it is a potent induction of the cytochrome P-450 enzymes (e.g., CYP3A4) and P-glycoprotein. A potentially fatal interaction between cyclosporine and St. John's wort has been well documented.<sup>80-83</sup> Heart, kidney, or liver transplant recipients who were stabilized on a dose of cyclosporine experienced decreased plasma concentrations of cyclosporine and, in some cases, acute rejection episodes after taking St. John's wort. A summary of the most commonly used herbal remedies and their potential perioperative complications is shown in E-Table 4-4.

To avoid potential perioperative complications, the ASA has encouraged the discontinuation of all herbal medicines 2 weeks before surgery,<sup>84</sup> although this recommendation is not evidence based. Indeed, some herbs such as valerian, a treatment for insomnia (*Valeriana officinalis*), should *not* be discontinued abruptly but tapered; otherwise, abrupt discontinuation may result in a paradoxical and severe reaction.<sup>85</sup> Each herb should be carefully evaluated using standard resource texts, and a decision should be made regarding the timing of or need for discontinuation as determined on a case-by-case basis.<sup>86</sup>

### Anesthesia and Vaccination

Children may present for surgery after having been recently immunized. The anesthesiologist and surgeon must then consider (1) whether the immunomodulatory effects of anesthesia and surgery might affect the efficacy and safety of the vaccine

and (2) whether the inflammatory responses to the vaccine will alter the perioperative course.

What do anesthesiologists think about anesthesia and vaccination? An international survey<sup>87</sup> revealed that only one third of responding anesthesiologists had the benefit of a hospital policy, ranging from a formal decision to delay surgery to an independent choice by the anesthesiologist. Sixty percent of respondents would anesthetize a child for elective surgery within 1 week of receiving a live attenuated vaccine (such as oral polio vaccine or measles, mumps, and rubella [MMR] vaccine), whereas 40% would not. The survey also revealed that 28% of anesthesiologists would delay immunization for 2 to 30 days after surgery.

Is there a consensus statement on anesthesia and vaccination? A scientific review of the literature associating anesthesia and vaccination in children resulted in recommendations for the care of children under these circumstances.<sup>88</sup> The review demonstrated a brief and reversible influence of vaccination on lymphoproliferative responses that generally returned to preoperative values within 2 days. Vaccine-driven adverse events (e.g., fever, pain, irritability) might occur but should not be confused with perioperative complications. Adverse events to inactivated vaccines such as diphtheria-tetanus-pertussis (DPT) become apparent from 2 days and to live attenuated vaccines such as MMR from 7 to 21 days after immunization.<sup>88</sup> Therefore, appropriate delays between immunization and anesthesia are recommended by type of vaccine to avoid misinterpretation of vaccine-associated adverse events as perioperative complications. Because children remain at risk of contracting vaccine-preventable diseases, the minimum delay seems prudent, especially in the first year of life. Likewise, it seems reasonable to delay vaccination *after* surgery until the child is fully recovered. Other immunocompromised patients, such as human immunodeficiency virus (HIV)-positive children, cancer patients, and transplant recipients, have distinct underlying immune impairments, and the influence of anesthesia on vaccine responses has not been comprehensively investigated.

### Allergies to Medications and Latex

The details pertaining to all allergies to medications and materials should be described in the child's record. These include the age of onset, frequency, severity, investigations, and treatments. The vast majority of reported allergies on children's charts are either nonimmunologic reactions or known (or unknown) drug adverse effects. The most common medication- and hospital-related allergies in children are penicillin and latex allergy.

Most cases of reported penicillin allergy consist of a maculopapular rash after oral penicillin. This occurs in 1% to 4% of children receiving penicillin or in 3% to 7% of those taking ampicillin, usually during treatment.<sup>89</sup> Rarely are signs or symptoms that suggest an acute (immunoglobulin E-mediated) allergic reaction present (i.e., angioedema), and even less frequently is skin testing conducted to establish penicillin allergy. Given the frequency of penicillin allergy, most of these unverified allergies in fact are not allergies to penicillin but rather minor allergies to the dye in the liquid vehicle or a consequence of the (viral) infection. If the child has not received penicillin for at least 5 years since the initial exposure and has not been diagnosed with a penicillin allergy by an immunologist or allergist, then a reexposure is warranted. If the child has been tested immunologically for penicillin allergy, then it is best to avoid this class of antibiotics. Although there is a 5% to 10% cross-reactivity between first-generation cephalosporins and penicillin, there is no similar

**E-TABLE 4-4 Pharmacologic Effects and Potential Perioperative Complications of Eight Commonly Used Herbal Remedies**

Name of Herb	Common Uses	Pharmacologic Effects	Potential Perioperative Complications
Echinacea, purple coneflower root	Prophylaxis and treatment of viral, bacterial, and fungal infection	Stimulation of the immune system. With long-term use may be immunosuppressive.	Reduced effectiveness of immunosuppressants. Potential for wound infection. May cause hepatotoxicity.
Ephedra, ma huang	Diet aid	Indirect- and direct-acting sympathomimetic	Dose-dependent increase in heart rate and blood pressure with potential for perioperative myocardial infarction and stroke. Arrhythmias with halothane. Tachyphylaxis with intraoperative ephedrine.
Garlic, ajo	Antihypertensive, lipid-lowering agent, anti-thrombus forming	Inhibits platelet aggregation (partially irreversibly) in a dose-dependent manner. Lowers serum lipid and cholesterol levels.	May potentiate other platelet inhibitors. Concerns for perioperative bleeding.
Ginkgo, maidenhair; fossil tree	Circulatory stimulant. Used to treat Alzheimer disease, peripheral vascular disease, and erectile dysfunction.	Inhibits platelet-activating factor. Antioxidant. Modulates neurotransmitter activity.	Concerns for perioperative bleeding. May potentiate other platelet inhibitors.
Ginseng	Used to protect the body against stress and restore homeostasis	Poorly understood. Inhibits platelet aggregation (partly irreversibly).	Potential to increase perioperative bleeding. Potential for hypoglycemia.
Kava, ava pepper	Anxiolytic	Possible potentiation of $\gamma$ -aminobutyric acid (GABA) transmission	Potentiates sedative effects of anesthetic agents. Possible withdrawal syndrome after sudden abstinence. Kava-induced hepatotoxicity.
St. John's wort, goat weed, amber, hard hay	Treatment of depression and anxiety	Central inhibition of serotonin, norepinephrine, and dopamine. Induction of cytochrome P-450 3A4.	Decreased effectiveness of drugs metabolized by CYP3A4 such as cyclosporine, alfentanil, midazolam, lidocaine, calcium-channel blockers, and digoxin
Valerian, vandal root, all heal, Jacob's ladder	Anxiolytic and sleep aid	Potentiation of GABA neurotransmission	Potentiates sedative effects of anesthetic agents. Withdrawal-type syndrome with sudden abstinence.

Modified from Skinner CM, Rangasami J. Preoperative use of herbal medicines: a patient survey. Br J Anaesth 2002;89:792-5.

cross-reactivity with second- and third-generation cephalosporins. To date, there have been no fatal anaphylactic reactions in penicillin allergic children from a cephalosporin.<sup>89</sup>

Latex allergy is an acquired immunologic sensitivity resulting from repeated exposure to latex, usually on mucous membranes (e.g., children with spina bifida or congenital urologic abnormalities who have undergone repeated bladder catheterizations with latex catheters, those with more than four surgeries, those requiring home ventilation). It occurs more frequently in atopic individuals and in those with certain fruit and vegetable allergies (e.g., banana, chestnut, avocado, kiwi, pineapple).<sup>90-96</sup> For a diagnosis of latex anaphylaxis, the child should have personally experienced an anaphylactic reaction to latex, skin-tested positive for anaphylaxis to latex, or experienced swelling of the lips after touching a toy balloon to the lips or a swollen tongue after a dentist inserted a rubber dam into the mouth.<sup>96</sup> The avoidance of latex within the hospital will prevent acute anaphylactic reactions to latex in children who are at risk.<sup>97</sup> Latex gloves and other latex-containing products should be removed from the immediate vicinity of the child. Prophylactic therapy with histamine H<sub>1</sub> and H<sub>2</sub> antagonists and steroids do not prevent latex anaphylaxis.<sup>90,98</sup> Latex anaphylaxis should be treated by removal of the source of latex, administration of 100% oxygen, acute volume loading with balanced salt solution (10 to 20 mL/kg repeated until the systolic blood pressure stabilizes), and administration of intravenous epinephrine (1 to 10 µg/kg according to the severity of the anaphylaxis). In some severe reactions, a continuous infusion of epinephrine alone (0.01 to 0.2 µg/kg/min) or combined with other vasoactive medications may be required for several hours.

### Family History

It is important to inquire about a family history, particularly focusing on a number of conditions, including malignant hyperthermia, muscular dystrophy, prolonged paralysis associated with anesthesia (pseudocholinesterase deficiency), sickle cell disease, bleeding (and bruising) tendencies, and drug addiction (drug withdrawal, HIV infection). The precise relationship to the proband must be documented.

### LABORATORY DATA

The laboratory data obtained preoperatively should be appropriate to the history, illness, and surgical procedure. Routine hemoglobin testing or urinalysis is not indicated for most elective procedures; the value of these tests is questionable when the surgical procedure will not involve clinically significant blood loss.<sup>99</sup> There are insufficient data in the literature to make strict hemoglobin testing recommendations in healthy children. A preoperative hemoglobin value is usually determined only for those who will undergo procedures with the potential for blood loss, those with specific risk factors for a hemoglobinopathy, formerly preterm infants, and those younger than 6 months of age. Coagulation studies (platelet count, INR, and PTT) may be indicated if major reconstructive surgery is contemplated, especially if warranted by the medical history, and in some centers before tonsillectomy. In addition, collection of a preoperative type-and-screen or type-and-crossmatch sample is indicated in preparation for potential blood transfusions depending on the nature of the planned surgery and the anticipated blood loss.

In general, routine chest radiography is not necessary; studies have confirmed that routine chest radiographs are not cost-effective in children.<sup>100,101</sup> The oxygen saturation of children who

are breathing room air is very helpful. Baseline saturations of 95% or less suggest clinically important pulmonary or cardiac compromise and warrant further investigation.

Special laboratory tests, such as electrolyte and blood glucose determinations, renal function tests, blood gas analysis, blood concentrations of seizure medication and digoxin, electrocardiography, echocardiography, liver function tests, computed tomography (CT), magnetic resonance imaging (MRI), or pulmonary function tests, should be performed when appropriate.

### PREGNANCY TESTING

Although pregnancy rates among teenagers in the United States are declining,<sup>102</sup> a small percentage of young women may still present for elective surgery with an unsuspected pregnancy. In 2003, the birth rate in girls aged 15 to 19 years was 41.6 births per 1000, and for girls aged 10 to 14 years it was 0.6 per 1000. However, routine preoperative pregnancy testing in adolescent girls may present ethical and legal dilemmas, including social and confidentiality concerns. This places the anesthesiologist in a predicament when faced with a question of whether to perform routine preoperative pregnancy screening.<sup>102</sup> Each hospital should adopt a policy regarding pregnancy testing to provide a consistent and comprehensive policy for all females who have reached menarche.

A survey of members of the Society for Pediatric Anesthesia practicing in North America revealed that pregnancy testing was routinely required by approximately 45% of the respondents regardless of the practice setting (teaching versus nonteaching facilities).<sup>99</sup> A retrospective review of a 2-year study of mandatory pregnancy testing in 412 adolescent surgical patients<sup>103</sup> revealed that the overall incidence of positive tests was 1.2%. Five of 207 patients aged 15 years and older tested positive, for an incidence of 2.4% in that group. None of the 205 patients younger than the age of 15 years had a positive pregnancy test.

The most recent ASA Task Force on Preanesthesia Evaluation<sup>104</sup> recognized that a history and physical examination may not adequately identify early pregnancy and issued the following statement: *"The literature is insufficient to inform patients or physicians on whether anesthesia causes harmful effects on early pregnancy. Pregnancy testing may be offered to female patients of childbearing age and for whom the result would alter the patient's management."*<sup>105</sup> Because of the risk of exposing the fetus to potential teratogens and radiation from anesthesia and surgery, the risk of spontaneous abortion, and the risk of apoptosis reported in the rapidly developing fetal animal brain, elective surgery with general anesthesia is not advised during early pregnancy. Therefore, if the situation is unclear, and when indicated by medical history, it is best to perform a preoperative pregnancy test. If the surgery is required in a patient who might be pregnant, then using an opioid-based anesthetic such as remifentanyl and the lowest concentration of inhalational agent or propofol that provides adequate anesthesia is preferred.

## Premedication and Induction Principles

### GENERAL PRINCIPLES

The major objectives of preanesthetic medication are to (1) allay anxiety, (2) block autonomic (vagal) reflexes, (3) reduce airway secretions, (4) produce amnesia, (5) provide prophylaxis against pulmonary aspiration of gastric contents, (6) facilitate the induction of anesthesia, and (7) if necessary, provide analgesia. Premedication may also decrease the stress response to anesthesia

and prevent cardiac arrhythmias.<sup>106</sup> The goal of premedication for each child must be individualized. Light sedation, even though it may not eliminate anxiety, may adequately calm a child so that the induction of anesthesia will be smooth and a pleasant experience. In contrast, heavy sedation may be needed for the very anxious child who is unwilling to separate from his or her parents.

Factors to consider when selecting a drug or a combination of drugs for premedication include the child's age, ideal body weight, drug history, and allergic status; underlying medical or surgical conditions and how they might affect the response to premedication or how the premedication might alter anesthetic induction; parent and child expectations; and the child's emotional maturity, personality, anxiety level, cooperation, and physiologic and psychological status. The anesthesiologist should also consider the proposed surgical procedure and the attitudes and wishes of the child and the parents.

The route of administration of premedicant drugs is very important. Premedications have been administered by many routes including the oral, nasal, rectal, buccal, intravenous, and intramuscular routes. Although a drug may be more effective and have a more reliable onset when given intranasally or intramuscularly, most pediatric anesthesiologists refrain from administering parenteral medication to children without intravenous access. Many children who are able to verbalize report that receiving a needle puncture was their worst experience in the hospital.<sup>107,108</sup> In most cases, medication administered without a needle will be more pleasant for children, their parents, and the medical staff. Oral premedications do not increase the risk of aspiration pneumonia unless large volumes of fluids are ingested.<sup>109</sup> In general, the route of delivery of the premedication should depend on the drug, the desired drug effect, and the psychological impact of the route of administration. For example, a small dose of oral medication may be sufficient for a relatively calm child, whereas an intramuscular injection (e.g., ketamine) may be best for an uncooperative, combative, extremely anxious child. Intramuscular administration may be less traumatic for this type of child than forcing him or her to swallow a drug, giving a drug rectally, or forcefully holding an anesthesia mask on the face.<sup>110</sup>

Since Water's classic work in 1938 on premedication of children, numerous reports have addressed this subject.<sup>111</sup> Despite the wealth of studies, no single drug or combination of drugs has been found to be ideal for all children. Many drugs used for premedication have similar effects, and a specific drug may have various effects in different children or in the same child under different conditions.

## MEDICATIONS

Several categories of drugs are available for premedicating children before anesthesia (Table 4-3). Selection of drugs for premedication depends on the goal desired. Drug effects should be weighed against potential side effects, and drug interactions should be considered. Premedicant drugs include tranquilizers, sedatives, hypnotics, opioids, antihistamines, anticholinergics, H<sub>2</sub>-receptor antagonists, antacids, and drugs that increase gastric motility.

### Tranquilizers

The major effect of tranquilizers is to allay anxiety, but they also have the potential to produce sedation. This group of drugs includes the benzodiazepines, phenothiazines, and butyrophenones. Benzodiazepines are widely used in children, whereas phenothiazines and butyrophenones are infrequently used.

**TABLE 4-3 Doses of Drugs Commonly Administered for Premedication**

Drug	Route	Dose (mg/kg)
<b>Barbiturates</b>		
Methohexital	Rectal	(10% solution) 20-40
	Intramuscular	(5% solution) 10
Thiopental	Rectal	(10% solution) 20-40
<b>Benzodiazepines</b>		
Diazepam	Oral	0.1-0.5
	Rectal	1 mg/kg
Midazolam	Oral	0.25-0.75
	Nasal	0.2
	Rectal	0.5-1
	Intramuscular	0.1-0.15
Lorazepam	Oral	0.025-0.05
<b>Phencyclidine</b>		
Ketamine*	Oral	3-6
	Nasal	3
	Rectal	6-10
	Intramuscular	2-10
<b>α<sub>2</sub>-Adrenergic Agonist</b>		
Clonidine	Oral	0.004
<b>Opioids</b>		
Morphine	Intramuscular	0.1-0.2
Meperidine†	Intramuscular	1-2
Fentanyl	Oral	0.010-0.015 (10-15 µg/kg)
	Nasal	0.001-0.002 (1-2 µg/kg)
Sufentanil	Nasal	0.001-0.003 (1-3 µg/kg)

\*With atropine 0.02 mg/kg.

†Only a single dose is recommended due to metabolites that may cause seizures.

### Benzodiazepines

Benzodiazepines calm children, allay anxiety, and diminish recall of perianesthetic events. At low doses, minimal drowsiness and cardiovascular or respiratory depression are produced.

*Midazolam*, a short-acting, water-soluble benzodiazepine with an elimination half-life of approximately 2 hours, is the most widely used premedication for children.<sup>112,113</sup> The major advantage of midazolam over other drugs in its class is its rapid uptake and elimination.<sup>114</sup> It can be administered intravenously, intramuscularly, nasally, orally, and rectally with minimal irritation, although it leaves a bitter taste in the mouth or nasopharynx after oral or nasal administration, respectively.<sup>115-121</sup> Peak plasma concentrations occur approximately 10 minutes after intranasal midazolam administration, 16 minutes after rectal administration, and 53 minutes after oral administration.<sup>114,121,122</sup> The relative bioavailability of midazolam is approximately 90% after intramuscular injection, 60% after intranasal administration, 40% to 50% after rectal administration, and 30% after oral administration, compared with intravenous administration (see Chapter 6).<sup>122,123</sup> After oral or rectal administration, there is incomplete absorption and extensive hepatic extraction of the drug during the first pass through the liver—hence, the need for large doses through these routes. Most children are adequately sedated after receiving a midazolam dose of 0.025 to 0.1 mg/kg intravenously, 0.1 to 0.2 mg/kg intramuscularly, 0.25 to 0.75 mg/kg orally, 0.2 mg/kg nasally, or 1 mg/kg rectally.

Orally administered midazolam is effective in calming most children and does not increase gastric pH or residual volume.<sup>124,125</sup> The current formulation of oral midazolam (2 mg/mL) is a commercially prepared, strawberry-flavored liquid. Two multicenter studies yielded slightly different responses to this preparation of oral midazolam in children.<sup>126,127</sup> In one study, 0.25, 0.5, and 1.0 mg/kg all produced satisfactory sedation and anxiolysis within 10 to 20 minutes,<sup>127</sup> whereas in the other study, 1.0 mg/kg provided greater anxiolysis and sedation than 0.25 mg/kg.<sup>126</sup> These differing results may be attributed to the older ages of children in the former study.<sup>126</sup>

Recent evidence suggests that the required dose of midazolam increases as age decreases in children, similar to that for inhaled agents and intravenous agents.<sup>128</sup> An increased clearance in younger children contributes to their increased dose requirement.<sup>129</sup> Thus, greater doses may be required in younger children to achieve a similar degree of sedation and anxiolysis. However, the formulation of the oral solution may also attenuate its effectiveness.<sup>130,131</sup> A number of medications that affect the cytochrome oxidase system, significantly affect the first-pass metabolism of midazolam, including grapefruit juice, erythromycin, protease inhibitors, and calcium-channel blockers that decrease CYP3A4 activity, which in turn increases the blood concentration of midazolam and prolongs sedation.<sup>132-138</sup> Conversely, anticonvulsants (phenytoin and carbamazepine), rifampin, St. John's wort, glucocorticoids, and barbiturates induce the CYP3A4 isoenzyme, thereby reducing the blood concentration of midazolam and its duration of action.\* The dose of oral midazolam should be adjusted in children who are taking these medications.

Concerns have been raised about possible delayed discharge after premedication with oral midazolam. Oral midazolam, 0.5 mg/kg, administered to children 1 to 10 years of age did not affect awakening times, time to extubation, postanesthesia care unit, or hospital discharge times, after sevoflurane anesthesia.<sup>139</sup> Similar results have been reported in children and adolescents after 20 mg of oral midazolam, however, detectable preoperative sedation in this group of children was predictive of delayed emergence.<sup>140</sup> In children aged 1 to 3 years undergoing adenoidectomy as outpatients, premedication with oral midazolam, 0.5 mg/kg, slightly delayed spontaneous eye opening by 4 minutes and discharge by 10 minutes compared with placebo; children who had been premedicated, however, exhibited a more peaceful sleep at home on the night after surgery.<sup>141</sup>

Likely the greatest effect of oral midazolam on recovery occurs with its use in children undergoing myringotomy and tube insertion, a procedure that normally takes 5 to 7 minutes. In this surgery, the use of this premedication must be carefully considered. Oral midazolam decreased the infusion requirements of propofol by 33% during a propofol-based anesthesia, although the time to discharge readiness was delayed.<sup>142</sup> After oral midazolam premedication (0.5 mg/kg), induction of anesthesia with propofol, and maintenance with sevoflurane, emergence and early recovery were delayed by 6 and 14 minutes, respectively, in children 1 to 3 years of age compared with unpremedicated children, although discharge times did not differ.<sup>143</sup> Increased postoperative sedation may be attributed to synergism between propofol and midazolam on  $\gamma$ -aminobutyric acid (GABA) receptors.<sup>144</sup>

One notable benefit of midazolam is anterograde amnesia; children who were amnesic about their initial dental extractions tolerated further dental treatments better than those who were

not amnesic.<sup>145</sup> It appears that memory becomes impaired within 10 minutes and anxiolytic effects are apparent as early as 15 minutes after oral midazolam.<sup>146</sup>

Although anxiolysis and a mild degree of sedation occur in most children after midazolam, a few develop undesirable adverse effects. Some children become agitated after oral midazolam.<sup>147</sup> If this occurs after intravenous midazolam (0.1 mg/kg), intravenous ketamine (0.5 mg/kg) may reverse the agitation.<sup>148</sup> Adverse behavioral changes have been reported in the postoperative period after midazolam premedication. One study found that oral midazolam suppresses crying during induction of anesthesia but may cause adverse behavioral changes (nightmares, night terrors, food rejection, anxiety, and negativism) for up to 4 weeks postoperatively compared with placebo<sup>149</sup>; this finding has not been substantiated.<sup>59</sup> One undesirable effect associated with midazolam, independent of the mode of administration (rectal, nasal, or oral), is hiccups (approximately 1%); the etiology is unknown.

Anxiolysis and sedation usually occur within 10 minutes after intranasal midazolam,<sup>150</sup> although it may be less effective in children with an upper respiratory tract infection (URI) and excessive nasal discharge.<sup>121</sup> Intranasal midazolam does not affect the time to recovery or discharge after surgical procedures at least 10 minutes in duration.<sup>151,152</sup> Although midazolam reduces negative behavior in children during parental separation, nasal administration is not well accepted because it produces irritation, discomfort, and a burning aftertaste that may overshadow its positive sedative effects.<sup>153-155</sup> Another theoretical concern for the nasal route of administration of midazolam is its potential to cause neurotoxicity via the cribriform plate.<sup>121</sup> There are direct connections between the nasal mucosa and the central nervous system (CNS) (E-Fig. 4-2). Medications administered nasally reach high concentrations in the cerebrospinal fluid very quickly.<sup>156-158</sup> To date, no such sequelae have been reported. Because midazolam with preservative has been shown to cause neurotoxicity in animals, we recommend only preservative-free midazolam for nasal administration.<sup>159,160</sup>

Sublingual midazolam (0.2 mg/kg) has been reported to be as effective as, and better accepted than, intranasal midazolam.<sup>161</sup> Oral transmucosal midazolam given in three to five small allotments (0.2 mg/kg total dose) placed on a child's tongue (8 months to 6 years of age) was found to provide satisfactory acceptance and separation from parents in 95% of children.<sup>162</sup>

There is another pharmacodynamic difference among benzodiazepines that is important to consider when these drugs are administered intravenously. Entry into the CNS is directly related to fat solubility.<sup>163,164</sup> The greater the fat solubility, the more rapid the transit into the CNS. The time to peak CNS electroencephalographic effect in adults is 4.8 minutes for midazolam but only 1.6 minutes for diazepam (see Fig. 47-7). Therefore, when administering intravenous midazolam, one must wait an adequate interval between doses to avoid excessive medication and oversedation.

*Diazepam* is only used for premedication of older children. In infants and especially preterm neonates, the elimination half-life of diazepam is markedly prolonged because of immature hepatic function (see Chapter 6). In addition, the active metabolite (desmethyldiazepam) has pharmacologic activity equal to that of the parent compound and a half-life of up to 9 days in adults.<sup>165</sup> The most effective route of administration of diazepam is intravenous, followed by oral and rectal. The intramuscular route is not recommended because it is painful and absorption is erratic.<sup>166-170</sup> The combination of oral midazolam 0.25 mg/kg and diazepam

\*See [http://www.medicine.iupui.edu/clinpharm/ddis/p450\\_Table\\_Oct\\_11\\_2009.pdf](http://www.medicine.iupui.edu/clinpharm/ddis/p450_Table_Oct_11_2009.pdf) (accessed July 1, 2012).

**E-FIGURE 4-3** **A**, Some children are more comfortable sitting in the lap of the anesthesiologist (or parent). In this situation, asking the child to “blow up the balloon” is often a successful distraction, resulting in a smooth inhalation induction. **B**, Other children can be distracted and comforted by having a favorite toy, stuffed animal, or security blanket during induction; in this case, we allowed the child to hold a face mask on her stuffed rabbit while we held the mask on her face.

**E-FIGURE 4-4** If a parent requests or is asked to accompany the child to the operating room, it is vital to explain to the parent all the things that might be seen in the operating room as well as the child’s responses during induction (see text for details). Often a small child can be anesthetized in the parent’s lap, first starting with “laughing gas” (nitrous oxide). Note that this child is laughing during induction (**A**). After observing the desired effect of nitrous oxide, the potent inhalation agent (sevoflurane or halothane) is introduced as tolerated. As soon as the child is induced, we place the child on the operating room table, briefly remove the mask, ask the parent to kiss the child (**B**), and then request that he or she leave the operating room. It is important to have someone available to escort the parent back to the waiting area.

**FIGURE 4-3** **A**, Infants 6 months of age or younger are often consoled during induction by placing the little finger ("pinky finger") of your hand in their mouth while you hold the face mask near their face with the rest of the hand. In general, they are so hungry that they will stop crying and eagerly suckle on your pinky finger. **B**, As the infant loses consciousness, the intensity of the suckling diminishes, the pinky finger is gently removed, and the face mask is fully applied.

of  $N_2O$  is achieved. Offering children the choice of a scented mask or "sleepy air," such as bubble gum or strawberry flavor, applied to the inside of the face mask may disguise the odor of the plastic. Sevoflurane is then introduced and can be rapidly increased to 8% in a single stepwise increase, without significant bradycardia or hypotension in otherwise healthy children. After anesthesia is induced, the sevoflurane concentration should be maintained at the maximum tolerable concentration until intravenous access is established, but this concentration should be reduced if controlled ventilation is initiated so as to avoid overdose. The reason for maintaining delivery of a high concentration of sevoflurane is to minimize the risk of awareness during the early period of the induction sequence. Data from unmedicated children (aged  $\geq 3$  years) indicate that sevoflurane is associated with small increases in heart rate, although heart rate does decrease to 80 to 100 beats per minute in some children after breathing sevoflurane for a period of time.<sup>350</sup> In contrast to halothane,<sup>351</sup> sevoflurane does not increase the myocardial sensitivity to epinephrine.<sup>352</sup> In a study of three techniques for delivering sevoflurane for induction of anesthesia, minimal differences were detected among the three: incremental increases in sevoflurane (2%, 4%, 6%, and 7%) in oxygen, a high concentration of sevoflurane (7%) in oxygen, and a high concentration of sevoflurane in a 1:1 mixture of  $N_2O$  and  $O_2$ .<sup>353</sup> When  $N_2O$  was added, there was a decreased time to loss of the eyelash reflex and a decreased incidence of excitement during the induction. Agitation or excitement in early induction (shortly after loss of eyelash reflex) with sevoflurane has been observed; this is discussed in detail in Chapter 6.

#### Inhalation Induction with Halothane

Halothane has largely been replaced by sevoflurane for inhalation induction of anesthesia because of halothane's slower wash-in and emergence and greater incidence of bradycardia, hypotension, and arrhythmias. When anesthesia is induced with halothane, the inspired concentration is gradually increased by 0.5% every two to three breaths up to 5%. Alternatively, a single-breath induction of anesthesia with 5% halothane can yield a rapid induction of anesthesia without triggering airway reflex responses.<sup>354</sup>

The inspired concentration of halothane should be decreased as soon as anesthesia is established to avoid heart rate slowing and myocardial depression. The child will autoregulate the depth of anesthesia as long as he or she is allowed to breath spontaneously; however, if respirations are controlled, then anesthetic overdose may easily occur (see Chapter 6).<sup>355,356</sup> Halothane sensitizes the heart to catecholamines, and ventricular arrhythmias may commonly be seen, especially during periods of hypercapnia or light anesthesia.<sup>357</sup>

If vital signs become abnormal during induction, the concentration of halothane should be reduced or discontinued and the circuit flushed with 100% oxygen. If bigeminy or short bursts of ventricular tachycardia occur, then the following strategies should be considered: (1) hyperventilation (to reduce the arterial carbon dioxide tension [ $PaCO_2$ ]) (2) deepening of the halothane anesthesia, or (3) changing to an alternate potent inhalation agent.<sup>357</sup> There is no role for intravenous lidocaine to treat these arrhythmias.

During inhalation induction with either sevoflurane or halothane, if the oxygen saturation decreases (and there is no mechanical cause for the desaturation such as partial dislodgement of the oximeter probe, patient clenching of fingers or toes, or blood pressure cuff inflating), 100% oxygen should be administered until the oxygen saturation returns to normal while the cause of the desaturation is addressed. If the cause of the desaturation is not related to upper airway obstruction, the most common cause in a healthy child is a ventilation-perfusion mismatch due to segmental atelectasis. Recruitment of alveoli may be achieved by applying a sustained inflation of the lungs to 30 cm  $H_2O$  for 30 seconds or as tolerated.<sup>358</sup> This may be difficult to complete before tracheal intubation, because the stomach may inflate. In such a case, recruitment should be abandoned. Alternatively, mild to moderate upper airway obstruction from collapse of the hypopharyngeal structures or the development of mild laryngospasm causes hypoventilation and desaturation. In general, this upper airway obstruction is readily relieved by gently applying a tight mask fit, closing the pop-off valve sufficiently to generate 5 to 10 cm of positive end-expiratory pressure, and allowing the distending pressure of the bag to stent open the airway until the child is adequately anesthetized to tolerate the placement of an

oral airway (see Fig. 12-10 and Fig. 31-6). Cephalad pressure should be applied to the superior pole of the condyle of the mandible to sublux the temporomandibular joint, because this maneuver opens the mouth and pulls the tongue off the posterior and nasopharyngeal walls, opening the laryngeal inlet (Video 4-3, *A* and *B*).<sup>359</sup> This maneuver may supplant the need for an oral airway. It is very important to avoid applying digital pressure to the soft tissues of the submental triangle, because this pushes the tongue and soft tissues into the hypopharynx, occluding the oropharynx and nasopharynx. If the child develops symptomatic bradycardia, then oxygenation and ventilation must first be established, followed by intravenous atropine (0.02 mg/kg) and, if necessary, chest compressions and intravenous epinephrine (see Chapter 39).

### Inhalation Induction with Desflurane

Desflurane is very pungent, as evidenced by severe laryngospasm (49%), coughing, increased secretions, and hypoxemia during induction.<sup>360</sup> Therefore, *desflurane is not recommended for inhalation induction in children* but may be used safely for maintenance of general anesthesia after the trachea has been intubated.

### Hypnotic Induction

Hypnosis can reduce anxiety and pain in children with chronic medical problems and those undergoing painful procedures<sup>361,362</sup> as well as reduce preoperative anxiety. Hypnosis is an altered state of consciousness with highly focused attention, based on the principle of dissociation.<sup>363</sup> Hypnosis results in a state of inner absorption that leads to a reduction in awareness of immediate physical surroundings and experiences. Children are more likely to be absorbed in fantasy, and their natural power of play making them more hypnotizable than adults.<sup>364</sup> Although an anesthesiologist may not have training in hypnosis, he or she can use hypnotic suggestions to help children even though an actual trance state is not induced. It may be helpful to engage children in age-appropriate scenarios, such as going to the zoo, a fancy tea party, a baseball game, or flying a jet. Words should be spoken slowly and rhythmically with descriptions of sights and sounds that are familiar to the child as well as repeated suggestions of “feeling good.” The hypnotic suggestions distract the child so that the smell of anesthetic agent becomes the scent of the zoo animals, the tea brewing, the aviation fuel, and so on. Any number of stories can be told with the same result as long as one remembers to repeatedly say things that can be identified by the child and that fit with what the child is experiencing at the time of induction.

When hypnosis was administered 30 minutes before surgery, it significantly reduced preoperative anxiety at the time of face mask application and the frequency of behavior disorders postoperatively when compared with oral midazolam, 0.5 mg/kg.<sup>365</sup> Hypnosis provided a relaxed state of well-being and enabled children to actively participate in anesthesia, thus leaving them with a pleasant memory. Unlike the anterograde amnesia associated with midazolam, hypnosis offers the benefit of maintaining a pleasant memory to prevent fear during future anesthetics.

### Modified Single-Breath Induction

The single-breath induction is especially appealing to children who desire to fall asleep “really fast” with a face mask, because loss of consciousness is achieved much more rapidly than with a traditional escalating dose technique. It works best with older children, although some as young as 3 years of age can be

anesthetized with this technique if they are cooperative. Before beginning, the child should be coached through a mock induction by instructing him or her to “breathe in the biggest breath, possible” through the mouth (not the nose) and then “breathe all the way out until there is no more air in the lungs.” If the child is used to swimming and holding the breath underwater, this makes the exercise much easier. Once this has been practiced a few times, then a practice run is repeated with only the mask (no circuit) on the face.

Before induction, the circuit and reservoir bag are primed with 70% N<sub>2</sub>O in O<sub>2</sub> and the maximum concentration of concentration of halothane or sevoflurane the vaporizer can deliver. This is achieved by running modest fresh gas flows through the circuit and intermittently emptying the reservoir bag manually into the scavenger system (i.e., with the circuit Y-connector occluded). Once the circuit is primed with the maximum concentration of inhalation agent, the mask is placed on the Y-connector, then the distal end of the circuit is occluded (to avoid contaminating the operating room), and the child is instructed to take a deep breath of room air and to exhale all the air and hold expiration. The face mask is then placed securely over the child’s mouth and nose while he or she is instructed to take in the “deepest breath ever through their mouth” and “hold it, now just breathe normally.” Loss of consciousness, as noted by loss of the eyelash reflex, occurs within 15 to 30 seconds after this vital capacity breath (Fig. 4-4, *A*, *B* and *C*, and Video 4-4).<sup>354,366</sup>

### INTRAVENOUS INDUCTION

Intravenous induction is usually reserved for older children, those who request an intravenous induction, those with a previously established intravenous catheter, those with potential cardiovascular instability, and those who need a rapid-sequence induction (RSI) because of a full stomach. There are many different options as far as medications that can be used for an intravenous induction in a child (Table 4-5). Ideally, all children should breathe 100% oxygen before intravenous induction; if the face mask is met with objections, oxygen may be insufflated without a mask by simply holding the Y-connector of the circuit between your fingers over or near the child’s face.

### Thiopental

Thiopental (sodium pentothal) has been replaced by propofol as the most commonly used intravenous induction agent. The recommended induction dose of thiopental in healthy, unpremedicated children is 5 to 6 mg/kg<sup>367</sup>; neonates require a smaller dose (3 to 4 mg/kg).<sup>368</sup> Debilitated or severely ill patients, those who are hypovolemic, and those who have been premedicated may also require a smaller dose for induction of anesthesia. The beta-elimination half-life of thiopental in neonates is twice that in

**TABLE 4-5 Doses of Commonly Used Intravenous Induction Agents**

Drug	Dose (mg/kg)
Thiopental or thiamylal*	5-8
Methohexital	1-2.5
Propofol	2.5-3.5
Etomidate	0.2-0.3
Ketamine	1-2

\*No longer available in the United States.

**FIGURE 4-4** A single-breath induction is another useful method that is most appropriate for children 5 to 10 years of age. It is important to practice several times without the mask attached to the circuit before the actual induction (see text for details of preparing the circuit). This allows the child to become familiar with the feel of the mask as it is applied to the face and to properly time the sequence of events. **A** and **B**, Typically, we ask the child to take “the biggest breath possible and hold it.” Then we ask the child to “breathe all the way out until you have no more air in your lungs and hold it” and place the face mask on the child’s face. **C**, We then ask the child to take in “the biggest breath you have ever taken, hold it, then breathe normally.” If a full vital capacity breath is taken with a good mask seal around the mouth and nose, most children will lose their lid reflex within 15 to 30 seconds, which is similar to intravenous induction agents.

their mothers (15 versus 7 hours), so a single dose may produce excessively prolonged effect in neonates.<sup>369</sup> This drug is no longer available in the United States.

#### Methohexital

Methohexital is an ultra-short-acting oxybarbiturate that is infrequently used for induction. The induction dose for unpremedicated children ranges from 1.0 to 2.5 mg/kg<sup>370</sup>; premedicated children require a smaller dose. Recovery after intravenous administration is more rapid than after thiopental.<sup>371</sup> Larger doses cause skeletal muscle hyperactivity, myoclonic movements, and hiccups.<sup>370</sup> Pain at the injection site is common, necessitating pretreatment with intravenous lidocaine.

#### Propofol

Propofol is the most commonly used nonbarbiturate intravenous induction agent in children. The induction dose of propofol varies with age: the median effective dose (ED<sub>50</sub>) for a satisfactory induction in healthy infants 1 to 6 months old is  $3.0 \pm 0.2$  mg/kg, and in healthy children 10 to 16 years old it is  $2.4 \pm 0.1$  mg/kg.<sup>372</sup> The 95% effective dose (ED<sub>95</sub>) in healthy unpremedicated children 3 to 12 years of age is 2.5 to 3.0 mg/kg.<sup>373</sup> The early distribution half-life is about 2 minutes, and the terminal elimination half-life is about 30 minutes.<sup>374</sup> Clearance is very large ( $2.3$

$\pm 0.6$  L/min) and exceeds liver blood flow.<sup>374</sup> Advantages to propofol for induction of anesthesia include a reduced incidence of airway-related problems (e.g., laryngospasm, bronchospasm), more rapid emergence,<sup>375,376</sup> and a reduced incidence of nausea and vomiting.<sup>377,378</sup> The major disadvantage of propofol is pain at the site of injection, especially when administered in small veins (e.g., the back of the hand).<sup>372</sup> The administration of lidocaine (0.5 to 1.0 mg/kg) while applying tourniquet pressure proximal to the injection site (mini-Bier block) for 30 to 60 seconds before injecting the propofol effectively eliminates the pain in more than 90% of patients. However, younger children may not tolerate even the discomfort from the Bier block, which is the reason to consider using nitrous oxide to as an alternative and equally effective strategy (see Chapter 6). Other techniques reported to attenuate the pain include mixing lidocaine (0.5 to 1 mg/kg) with the propofol (but this should be done within 60 seconds of administration of the propofol), mixing thiopental with the propofol, refrigerating the propofol, pretreating with an opioid or ketamine, and diluting propofol to a 0.5% solution.<sup>379-388</sup>

In addition to its use as an induction agent, propofol can be administered by infusion for total intravenous anesthesia (see Chapter 7) because of its relatively low context-sensitive half-life. It is especially useful for pediatric patients undergoing nonoperating room procedures such as CT, MRI, radiotherapy, bone

marrow biopsy, upper and lower gastrointestinal endoscopy, and lumbar puncture.

### Etomidate

Etomidate is a hypnotic induction agent that provides marked cardiovascular stability. Etomidate is available for use in the United States and several other countries, but it is not available in many others due to concern for adrenal suppression. It is indicated for the induction of anesthesia in children with sepsis, cardiac instability, cardiomyopathy, or hypovolemic shock. The recommended induction dose is 0.2 to 0.3 mg/kg depending on the cardiovascular status of the child. Etomidate causes pain and myoclonic movements when injected intravenously<sup>389</sup> and may suppress adrenal steroid synthesis (see also Chapter 6).<sup>390</sup>

### Ketamine

Ketamine is a very useful induction agent for children with cardiovascular instability, especially in hypovolemic states, or for those who cannot tolerate a reduction in systemic vascular resistance, such as those with aortic stenosis or congenital heart disease in whom the balance between pulmonary and systemic blood flow is vital for maintaining cardiovascular homeostasis. In children whose circulation is already maximally compensated by endogenous catecholamines, ketamine is a myocardial depressant that can result in systemic hypotension.<sup>391</sup> The induction dose of ketamine in healthy children is 1 to 2 mg/kg. The dose should be reduced in the presence of severe hypovolemia. Smaller doses of intravenous ketamine (0.25 to 0.5 mg/kg) have also been used successfully for procedural sedation.

Ketamine causes sialorrhea, psychomimetic side effects (hallucinations, nightmares), and postoperative nausea and vomiting. The administration of an antisialagogue and midazolam is recommended to attenuate these side effects.

### INTRAMUSCULAR INDUCTION

Although it is preferable to avoid intramuscular injections in children, there are occasions when this route may be indicated, such as for the uncooperative child or adolescent who refuses all other routes of sedation (oral, intranasal, intravenous), those susceptible to malignant hyperthermia, those with congenital heart disease, and those who have poor venous access. In infants, but especially in older children, intramuscular ketamine is a very useful medication because it is available in a concentrated solution (100 mg/mL) (see earlier discussion).<sup>110</sup> In infants and very small children, intramuscular methohexital (10 mg/kg of a 5% solution) produces a state of anesthesia within several minutes.

### RECTAL INDUCTION

Rectal drug administration is ideally suited for an extremely frightened young child who rejects other forms of premedication and for those who are developmentally delayed. It is usually limited to children younger than 5 or 6 years of age or smaller than 20 kg, owing to volume limitations on the fluid injected and concern over emotional consequences. Methohexital, thiopental, ketamine, and midazolam have all been investigated as agents for rectal induction. For unpremedicated children, the induction doses are 30 to 40 mg/kg thiopental, 20 to 25 mg/kg methohexital,<sup>392</sup> 1.0 mg/kg midazolam,<sup>393</sup> and approximately 5 mg/kg ketamine.

Disadvantages of rectal drug administration include failure to induce anesthesia because of poor drug bioavailability or defecation and delayed recovery from anesthesia after brief

procedures due to the variability of rectal drug absorption. Conversely, there can be a very rapid drug uptake leading to respiratory compromise.

### FULL STOMACH AND RAPID-SEQUENCE INDUCTION

A full stomach is one of the most common problems that pediatric anesthesiologists face. The preferred method to secure the airway in the presence of a full stomach is intravenous RSI. Before this is undertaken, the anesthesiologist must ensure that the proper equipment is at hand: two functioning laryngoscope blades and handles (should a bulb or contact fail, a spare is available), two suctions (should the suction be blocked by vomitus or blood, a second is available), anesthetic medications, a checked anesthesia workstation with a checked breathing circuit, tracheal tubes of appropriate sizes, and stylet. All monitors should be properly functioning, and, at a minimum, the pulse oximeter, blood pressure cuff, and precordial stethoscope should be applied (in a crying, struggling child the pulse oximeter may not function properly until after anesthetic induction).

After intravenous access is established, the child should breathe 100% oxygen (preoxygenated) if possible. Studies of adult patients demonstrated that oxygen saturation remains greater than 95% for 6 minutes after only four vital capacity breaths of 100% oxygen.<sup>394</sup> Similar studies have not been performed in either cooperative or uncooperative children; however, without preoxygenation, younger infants and children desaturate very rapidly after induction of anesthesia, and much more rapidly than older children and adults.<sup>395,396</sup> One study demonstrated a more rapid increase in the inspired oxygen concentration in infants compared with older patients and that preoxygenation to a fractional concentration of O<sub>2</sub> in expired gas (FEO<sub>2</sub>) of 0.9 can be achieved in 100 seconds.<sup>397</sup> Even with a crying child, it is possible to increase the arterial oxygen tension (PaO<sub>2</sub>) by enriching the immediate environment with high gas flows of oxygen.

Preoxygenation should not be carried out in such a way that it upsets a child. Premedication (e.g., intravenous midazolam, 0.05 to 0.1 mg/kg) in divided doses may alleviate fear and anxiety before induction. It is important to preoxygenate children to avoid positive-pressure ventilation before tracheal intubation because positive-pressure ventilation might distend the already full stomach, leading to regurgitation and aspiration. After preoxygenation (and atropine 0.02 mg/kg), anesthesia is induced with intravenous thiopental (5 to 6 mg/kg),<sup>367</sup> propofol (3 to 4 mg/kg),<sup>398,399</sup> ketamine (1 to 2 mg/kg), or etomidate (0.2 to 0.3 mg/kg), followed immediately by 2 mg/kg of succinylcholine. Succinylcholine is still the paralytic agent of choice for rapid onset and short duration. However, high-dose rocuronium may be used as an alternative muscle relaxant for RSI if succinylcholine is contraindicated. Intubating conditions 30 seconds after 1.2 mg/kg rocuronium were similar to those after 1.5 mg/kg succinylcholine.<sup>400</sup> The mean time to return 25% of the twitch response was 46 ± 23 minutes (range, 30 to 72 minutes) for rocuronium compared with 5.8 ± 3.3 minutes (range, 1.5 to 8.2 minutes) for succinylcholine. However, if thiopental is used for induction of anesthesia and followed by rocuronium, the thiopental must be cleared from the tubing before the rocuronium is administered to prevent thiopental from precipitating.<sup>401</sup> The availability of a new reversal agent (sugammadex) for rocuronium (and potentially vecuronium) may reduce concern about the risks associated with a prolonged duration of action of rocuronium, particularly in the presence of a difficult airway, and eliminate the need for intravenous succinylcholine (see Chapter 6).

**TABLE 4-6** Contraindications to Cricoid Pressure

Contraindication	Potential Complication
Active vomiting	• Possible rupture of esophagus
Airway issues	• Fractured cricoid cartilage may be made worse. • Sharp foreign body in larynx may result in further laryngeal injury.
Esophageal issues	• Zenker diverticulum • Sharp foreign body in upper esophagus may result in further esophageal injury.
Vertebral/neurologic issues	• Unstable cervical spine may result in spinal cord injury. • Sharp foreign body in the neck may result in injury to other structures in the neck.

From Thiagarajah S, Lear E, Keh M. Anesthetic implications of Zenker's diverticulum. *Anesth Analg* 1990;70:109-11.

Cricoid pressure (Sellick maneuver) should be applied as anesthesia is induced, and the pressure should be maintained until the tracheal tube has been successfully placed between the vocal cords.<sup>402,403</sup> Unfortunately, few apply cricoid pressure as originally described by Sellick. The neck is not hyperextended, and a hard neck rest is not placed beneath the cervical curve. By obliterating the esophageal lumen, cricoid pressure is intended to prevent regurgitated material from passing from the stomach to the pharynx. Before induction of anesthesia, the cricoid ring is palpated between the thumb and the middle finger, and as soon as the child loses consciousness, pressure is steadily increased using the index finger. To prevent passive gastroesophageal reflux, a force of 30 to 40 Newtons (3 to 4 kg of force) must be applied to the upper esophagus (in adults), which creates an intraluminal pressure of approximately 50 cm H<sub>2</sub>O in the upper esophagus.<sup>404</sup> However, active vomiting may create esophageal pressures in excess of 60 cm H<sub>2</sub>O that could overcome cricoid pressure and result in regurgitation and pulmonary aspiration. Alternatively, if cricoid pressure is not relieved immediately, spontaneous rupture of the esophagus (Boerhaave syndrome) may occur. Hence, the contraindications to cricoid pressure should be carefully reviewed to avoid complications from this maneuver (Table 4-6). Gastric insufflation is prevented in children by cricoid pressure during mask ventilation with peak inspiratory pressures up to 40 cm H<sub>2</sub>O.<sup>405</sup> The Sellick maneuver should seal the esophagus in the presence of a nasogastric tube,<sup>406</sup> but removal of the nasogastric tube before intubation provides a better mask fit on the face and exposure for laryngoscopy and intubation. If the nasogastric tube is left in place, leaving it open to atmospheric pressure will vent liquid and gas present in the stomach.

The results of surveys from the United Kingdom showed that cricoid pressure was used in only 40% to 50% of children in whom it was indicated.<sup>407,408</sup> Reluctance to apply cricoid pressure may be attributed to a number of reasons, including the indications for its use and how often it is applied with the correct position and pressure.<sup>409-411</sup> In adults evaluated with MRI, the esophagus was situated lateral to the cricoid cartilage in more than 50% of patients without cricoid pressure and was laterally displaced more than 90% of the time when cricoid pressure was applied.<sup>412</sup> In addition, cricoid pressure may distort the anatomy of the upper airway, making laryngoscopy more

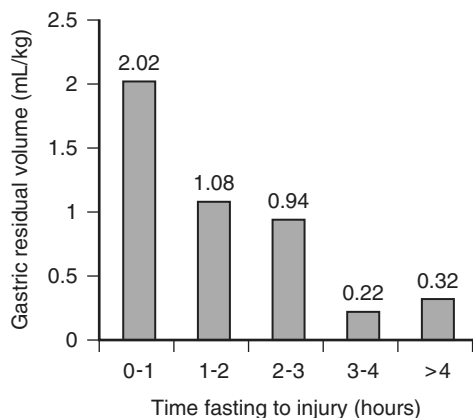

**FIGURE 4-5** Mean gastric residual volume is plotted against hours of fasting before anesthetic induction in emergency pediatric cases. These data suggest that a 4-hour fast, if it does not compromise patient safety, may reduce gastric residual volume and therefore reduce (but not eliminate) risk for aspiration. (Data abstracted from Schurizek BA, Rybro L, Boggild-Madsen NB, Juhl B. Gastric volume and pH in children for emergency surgery. *Acta Anaesthesiol Scand* 1986;30:404-8.)

difficult, and it must sometimes be released to facilitate a clear view of the larynx and tracheal intubation, particularly in infants.<sup>413</sup> Cricoid pressure also decreases the tone of the upper and lower esophageal sphincters.<sup>404,414</sup> However, properly applied cricoid pressure can facilitate intubation with RSI and mask ventilation.

Evidence suggests that the gastric residual volume in children undergoing emergency surgery is greater if a child is anesthetized within 4 hours after hospital admission (1.1 mL/kg).<sup>415</sup> If, on the other hand, surgery can be delayed for at least 4 hours, then the mean gastric residual volume is on average much less (0.51 mL/kg)<sup>415</sup>; this gastric residual volume is in fact similar to that observed in children who have fasted for routine surgical procedures (Fig. 4-5).<sup>1</sup> This does not imply that these children should not be regarded as having a full stomach; rather, the risk may be somewhat reduced if surgery can be delayed several hours. In addition, evidence suggests that in emergency cases, the gastric residual volume depends in part, on the time interval between the last food ingestion and the time of the injury as well as the severity of the injury.<sup>415</sup> Children who last ate more than 4 hours before the injury have a gastric residual volume similar to those who fasted as if they were elective surgery (Fig. 4-6). *There is some comfort in these numbers, but one should never consider such children as not having a full stomach but rather as having a less full stomach.* Additionally, the possible value of H<sub>2</sub>-blocking agents, metoclopramide, and clear antacids may be considered, but their use in this regard is not evidence based.

A modified RSI may be preferred in small infants who will likely desaturate during brief periods of apnea and will therefore require assisted ventilation before the trachea is secured. Neonates may be intubated awake if indicated; this may provide a greater margin of safety because it preserves spontaneous ventilation as well as laryngeal reflexes. Skillfully performed awake intubation in neonates is not associated with either significant adverse cardiovascular responses or neurologic sequelae<sup>416</sup> and may be preferred in infants with hemodynamic instability.<sup>417</sup>

**FIGURE 4-6** Mean gastric residual volume is plotted against time from last food ingestion to time of injury. These data suggest that the longer the time from ingestion to injury, the lower the risk for pulmonary aspiration of gastric contents. Also, if more than 4 hours has elapsed between the time of last food ingestion and time of injury, the risk is similar to that for patients with routine fasting. However, even with a 4-hour fasting time period, these patients must still be treated as though they have a full stomach. It should be noted that these volumes also relate to the severity of injury (increased volumes with increased injury severity). (Data abstracted from Bricker SRW, McLuckie A, Nightingale DA. Gastric aspirates after trauma in children. *Anesthesia* 1989;44:721-4.)

## Special Problems

### THE FEARFUL CHILD

This is a difficult problem without a satisfactory solution. The child's fear is generally based on the child's developmental status, the hospital environment, and the impending surgery. This is why it is so vital that as much information as possible be presented and queries as to why the child is afraid are so important. Frequently, a few well-directed questions and honest answers will resolve most of the child's concerns. Often, allowing a parent to hold the child during induction of anesthesia or allowing the child to hold the anesthetic mask himself or herself, will stop the flow of tears and settle the child's emotional upheaval. In other situations, one commonly practiced solution is to use intramuscular ketamine.

### AUTISM

Autism is characterized by a delay in the development of socialization and communication skills and is the best-studied form of pervasive developmental disorders. Other types include Asperger syndrome, Rett syndrome, and childhood disintegrative disorder. Autism is a clinical diagnosis, with an onset before the age of 3 years. The diagnostic criteria as listed in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) are (1) qualitative impairment in social interaction, (2) qualitative impairment in verbal and nonverbal communication, and (3) restricted repetitive and stereotypical patterns of behavior, interests, and activities.

The overall estimated prevalence of autism spectrum disorders (ASD) is 1 in 88 (11.3 per 1000), which is an increase over previous estimates of 1 in 150 (6.4 per 1000) owing to better ascertainment and a broadening of the diagnostic concept.<sup>418,418a</sup> Autism affects boys more commonly than girls in a ratio of 4:1 to 5:1 with equal distribution in all socioeconomic groups.<sup>419</sup> Behavior

and cognitive training is the most effective therapy, but it must be initiated at as early an age as possible to achieve the best possible neurologic improvement. Serotonin reuptake inhibitors may suppress aggression and repetitive behavior.<sup>420-422</sup> Naltrexone may be used to decrease the effects of the hypersecretion of endorphins.<sup>422,423</sup> Seizures are present in about 25% of autistic children and usually manifest in adolescence.<sup>420,421,424</sup>

The perioperative period can be a stressful time for the child with autism and his or her family. These children do not respond well to any change in their routine and may challenge the ingenuity of the anesthesiologist. They are very sensitive to stimuli such as light, sound, touch, and pain. The hospital setting is anxiety provoking and usually upsets most autistic children until they become totally disruptive and uncooperative.

The anesthesiologist's approach to the autistic child depends on the severity of the disorder. Information regarding the child's previous anesthetic experience, assessment of the child's behavior and idiosyncrasies, and bonding with parents or caregivers should be accomplished during the preanesthetic visit. Sedative premedication can work very well in these children. The decision to administer premedication needs to be made on an individual basis (see "Premedication and Induction Principles"). Oral midazolam (0.5 to 1 mg/kg)<sup>126</sup> is the most commonly used preoperative anxiolytic for children, although other choices include oral ketamine (6 mg/kg)<sup>227</sup> and a combination of oral midazolam (0.5 mg/kg) and ketamine (3 mg/kg).<sup>230</sup> The overly anxious child may be uncooperative with oral medication and may require intramuscular ketamine. Parents can also offer insight into which strategies would make their child's life easier during this difficult time. It is important to take the time to address parental concerns and establish a trust relationship with the family.

There is great variation in the severity of autism and hospital needs of these children.<sup>425</sup> The focus for optimal management of these children in one institution was on early communication to provide a flexible and individualized admission process and anesthetic plan.<sup>425</sup> A quiet room may offer advantage preoperatively for more severe cases. Where premedication was indicated, oral midazolam (0.5 mg/kg) was effective for mild cases and oral ketamine (7 mg/kg) was most reliable for moderate and severe cases. The oral medication was mixed in the child's favorite clear liquid.

Although parental presence during induction combined with oral midazolam is no more beneficial in reducing a child's anxiety than oral midazolam alone,<sup>125</sup> for this population parental presence is most often beneficial (since the child knows and trusts their parent or parents) in helping the child reach the operating room. Finally, the appropriate use of parents in the postanesthesia care unit can facilitate the transition from surgery to recovery. Studies have shown that children who are reunited with their parents sooner require less pain medication and are discharged earlier in an ambulatory setting.<sup>426</sup>

### ANEMIA

The minimum hematocrit necessary to ensure adequate oxygen transport in children has not been well established. Preoperative hemoglobin testing, however, is of limited value in healthy children undergoing elective surgery when minimal blood loss is expected.<sup>427</sup> Children with chronic anemia, such as those with renal failure, do not require preoperative transfusion because of compensatory mechanisms, such as increased 2,3-diphosphoglycerate, increased oxygen extraction, and increased cardiac output. Elective surgery for children who are

anemic should take into consideration their medical history, underlying diseases (e.g., hemoglobinopathies, von Willebrand, sickle cell, other factor deficiency), the nature of the surgery, and its urgency. Most pediatric anesthesiologists would recommend a hematocrit greater than 25% before elective surgery in the absence of chronic disease. If significant blood loss is anticipated and the surgery is elective, then the cause of anemia should be investigated and treated and the surgery postponed until the hematocrit is restored to the normal range. *Healthy children scheduled for elective surgery that is not expected to cause substantive bleeding should not routinely receive a blood transfusion just to bring their hematocrit to an arbitrary limit such as 30%.*

Physiologic anemia of infancy occurs between 2 and 4 months of postnatal age. At this time, there is an increased production of hemoglobin A and an increase in red cell 2,3-diphosphoglycerate, which contribute to a right shift of the oxygen-hemoglobin dissociation curve (see Chapter 9). Therefore, in infants 2 to 4 months of age, a reduced hemoglobin value is acceptable. Anemia, with a hematocrit of less than 30%, in formerly preterm infants represents a special category of patients who may have an increased incidence of postoperative apnea (see later discussion), but transfusion is still not recommended.<sup>428</sup>

### UPPER RESPIRATORY TRACT INFECTION

Most anesthesiologists agree that the presence of an acute purulent upper respiratory tract infection (URI), fever, change in mental state or behavior, or signs pertaining to a lower respiratory tract infection (i.e., wheezing and rales) are sufficient grounds to postpone elective surgery for approximately 4 weeks.<sup>429</sup> However, the child with a nonpurulent active or recent URI (within 4 weeks) often presents a conundrum, even for the most experienced anesthesiologist.

Between 20% and 30% of all children have a runny nose during a significant part of the year. In the preanesthetic evaluation, we must rely on history, physical examination, and, rarely, laboratory data to decide whether to proceed with the anesthesia. A differential diagnosis of a child with a runny nose is presented in Table 4-7.

The perioperative and postoperative risks of anesthetizing children with URIs are poorly understood. In part, this stems

from study bias in that procedures for many children with symptomatic URIs are cancelled before the day of surgery, thus precluding them from inclusion in the studies. Another difficulty is the variable definition of a URI, which limits the external validity of these studies. Finally, study design flaws or inadequacies including retrospective, nonrandomized, and nonblinded studies have created inconsistencies among the published results.

A number of perioperative risks have been studied.<sup>429</sup> The risk of postintubation croup was similar in children who had an active URI and those who did not. However, some children in that study had “tight-fitting” tracheal tubes, which may have confounded the results.<sup>430</sup> Intraoperative complications including atelectasis and cyanosis were described in a series of children with a history of a recent URI. Very severe complications have been associated with the administration of anesthesia in children with recently infected airways, although the study was retrospective and lacked a case-matched control population.<sup>431</sup> In another retrospective study, the incidence of intraoperative complications in children with URIs was similar to that in children without URIs.<sup>432</sup> This study included children with an active URI at the time of anesthesia and some whose tracheas were intubated. However, the authors did report a greater incidence of respiratory complications in those who had recently had a URI. In a prospective cohort study in which children who were scheduled for myringotomy and tube placement for chronic ear infection were matched with controls who did not have a URI, the morbidity from face mask general anesthesia was no different from that in the children who did not have a URI.<sup>433</sup> However, it is difficult to evaluate this study because bronchospasm would not be expected without tracheal intubation.<sup>434,435</sup> Bronchospasm occurs more frequently in children whose tracheas are intubated and who have active URIs.<sup>435</sup> The incidence of bronchospasm in children with a URI (41 : 1000) is 10-fold greater than it is in those without a URI. Mechanical stimulation of the airway appears to be an important trigger for bronchospasm.<sup>434</sup> The incidence of laryngospasm in children with a URI (96 : 1000) is fivefold greater than it is in children without a URI (17 : 1000).<sup>436</sup> The incidence of minor but not major intraoperative hemoglobin desaturation events in children with a URI is greater than in those without a URI.<sup>435</sup> Lastly, the incidence of all respiratory-related adverse events combined in children with a URI was 9-fold greater than in those without a URI and 11-fold greater in children who had a URI and required tracheal intubation.<sup>437</sup>

When the a tracheal tube and LMA were compared in children with a URI, the incidence of mild bronchospasm, major desaturation events, and overall respiratory events was reduced in the presence of a LMA, although the incidence of laryngospasm was similar with the two airway devices.<sup>438,439</sup>

Prognostic factors of adverse anesthetic events in children with URIs who were scheduled for elective surgery include the type of airway management (tracheal intubation > LMA), that the parent states that the child has a “cold,” the presence of nasal congestion, snoring, passive smoking, the induction agent (thiopental > halothane > sevoflurane ~ propofol), sputum production, and whether the neuromuscular agent was antagonized.<sup>440</sup> Propofol depresses laryngeal reflexes and may decrease airway responsiveness by relaxation of bronchial smooth muscle.<sup>441,442</sup> Several variables, including wheezing, fever, malaise, and age, could not be excluded as predictors of adverse events because procedures in some children were deferred or cancelled after their preoperative visit.

**TABLE 4-7** Differential Diagnosis of a Child with a Runny Nose

<b>Noninfectious Causes</b>
Allergic rhinitis: seasonal, perennial, clear nasal discharge; no fever
Vasomotor rhinitis: emotional (crying); temperature changes
<b>Infectious Causes</b>
<i>Viral infections</i>
Nasopharyngitis (common cold)
Flu syndrome (upper and lower respiratory tract)
Laryngotracheal bronchitis (infectious croup)
<i>Viral exanthems</i>
Measles
Chickenpox
<i>Acute bacterial infections</i>
Acute epiglottitis
Meningitis
Streptococcal tonsillitis

In a similar study, three children with a recent or active URI required unanticipated admission to hospital.<sup>443</sup> Logistic regression determined that the risk factors associated with adverse outcomes in children with URIs included the presence of copious secretions ( $P = 0.0001$ ), nasal congestion ( $P = 0.014$ ), passive (parental) smoking ( $P = 0.018$ ), and reactive airway disease ( $P = 0.028$ ), as well as whether the child had been a premature infant ( $P = 0.007$ ). ASA status did not correlate with adverse outcomes. Age has not been an independent predictor of adverse events in children with URIs in most studies, although this study suggested that the incidence of bronchospasm in infants younger than 6 months old with active URIs was greater (20.8% versus 4.7%,  $P = 0.08$ ) than in older children.<sup>443</sup> This same study also demonstrated that the incidence of oxygen desaturation in children younger than 2 years of age was greater than it was in older children (21.5% versus 12.5%,  $P = 0.023$ ). Tracheal intubation in children younger than 5 years of age was an independent risk factor for postoperative respiratory adverse events ( $P = 0.0002$ ).<sup>443</sup> Neither the duration of anesthesia nor the depth of anesthesia at the time of extubation (awake versus deep) was a risk factor. Children with active URIs who were anesthetized and maintained with sevoflurane had the smallest incidence of adverse events. The greatest incidence of adverse respiratory events occurred in children undergoing airway surgery (e.g., tonsillectomy and adenoidectomy, direct laryngoscopy, bronchoscopy). This study concluded that children with active and recent URIs (within 4 weeks) are at greater risk for adverse respiratory events, particularly if there is a history of reactive airway disease, of surgery involving the airway, or of prematurity, passive smoke inhalation, nasal congestion or copious secretions, or requirement for a tracheal tube.

In another study that examined the risk factors for adverse anesthetic events in children with URIs, adverse respiratory events were greater in children who were premedicated with midazolam, in those who were extubated while deeply anesthetized, and in those who had peak URI symptoms that occurred within the preceding 4 weeks. However, specific preoperative symptoms were not useful in predicting respiratory adverse events during emergence from anesthesia.<sup>444</sup>

Cancellation of cardiac surgery carries special import because of the risk that the child's heart will deteriorate or the disease process will progress (e.g., pulmonary hypertension) as well as the extensive time, materials, and personnel committed to a planned case. In a prospective study of children scheduled for cardiac surgery, the incidences of respiratory adverse events (29.2% versus 17.3%,  $P < 0.01$ ), multiple postoperative complications (25% versus 10.3%,  $P < 0.01$ ), and bacterial infection (5.2% versus 1.0%,  $P = 0.01$ ) were greater in those with a URI than in those without.<sup>445</sup> Logistic regression identified the presence of a URI as an independent risk factor for both postoperative infections and multiple postoperative complications. Although the duration of the intensive care unit stay was greater for children with URIs ( $80 \pm 90$  versus  $60 \pm 60$  hours,  $P < 0.01$ ), the duration of hospital stay was not ( $8.4$  versus  $7.8$  days,  $P > 0.05$ ).

A national survey suggested that more experienced anesthesiologists are less likely to cancel surgery because of the presence of a URI.<sup>446</sup> Cancellation may also impose emotional and economic burdens on the parents.<sup>447,448</sup> Factors that should be considered when deciding whether to proceed with elective surgery in a child with a URI are summarized in Table 4-8.

On the basis of the best evidence available at the present time, a child with a mild URI that is not of acute onset may be safely

**TABLE 4-8** Factors Affecting Decision for Elective Surgery in a Child with Upper Respiratory Tract Infection

Proceed with Caution	Consider Cancellation
• Child has "just a runny nose," no other symptoms, "much better"	• Parents confirm symptoms: fever, malaise, cough, poor appetite, just developed symptoms last night
• Active and happy child	• Lethargic, ill-appearing
• Clear rhinorrhea	• Purulent nasal discharge
• Clear lungs and symptoms have leveled off or have improved	• Wheezing, rales that do not clear
• Older child	• Child <1 year, ex-premie
• Social issues: hardship for parents to be away from work, insurance will run out	• Other factors: history of reactive airway disease, major operation, endotracheal tube required
• No fever	• Fever $>38.5^{\circ}\text{C}$
• Outpatient procedure that will not expose immunocompromised children to possible infectious agent	• Inpatient procedure that may result in exposure of immunocompromised children to viral/bacterial infection

From Tait AR, Malviya S. Anesthesia for the child with an upper respiratory tract infection: still a dilemma? *Anesth Analg* 2005;100:59-65.

anesthetized for minor surgical procedures; if a tracheal tube is required, then the risk of bronchospasm, laryngospasm, and desaturation events increases.<sup>430,432-437,440,443</sup> It is reassuring to note that most such adverse perioperative events are not associated with significant morbidity; that is, the severity of oxygen-hemoglobin desaturation is similar in children with and without a URI.<sup>435</sup> Such children may also be more susceptible to mild episodes of oxygen desaturation in the recovery room. Once again, these episodes are readily treated with supplemental oxygen administration.<sup>449</sup>

Insofar as which techniques will help to prevent complications from a URI, pretreating healthy children who either had a URI within the preceding 6 weeks or had an active URI with bronchodilators, either inhaled ipratropium or albuterol, before anesthesia provided no benefit. In addition, there was no association between either a recent URI or an active URI and the incidence of desaturation, wheezing, coughing, stridor, or laryngospasm causing desaturation.<sup>450</sup> However, in another study, children with a recent URI ( $\leq 2$  weeks in duration) who received preoperative salbutamol experienced a significantly reduced incidence of laryngospasm, bronchospasm, oxygen desaturation ( $<95\%$ ) and severe coughing with an LMA or tracheal tube.<sup>451</sup> Humidification, intravenous hydration, and anticholinergics may also decrease perioperative complications,<sup>446</sup> although the results of at least one study suggested that glycopyrrolate did not reduce the incidence of perioperative adverse respiratory events when it was given after induction of anesthesia to children with URIs.<sup>452</sup>

If a child is recovering from a URI, the child's physical examination should be near normal. If this is true, anesthesia can generally proceed without increasing the risks substantively. However, if the child with a URI requires prolonged tracheal intubation, the clinician must use his or her judgment and experience together with consultation with the parents and surgeon to determine whether to proceed with or postpone anesthesia.<sup>434-436,446,453</sup>

If the decision is to postpone anesthesia, then how long should one wait before undertaking general anesthesia? Bronchial hyperreactivity, which is associated with URIs in children, shows spirometric changes in the lungs for as long as 7 weeks after a URI.<sup>453,454</sup> Although studies suggest that surgery should be postponed for at least 7 weeks after resolution of a URI, this plan is impractical because most children will be infected with a new URI by that time. Postponing surgery until 2 weeks after resolution of the URI is a common but as yet unproven strategy. In fact, some data suggest that the incidence of adverse respiratory events is just as great in this population as it is in those who were anesthetized during the acute phase of the URI.<sup>433,455</sup> This 2-week waiting period may be acceptable in a child with uncomplicated nasopharyngitis.<sup>456</sup> Unfortunately, there is no consensus on the optimal time interval before surgery is rescheduled. In a survey of anesthesiologists, most wait 3 to 4 weeks before proceeding with surgery.<sup>446</sup> The rationale for this time period is that the risk of respiratory complications is unchanged for 4 to 6 weeks.<sup>443</sup>

In conclusion, there are always risks associated with anesthesia, even in children without URIs. In children with URIs, we must wait 4 to 6 weeks or longer for these risks to return to baseline. Therefore, in children who have had a URI, we can tailor our anesthetic management to further decrease these risks (by using propofol, an LMA, or a face mask instead of a tracheal tube), but the risk cannot be reduced to zero. Good judgment, common sense, clinical experience, and informed consent from the parents or guardians must be used when deciding whether to proceed or postpone the surgery. All of these deliberations and discussions including the risks and benefits should be documented in the chart (see Chapter 11 for additional discussion and perspectives).

### OBSTRUCTIVE SLEEP APNEA SYNDROME

Sleep apnea is a sleep-related breathing disorder in children characterized by a periodic cessation of air exchange, with apnea episodes lasting longer than 10 seconds and an apnea-hypopnea index (AHI) indicating that the total number of obstructive episodes per hour of sleep is greater than 1 (AHI 1-5 = mild OSA, 6-10 = moderate OSA, >10 = severe OSA).<sup>457</sup> Sleep apnea may be defined as central (absent gas flow, lack of respiratory effort), obstructive (absent gas flow, upper airway obstruction and paradoxical movement of rib cage and abdominal muscles) or mixed (due to both CNS defect and obstructive problems). Diagnosis is made by clinical assessment (see later discussion), nocturnal pulse oximetry, or polysomnography studies.

Obstructive sleep apnea syndrome (OSAS) is manifested by episodes that disturb sleep and ventilation. These episodes occur more frequently during rapid-eye-movement (REM) sleep and increase in frequency as more time is spent in REM sleep periods as the night progresses. OSAS occurs in children of all ages (about 2% of all children) but more commonly in children 3 to 7 years of age. It occurs equally in boys and girls, although the prevalence is greater in African American children.<sup>458</sup>

Signs of OSAS are sleep disturbances (including daytime sleepiness), irritability, night terrors, nocturnal enuresis, snoring loud enough to hear through a closed door, pauses and/or gasps during the night, failure to thrive resulting from poor intake due to tonsillar hypertrophy, speech disorders, and decreased size (decreased growth hormone release during disturbed REM sleep). With the worldwide increase in childhood obesity, the presence of obesity in children with OSAS

exacerbates the signs and symptoms of OSAS. Parents of obese children should be specifically asked about such signs and symptoms. This syndrome can cause significant cardiac, pulmonary, and CNS impairment due to chronic oxygen desaturation. Indeed, both OSAS and obesity are systemic inflammatory responses.<sup>459</sup> When they occur together in a child, the severity of the signs and symptoms are greater than if only one had occurred, and resolution of the OSAS after tonsillectomy is less likely. In children with OSAS and morbid obesity, the incidences of hypertension and diabetes are greater than in the absence of these disorders. Therefore it is important to evaluate the cardiovascular status; although right ventricular dysfunction with pulmonary hypertension is classic, biventricular hypertrophy can develop. It is more likely to occur in children with severe OSAS but has been reported in children with only mild OSAS.<sup>460</sup> Cardiac evaluation is recommended for any child with signs of right ventricular dysfunction, systemic or pulmonary hypertension, or multiple episodes of desaturation below 70%. Electrocardiography and chest radiography are insensitive diagnostic tests; rather, echocardiography is recommended.<sup>461</sup> Relief of the tonsillar/adenoidal obstruction can reverse many of these disorders and prevent progression of others (pulmonary hypertension and cor pulmonale) within 6 months after tonsillectomy, although approximately 30% of children with severe OSAS will not have resolution of the OSAS after tonsillectomy.

Children with OSAS may be premedicated with caution with oral midazolam. Despite an incidence of self-limited preoperative desaturation of less than 1.5%, post-premedication monitoring of hemoglobin saturation in these children would seem reasonable.<sup>462</sup> Avoidance of premedication may, however, be more advantageous postoperatively.

Children who are at increased risk for postoperative upper airway obstruction after tonsillectomy and/or adenoidectomy for OSAS include age younger than 2 years, craniofacial anomalies, failure to thrive, hypotonia, morbid obesity, previous upper airway trauma, cor pulmonale, a polysomnogram with a respiratory distress index (RDI) greater than 40 or O<sub>2</sub> saturation nadir less than 85%, and a child undergoing an additional uvulopalatopharyngoplasty (UPPP).<sup>463</sup> *Nocturnal desaturation to less than 85% upregulates the genes responsible for control of opioid receptors, resulting in an increased sensitivity to opioids; opioid requirement is reduced by approximately 50%, making standard doses of opioids a relative overdose in children with severe OSA.* This has been demonstrated in both animals and humans.<sup>464,465</sup> To attenuate the risk of perioperative respiratory complications, opioids should be carefully titrated to the respiratory responses during surgery, and if an increased sensitivity to opioids is detected, all perioperative opioids should be reduced accordingly (see Chapter 31 for further details).<sup>466</sup> If nocturnal upper airway obstruction continues after tonsillectomy, ancillary strategies that have been met with variable success have been used: nasal continuous positive airway pressure (CPAP) or bi-level positive airway pressure (BiPAP), nasal steroids, oxygen therapy, and weight loss, although nasal CPAP/BiPAP is rarely tolerated in children.<sup>463</sup>

The American Academy of Pediatrics (AAP) Clinical Practice Guidelines<sup>458</sup> provide recommendations for inpatient monitoring of children at high risk for postoperative complications who have OSAS and are undergoing adenotonsillectomy (Table 4-9). It should be noted that there is an ongoing concern regarding where these children should undergo surgery (in an ambulatory center or in a hospital) and the monitoring these children should have postoperatively (extended observation followed by

OSAS, Obstructive sleep apnea syndrome.

discharge home or overnight observation). In addition to the AAP guidelines, the ASA considers this such a growing problem for both adults and children that they also have formulated a Practice Guideline. Tables 4-10 and 4-11 (modified for children) help to clarify the identification and assessment of children potentially at risk for OSA and offer a proposed (although as yet unvalidated) risk assessment scoring system.<sup>467</sup> This system attempts to characterize those patients who are at significantly increased risk for perioperative complications.

Among children 1 to 18 years of age with OSAS, those without complicating medical conditions such as neuromuscular disease, obesity, or craniofacial abnormalities but with mild sleep apnea may have either no or some improvement in their airway obstruction on the night of surgery. Based on current literature, one may consider discharging children 3 to 12 years of age home on the day of surgery after an extended period of observation (4 to 6 hours), if they meet these criteria. However, those with moderate to severe OSA (particularly obese children) may actually experience worse OSA on the night of their surgery.<sup>468,469</sup> These children should receive reduced doses of opioids and be admitted for overnight monitoring with pulse oximetry and an apnea monitor.<sup>470</sup>

### ASYMPTOMATIC CARDIAC MURMURS

The presence of a cardiac murmur is a common finding in children<sup>471</sup> and may have significant anesthetic implications. Never underestimate the potential implications of a newly diagnosed heart murmur. A history should be obtained to delineate the nature of the murmur. In most cases, the parents will report that the murmur was detected previously by the child's pediatrician and determined to be an "innocent flow murmur" without any anatomic or physiologic abnormalities. When a pediatric cardiologist confirms the classic clinical features of an innocent murmur, an echocardiogram seldom reveals heart disease, especially if the child is older at presentation.<sup>472</sup> *However, even an experienced cardiologist can occasionally make a misdiagnosis; the only certain means to exclude a structural defect within the heart is with*

**TABLE 4-10** Candidate Criteria for Identification and Assessment of OSA\*

#### A: Clinical Signs and Symptoms Suggesting Obstructive Sleep Apnea (OSA)

##### 1. Predisposing physical characteristics

- ≥95th percentile for age and gender
- Craniofacial abnormalities affecting the airway (e.g., Down syndrome)
- Anatomic nasal obstruction
- Tonsils nearly touching or touching in the midline (kissing tonsils)

##### 2. History of apparent airway obstruction during sleep (two or more of the following are present; if patient sleep is not observed by another person, then only one of the following needs to be present)

- Snoring (loud enough to be heard through a closed door)
- Frequent snoring
- Observed pauses in breathing during sleep
- Awakened from sleep with choking sensation
- Frequent arousal from sleep
- Intermittent vocalizations during sleep
- Parental report of restless sleep, difficulty breathing, or struggling respiratory efforts during sleep
- Parental report of enuresis

##### 3. Somnolence (one of the following is present)

- Frequent somnolence or fatigue despite adequate "sleep"
- Falls asleep easily in a nonstimulating environment (e.g., watching television) despite adequate "sleep"
- Parent or teacher comments that the child appears sleepy during the day, is easily distracted, is overly aggressive, or has difficulty concentrating
- Child is often difficult to arouse at usual awakening time

#### B: Determination of Severity

- If a child has signs or symptoms in two or more of the above categories, there is a significant probability that he or she has OSA. The severity of OSA may be determined by sleep study. If a sleep study is not available, such patients should be treated as though they have moderate sleep apnea unless one or more of the signs of symptoms above is severely abnormal (e.g., ≥95th percentile for age and gender, respiratory pauses that are frightening to the observer, child snores loudly enough to be heard through a closed door, child regularly falls asleep within minutes after being left unstimulated), in which cases patients should be treated as though they have severe sleep apnea.
- If a sleep study has been done, the result should be used to determine the perioperative anesthetic management of a child. (Review the polysomnogram for evidence of nocturnal desaturations <85%, which increases sensitivity to opioids). However, because sleep laboratories differ in their criteria for detecting episodes of apnea and hypoxemia, the Task Force recommends that the sleep laboratory's assessment (none, mild, moderate, or severe) take precedence over the actual apnea-hypopnea index (AHI, the number of episodes of sleep-disordered breathing per hour). If the overall severity is not indicated, it may be determined by using the following table:

Severity of OSA	Adult AHI	Pediatric AHI
None	0-5	0
Mild OSA	6-20	1-5
Moderate OSA	21-40	6-10
Severe OSA	>40	>10

Modified from Gross JB, Bachenberg KL, Benumof JL, et al. Practice guidelines for the perioperative management of patients with obstructive sleep apnea: a report by the American Society of Anesthesiologists Task Force on Perioperative Management of Patients with Obstructive Sleep Apnea. Anesthesiology 2006;104:1081-93.

\*Note: This table has been modified for children; the scoring system is intended only as a guide and has not been validated.

**TABLE 4-11 OSA Risk Scoring System: Example\***

<b>A. Severity of Sleep Apnea Based on Sleep Study (or Clinical Indicators if Sleep Study Is Not Available: Point Score 0-3<sup>†‡</sup>)</b>	
<i>Severity of OSA</i>	
None	0
Mild	1
Moderate	2
Severe	3
<b>B. Invasiveness of Surgery and Anesthesia: Point Score 0-3</b>	
<i>Type of surgery and anesthesia</i>	
Superficial surgery under local or peripheral nerve block anesthesia without sedation	0
Superficial surgery with moderate sedation or general anesthesia	1
Peripheral surgery with spinal or epidural anesthesia (with no more than moderate sedation)	1
Peripheral surgery with general anesthesia	2
Airway surgery with moderate sedation	2
Major surgery with general anesthesia	3
Airway surgery with general anesthesia (e.g., tonsillectomy)	3
<b>C. Requirement for Postoperative Opioids: Point Score 0-3</b>	
<i>Opioid requirement</i>	
None	0
Low-dose oral opioids (tonsillectomy)	1
High-dose oral opioids, parenteral or neuraxial opioids	3
<b>D. Estimation of Perioperative Risk—Overall Score Equals the Score for “A” Plus the Greater of the Score for “B” or “C”: Possible Score 0-6<sup>§</sup></b>	

Modified from Gross JB, Bachenberg KL, Benumof JL, et al. Practice guidelines for the perioperative management of patients with obstructive sleep apnea: a report by the American Society of Anesthesiologists Task Force on Perioperative Management of Patients with Obstructive Sleep Apnea. *Anesthesiology* 2006;104:1081-93.

\*Note: This table has been modified for children. A scoring system similar to this table may be used to estimate whether a child is at increased perioperative risk of complications from OSA. This example has not been clinically validated, and such a scoring system is simply meant to provide guidance.

<sup>†</sup>One point may be subtracted if a patient has been on continuous positive airway pressure (CPAP) for noninvasive positive-pressure ventilation before surgery and will be using his or her appliance consistently during the postoperative period.

<sup>‡</sup>One point should be added if a child with mild or moderate OSA also has a resting arterial carbon dioxide tension greater than 50 mm Hg.

<sup>§</sup>Children with a score of 4 may be at increased perioperative risk from OSA; children with a score of 5 or 6 may be at significantly increased perioperative risk from OSA.

*an echocardiogram.*<sup>473</sup> In general, nonpathologic murmurs occur during systole and are soft and nonradiating with normal feel to peripheral pulses; there are normal blood pressures in both upper and lower extremities. However, if the murmur is harsh and difficult to localize, if there are bounding pulses, if the murmur is louder than grade II/VI, or if it is accompanied by other findings (Tables 4-12 and 4-13), then further evaluation is warranted.<sup>474</sup> If the murmur has not been detected previously, referral to a pediatric cardiologist is indicated or an echocardiogram by an experienced pediatric echocardiographer should be obtained before induction of anesthesia.<sup>475</sup>

## FEVER

The presence of a low-grade fever before elective surgery poses a dilemma whether to proceed with anesthesia or to delay. In

**TABLE 4-12 Grading of Heart Murmurs**

Grade I	Heard only with intense concentration
Grade II	Faint, but heard immediately
Grade III	Easily heard, of intermediate intensity
Grade IV	Easily heard, palpable thrill/vibration on chest wall
Grade V	Very loud, thrill present, audible with only edge of stethoscope on chest wall
Grade VI	Audible with stethoscope off the chest wall

Modified from Emmanouilides GC, Allen HD, Riemenschneider TA, Gutgesell HP. Moss and Adams heart disease in infants, children, and adolescents including the fetus and young adult. 5th ed. Baltimore: Williams & Wilkins; 1995.

**TABLE 4-13 Symptoms and Signs of Heart Disease**

- Feeding difficulties: disinterest, fatigue, diaphoresis, tachypnea, dyspnea
- Poor exercise tolerance
- Tachypnea, dyspnea, grunting, nasal flaring, and intercostal, suprasternal, or subcostal retractions
- Frequent respiratory tract infections (a result of compression of airways by plethoric vessels leading to stasis of secretions and atelectasis)
- Central cyanosis (involving warm mucous membranes: tongue and buccal mucosa) or poor capillary refill
- Absent or abnormal peripheral pulses

Modified from Pelech AN. Evaluation of the pediatric patient with a cardiac murmur. *Pediatr Clin North Am* 1999;46:167-88.

general, if a child has only 0.5° C to 1.0° C of fever and no other symptoms, this degree of fever is not a contraindication to general anesthesia. However, if the fever is associated with a recent onset of rhinitis, pharyngitis, otitis media, dehydration, or any other sign of impending illness, it is prudent to postpone the procedure. If the planned surgery is of an urgent nature, every effort should be made to reduce the fever before induction of anesthesia, primarily to reduce oxygen demands. Reduction of the fever should not include aspirin, because aspirin may interfere with platelet function and is associated with Reye syndrome. Ibuprofen may be associated with an increase in bleeding time<sup>313</sup> and should be avoided before surgery. On the other hand, acetaminophen has no effect on platelet function and is an excellent antipyretic. It is rapidly absorbed when administered orally, producing adequate blood concentrations within several minutes. In contrast, rectal administration requires at least 60 minutes to achieve a significant blood concentration.<sup>287,476</sup> There is no evidence that an existing fever predisposes to a malignant hyperthermic reaction.<sup>477</sup>

## POSTANESTHESIA APNEA IN FORMERLY PRETERM INFANTS

The formerly preterm infant may have a multitude of residual problems owing to intensive care therapy, prolonged intubation, and still-maturing organogenesis. The incidence of subglottic stenosis is increased in this population. These infants are also prone to developing perioperative respiratory complications.<sup>478</sup> At the time surgery is scheduled, these infants may or may not have intermittent apnea spells, although they often appear normal for their age. Since the original descriptions of this subgroup of infants, a number of prospective studies have defined

**FIGURE 4-7** The predicted probability of apnea for all infants was inversely related to gestational age at the time of birth and postconceptional age at the time of surgery. The probability of apnea was the same regardless of postconceptional age or gestational age for infants with anemia. (dashed magenta line) (From Coté CJ, Zaslavsky A, Downes JJ, et al. Postoperative apnea in former preterm infants after inguinal herniorrhaphy: a combined analysis. *Anesthesiology* 1995;82:807-8.)

the population at greatest risk for postoperative apnea.<sup>428,478-487</sup> Formerly premature infants of less than 44 weeks postconceptional age (PCA) are at a greater risk for apnea after general anesthesia than are those older than 44 weeks PCA, although the risk of postanesthetic apnea in preterm infants who are older than 44 weeks PCA remains substantial (approximately 5%).<sup>488</sup> In an analysis of eight published prospective papers from four institutions conducted over 6 years, the incidence of apnea varied inversely with the both gestational age and PCA (E-Fig. 4-5).<sup>488</sup> For example, consider two infants who are now 45 weeks PCA: one was born at 28 weeks and the other at 32 weeks of gestation. The risk of apnea in the 28-week gestational age infant is twice that in the 32-week gestational age infant (Fig. 4-7).<sup>488</sup> Similarly, consider two infants of the same gestational age: one anesthetized at 45 weeks PCA and the other at 50 weeks PCA. The younger-PCA infant would be at greater risk for postoperative apnea.

The diagnosis of apnea in the postoperative period depends on the type of apnea device used to monitor the infants (E-Fig. 4-5). For example, simple observation and impedance pneumography are more likely to miss an apneic episode than are continuous recording devices.<sup>488-490</sup> Preterm infants with anemia (hematocrit <30%) are more prone to apnea, and the incidence is unrelated to PCA or gestational age (see Fig. 4-7).<sup>428,488</sup> It appears that the risk for apnea exceeds 1% with statistical certainty until approximately 56 weeks PCA in infants with a gestational age of 32 weeks or 54 weeks PCA in those with a gestational age of 35 weeks, if one excludes anemic infants and those with obvious apnea in the recovery room. This analysis determined that (1) apnea was strongly and inversely related to both gestational age and PCA; (2) ongoing apnea at home is a risk factor; (3) small-for-gestational-age infants are protected from apnea compared with appropriate- and large-for-gestational-age infants; (4) anemia is a significant risk factor, particularly for infants of more than 44 weeks PCA; and (5) a history of necrotizing enterocolitis, neonatal apnea, respiratory distress syndrome, bronchopulmonary dysplasia, or operative use of opioids or muscle relaxants did not correlate with postoperative apnea.<sup>488</sup> Each clinician must decide how to balance the risk of an unrecognized apnea with the benefit of proceeding with the surgery in terms

of cost savings and not hospitalizing the infant for overnight monitoring.<sup>491</sup> The most practical and appropriate plan is to admit and monitor all formerly preterm infants who are less than 60 weeks PCA until they are free of apnea for a minimum of 12 hours.

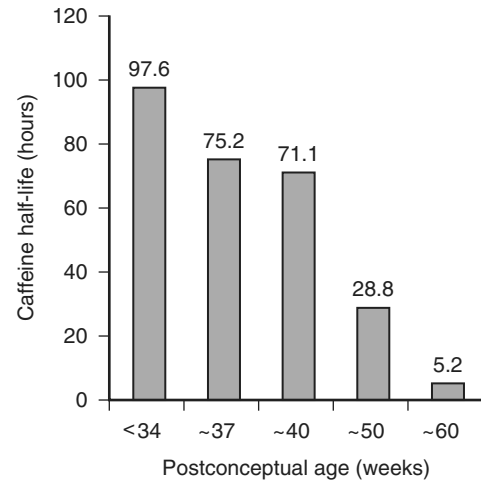

In a subsequent study of preterm infants, four anesthetic techniques were compared: sevoflurane induction and maintenance, halothane induction and maintenance, halothane induction/desflurane maintenance, and thiopental induction/desflurane maintenance.<sup>492</sup> No major episodes of apnea occurred in any of the 40 formerly preterm infants who were less than 60 weeks PCA and undergoing hernia repair, although there was at least one episode of breath-holding or self-limited apnea in each group. In view of the small sample size in this study, the upper 95% confidence interval that no apnea episodes will occur in all formerly preterm infants is only 92%. *Although the majority of formerly preterm infants in a microanalysis of eight studies were anesthetized with halothane,<sup>488</sup> apnea has been reported with all anesthetics, including sevoflurane, desflurane, and regional anesthesia (spinal or caudal epidural, discussed later).*<sup>493,494</sup>

The preoperative evaluation of these infants requires discussion with the pharmacy regarding the availability of intravenous caffeine, discussion with the intensive care unit regarding availability of a monitored bed postoperatively, and discussion with the family regarding the perioperative risks of anesthesia and apnea. If the child is receiving theophylline or caffeine preoperatively, this therapy should be continued postoperatively.<sup>495</sup> If the child is not receiving theophylline or caffeine preoperatively, there is no evidence to support the administration of aminophylline postoperatively, but there is weak evidence that caffeine (10 mg/kg) may prevent postoperative apnea spells in high-risk infants.<sup>486,487</sup> The pharmacokinetics of caffeine in preterm and full-term neonates suggest that a single intravenous dose of caffeine will have a clinical effect that may last for several days. However, the pharmacokinetics of caffeine change dramatically with age: in older infants (e.g., those who are 60 weeks PCA), the half-life of caffeine is reduced to approximately 5 hours (E-Fig. 4-6).<sup>496</sup> Larger, well-controlled studies are indicated before caffeine can be advocated for all infants at risk for postoperative apnea. A Cochrane review of prophylactic caffeine to prevent postoperative apnea after general anesthesia in formerly preterm infants concluded that although caffeine can be used to prevent postoperative apnea, bradycardia, and episodes of oxygen desaturation in growing preterm infants, there was insufficient evidence to adopt this as routine anesthetic practice.<sup>497</sup> *If caffeine is administered to a formerly preterm infant, postoperative admission and overnight respiratory monitoring are still required, because caffeine is not 100% effective in preventing postoperative apnea.*

Apnea may be related to many causes besides prematurity (Fig. 4-8). The most common causes after surgery, however, relate to metabolic derangements, pharmacologic effects, or CNS immaturity. Metabolic causes of apnea such as hypothermia, hypoglycemia, hypocalcemia, acidosis, and hypoxemia should also be considered and avoided (see Chapters 35 and 36). Pharmacologic effects cannot be avoided, because administering anesthesia requires the use of drugs, and most drugs used in anesthesia depress the respiratory system either directly or indirectly. Most inhalation agents, opioids, and sedatives depress the central response to carbon dioxide in adults in a dose-related fashion.<sup>498</sup> Respiratory depression is probably even more likely to occur in neonates who have an immature respiratory center. Studies of adults have demonstrated both ablation of the

**E-FIGURE 4-5** Predicted probability of apnea in recovery room and post-recovery room by weeks postconceptual age for all patients for each investigator. Bottom marks indicate the number of data points versus postconceptual age. The curves for the Kurth et al. and Welborn et al. studies are nearly identical in the upper range, and for the Malviya et al. and Warner et al. studies in the lower range. There was significant institution-to-institution variability. The reasons for this are unclear but may represent differences in monitoring technology as well as patient populations, because the studies with the highest rate of apnea were also those that used continuous recording devices. (From Cote CJ, Zaxlavsky A, Downes JJ, et al. Postoperative apnea in former preterm infants after inguinal herniorrhaphy: a combined analysis. *Anesthesiology* 1995;82:809-22.)

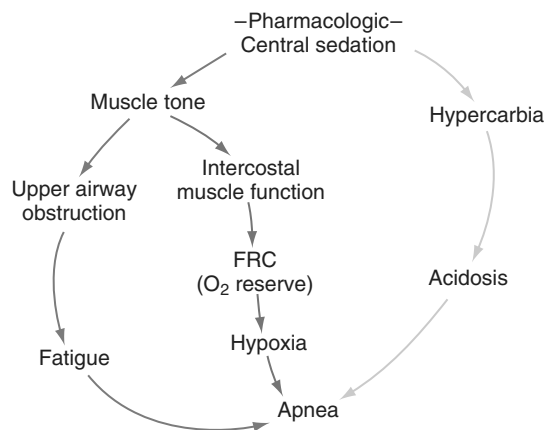

**E-FIGURE 4-6** The approximate caffeine beta-elimination half-life (hours) is plotted against weeks of postconceptual age. Note that there is rapid maturation of the ability to excrete caffeine and that by 60 weeks of postconceptual age the half-life is only about 5 hours. One should not expect a single dose of caffeine to completely eliminate the potential for apnea in formerly preterm infants. (Data from DeCarolis MP, Romagnoli C, Muzil U, et al. Pharmacokinetic aspects of caffeine in premature infants. *Dev Pharmacol Ther* 1991;16:117-22.)

**FIGURE 4-8** Apnea, defined as the absence of movement of air at the mouth or nose, may have many causes. Those that anesthesiologists are most often involved with are of metabolic, pharmacologic, or respiratory origins.

**FIGURE 4-9** Pharmacologic interventions may result in several sequences of events leading to apnea. FRC, Functional residual capacity.

response to hypoxia and potentiation of that response by hypercarbia in the presence of halothane in concentrations as low as 0.1%; therefore, residual anesthetic action may contribute to the development of apnea in infants.<sup>499</sup> In addition, most pharmacologic agents used in anesthesia decrease muscle tone of the upper airway, thus contributing to the development of upper airway obstruction, more labored breathing, fatigue, and apnea in the perioperative period.<sup>485</sup> Potent inhalation anesthetic agents also decrease intercostal muscle tone, reducing functional residual capacity and thereby increasing the propensity to develop hypoxemia (Fig. 4-9).<sup>500</sup>

Regional anesthesia has been used to reduce the risk of postoperative apnea associated with general anesthesia. Regional techniques may offer advantages over general anesthesia, but apnea has been associated with regional anesthesia techniques.<sup>480,501-503</sup> In a study that compared spinal with general anesthesia, the incidence of desaturation and bradycardia but not apnea was reduced in the spinal group.<sup>493</sup> In a review of four studies that utilized regional (spinal, epidural, caudal) versus general anesthesia in formerly preterm infants undergoing inguinal herniorrhaphy in early infancy, there was no convincing evidence to support the use of spinal anesthesia as part of the standard practice in inguinal herniorrhaphy, although there was some evidence that spinal anesthesia reduced the incidence of postoperative apnea in an infant population who were not given additional sedation.<sup>504</sup> Additive drugs used to prolong the duration of a spinal or caudal block, such as clonidine, have been associated with

apnea.<sup>505-508</sup> Spinal anesthesia is also associated with a significant failure rate and the need for multiple attempts to achieve accurate placement of the needle,<sup>509,510</sup> although in experienced hands, the success rate for placing a spinal block was 97.4% and an adequate level of spinal anesthesia was achieved in 95.4% of infants. *In summary, formerly preterm infants should not be anesthetized as outpatients even when a regional technique has been used; they require admission for postoperative monitoring overnight for apnea.*

With respect to full-term neonates, three reports have described infants who developed apnea after apparently uneventful general anesthetics.<sup>511-513</sup> Therefore, if a full-term infant who is younger than 44 weeks PCA demonstrates any abnormality of respiration after anesthesia, we recommend that they be admitted overnight for monitoring for apnea. The algorithms in Figure 4-10 can be used as a decision tree for outpatient surgery in the term and formerly preterm infant.

### HYPERALIMENTATION

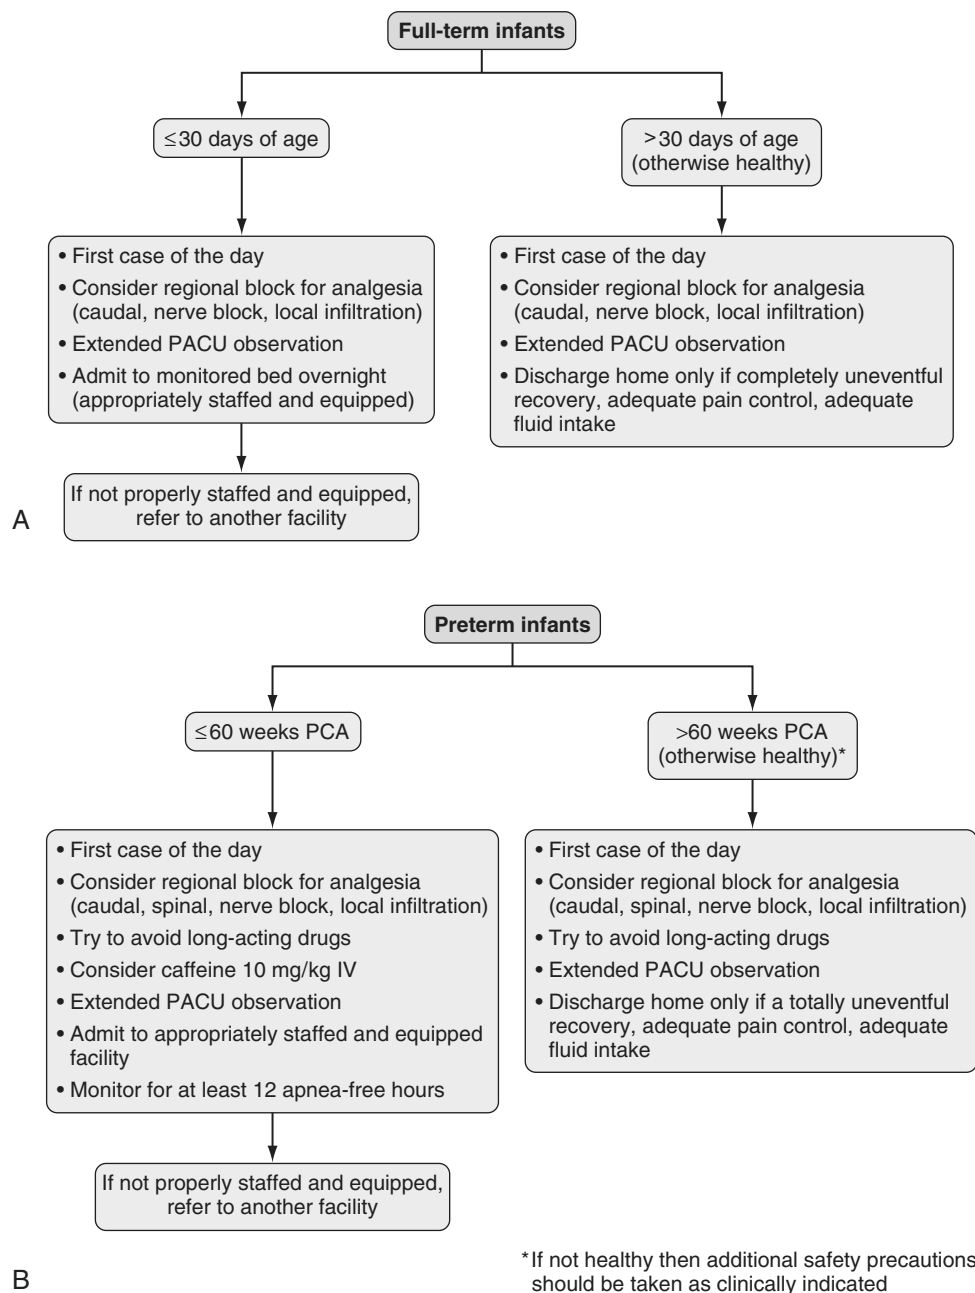

Intravenous alimentation is frequently used as a means of life support and to prepare children for surgery. It is important for anesthesiologists to identify the composition and rate of administration of these fluids so that potential intraoperative complications can be avoided. Most of these solutions are hypertonic, have high glucose content, and must be administered through a centrally placed intravenous route.

The basic principles of care are as follows:

1. Avoid contaminating the line. It is best not to puncture the line for administering medications or changing fluid.
2. Do not discontinue the glucose-containing solution, because the relative hyperinsulinemic state could induce hypoglycemia, the signs of which might be masked by general anesthesia. In contrast, intralipid infusions should be discontinued before surgery, because it is a culture medium if contaminated.
3. An infusion device should be used at all times so that the rate of infusion is constant. Accidental rapid infusion of large amounts of hyperalimentation fluid can cause a hypertonic nonketotic coma.<sup>514</sup> There is no consensus on the intraoperative management of hyperalimentation solutions. Some clinicians reduce the infusion rate by 33% to 50% to avoid hyperglycemia resulting from a reduced metabolic rate due to the effects of anesthetic agents and a reduced body temperature, whereas others leave the infusion rate unchanged to avoid intraoperative hypoglycemia.
4. Perioperative and intraoperative monitoring of glucose, potassium, sodium, and calcium, as well as acid-base status, is important for long procedures.
5. Preoperative confirmation of correct intravascular line placement (radiography or aspiration of blood) is important to avoid intraoperative complications such as hydrothorax or hemothorax.

### DIABETES

Diabetes mellitus is the most common endocrine problem encountered in children. Preoperative assessment should include a thorough knowledge of the child's insulin schedule. The preoperative fasting time should be the same as that recommended for nondiabetics. Every attempt should be made to schedule a diabetic child as the first case of the day to minimize the fasting period. Several protocols have been advocated for glycemic control in diabetics. An intravenous infusion that contains 5% glucose and electrolytes at a maintenance infusion rate should

**FIGURE 4-10** Algorithms used as a decision tree for outpatient surgery in term infants (A) and in former preterm infants (B). PACU, Postanesthesia care unit; PCA, postconceptional age.

be started to avoid hypoglycemia. Blood glucose concentrations should be monitored just prior to induction, intraoperatively, and postoperatively until the child is back on a routine schedule. A more detailed discussion of the perioperative management of the child with diabetes is presented in Chapter 25.

### BRONCHOPULMONARY DYSPLASIA

Bronchopulmonary dysplasia is a form of chronic lung disease associated with prolonged mechanical ventilation and oxygen toxicity in preterm neonates. Antenatal glucocorticosteroids, early surfactant therapy, and gentler ventilation modalities currently utilized have reduced the severity of lung injury. The clinical manifestations of bronchopulmonary dysplasia include

tachypnea, dyspnea, and airway hyperactivity, as well as oxygen dependence. These infants suffer from hypoxemia, hypercarbia, abnormal functional airway growth, tracheomalacia, bronchomalacia, subglottic stenosis, increased pulmonary vascular resistance, and congestive heart failure. Pulmonary function abnormalities, including a reduced functional residual capacity, reduced diffusion capacity, airway obstruction, and reduced exercise tolerance, may persist into the school-age years. Many also suffer neurodevelopmental problems and seizures. Some also have a cardiomyopathy due to corticosteroid therapy in the neonatal period or the combination of corticosteroid therapy and viral infections; others have systemic hypertension. These children are often cared for at home on oxygen therapy with diuretics, digoxin, and

$\beta_2$ -agonists. Preoperative preparation should focus on optimizing oxygenation, reducing airway hyperactivity, and correcting electrode abnormalities caused by chronic diuretic therapy. Particular attention should be paid to fluid balance and avoiding excessive hydration. Chronic hearing problems may be an additional concern and may necessitate avoiding nitrous oxide. Adequate expiratory time to avoid excessive positive-pressure ventilation is important, and the potential for subglottic stenosis may necessitate using a smaller than expected tracheal tube. Use of an LMA may offer some advantage in select situations by reducing the incidence of coughing, wheezing, and hoarseness.

### SEIZURE DISORDER

Management of children with seizure disorders requires a knowledge of the antiseizure medications, medication schedule, and possible interactions between these medications and anesthetic drugs. The stress of surgery and anesthesia may lower the seizure threshold and cause a seizure. Seizure medications should be continued until the time of elective surgery. Characterization of the clinical manifestations of the seizure is useful so as to be able to diagnose potential seizures postoperatively. If the child is expected to have a significant problem with oral intake postoperatively, then a game plan with the child's neurologist should be developed so as to build a transition to intravenous antiseizure medications. Preoperative and postoperative management of anticonvulsant blood concentrations may also ensure proper therapeutic effect (see also Chapter 22).

### SICKLE CELL DISEASE

Whenever a child presents with either sickle cell disease or sickle cell trait, the anesthetic and postanesthetic management must be modified (see also Chapters 9 and 11). It is important to obtain a detailed family history, and if the child has not been previously tested, a sickle preparation should be obtained. If a sickle test is positive and the surgery is elective, then surgery should be postponed pending a hemoglobin electrophoresis to more carefully delineate the nature of the hemoglobinopathy. It must be emphasized that the status of hydration and oxygenation is critical for all children with sickle cell disease or trait. A secure intravenous route with hydration of at least 1.5 times maintenance is recommended well into the postoperative period, especially after procedures in which ileus may result. Meticulous attention to detail to ensure stable cardiovascular and ventilatory status establishes adequate oxygenation to prevent sickling. Pulse oximetry is of particular value in managing these children by providing an early warning of desaturation. Children with hemoglobin SC are especially at risk because they have a relatively normal hemoglobin level yet are extremely vulnerable to sickling. Further recommendations regarding management of these children, including indications for preoperative transfusion to bring the hemoglobin concentration to 10 g/dL, are discussed in Chapter 9.

### ACKNOWLEDGMENT

We wish to thank John F. Ryan, MD, Letty M. P. Liu, I. D. Todres, MD, Nishan G. Goudsouzian, MD, and Leila Mei Pang, MD, for their prior contributions to these topics.

- Premedication of children with midazolam is not only beneficial in reducing preoperative anxiety but also results in fewer negative behavioral changes during the first postoperative week.*
- Schwengel DA, Sterni LM, Tunkel DE, Heitmiller ES. Perioperative management of children with obstructive sleep apnea. *Anesth Analg* 2009;109:60-75.
- An excellent review article on the diagnosis, treatment, and anesthetic management of children with obstructive sleep apnea syndrome.*
- Skinner CM, Rangasami J. Preoperative use of herbal medicines: a patient survey. *Br J Anaesth* 2002;89:792-5.
- Self-administration of herbal medicine is common in patients presenting for anesthesia. Because of the potential for side effects and drug interactions, it is important for anesthesiologists to be aware of their use. This is a good overview of herbal medicines and potential perioperative complications with their use.*
- Tait AR, Malviya S, Voepel-Lewis T, et al. Risk factors for perioperative adverse respiratory events in children with upper respiratory tract infections. *Anesthesiology* 2001;95:299-306.
- Several risk factors for perioperative adverse respiratory events in children were identified: use of an endotracheal tube (<5 years of age), history of prematurity, history of reactive airway disease, paternal smoking, surgery involving the airway, presence of copious secretions, and nasal congestion.*
- Warner MA, Warner ME, Warner DO, Warner LO, Warner EJ. Perioperative pulmonary aspiration in infants and children. *Anesthesiology* 1999;90:66-71.
- The frequency of perioperative pulmonary aspiration in children is quite low. Serious respiratory morbidity is rare, and there were no associated deaths in this review. Infants and children with clinically apparent pulmonary aspiration in whom symptoms did not develop within 2 hours did not have respiratory sequelae.*

The Ethics Consultation Service

THERE ARE TWO OVERARCHING THEMES of this chapter: (1) Anesthesiologists must take seriously “the experience, perspective, and power of children,”<sup>1</sup> and (2) anesthesiologists should treat every child and family with the grace and consideration with which they would want their own child and family treated.

Taking seriously the experience of children means involving interested children in developmentally appropriate decision making. Anesthesiologists should not solicit a child’s views without intending to seriously consider them. *Pro forma* solicitations are harmful.

Treating every child like your own means taking time to allow premedication to work, even if it leads to criticism for a delayed anesthesia start time. It means rigorously following sterile practice protocols for central lines. It means patiently explaining anesthetic options to the parents as many times as needed.

Bioethics helps motivated physicians to identify and resolve ethical dilemmas. Solving ethical dilemmas is not solely a matter of being moral. Consider a child with an upper airway respiratory infection. Usually, the surgery would be postponed, but suppose the child has missed two previous surgical dates because of an unstable home situation. While the anesthesiologist is explaining the risks of proceeding, the mother distractedly says to proceed because “we’re already here.” The anesthesiologist has to determine what is in the child’s best interest by weighing the risks of proceeding or not proceeding, the duty to ensure that the child receives necessary health care, the weight to be given the mother’s consent to proceed, and the duty to “do no harm.” Mindful anesthesiologists will seek to identify lurking conflicts of interest in considering whether to proceed.

## Informed Consent

The American Academy of Pediatrics (AAP) bases pediatric informed consent on assent, informed permission, and the best interests standard.<sup>1</sup>

### THE INFORMED CONSENT PROCESS

#### Assent: The Role of the Patient

Although most children cannot legally consent to medical care, children should share in decision making to the extent that their

development permits (Table 5-1). As children grow older, participation in decision making should increase, depending on both their maturity and the consequences involved in the decision.<sup>2</sup>

School-age children are developing decision-making capacity, so anesthesiologists should seek both informed permission from the parent and assent and participatory decision making from the child. School-age children are capable of using logic and reason and are able to define and relate multiple aspects of a situation. Such situations may include whether to sedate a 6-year-old before an inhalation induction, whether to use an inhalation or intravenous induction of anesthesia in an 8-year-old, and whether to place an epidural for postoperative analgesia in a 12-year-old.

Many adolescents older than 14 years of age have the ability to use abstract thought, apply complex reasoning, foresee outcomes, simultaneously evaluate multiple options, and understand concepts such as probability. Anesthesiologists should try to fulfill the ethical requirements of consent while obtaining assent. Although some adolescents have cognitive abilities similar to those of adults, adolescents may be hindered by insufficient emotional development. Situations involving these aspects may include obtaining consent from a 14-year-old for anesthesia for scoliosis surgery or from a 16-year-old for an awake thoracic epidural placement for a pectus repair.

#### Informed Permission and the Best Interests Standard

Parents have traditionally acted as the surrogate decision makers for their children, and legally they give consent. But surrogate consent does not fulfill the spirit of consent, which is based on obtaining an individualized autonomous decision from the patient receiving the treatment. The AAP has suggested that the proper role for the surrogate decision maker is to provide *informed permission*.<sup>1</sup> Informed permission has the same requirements as informed consent, but it recognizes that the doctrine of informed consent cannot apply.

The *best interests standard* requires decision makers to select the objectively best care. It acknowledges that the cornerstone of informed consent, the right to self-determination, is inapplicable when it is impossible to know or surmise from previous interactions a child’s likely preference. Using this standard requires determining (1) who will make the decision and (2) what is the

**TABLE 5-1** Graduated Involvement of Minors in Medical Decision Making\*

Age	Decision-Making Capacity	Techniques
<6 year	None	Best interests standard
6-12 year	Developing	Informed permission Informed assent
13-18 year	Mostly developed	Informed assent Informed permission
Mature minor	Developed, as legally determined by a judge, for a specific decision. Although particulars vary by state, the mature minor doctrine in general requires adolescents to be at least 14 years old and tends to permit decisions of lesser risk.	Informed consent
Emancipated minor	Developed as determined by statutes defining eligible situations (e.g., being married, in the military, economically independent).	Informed consent

\*This broad outline should be viewed as a guide. Specific circumstances should be taken into consideration.

best care. The difficulties arise in assuming that there is always one best choice, because if there is, it should not matter who makes the decision. In our society, acceptable decision making is broadly defined. Parents capable of participating in the decision-making process are the appropriate primary decision makers. This is in part due to society's respect for the concept of the family and the assumption that parents care greatly for their children. Although a child's preferences cannot be known, it is reasonable to assume that because children will incorporate some of the parents' values as they mature, parental values are a good first approximation for the child's future values.<sup>3</sup> A few have argued that the presumption that parents are the best decision makers needs to be more closely examined.<sup>4</sup> These objections center on the legitimacy of the parents' knowledge of the preferences of the child's future self. Although these concerns are theoretically interesting and help physicians understand the complexities of the best interests standard, the standard is that parents have extensive leeway in determining what is in a child's best interests.

One way to decide what is in the best interests of the child is to define what choices fall outside the range of acceptable decision making. Criteria to make this determination include the extent of harm to the child deriving from the intervention or its absence, the likelihood of success, and the overall risk-to-benefit ratio. In the classic Baby Doe case, a child was born with Down syndrome and duodenal atresia and was permitted to die without intervention. Public discussion ensued, and it was thought that not repairing a correctable lesion was outside the bounds of acceptable undertreatment. The case spurred passage of so-called Baby Doe regulations, which define what care must be given to certain infants. In this effort to avoid unacceptable undertreatment, some believe that such regulations cause unacceptable overtreatment of patients, primarily because regulations are crude instruments for dissecting complex clinical situations.

Parents can make bad decisions. Although anesthesiologists must respect the diversity values and the parent-child relationship, decision making that imperils the health of a child needs to be challenged. If parents are choosing unacceptable treatments, anesthesiologists should determine the basis of their judgment, address those specific concerns, and involve other clinicians both to offer an assessment of the appropriateness of care and to engage the parents in discussion. Charging parents with not acting in the child's best interests is serious and can have significant social, fiscal, and familial ramifications. If the parents remain steadfast, however, anesthesiologists should report the situation to proper child welfare authorities for possible legal action.

### Disclosure

The "reasonable person" standard, the legal standard for most of the United States, requires that the information disclosed be sufficient to satisfy a hypothetical reasonable person. However, this standard does not define exactly what information should be given, and it does not take into account the patient's desires and needs. The "subjective person" standard suggests that informed consent should be matched to the wants and needs of the decision makers. Although the subjective person standard better fulfills the spirit of informed consent, its greater ambiguity makes it difficult to use as a legal standard.

Rather than rely on a rote informed consent process, anesthesiologists should seek to satisfy the needs of the decision makers by meeting their information and decision-making needs. Patients and surrogates differ in the extent to which they prefer to receive information and to participate in decision making.<sup>5-8</sup> In general, 10% to 15% of patients may prefer less information than their peers. Overall, a quarter of patients want to be the primary decision maker, a quarter want the physician to be the primary decision maker, and half want some form of shared decision making.<sup>6,9,10</sup>

Anesthesiologists should inform families about matters that the anesthesiologist feels must be communicated and about options that affect the perioperative experience (e.g., regional versus general anesthesia). Following this baseline, anesthesiologists can then ask whether the decision makers wish to know more. By being attentive to the words and actions of the decision makers, anesthesiologists can tailor the process. The likelihood of being sued based on informed consent malpractice issues is very rare. Patient-driven interactions likely reduce malpractice lawsuits.<sup>11</sup>

Performing patient-centered informed consent often requires communication of the anesthesiologist's opinion along with an explanation of the supporting reasons. With this information, the patient is better able to determine which anesthetic approach provides the most desired benefits.

### Informed Refusal

The requirements to achieve an informed refusal of a procedure are similar to the requirements for informed consent in that decision makers should be substantially well versed about the risks, benefits, and alternatives before declining. When parents refuse what clinicians believe is necessary care for a child who cannot participate in the decision-making process, clinicians may invoke the best interests standard. This situation is more complicated when the child expresses significant decision-making capacity and refuses nonemergent procedures. Anesthesiologists should respect the right of children (typically those over the age

of 10 years) not to assent to a procedure, and they should not coerce the child to proceed. In children, particularly adolescents, the distinction between persuasion and coercion is critical. *Persuasion*, the act of using argument and reason to influence a patient's decision, is appropriate. *Coercion*, the outright use of a credible threat, manipulation, or misleading information, is not. Achieving the child's assent may necessitate further discussions with the child, parents, and other providers, and such discussions may best take place away from the operating room.

Consider a 15-year-old who is scheduled for an elective knee arthroscopy. The day before the procedure, she gave assent and her parents gave informed permission for anesthesia and surgery. She is now crying in the preoperative area and refusing to cooperate. Rather than forcibly or surreptitiously sedating her, the anesthesiologist should discuss her concerns. If she is unable to discuss the issues, the anesthesiologist should consider removing her from the area and giving her time to regain composure before readdressing the situation. Simple actions often allow the situation to be resolved. If the withdrawal of assent was in part related to anxiety, the child may assent to receiving ample premedication before returning to the holding area. Anesthesiologists must obtain her assent before administering the sedation, however, and not simply assume that forceful or surreptitious administration is justified.

### Doctor, If This Were Your Child, What Would You Do?

Physicians should respond to requests for advice by using medical facts to explain how different paths support specific values, so that decision makers can choose the most concordant path. However, the question, "If this were your child, what would you do?" can be asked for a number of different reasons, forcing physicians to put the question into a broader context.<sup>12,13</sup>

For example, parents may be declaring that they are having difficulty comprehending the overwhelming information and need help making a reasonable decision. Perhaps they are actually asking what would give their child the best chance of getting better. In this situation, physicians should explain the reasons and values underlying their personal choice.

Parents may be looking for support that they are making the right choice in an untenable situation. Physicians should answer with their best judgment if they agree with the family. If they disagree, physicians should lend support through comments such as, "Other parents in the same situation have made the same choice," or by acknowledging that it is normal to feel uncertain.<sup>12</sup> If the family persists in asking what they should do, physicians may wish to acknowledge that their choice might have been different. Physicians should emphasize, however, that parental values are more valid than physician values when referring to their own child.

Parents may be asking for help in making a life-altering decision. One way of approaching this question is to offer a process for answering the question (e.g., "I would talk with the chaplain"). Physicians should feel comfortable admitting that are unable to determine what they would do if in the same situation. Honesty reinforces the difficulty of the decision for the parents.

### Disclosure and Apology of Medical Errors

Hiding medical errors is indecent and breaches informed consent.<sup>14</sup> Fear, inadequate support, and lack of education prevent physicians from disclosing and apologizing appropriately.<sup>14-18</sup> Forthrightly disclosing medical errors, although upsetting, often strengthens the patient-physician relationship. Learning about a

hidden medical error destroys trust and rapidly (and often appropriately) triggers legal action.

Physician apologies or sympathetic comments often are prohibited as legal evidence of wrongdoing.<sup>19</sup> Nonetheless, disclosing and apologizing may influence whether patients pursue legal action and whether such action is successful.<sup>20,21</sup> Sincere (not *pro forma*!) apologies and subsequent redress to prevent future occurrences improves the patient-physician relationship, minimizing the likelihood of legal action.<sup>11</sup>

Physicians without expertise in disclosure and apology often botch the process. Disclosure is a process over time. Initial disclosure should take place as soon as possible after an event and should center on the medical implications.<sup>22-24</sup> Do not speculate about cause or fault. When disclosing, it is wise to bring along an appropriate colleague who can help with the disclosure by providing psychological support for the patient and family. Soon thereafter, a specific, permanent liaison to the family should be identified. The liaison should be available to arrange meetings, explain the results of the investigation into the cause of the event, and describe plans to prevent future events. The liaison should be trained and experienced in apology and disclosure (e.g., a colleague in risk management).

*An apology expresses regret or sorrow. Sincere apologies followed by consistent actions are priceless; insincere apologies are costly.* It is always appropriate to apologize for the adverse effects of an event. And although the standard teaching is that physicians should not assume responsibility for an event before an investigation is performed, it seems bizarre to dissemble about clear errors. As an example, after reassuring the parents that their child is unharmed, I would readily admit that because I had inadvertently given a muscle relaxant instead of an anticholinesterase, their child will require a brief stay in the intensive care unit until ready for tracheal extubation. To evade responsibility (e.g., "Somehow one drug was given when another was intended") for a clear error mocks the apology.

Anesthesiologists should also acknowledge, apologize, and recommend remedies for future difficult situations such as multiple intravenous catheter insertions or a very stressful anesthetic induction.

## SPECIAL SITUATIONS IN PEDIATRIC INFORMED CONSENT

### Confidentially for Adolescents

The obligation to maintain confidentiality requires physicians to protect patient information from unauthorized and unnecessary disclosure. Confidentiality is necessary for an open flow of information.<sup>25</sup> The anesthesiologist enhances trust by interviewing the adolescent in private, acknowledging the adolescent's concerns about confidentiality, and following through on promises. Emancipated and mature minors have a right to complete confidentiality. For other adolescents, if maintaining confidentiality entails minimal harm, physicians should encourage adolescents to be forthright with parents but respect their decision not to be. If maintaining confidentiality may result in serious harm to the adolescent, physicians may be ethically justified in notifying the parents.<sup>25</sup>

### The Pregnant Adolescent

Anesthesiologists face confidentiality issues when an adolescent has a positive pregnancy test before anesthesia. Given the principles of confidentiality, it is ethically appropriate to inform only the adolescent of the positive pregnancy test.<sup>26</sup> Because many locales statutorily prohibit sharing pregnancy information with

anyone other than the adolescent, anesthesiologists must share this information with the adolescent without letting the parents know. Anesthesiologists should involve pediatricians, gynecologists, and social workers with expertise in adolescent issues in this discussion.

Matters may become more complex if the surgeon, anesthesiologist, adolescent, and other advisors believe the case should be postponed and the adolescent chooses not to inform her parents about the pregnancy test. Anesthesiologists must be careful not to inadvertently inform the parents of the pregnancy test while postponing anesthesia and surgery. Nor should anesthesiologists betray the adolescent by saying, "The case is postponed. If you want to know why, ask your daughter." Although such a statement is factually true and within the letter of the law of confidentiality, terse obliqueness scorns the spirit of confidentiality.

As a parent of an impregnable adolescent, I understand the desire of anesthesiologists to tell the parents. But I would suggest that anesthesiologists who feel that way are too narrowly applying their own experiences and expectations. Not all parents are wise and gentle, and not all homes are safe and healthy. Confidentially statutes specifically address concerns about child abuse in pregnant adolescents.

To what extent anesthesiologists should protect the adolescent's confidentiality is debatable. Nonetheless, because the parents have no legal right to that information, I believe that more active deception, although less desirable, is appropriate if necessary. Successful deception avoids initiating diagnostic evaluations or treatment and does not unduly worry parents. For example, attributing the delay to "hearing a new murmur" or an abnormal laboratory value "just found" are poor reasons to give to parents. Vague, unremarkable reasons such as "an oncoming child" are best.

It is rare to condone deception. Deception should not be undertaken without serious reservations. But under certain circumstances, the obligation to the patient may supersede prohibitions on deception. At times, the harms of not deceiving outweigh the harms of deceiving.

### The Adolescent and Abortion

Even though pediatric patients who are pregnant may be considered emancipated, many states require some form of parental involvement, such as parental consent or notification, before an elective abortion.<sup>27,28</sup> If a state requires parental involvement, the ability of the minor to circumvent this regulation by seeking relief from a judge, known as *judicial bypass*, must be available. Requirements and enforcement of statutes vary from state to state.<sup>29</sup> The need for parental involvement in a minor's planned abortion is not always legally straightforward, and it may be best to consult with hospital counsel in determining these issues. Although this is clearly an area in which honorable people disagree, it is worth noting that both the AAP and the American Medical Association (AMA) have affirmed these rights.<sup>25,29,30</sup>

### Children of Jehovah's Witnesses

Jehovah's Witnesses interpret biblical scripture as prohibiting transfusion therapy because blood holds the "life force" and anyone who takes blood will be "cut off from his people" and not earn eternal salvation.<sup>27,28</sup> Adults may refuse transfusion therapy because it is assumed they are making an informed decision about the risks and benefits of transfusion. However, based on the obligations of the state to protect the interests of

incompetent patients, courts have uniformly intervened when parents desire to refuse transfusion therapy on behalf of their children.

Obtaining informed permission and assent for the care of a ward of a Jehovah's Witness should address transfusion therapy. Anesthesiologists should clarify which therapy is acceptable. Synthetic colloid solutions, dextran, erythropoietin, desmopressin, and preoperative iron are usually acceptable. Note that erythropoietin is available in two forms: lyophilized, and dissolved in saline with trace concentrations of albumin. Jehovah's Witnesses who accept albumin will accept either formulation, whereas those who refuse albumin should be offered the lyophilized formulation. Some Jehovah's Witnesses will accept the removal and return of blood in a continuous loop (e.g., cell saver blood). The family should understand, however, that in a life-threatening situation, the anesthesiologist will seek a court order authorizing the administration of life-sustaining blood. In instances in which the likelihood of requiring blood is high or the local judiciary is not that familiar with case law for Jehovah's Witnesses, the anesthesiologist may choose to obtain a court order in advance of the operation.

A common concern is the sudden need for an emergent transfusion in a healthy child undergoing a low-risk procedure. In emergencies, based on the obligation to protect children, anesthesiologists should take the legally correct and ethically appropriate action to protect the child by transfusing blood without a court order. A court order may then be sought if desired.

For procedures that may be safely delayed, decision makers may consider postponing the procedure until the child is of sufficient age and maturity to decide about transfusion therapy. The complexity is whether the delay may increase the risk or decrease the likelihood of a good outcome. This decision requires the same balancing act as for determining the best interests for a child. Relevant factors include the quantitative change in risk or benefit and the significance of the type of risk or benefit. For example, it may be easier to wait on a procedure that is purely cosmetic than on a procedure for which waiting entails a small chance of causing a permanent injury. If individual clinicians choose to honor the wishes of a mature minor, they must ensure the fidelity of the agreement by making certain that postoperative and on-call clinicians will honor the mature minor's wishes.

### Emergency Care

Anesthesiologists should provide necessary emergent care for minors who do not have a parent available to give legal consent.<sup>31</sup> Emergencies include problems that could cause death, disability, and the increased risk of future complications.

The right of an adolescent to refuse emergency care treatment turns on the adolescent's decision-making capacity and the resulting harm from refusal of care.<sup>1</sup> If the harm is significant and the adolescent's rationale is decidedly short-term or filled with misunderstanding, it becomes necessary to consider whether the adolescent has sufficient decision-making capacity for this decision. In this situation, it may be appropriate to consider what is in the best interests of the adolescent. For example, a 15-year-old football player with a cervical fracture might refuse emergency stabilization, stating that he does not want to live life without football. Most would hold that his conclusion overly values short-term implications, especially in light of the suddenness of the injury, and that he should receive emergency treatment.

## THE IMPAIRED PARENT

Parents may be unable to fulfill surrogate responsibilities because of acutely impaired judgment, such as being intoxicated.<sup>32</sup> Anesthesiologists will then have to weigh the benefits of waiting for appropriate legal consent against what is in the best interests of the child. It may be in the child's best interests to proceed with a routine procedure in the situation of an impaired parent who is unable to give legal consent. Anesthesiologists may wish to consult legal and risk management colleagues for guidance.

## End-of-Life Issues

### FORGOING POTENTIALLY LIFE-SUSTAINING TREATMENT

#### Perioperative Limitations on Life-Sustaining Medical Therapy

The concept of limiting potentially life-sustaining medical therapy (LSMT) is the same for children as is for adults. Decision makers choose to limit LSMT because they do not consider the potential burdens worth the potential benefits.<sup>33</sup> The AAP, the American Society of Anesthesiologists (ASA), and the American College of Surgery mandate reevaluation of any limitations on LSMT before proceeding to the operating room.<sup>34-36</sup>

Readers will note a shift from the term "Do Not Resuscitate" to terms similar to "Life-Sustaining Medical Therapy." One purpose of this shift is to emphasize that desired limitations on medical treatment are continuous rather than dichotomous. The term "potentially" is often used to modify LSMT to emphasize the uncertainty about whether a therapy will be life sustaining.

Reevaluation of LSMT preferences for the perioperative period starts with clarifying the patient's goals for the proposed surgery and end-of-life care (Table 5-2). Anesthesiologists should involve the patient, family, and other clinicians such as surgeons, intensivists, and pediatricians in determining what is in the best interests of the child.

**TABLE 5-2** Components of a Pediatric Perioperative LSMT Discussion

- Planned procedure and anticipated benefit to child
- Advantages and opportunities of having specific, identified clinicians providing therapy for a defined period
- Likelihood of requiring resuscitation
- Reversibility of likely causes for resuscitation
- Description of potential interventions and their consequences
- Chances of successful resuscitation including improved outcomes of witnessed arrests compared to unwitnessed arrests
- Ranges of outcomes with and without resuscitation
- Responses to iatrogenic events
- Intended and possible venues and types of postoperative care
- Postoperative timing and mechanisms for reevaluation of the limitations on LSMT
- Establishment of an agreement (which may include a full resuscitation status) through a goal-directed approach
- Documentation

Adapted from Truog RD, Waisel DB, Burns JP. DNR in the OR: a goal-directed approach. *Anesthesiology* 1999;90:289-95; and Fallat ME, Deshpande JK. Do-not-resuscitate orders for pediatric patients who require anesthesia and surgery. *Pediatrics* 2004;114:1686-92.

LSMT, Life-sustaining medical therapy.

Benefits of potentially LSMT include an improved quality of life and prolongation of life under certain circumstances. Burdens include intractable pain and suffering, disability, and events that cause a decrement in the quality of life, as viewed by the patient.<sup>37</sup> These guidelines help in considering short- and long-term goals and putting into appropriate context specific fears such as long-term ventilatory dependency, pain, and suffering.

Legitimate procedures for a child with limitations on LSMT include procedures that decrease pain, provide vascular access, enable the child to be at home, treat an urgent problem unrelated to the primary problem (e.g., appendicitis), or treat a problem that may be related but is not considered a terminal event (e.g., bowel obstruction). But seeking these interventions does not obviate the desire to avoid potential postresuscitation burdens such as need for extensive ventilator support, cognitive deficits, or physical limitations.

The goal-directed approach for perioperative limitations on LSMT permits decision makers to guide therapy by prioritizing outcomes rather than procedures.<sup>33</sup> After defining desirable outcomes, decision makers have anesthesiologists use their clinical judgment to determine how specific interventions will affect achieving the specific goals. Predictions about the success of interventions made at the time of the resuscitation are more accurate than predictions made preoperatively, when the quality and nature of the problems are unknown. Therapy may be guided by goals rather than specific procedures (as is done on the ward), because during the perioperative period children are cared for by dedicated anesthesiologists for brief, defined periods. It is helpful to define a goal-directed approach by discussing the acceptable burdens, the desirable benefits, and the likelihood of distinct outcomes. Most decision makers choose a goal-directed approach indicating that they would desire therapy if the interventions and burdens were temporary and reversible (i.e., if they could return to the present state without suffering too much).

Prior determination of acceptable postoperative LSMT is less critical in pediatrics, because usually parents are available in the postoperative period to make decisions regarding therapy. Nonetheless, when a sufficiently mature child participates in discussions about LSMT, anesthesiologists should ensure that the discussion incorporates the child's preferences for postoperative trials of therapy. The willingness to undergo a trial of therapy indicates a belief that the burdens of the trial (e.g., a few days of ventilator support) may be worth the benefits (e.g., extubation of the trachea) initially, but at some point the increasing burdens may not be worth the decreasing likelihood of the benefits.

### Barriers to Honoring Preferences for Resuscitation

Barriers to honoring limitations center on clinician attitudes, time pressures, and inadequate knowledge about policy, law, and ethics.<sup>38-43</sup> In short, whereas patients prioritize functional status in choosing to limit LSMT, clinicians tend to base their opinions on diagnosis and life expectancy.

Anesthesiologists may falsely believe that law or hospital policy requires full resuscitation during the perioperative period. Physicians who act in accordance with statutory requirements are often explicitly protected from liability when they honor a child's or family's refusal of resuscitation.<sup>44</sup> Given the well-established right of children and parents to refuse medical treatment and the paucity of cases finding physicians liable for honoring limitations on LSMT, the risk of liability for honoring an appropriately documented perioperative limitation on LSMT is not high and is likely to be lower than the risk of not honoring the limitations.<sup>44</sup>

Iatrogenic problems such as cardiac arrest do not obviate decisions to limit LSMT.<sup>45</sup> To decision makers, the cause of the arrest is irrelevant. Decision makers care about the factors they considered in requesting limited resuscitation, including likelihood of successful resuscitation and physical and mental status after the arrest. The benefits of continued therapy after certain types of iatrogenic arrests should be addressed as part of the perioperative discussion.<sup>45</sup>

### Inadvisable Care

Treatments with low likelihoods of success may be considered inadvisable because of the burden to the child, cost, or uncertain benefit. Discussions about inadvisable treatment should bear in mind the goals of the treatment and the likelihood of achieving a defined result. When offering the likelihood of a result, physicians should be clear whether the information used to form the estimation is based on intuition, clinical experience, or rigorous scientific studies. Scoring systems that are useful for population predictions in determining potentially inadvisable care should be considered as contributory but not determinative for decision making for individuals.

Decision making for a child near the end of life should be based on the best interests of the child. A useful approach to resolving conflicts has been proposed by the Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research (Table 5-3).<sup>3</sup> In short, physicians may override parental preferences only if a therapy is clearly beneficial (e.g., blood transfusion for anemia). When physicians override parental preferences, the appropriateness of the treatment and the process of decision making should undergo an external review, which will often be medical, ethical, or legal in nature.

The improvement in long-term outcomes for the most preterm babies makes it very hard to predict the likelihood of successful treatment in very young children. The best information suggests that for those infants at the threshold of viability (22 to 25 weeks), survival increases with each week of gestation but the rate of moderate or worse disability does not improve and remains at 30% to 50%.<sup>46,47</sup>

Policies to help resolve differences of opinion about applying treatments with low likelihoods of success are important. Good policies are procedure based, are public, reflect the moral values

of the community, and include processes for identifying stakeholders, initiating and conducting the policy, commencing appellate mechanisms, and determining relevant information.<sup>48</sup>

### IMPROVING COMMUNICATION IN PEDIATRIC INTENSIVE CARE UNITS

Pediatric intensivists should emphasize interdisciplinary communication, tailor the communication style to the parents, and maximize meaningful parental participation in the child's care.<sup>49</sup> The goal is to be an empathic professional who establishes compassionate relationships with the child and family by managing emotional, informational, and care needs.<sup>50</sup> In almost all conversations, clinicians should explain the meaning of the conversation in terms of overall care.<sup>51</sup> Table 5-4 lists characteristics of good communication in the intensive care unit.

### PALLIATIVE CARE

Anesthesiologists, in their role as pain management specialists, as intensive care unit doctors, or in the operating room, may participate in pediatric palliative care.<sup>52,53</sup> Palliative care emphasizes relationship-centered care and should be available to children with a wide variety of diseases (Table 5-5).<sup>54</sup> Although pediatric palliative care has struggled for recognition, in 2011 there are signs of improvement.<sup>55,56</sup>

### EUTHANASIA

Although euthanasia has been permitted in the Netherlands for some time, only recently have there been reports of euthanasia for children. Sixteen-year-olds may now request euthanasia, and 12- to 15-year-olds may request euthanasia with their parent's approval. On reflection, it is reasonable for teenagers to want to minimize suffering and pain at the end of life. Similar to euthanasia in the adult patient, the adolescent must have decision-making capacity; must clearly, voluntarily, and repeatedly request to die; must have an incurable condition associated with severe, unrelenting, and intolerable suffering; and should not be making the request due to inadequate comfort care.<sup>56,57</sup> In the Netherlands, the deliberate ending of a neonate's life is permitted under certain circumstances depending on the neonate's life expectancy and intensive care dependency.<sup>57,58</sup>

### DONATION AFTER CARDIAC DEATH

In organ procurement after a declaration of death through neurologic criteria (i.e., brain death), the child is declared dead before being brought to the operating room. The organs are then retrieved while body homeostasis is maintained through mechanical ventilation, pharmacologic therapy, and other standard resuscitative techniques.<sup>59</sup>

Concern about limited availability of organs for transplantation has resulted in the now widely accepted concept of donation after cardiac death (DCD).<sup>60,61</sup> In DCD, the child is not declared dead before being brought to the operating room for organ retrieval. Instead, after it is determined that therapy should be withdrawn based on a standard benefits and burdens assessment, the child is brought to the operating room and therapy is withdrawn. If the child dies after life-sustaining therapy is withdrawn, he or she is declared dead by cardiac criteria and the organs are retrieved. Ethical issues regarding DCD protocols center on whether the protocols seriously alter the dying process by shifting decision making away from the best interests of the dying child and by interfering with the family's ability to be with their dying child (Table 5-6).

**TABLE 5-3** Suggested Grid for Resolving Disputes about Appropriate Care

	Parents Prefer to Accept Treatment	Parents Prefer to Forgo Treatment
Physicians consider treatment <i>clearly beneficial</i>	Treat	Provide treatment during review process
Physicians consider treatment to be of <i>ambiguous or uncertain benefit</i>	Treat	Forgo
Physicians consider treatment to be <i>inadvisable</i>	Provide treatment during review process	Forgo

From President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research. Deciding to forgo life-sustaining treatment: ethical, medical and legal issues in treatment decisions. Washington, D.C.: U.S. Government Printing Office; 1983.

**TABLE 5-4 Parents' Desires for Communication in the Intensive Care Units**

1. **Honest and complete information** should be tailored to the parents' needs and information-receiving preferences. Comprehension of the child's potential trajectories permits better participation in care and a greater chance of appropriate end-of-life care.
2. **Ready access to staff** should include periodic scheduled informal visits to the bedside and the availability of e-mail interactions. The goal is to provide the parents with easy and frequent opportunities to have their questions answered, with sufficient repetition and clarification of the "big picture."
3. To maximize successful **communication**, clinicians should actively assess the parents' preferences for communication and decision making. This includes considering how to relate information to parents when clinicians have different management opinions. Parents frequently recognize that there are differences between options, and some prefer to hear the range of options whereas others prefer to hear only the recommended option.
4. **Emotional expression and support by staff** are critical to parents. To do this successfully, clinicians should adapt their style to parents' preferences. Most clinicians should adopt practices that give parents more room to control the conversation, including talking less, listening more, and tolerating silence as parents gather themselves to continue communicating.
5. Parents respond and benefit from the **relational aspects of compassion, mercy, authenticity, and integrity**.<sup>52</sup> More colloquially, the relational aspect is referred to as "being there," interacting with the parents as a caring person with feelings and emotions.<sup>53</sup> For example, although some clinicians may believe it is inappropriate to show emotion, parents appreciate compassion and some level of distress at the sharing of bad news, rather than cold hard professionalism.<sup>51</sup>
6. **Preservation of the integrity of the parent-child relationship** means enabling parents to continue in their self-identified and prominent role as decision maker and protector. Loss of this role harms parents and may impair their ability to participate in decision making for the child.
7. **Faith and spiritual matters** are highly personal, and parents may feel uncomfortable expressing their faith in an institutional setting. Spiritual matters should be accepted and integrated into the intensive care unit practice to assist those who benefit from spiritual support.
8. **Parents' lifelong views of these events** are profoundly colored by vivid memories and strong feelings about seminal discussions. How difficult discussions are handled and the quality of the communication among clinicians and families often become the bases for the family's lifelong narrative of these events.

Modified from Meyer EC, Ritholz MD, Burns JP, Truog RD. Improving the quality of end-of-life care in the pediatric intensive care unit: parents' priorities and recommendations. *Pediatrics* 2006;117:649-57.

## Clinical and Academic Practice Issues

### PEDIATRIC RESEARCH

The anesthesiologist Henry K. Beecher was one of the first to propose different requirements for pediatric research as compared to adult research.<sup>62</sup> Pediatric research is closely examined because children are incapable of consenting to experiments, and because the developing child is at greater risk for long-term harm.<sup>62</sup> Federal guidelines give four categories of pediatric research, with each ascending category requiring greater scrutiny of the risk-to-benefit ratio, especially in research without

therapeutic benefit for the subject (Table 5-7).<sup>63</sup> Whereas obtaining the assent of the child whenever possible is important for therapeutic medical procedures, it is absolutely essential in the context of research, along with the informed permission of the parents.

### Minimal Risk

Minimal risks are defined as those risks that are not greater in and of themselves than those ordinarily encountered in daily life or during the performance of routine physical or psychological examinations. Most interpret this to mean the risks encountered

**TABLE 5-6 Ethical Issues Surrounding Donation after Cardiac Death (DCD)**

Should interventions be permitted prior to withdrawal of care?	The burdens from the interventions are not in the best interests of the child. On the other hand, the burdens of the interventions are mostly theoretical and may improve the quality of the transplanted organs.
Should withdrawal of therapy occur in the intensive care unit (ICU) or in the operating room?	Withdrawing therapy in the operating room may increase the quality of the organs transplanted. Withdrawing therapy in the ICU is likely to be less jarring to the family and more consistent with the premise of withdrawing therapy for the child's benefit. In addition, it may remove some of the awkwardness that may occur if the child does not die within the defined interval.
Who should withdraw therapy?	To be consistent with the premises of withdrawal of therapy, it should be the same person who would normally withdraw therapy from the child. Even if the decision is made to withdraw therapy in the operating room, an anesthesiologist who has not been caring for the child should not be asked to withdraw therapy because of the physical location of the event.
How long should cessation of cardiac function exist for a child to be declared dead?	Proposed times may be based on the premises of how long it would take to autoresuscitate compared with how long it would take to be resuscitated through medical intervention.
What are the contents of a good DCD policy?	<ul style="list-style-type: none"> <li>• Acceptable interventions before withdrawing therapy</li> <li>• Acceptable locations of withdrawing therapy</li> <li>• Amount of time to wait until death before forgoing procurement</li> <li>• Which individual should withdraw therapy</li> <li>• What to do if the family will not leave after death is declared</li> </ul>

**TABLE 5-7 Federal Classification of Pediatric Research**

- Research not involving greater than minimal risk
  - IRB determines minimal risk
  - IRB finds and documents that adequate provisions are made for soliciting assent from children and permission from their parents or guardians
- Research involving greater than minimal risk but presenting the prospect of direct benefit to the individual subject
  - IRB justifies the risk by the anticipated benefit to the subjects
  - The relationship of the anticipated benefit to the risk is at least as favorable as that presented by available alternative approaches
  - Adequate provisions are made for assent and permission
- Research that involves greater than minimal risk and no prospect of direct benefit to the individual subject but is likely to yield generalizable knowledge about the subject's disorder or condition
  - IRB determines that the risk represents a minor increase over minimal risk
  - The intervention or procedure presents experiences to subjects that are reasonably commensurate with those inherent in their actual or expected medical, dental, psychological, social, or educational situations
  - The intervention or procedure is likely to yield generalizable knowledge ... which is of vital importance for the understanding or amelioration of the subject's disorder or condition
  - Adequate provisions are made for assent and permission
- Research not otherwise approvable, which presents an opportunity to understand, prevent, or alleviate a serious problem affecting the health or welfare of children

From U.S. Department of Human Services: 45 CFR 46 Subpart D. Additional protection for children involved as subjects in research. 2009.  
IRB, Institutional review board.

in daily life by healthy children, such as running in the backyard, playing sports, or riding in a car.<sup>64,65</sup> A less favored relative interpretation uses as a benchmark those risks encountered in the daily lives of children who will be enrolled in the research. In other words, if a child were living in a manner that exposed the child to risk (e.g., undergoing repeated general anesthesia), then it would be acceptable to expose the child up to that level of risk in a study.

**TABLE 5-8 Strategies Used by Drug Companies to Influence Physicians**

- Teach sales people subtle verbal and nonverbal techniques to influence physicians.
- Instruct sales people to misdirect and to dissemble when questioned about possible complications.
- Cherry-pick which data are distributed to physicians.
- Prohibit distribution of studies that may criticize the product. (One strategy is to classify concerning studies as background studies and then prohibit distribution of background studies.)
- Seek "opinion leaders" to speak in favor of the product.
- Continue the well-established gift-giving strategy to subconsciously curry favor with the physician and to develop a positive association about the product and the company.

Individuals are poor at estimating the risk levels of activities and often correlate risk to familiarity, control of the activity, and reversibility of the potential harms.<sup>65</sup> Institutional review boards (IRB) may reject low-risk studies because they involve unfamiliar matters while approving studies that have excessive risks.

### Minor Increase over Minimal Risk

The pediatric research category that involves "greater than minimal risk and no prospect of direct benefit to the individual subject but is likely to yield generalizable knowledge about the subject's disorder or condition ... which is of vital importance" (see Table 5-8) is based on the idea that it is acceptable to expose a child to a "minor increase over minimal risk" under certain conditions.<sup>66</sup> Parsing the regulation may help clarify this somewhat unhelpful definition. One suggestion has been that *minor increase* means that the pain, discomfort, or stress must be transient, reversible, and not severe.<sup>64</sup> *Condition* of the subject should be used to mean a set of characteristics "that an established body of scientific or clinical evidence has shown to negatively affect children's health and well-being or to increase the risk of developing a health problem in the future."<sup>64</sup> Interpreting condition to include "having the potential to have the condition" permits

otherwise healthy children to participate in research for diseases that they may develop (e.g., cellulitis). The term *vital importance* implies that the evidence supporting the relevance of the study should require a higher order of proof.

### Socioeconomic Concerns and Distribution of Risk

Socioeconomically disadvantaged children living in urban areas may be overrepresented in research studies because urban academic centers in disadvantaged areas perform the majority of clinical research.<sup>67</sup> Children living in socioeconomically disadvantaged areas are often more affected by diseases associated with their environment, such as asthma or nutritional disorders complicated by limited access to stocked grocery stores. One could argue that this unequal burden of risk, primarily manifested by greater participation of socioeconomically disadvantaged children in research studies, is reasonable because these children are more likely to develop these diseases and therefore are more likely to benefit from the research.<sup>68</sup> Most reject that view and believe that in some sense, socioeconomically advantaged patients gratuitously gain the benefits of the research without sharing the risks. The disproportionate risk borne by one segment of society compared with another likely breaches the most accepted interpretation of the core ethical value of justice.

Socioeconomically disadvantaged families may be more likely to be influenced by the small gifts offered to research participants. Aside from compensating for costs (e.g., parking vouchers), gifts should not of themselves encourage participation. The problem is that gifts that represent a small expression of gratitude for some families may provide an incentive for participation for socioeconomically disadvantaged families.<sup>69</sup>

### IMPERATIVE FOR PHARMACOLOGIC RESEARCH

Through the mid-1990s, more than 70% of new molecular entities were without pediatric drug labeling. Inadequate information exposed children to age-specific adverse reactions, ineffective treatment due to inappropriate dosing, and lack of access to new drugs because physicians tended to prescribe less effective, known medications. Inadequate research into pediatric drugs forced physicians to prescribe drugs in nonstandard ways, such as sprinkled or crushed tablets. Even when there is some pediatric labeling, there is scant labeling for children younger than 2 years of age. In 2009, a survey of a Canadian pediatric tertiary hospitals found that even when comparing off-label use to contemporary pediatric references (an unofficial and very liberal interpretation), 16% of drug administrations during the perioperative period were considered off-label. Based on a more traditional standard of the *Canadian Compendium of Pharmaceutical Specialties*, 55% of drugs administered were used off-label.<sup>70</sup>

The following selective history highlights the overall intent to ensure (1) that children get the same benefits of pharmacologic advances as adults and (2) that research is performed in the youngest children. Readers should also learn from this history that persistent advocacy is often required before regulatory change can be successfully obtained. In 1962, the Kefauver-Harris Amendments (passed after the thalidomide disaster) required that drug companies demonstrate safety and efficacy before marketing a drug. Because the vast majority of drugs did not undergo pediatric-specific investigation, this requirement actually led to less pediatric labeling, with the package insert (drug label) often reading, "Safety and efficacy have not been demonstrated for children <12 years," because of the expense of getting this

information (see also Chapter 6). In 1994, the U.S. Food and Drug Administration (FDA) began requiring sponsors to explain why pediatric labeling cannot occur but did not require sponsors to perform pediatric studies.

The 1997 FDA Modernization Act and the 1998 Final Rule were legislative initiatives designed to gain more data from drug companies through pediatric studies in exchange for the benefit of an additional 6 months of patent exclusivity. This effort was further codified with the passage of the Best Pharmaceutical Act for Children in 2002. With these requirements, the FDA mandated pediatric studies if a new drug might be used in a substantial number of children, if it might provide a meaningful therapeutic benefit, or if inadequate labeling could pose significant risks. The pharmaceutical industry responded with an explosion of pediatric studies. However, the exclusivity provision did not encourage study of generic drugs or drugs with insufficient sales. Further, once exclusivity was credited for older pediatric age groups, there was no incentive to conduct studies in younger groups.

In December 2003, the Pediatric Research Equity Act required pediatric studies for all drugs and biologic products that have a new indication, new dosage form, new route, new dosing regimen, or new active ingredient. Studies could be waived if they were impracticable, if the therapy would be ineffective or unsafe in pediatric patients, or if there would be no meaningful therapeutic benefit over existing therapies and the moiety would not be used in a substantial number of children.

Other nations have adopted similar regulatory requirements and incentives to encourage drug research. The European Union offers scientific help for performance of studies and requires that drug applications contain pediatric information that covers "all paediatric age groups and all necessary age-appropriate formulations," unless an exception is granted.<sup>71</sup> Performing pediatric testing earns patent extensions even if the drug is not approved for pediatric use.

### MANAGING POTENTIAL CONFLICTS OF INTEREST

A *conflict of interest* is "a set of conditions in which professional judgment concerning a primary interest (such as a patient's welfare or the validity of research) tends to be unduly influenced by a secondary interest."<sup>72</sup> Because these conditions in an individual are internal, they are best characterized by describing situations that may create the potential for conflicts of interest. Focusing on potential conflicts of interest moves the concept away from attacking an individual's morals and toward more uniform definitions. Conflicts of interest may be induced by financial, personal, and professional benefits such as prestige, promotion, and personal gratification.<sup>73</sup> Anesthesiologists should be mindful of these potential conflicts, and attempt to identify them to better understand the likelihood of compromised judgment.

### Conducting Research

Perhaps the most powerful conflict in conducting research is the loss of equipoise that can come from originating and developing an idea. Other sources of conflict related to research center on academic promotion and reputation. Physician disclosures do not help identify conflicts of interest. In one study, only 80% of physicians disclosed payments related to the research, and only 50% disclosed payments from the same company but unrelated to the product being discussed. Indirect payments were just as likely to influence behavior as direct payment.<sup>74</sup>

In 2009, an anesthesiologist was accused of falsifying data that had encouraged multimodal pain therapy. A routine audit had found the irregularities that initiated the subsequent evaluation (supporting the benefits of oversight). Major journals retracted articles. Steven Shafer, editor of *Anesthesia and Analgesia*, was quoted as saying, “We are left with a large hole in our understanding of this [multimodal pain therapy].”<sup>75</sup> Shafer called the scandal “a tragedy” for the profession, for patients, and for the anesthesiologist involved personally. Given that the anesthesiologist’s studies were “robust” and influential, “the big chunk of what people have based their [multimodal] protocol on is gone.”<sup>75,76</sup> It is important to emphasize that the anesthesiologist’s coauthors were deceived by him and were not complicit. If fact, they assisted in assessing the legitimacy of articles that were not retracted.<sup>77</sup>

Conflicts of interest also come from industry support of research. To be clear, the academic–anesthesia–industry research complex is necessary to continue the rapid advancement of science. Rigorous oversight minimizes these abuses. Researchers need to be involved in trial development, must have access to raw data, and must be able to publish without the company’s authorization. Cozy relationships between powerful members of the local academic community and industry should be examined and brought to light to minimize influence and potential conflicts of interest.

### Interaction with Industry

Anesthesiologists need to be suspicious of industry attempts to “selflessly” educate clinicians.<sup>78</sup> Physicians should independently evaluate information supplied by industry. Industry representatives and materials routinely overrepresent the benefits and underrepresent the risks of drugs (Table 5-8).<sup>79</sup> Wisely, there has been a strong movement in academic centers to stiffen rules about physician exposure to industry representatives.<sup>80</sup>

Risks associated with industry misrepresentation will increase as increasing physician workload decreases time for study. For these reasons, it is instructive to look more closely at this problem. Evidence published in the 2000 VIGOR study indicated that the popular antiinflammatory drug rofecoxib (Vioxx) dramatically increased the rate of myocardial infarction in patients. In 2001, the FDA determined that physicians should be made aware of the cardiovascular effects of rofecoxib, and in 2004 it was withdrawn from the market. Congressman Henry Waxman later wrote the following<sup>81</sup>:

*Merck, the manufacturer of Vioxx, ... has an excellent reputation within the drug industry and supports many products, such as vaccines, that are medically essential but not very profitable.... Yet as we learned, even a company like Merck can direct its sales force to provide clinicians with a distorted picture of the relevant scientific evidence....*

On February 7, 2001, the Arthritis Drugs Advisory Committee of the Food and Drug Administration (FDA) ... voted unanimously that physicians should be made aware of VIGOR’s cardiovascular results.

The next day, Merck sent a bulletin to its rofecoxib sales force [which] ordered, “DO NOT INITIATE DISCUSSIONS ON THE FDA ARTHRITIS ADVISORY COMMITTEE ... OR THE RESULTS OF THE ... VIGOR STUDY.” It advised that if a physician inquired about VIGOR, the sales representative should indicate that the study showed a gastrointestinal benefit and then say, “I cannot discuss the study with you.”

Merck further instructed representatives to show those doctors who asked whether rofecoxib caused myocardial infarction a

pamphlet called “The Cardiovascular Card.” This pamphlet, prepared by Merck’s marketing department, indicated that rofecoxib was associated with 1/8 the mortality from cardiovascular causes of that found with other antiinflammatory drugs.

The Cardiovascular Card ... did not include any data from the VIGOR study. Instead, it presented a pooled analysis of preapproval studies, in most of which low doses of rofecoxib were used for a short period of time. None of these studies were designed to assess cardiovascular safety.... In fact, FDA experts had publicly expressed “serious concerns” ... about using preapproval studies as evidence of the drug’s cardiovascular safety....

[B]ut it would be a mistake to restrict the lessons learned to a single company. The testimony we heard indicated that Merck’s marketing practices may be less aggressive and more ethical than many of its competitors. It should be noted that Merck eventually paid \$950 million USD to settle criminal charges and civil claims related to unlawful marketing of Vioxx and misleading statements about its safety.

### Production Pressure

Anesthesiologists are prone to production pressure, which has been defined as “the internal or external pressure on the anesthesiologist to keep the operating room schedule moving along speedily.”<sup>82,83</sup> Almost half of surveyed anesthesiologists reported seeing what they considered unsafe anesthetic practices in response to this production pressure.<sup>84</sup> As a consequence, anesthesiologists may not want to take the time to allow a child to ask questions about the anesthetic, to adequately premedicate an anxious child, or to engage the parents in a lengthy discussion about postponing the surgery because the child has a mild upper respiratory infection. Anesthesiologists should also be cognizant of their level of skill in providing anesthesia. For example, the “routine” tonsillectomy may be beyond some anesthesiologists’ ability in a child with multiple congenital deficits. Anesthesiologists have an obligation to the patient and themselves to only provide care that is within their skills and to recognize when economic and administrative pressures may induce them to do otherwise.

### THE FETUS

The positions of the AAP and the American College of Obstetricians and Gynecologists (ACOG) are helpful in considering care of the fetus (Table 5-9).<sup>85-87</sup> The statements indicate subtle differences when the interests of the mother and fetus diverge, such as when the mother wishes to refuse a treatment that would likely be beneficial for the fetus. Broadly, the AAP advocates more for the fetus, particularly when the intervention poses a small risk to the mother and can effectively treat a problem for the fetus that would otherwise cause irreversible harm. ACOG is more concerned about complex issues of overriding maternal autonomy, such as the criminalization of not complying with medical recommendations.

### PHYSICIAN OBLIGATIONS, ADVOCACY, AND GOOD CITIZENSHIP

An implicit social contract obligates physicians to serve society beyond directly caring for patients. Society supports medical students, physicians in training, and physicians through providing opportunities to train, to perform research, and, perhaps most importantly, to learn from and with patients.<sup>88</sup> In return, society expects pediatric anesthesiologists to “manage all things pediatric anesthesia” (Table 5-10).<sup>89-91</sup> Individual anesthesiologists are not expected to fulfill every obligation. “Units” of anesthesiologists,

**TABLE 5-9** Positions of the AAP and the ACOG Regarding Ethical Considerations and Maternal Choices in Fetal Therapy

American Academy of Pediatrics (AAP)	American College of Obstetricians and Gynecologists (ACOG)
<b>Priority</b>	
Respect for principle of maternal autonomy Fetal concerns may trump maternal autonomy	Respect for principle of maternal autonomy Fetal concerns may not trump maternal autonomy
<b>Type of Medical Treatment Worthy of Judicial or Physical Intervention</b>	
If the intervention has been demonstrated to be effective If nonintervention will lead to significant and irreversible harm If there is minimal maternal risk from the intervention	If there is a high probability of serious harm to the fetus without intervention If there is a high probability of significant benefit to the fetus from the intervention If there is a relatively small risk to the pregnant woman from the intervention If no comparably effective, less invasive options are available Intervention only under extraordinary circumstances of conflict
<b>Use of Physical Intervention</b>	
Physical intervention may be acceptable if judicial authorization has been obtained	Physical intervention is never acceptable
<b>Psychosocial Aspects</b>	
Psychosocial aspects of overriding a woman's autonomy are not addressed	Significant concern about overriding maternal autonomy, including <ul style="list-style-type: none"> <li>• criminalization of noncompliance with medical recommendations</li> <li>• loss of trust in the health care system</li> <li>• social costs of compromising liberty</li> </ul>
<b>Conflict Resolution</b>	
Does not ask physicians to consider subordinating their view Does not suggest it is reasonable to transfer the patient's care	Physicians should make reasonable attempts to explain recommended treatments and to persuade the woman to comply Physicians should subordinate their values if necessary, because it is the woman's decision Suggests it may be reasonable to transfer care

Data from Brown SD, Truog RD, Johnson JA, Ecker JL. Do differences in the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists positions on the ethics of maternal-fetal interventions reflect subtly divergent professional sensitivities to pregnant women and fetuses? *Pediatrics* 2006;117:1382-7; American Academy of Pediatrics, Committee on Bioethics. Fetal therapy: ethical considerations. *Pediatrics* 1999;103:1061-3; American College of Obstetricians and Gynecologists. Committee Opinion 321: Maternal decision making, ethics, and the law. *Obstet Gynecol* 2005;106:1127-37.

such as private practice groups, academic departments, and state societies, should fulfill these obligations collectively.

### Participating in Patient Safety Efforts

Medical errors come from human mistakes and system flaws.<sup>92</sup> Anesthesiologists have an obligation to work to reduce system flaws, including participating in quality improvement activities and data collection, following policies meant to improve care in high-risk situations (e.g., nosocomial infections), and actively engaging in policies designed to reduce medical errors, such as universal standards of patient identification.<sup>93</sup>

Although physicians may not see the big picture and therefore resent doing “extra” steps, it is vital for physicians to accept on faith that participation is good patient care.<sup>94</sup> Surreptitiously circumventing policies may harm patients, does not permit remediation of the policy, and weakens the fidelity of the entire system, encouraging others to “make their own rules.”<sup>95</sup> When anesthesiologists believe that policies are harmful or unnecessary, they are obligated to raise these questions through appropriate channels.

### Treating Suffering

Cassel described suffering as an intensely personal feeling that can be defined as “the state of severe distress associated with events that threaten the intactness of the person.”<sup>96</sup> Suffering should be considered when managing pain, and adequate steps should be taken to find and alleviate sources of suffering. Factors that contribute to a child's suffering include not knowing the origin or meaning of the pain, believing that pain is a punishment, and fearing that the pain will never be relieved.<sup>96</sup>

Anesthesiologists minimize suffering by clearly communicating about these issues with parents and children and affording children as much control of their care as possible.

### Suspicion of Child Abuse

Child abuse includes acts of physical abuse, sexual abuse, emotional abuse, and neglect. Anesthesiologists should be particularly sensitive to bruises or burns in the shape of objects, injuries to soft tissue areas such as the upper arms, unexplained mouth and dental injuries, fractures in infants, height and weight less than the 5th percentile, and injuries that are not explained by the history (see also Chapter 38).<sup>97,98</sup> Children who have physical or mental handicaps are particularly prone to abuse.<sup>99</sup> Anesthesiologists, like all physicians, are legally required to report the suspicion of child abuse or neglect to appropriate authorities. Indeed, in most jurisdictions, a physician can be criminally prosecuted if found liable for failing to report suspected child abuse.

### THE ETHICS CONSULTATION SERVICE

The ethical dilemmas that occur in the practice of anesthesiology may be difficult for the practitioner to resolve alone. Ethics committees and their consulting services act in an advisory role to help clinicians, patients, and families amicably resolve ethical dilemmas. Anesthesiologists may find ethics consultation helpful with questions about informed consent, decision-making capacity, and resuscitation decisions and in resolving disagreements among patients, families, and clinicians.

Although most ethics consultation services use a small group (typically three people) to perform consultations, some use the

**TABLE 5-10** Examples of Obligations of Anesthesiologists to Participate and Advocate

<b>Obligations of Pediatric Anesthesiologists</b>
Treat every child with the grace and consideration you would want for your child and family
Tailor the perioperative experience to the individual
Respond to problems that may harm children (e.g., impaired colleagues)
Practice mindfulness and critical self-reflection
Actively engage in continuing medical education
Support advancement of the science
Participate in quality improvement initiatives such as Wake Up Safe
Participate in professional organizations such as the Society for Pediatric Anesthesia and the American Academy of Pediatrics Section on Anesthesiology and Pain Medicine
Prepare future generations through teaching, mentoring, creating opportunities, and developing systems to enable anesthesiologists to fulfill these obligations
<b>Community Advocacy and Participation</b>
Raise public awareness about a health or social issue
Participating in public advocacy and lobbying
Encourage a medical society to act on an issue that concerns the public health
Serve in a local organization, political interest group, or political organization
Topics of particular relevance to pediatric anesthesiologists: <ul style="list-style-type: none"> <li>• Pediatric obesity</li> <li>• Pediatric sedation in hospitals</li> <li>• Child abuse</li> <li>• Health care access</li> <li>• Role of subspecialty training in improving care for children</li> </ul>

entire committee and some use a single individual.<sup>100</sup> Physicians, nurses, social workers, chaplains, administrators, and lay people serve on ethics committees and perform consultations. Common characteristics of ethics consultation services are that they permit anyone to request an ethics consultation; that they require notification (not permission) of the patient, parents, and attending physician prior to the consultation; and that choosing to follow the recommendations is wholly voluntary.

Following consultations, clinicians feel greater satisfaction in managing cases with ethical conflicts, not only because of their

heightened awareness of the expert consulting services available but also because of their increased knowledge and comfort in dealing with these issues. Ethics committees are also available to consult on policy development and to organize continuing educational programs.

**THE PHARMACOKINETICS AND PHARMACODYNAMICS** of most medications, when used in children, especially neonates, differ from those in adults.<sup>1–11</sup> Children exhibit different pharmacokinetics (PK) and pharmacodynamics (PD) from adults because of their immature renal and hepatic function, different body composition, altered protein binding, distinct disease spectrum, diverse behavior, and dissimilar receptor patterns.<sup>1,3,12–19</sup> PK differences necessitate modification of the dose and the interval between doses to achieve the desired clinical response and to avoid toxicity.<sup>7,20–22</sup> In addition, some medications may displace bilirubin from its protein binding sites and possibly predispose an infant to kernicterus.<sup>23–28</sup> The capacity of the end organ, such as the heart or bronchial smooth muscle, to respond to medications may also differ in children compared with adults (PD effects). In this chapter we discuss basic pharmacologic principles as they relate to drugs commonly used by anesthesiologists.

## Pharmacokinetic Principles and Calculations

Changes in drug concentrations within the body over time are referred to as *pharmacokinetics*. The principles and equations that describe these changes can be used to adjust drug doses rationally to achieve more effective drug concentrations at the site of action.<sup>29–33</sup> The equations in this section are intended for general and practical use, whereas the more rigorous mathematical intricacies of PK are covered elsewhere.<sup>34–37</sup>

Within the body, a drug may diffuse between several body fluids and tissues at different rates, yet the consistent change in its circulating concentration may be used to characterize its kinetics and to guide dosages. The rate of removal of drug

from the circulation is usually described using either first-order or zero-order exponential equations. The difference between these two types of rates has important implications for drug treatment.

### FIRST-ORDER KINETICS

Most drugs are cleared from the body with first-order exponential rates in which a constant fraction or constant proportion of drug is removed per unit of time. Because the proportion of drug cleared remains constant, the higher the concentration, the greater the amount of drug removed from the body. Such rates can be described by exponential equations that fit the following form:

$$C = C_0 e^{-kt} \quad (\text{Eq. 1})$$

where  $C$  is the concentration at time  $t$ ,  $C_0$  is the starting concentration (a constant determined by the dose and distribution volume), and  $k$  is the elimination rate constant with units of  $\text{time}^{-1}$ . First-order indicates that the exponent is raised to the first power ( $-kt$  in Equation 1). Second-order equations are those that are raised to the second power, such as  $e^{(z)^2}$ . First-order exponential equations, such as Equation 1, may be converted to the form of the equation of a straight line ( $y = mx + b$ ) by taking the natural logarithm of both sides, after which they may be solved by linear regression.

$$\ln C = \ln C_0 + (-kt) \quad (\text{Eq. 2})$$

If  $\ln C$  (i.e., natural logarithm of  $C$ ) is graphed versus time, the slope is  $-k$ , and the intercept is  $\ln C_0$ . If  $\log C$  (i.e., common logarithm of  $C$ ) is graphed versus time, the slope is  $-k/2.303$ , because  $\ln x$  equals  $2.303 \log x$ . When graphed on linear–linear axes, exponential rates are curvilinear and on semilogarithmic axes, they produce a straight line.

## HALF-LIFE

Half-life, the time for a drug concentration to decrease by one half, is a familiar exponential term used to describe the kinetics of many drugs. *Half-life is a first-order kinetic process, because the same proportion or fraction of the drug is removed during equal periods of time.* As described earlier, the greater the starting concentration, the greater the amount of drug removed during each half-life.

Half-life can be determined by several methods. If concentration is converted to the natural logarithm of concentration and graphed versus time, as described in Equation 2, the slope of this graph is the elimination rate constant,  $k$ . For both accuracy and precision, at least three concentration-time points should be used to determine the slope, and they should be obtained over an interval during which the concentration decreases at least in half. In clinical practice, for infants and small children, however,  $k$  is often estimated from just two concentrations obtained during the terminal elimination phase. With multiple data points, the slope of  $\ln C$  versus time may be calculated easily by least squares linear regression analysis. Half-life ( $T_{1/2}$ ) may be calculated from the elimination rate constant,  $k$  ( $\text{time}^{-1}$ ), as follows:

$$T_{1/2} = \frac{\text{Natural Logarithm } (2)}{k} = \frac{0.693}{k} \quad (\text{Eq. 3})$$

Graphic techniques may be used to determine half-life from a series of timed measurements of drug concentration. The concentration-time points should be graphed on semilogarithmic axes and used to determine the best fitting line either visually or by linear regression analysis. This approach is illustrated in Figure 6-1, in which the best-fitting line has been drawn to the concentration-points and crosses a concentration of 20  $\mu\text{g/mL}$  at 100 minutes and a concentration of 10  $\mu\text{g/mL}$  at 200 minutes. The concentration has decreased by one half in 100 minutes, so the half-life is 100 minutes. The elimination rate constant is  $(0.693/100) \text{ min}^{-1}$  or  $0.00693 \text{ min}^{-1}$ .

Elimination half-life is of no value in characterizing disposition of many intravenous (IV) anesthetic drugs during dosing periods relevant to anesthesia. A more useful concept is that of the context-sensitive half-time (CSHT) where “context” refers to the duration of the infusion. This is the time required for the plasma drug concentration to decrease by 50% after terminating

**FIGURE 6-1** Graphic determination of half-life. Half-life can be determined from a series of concentration time-points on a semilogarithmic graph, if the kinetics are first-order exponential. The concentrations are plotted on semilogarithmic axes; the best-fit line is drawn to the points; convenient concentrations are chosen that decrease in half, such as 20  $\mu\text{g/mL}$  and 10  $\mu\text{g/mL}$ , as illustrated; and the interval between those concentrations is the half-life, which is 100 minutes in the illustration.

the infusion.<sup>38</sup> The CSHT is the same as the elimination half-life for a one-compartment model and does not change with the duration of the infusion. However, most drugs in anesthesia conform to multiple compartment models and the CSHTs are markedly different from their respective elimination half-lives.

CSHT may be independent of the duration of the infusion (e.g., remifentanyl, 2.5 minutes); moderately affected (propofol, 12 minutes at 1 hour, 38 minutes at 8 hours); or display marked prolongation (e.g., fentanyl, 1 hour at 24 minutes, 8 hours at 280 minutes). This is a result of return of drug to plasma from peripheral compartments after stopping the infusion. Peripheral compartment sizes and clearances differ in children from adults and at termination of the infusion such that more or less drug remains in the body in children for any given plasma concentration compared with adults. The CSHT for propofol in children, for example, is greater than that in adults.<sup>39</sup> The CSHT gives insight into the PK of a drug, but the parameter may not be clinically relevant; the percentage decrease in concentration required for recovery from the drug effect is not necessarily 50%.

## FIRST-ORDER SINGLE-COMPARTMENT KINETICS

The number of exponential equations required to describe the change in concentration determines the number of compartments. Although a drug may diffuse among several tissues and body fluids, its clearance often fits first-order, single-compartment kinetics if it quickly distributes homogeneously within the circulation and is removed rapidly from the circulation through metabolism or excretion. This may be judged visually, if a semilogarithmic graph of the change in drug concentration fits a single straight line. Kinetics may appear to be single-compartment, when they are really multiple compartments, if drug concentrations are not measured soon enough after IV administration to detect the initial distribution phase ( $\alpha$  phase).

## FIRST-ORDER MULTIPLE-COMPARTMENT KINETICS

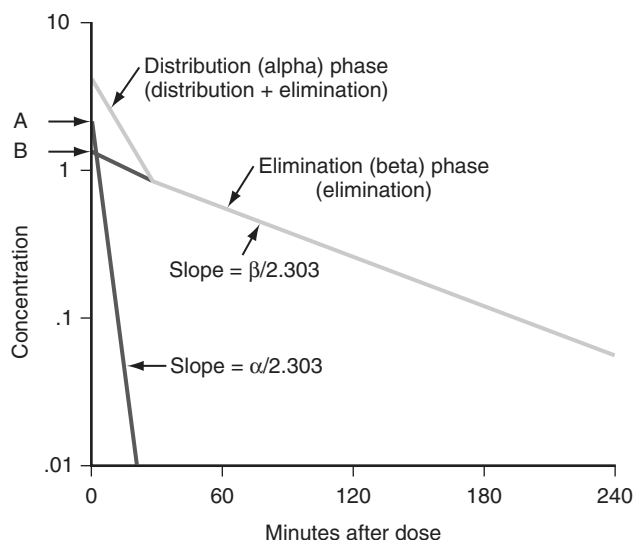

If drug concentrations are measured several times within the first 15 to 30 minutes after IV administration as well as during a more prolonged period, more than one rate of clearance is often present. This can be observed as a marked change in slope of a semilogarithmic graph of concentration versus time (Fig. 6-2). The number and nature of the compartments required to describe the clearance of a drug do not necessarily represent specific body fluids or tissues. When two first-order exponential equations are required to describe the clearance of drug from the circulation, the kinetics are described as first-order, two-compartment (e.g., central and peripheral compartments) that fit the following equation (Fig. 6-2)<sup>31</sup>:

$$C = Ae^{-\alpha t} + Be^{-\beta t} \quad (\text{Eq. 4})$$

where concentration is  $C$ ,  $t$  is time after the dose,  $A$  is the concentration at time 0 for the distribution rate represented by the purple line graph with the steepest slope,  $\alpha$  is the rate constant for distribution,  $B$  is the concentration at time 0 for the terminal elimination rate, and  $\beta$  is the rate constant for terminal elimination. Rate constants indicate the rates of change in concentration and each corresponds to the slope of the respective line divided by 2.303 for logarithm concentration versus time.

Such two-compartment or biphasic kinetics are frequently observed after IV administration of drugs that rapidly distribute out of the central compartment of the circulation to a peripheral compartment.<sup>31</sup> In such situations, the initial rapid decrease in concentration is referred to as the  $\alpha$  or distribution phase and

**FIGURE 6-2** Two compartment kinetics in a semilogarithmic graph. The initial rapid decrease in serum concentration reflects distribution and elimination followed by a slower decrease because of elimination. A is the concentration at time 0 for the distribution rate. Subtraction of the initial decrease in concentration resulting from elimination, using the concentrations from the elimination line extrapolated back to time 0 at B, produces the lower line with a steep slope =  $\alpha$ (distribution rate constant)/2.303. The terminal elimination phase has a slope =  $\beta$ (elimination rate constant)/2.303.

represents distribution to the peripheral (tissue) compartments in addition to drug elimination. The terminal ( $\beta$ ) phase begins after the inflection point in the line when elimination starts to account for most of the change in drug concentration. To determine the initial change in concentration as a result of distribution (Fig. 6-2), the change in concentration that results from elimination must be subtracted from the total change in concentration. The slope of the line representing the difference between these two rates is the rate constant for distribution.

These parameters (A, B,  $\alpha$ ,  $\beta$ ) have little connection with underlying physiology and an alternative parameterization is to use a central volume and three rate constants ( $k_{10}$ ,  $k_{12}$ ,  $k_{21}$ ) that describe drug distribution between compartments. Another common method is to use two volumes (central, V1; peripheral, V2) and two clearances (CL, Q). Q is the intercompartment clearance and the volume of distribution at steady state (Vdss) is the sum of V1 and V2. A more detailed mathematical discussion may be found elsewhere.<sup>31,40</sup>

Although many drugs demonstrate multiple-compartment kinetics, traditional studies of kinetics in neonates did not include enough samples immediately after dosing to determine more than one compartment. For clinical estimates of dose and dosing intervals, it is often not necessary to use multiple-compartment kinetics. To minimize cost, limit blood loss, and simplify PK calculations, dose adjustments are often based on only two plasma concentrations (peak and trough), and linear, single-compartment kinetics (such as that of gentamicin and vancomycin) is assumed. Because the elimination rate constant should be determined from the terminal elimination phase, it is important that peak concentrations of multiple-compartment drugs not be drawn prematurely, that is, during the initial distribution phase. If drawn too early, the concentrations will be greater than those during the terminal elimination phase (Fig. 6-2), which will

**FIGURE 6-3** Transition from exponential to saturation kinetics. During every-6-hour dosing, concentrations during the first 24 hours reflect exponential kinetics with a half-life of 3 hours ( $k = 0.231/\text{hr}$ ) followed by a change to saturation kinetics at 24 hours with elimination of 1 mg/hr, leading to drug accumulation to toxic concentrations.

overestimate the slope and the terminal elimination rate constant. Population modeling has improved analysis and interpretation of such data.<sup>41,42</sup>

## ZERO-ORDER KINETICS

The elimination of some drugs occurs with loss of a *constant amount per time*, rather than a *constant fraction per time*. Such rates are termed zero-order, and because  $e^0 = 1$ , the change in the amount of drug in the body fits the following equation<sup>40</sup>:

$$-dA/dt = k_0 \quad (\text{Eq. 5})$$

where dA is the change in the amount of drug in the body (in milligrams), dt is the change in time, and  $k_0$  is the elimination rate constant with units of amount per unit time. After solving this equation, it has the following form:

$$A = A_0 - k_0 t \quad (\text{Eq. 6})$$

where  $A_0$  is the initial amount of drug in the body and A is the amount of drug in the body (in milligrams) at time t.

Zero-order (also known as Michaelis-Menten) kinetics may be designated saturation kinetics, because such processes occur when excess amounts of drug saturate the capacity of metabolic enzymes or transport systems. In this situation, only a constant amount of drug is metabolized or transported per unit of time. If kinetics are zero order, a graph of serum concentration versus time is linear on linear-linear axes and is curved when graphed on linear-logarithmic (i.e., semilogarithmic) axes. Clinically, first-order elimination may become zero order after administration of excessive doses or prolonged infusions or during dysfunction of the organ of elimination. Certain drugs administered to neonates exhibit zero-order kinetics at therapeutic doses and may accumulate to excessive concentrations, including thiopental, theophylline, caffeine, diazepam, furosemide, and phenytoin.<sup>43</sup> Some drugs (e.g., phenytoin, ethyl alcohol) may exhibit mixed-order kinetics (i.e., first order at low concentrations and zero order after enzymes are saturated at higher concentrations). For these drugs, a small increment in dose may cause disproportionately large increments in serum concentrations (Fig. 6-3).

## APPARENT VOLUME OF DISTRIBUTION

The apparent volume of distribution (Vd) is a mathematical term that relates the dose to the circulating concentration observed immediately after administration. It might be viewed as the volume of dilution that can be used to predict the change in concentration after a dose is diluted within the body (i.e., a scaling factor). Vd does not necessarily correspond to a physiologic body fluid or tissue volume, hence the designation “apparent.” For drugs that distribute out of the circulation or bind to tissues, such as digoxin, Vd may reach 10 L/kg, a physical impossibility for a fluid compartment in the body. This illustrates the mathematical nature of Vd. The units used to express concentration are amount per unit volume, and it may help to remind the reader of the following equation that expresses the relation between dose in amount per kilogram and the Vd in volume per kilogram that dilutes the dose to produce the concentration:

$$\text{Concentration (mg/L)} = \frac{\text{Dose (mg/kg)}}{\text{Vd (L/kg)}} \quad (\text{Eq. 7})$$

If concentration is expressed with the unconventional units of milligrams per liter rather than micrograms per milliliter (which is equivalent), it is easier to balance the equation. This equation serves as the basis for most of the PK calculations because it is easily rearranged to solve for Vd and dose. It is also important to note that this equation represents the change in concentration after a rapidly administered IV dose of a drug whose elimination is great compared with its time for distribution. After a mini-infusion (e.g., of vancomycin or gentamicin), a more complex exponential equation may be required to account for drug elimination during the time of infusion.<sup>40</sup> For neonates in whom drug elimination is relatively slow, only a small fraction of drug is eliminated during the time of infusion, and such adjustments can be omitted, whereas more complex equations may be needed in older children.

Knowledge of the apparent Vd is essential for dosage adjustments. Vd may be calculated by rearranging Equation 7.

$$\text{Vd (L/kg)} = \frac{\text{Dose (mg/kg)}}{\text{C (postdose)} - \text{C (predose) (mg/L)}} \quad (\text{Eq. 8})$$

The concentration after a drug infusion, C (postdose), must be measured after the distribution phase to avoid overestimating the peak concentration that would, in turn, lead to an erroneously low Vd. For the first dose, the predose concentration is 0.

### Pharmacokinetic Example

The following example illustrates the application of these PK principles using a four-step approach: (1) calculate Vd; (2) calculate half-life; (3) calculate a new dose and dosing interval based on a desired peak and trough; and (4) check the peak and trough of the new dosage regimen.

For example, vancomycin was administered in a dose of 15 mg/kg IV over 60 minutes every 12 hours. The following plasma concentrations were measured on the third day of treatment (presumed steady-state). The predose or trough concentration was 12 mg/L; the peak concentration, measured 60 minutes after the end of the infusion, was 32 mg/L.

$$\begin{aligned} \text{Vd (L/kg)} &= \frac{15 \text{ mg/kg}}{32 \text{ mg/L} - 12 \text{ mg/L}} \\ &= \frac{15 \text{ mg/kg}}{20 \text{ mg/L}} \\ &= 0.75 \text{ L/kg} \end{aligned}$$

*Step 1:* Substituting the data into Equation 8, we calculate Vd.

*Step 2:* At steady-state, peak and trough concentrations reach the same levels after each dose. The time between the peak and trough concentrations is 10 hours, that is, 12 hours minus 1 hour infusion minus 1 hour to peak concentration. Half-life may be solved by rearranging Equation 2 to solve for  $k$  (elimination rate constant) and substituting the calculated  $k$  into Equation 3. In this case, the calculated elimination rate constant is 0.098 hour<sup>-1</sup> and the corresponding half-life is 7.1 hours. However, a practical and clinically applicable “bedside” approach may be used without need for logarithmic calculations. For example, the plasma concentration decreased from 32 to 16 mg/L in one half-life and then from 16 to 12 mg/L in a fraction of the second half-life. At the end of the second half-life, the concentration would have decreased to 8 mg/L. Because 12 mg/L is the midpoint between the first and second half-lives, 1.5 half-lives have elapsed during the 10 hours between the peak and trough. Thus, if one assumes a linear decline, the half-life may be estimated as 6.67 hours (10 hours ÷ 1.5 half-lives). Note that the error between the actual half-life of 7.1 hours and the estimated half-life (6.67 hours) is a result of the linear assumptions of this calculation between half-lives. In fact, first-order elimination is a nonlinear process and concentration will actually decline from 32 mg/L to 22.6 mg/L during the first 50% of the first half-life rather than from 32 mg/L to 24 mg/L using this linear approach. The same occurs during subsequent half-lives. However, the small error associated with this method is often acceptable for rapid bedside estimates of PK parameters.

*Step 3:* A new dosage regimen must be calculated if the concentrations are unsatisfactory. Accordingly, one must decide on a desired peak and trough concentration. If, for example, the desired vancomycin peak and trough concentrations were 32 mg/L (20 to 40 mg/L) and 8 mg/L (5 to 10 mg/L), respectively, then Equation 8 may be rearranged to solve for the new dose.

$$\begin{aligned} \text{Dose (mg/kg)} &= \text{Vd (L/kg)} [\text{C (peak desired)} - \text{C (trough desired) (mg/L)}] \\ \text{Dose (mg/kg)} &= 0.75 \text{ L/kg} (32 \text{ mg/L} - 8 \text{ mg/L}) \\ \text{Dose (mg/kg)} &= 18 \text{ mg/kg} \end{aligned} \quad (\text{Eq. 9})$$

The current dose produces a peak of 32 mg/L that is in the recommended therapeutic range, and lengthening the dosing interval to 2 half-lives (13½ hours) after the peak is reached (2 hours after beginning the dose infusion) will produce a trough concentration of 8 mg/L. The dose interval should be increased to 16 hours and the dose increased to 18 mg/kg.

*Step 4:* Estimating peak and trough concentrations with the new regimen provides a good double check against a mathematical error. Sixteen hours after the 15 mg/kg dose is administered (or approximately 2 half-lives after the measured peak), the trough should be approximately 8 mg/L. At this time, administration of 18 mg/kg will raise the concentration by 24 mg/L (assuming a Vd of 0.75 L/kg) to a peak concentration of 32 mg/L.

## REPETITIVE DOSING AND DRUG ACCUMULATION

When multiple doses are administered, the dose is usually repeated before complete elimination of the previous one. In this situation, peak and trough concentrations increase until a steady-state concentration (C<sub>ss</sub>) is reached (Fig. 6-3). The average C<sub>ss</sub> (AvgC<sub>ss</sub>) can be calculated as follows<sup>32</sup>:

$$\begin{aligned} \text{AvgC}_{ss} &= \frac{1}{\text{Clearance}} \cdot \frac{f \cdot D}{\tau} \\ &= \frac{1}{k \cdot V_d} \cdot \frac{f \cdot D}{\tau} \end{aligned} \quad (\text{Eq. 10})$$

$$= \frac{1.44 \cdot T_{1/2}}{V_d} \cdot \frac{f \cdot D}{\tau} \quad (\text{Eq. 11})$$

In Equations 10 and 11,  $f$  is the fraction of the dose that is absorbed,  $D$  is the dose,  $\tau$  is the dosing interval in the same units of time as the elimination half-life,  $k$  is the elimination rate constant, and 1.44 equals the reciprocal of 0.693 (see Equation 3). The magnitude of the average  $C_{ss}$  is directly proportional to the ratio of  $T_{1/2}/\tau$  and  $D$ .<sup>32</sup>

## STEADY STATE

Steady state occurs when the amount of drug removed from the body between doses equals the amount of the dose.<sup>33,37</sup> Five half-lives are usually required for drug elimination and distribution among tissue and fluid compartments to reach equilibrium. When all tissues are at equilibrium (i.e., steady state), the peak and trough concentrations are the same after each dose. However, before this time, constant peak and trough concentrations after intermittent doses, or constant concentrations during drug infusions, do not prove that a steady state has been achieved because drug may still be entering and leaving deep tissue compartments. During continuous infusion, the fraction of steady-state concentration that has been reached can be calculated in terms of multiples of the drug's half-life.<sup>32</sup> After three half-lives, the concentration is 88% of that at steady state. When changing doses during chronic drug therapy, the concentration should usually not be rechecked until several half-lives have elapsed, unless elimination is impaired or signs of toxicity occur. Drug concentrations may not need to be checked if symptoms improve.

## LOADING DOSE

If the time to reach a constant concentration by continuous or intermittent dosing is excessive, a loading dose may be used to reach plateau in the concentration more rapidly. This frequently is applied to initial treatment with digoxin, which has a 35- to 69-hour half-life in term neonates and an even longer half-life in preterm infants.<sup>44</sup> Use of a loading dose increases the circulating concentration of drug earlier in the therapeutic course, but for the equilibration to reach a true steady-state still requires treatment for five or more half-lives. Loading doses must be used cautiously, because they increase the likelihood of drug toxicity, as has been observed with loading doses of digoxin.<sup>3,16,17,44</sup>

Dose calculations using a 1-compartment model (Eq. 9) may not be applicable to many anesthetic drugs that are characterized using multi-compartment models. The use of  $V_1$  results in a loading dose too high, while the use of  $V_{dss}$  results in a loading dose too low. Too high a dose may cause transient toxicity, although slowing the rate of administration may prevent excessive concentrations during the distributive phase.

The time to peak effect ( $T_{peak}$ ) is dependent on clearance and effect-site equilibration half-time ( $T_{1/2keo}$ ). At a submaximal dose,  $T_{peak}$  is independent of dose. At supramaximal doses, maximal effect will occur earlier than  $T_{peak}$  and persist for longer duration because of the shape of the response curve (see later discussion). The  $T_{peak}$  concept has been used to calculate optimal initial bolus doses,<sup>45</sup> because  $V_1$  and  $V_{dss}$  poorly reflect the required scaling factor. A new parameter, the volume of

distribution at the time of peak effect-site concentration ( $V_{pe}$ ) is used and is calculated.

$$V_{pe} = \frac{V_1}{\left( \frac{C_{peak}}{C_0} \right)} \quad (\text{Eq. 12})$$

where  $C_0$  is the theoretical plasma concentration at  $t = 0$  after the bolus dose, and  $C_{peak}$  is the predicted effect-site concentration at the time of peak effect-site concentration. Loading dose ( $LD$ ) can then be calculated as

$$LD = C_{peak} \cdot V_{pe} \quad (\text{Eq. 13})$$

## Population Modeling

Pediatric anesthesiologists have embraced the population approach for investigating PK and PD. This approach, achieved through nonlinear mixed effects models, provides a means to study variability in drug responses among individuals representative of those in whom the drug will be used clinically. Traditional approaches to interpretation of time-concentration profiles relied on "rich" data from a small group of subjects. In contrast, mixed effects models can be used to analyze "sparse" (2 to 3 samples) data from a large number of subjects. Sampling times are not crucial for population methods and can be fit around clinical procedures or outpatient appointments. Sampling time-bands rather than exact times is equally effective and allows flexibility in children.<sup>45,46</sup> Interpretation of truncated individual sets of data or missing data is also possible with this type of analysis, rendering it particularly useful for pediatric studies. Population modeling also allows pooling of data across studies to provide a single robust PK analysis rather than comparing separate smaller studies that are complicated by different methods and analyses.

Mixed effects models are "mixed" because they describe the data using a mixture of fixed and random effects. Fixed effects predict the average influence of a covariate, such as weight, as an explanation of some of the variability between subjects in a parameter like clearance. Random effects describe the remaining variability between subjects that are not predictable from the fixed effect average. Explanatory covariates (e.g., age, size, renal function, sex, temperature) can be introduced that explain the predictable part of the between-individual variability. Nonlinear regression is performed by an iterative process to find the curve of best fit.<sup>47,48</sup>

## Pediatric Pharmacokinetic Considerations

Growth and development are two major aspects of children not readily apparent in adults. How these factors interact is not necessarily easy to determine from observations because they are quite highly correlated. Drug clearance, for example, may increase with weight, height, age, body surface area, and creatinine clearance. One approach is to standardize for size before incorporating a factor for maturation.<sup>49</sup>

## SIZE

Clearance in children 1 to 2 years of age, expressed as L/hr/kg, is commonly greater than that observed in older children and adolescents. This is a size effect and is not because of bigger livers or increased hepatic blood flow in that subpopulation. This "artifact of size" disappears when allometric scaling is used.

*Allometry* is a term used to describe the nonlinear relationship between size and function. This nonlinear relationship is expressed as

$$y = a \cdot \text{BodyMass}^{PWR} \quad (\text{Eq. 14})$$

where  $y$  is the variable of interest (e.g., basal metabolic rate [BMR]),  $a$  is a scaling parameter and  $PWR$  is the allometric exponent. The value of  $PWR$  has been the subject of much debate. BMR is the commonest variable investigated and camps advocating for a  $PWR$  value of  $\frac{2}{3}$  (i.e., body surface area) are at odds with those advocating a value of  $\frac{3}{4}$ .

Support for a value of  $\frac{3}{4}$  comes from investigations that show the log of BMR plotted against the log of body weight produces a straight line with a slope of  $\frac{3}{4}$  in all species studied, including humans. Fractal geometry mathematically explains this phenomenon. The  $\frac{3}{4}$ -power law for metabolic rates was derived from a general model that describes how essential materials are transported through space-filled fractal networks of branching tubes.<sup>50</sup> A great many physiologic, structural, and time related variables scale predictably within and between species with weight ( $W$ ) exponents ( $PWR$ ) of  $\frac{3}{4}$ , 1, and  $\frac{1}{4}$ , respectively.<sup>51</sup> These exponents have applicability to PK parameters, such as clearance (CL exponent of  $\frac{3}{4}$ ), volume ( $V$  exponent of 1) and half-time ( $T_{1/2}$  exponent of  $\frac{1}{4}$ ).<sup>51</sup> The factor for size ( $Fsize$ ) for total drug clearance may be expressed:

$$Fsize = \left( \frac{W}{70} \right)^{3/4} \quad (\text{Eq. 15})$$

Remifentanyl clearance in children aged 1 month to 9 years is similar to adult rates when scaled using an allometric exponent of  $\frac{3}{4}$ .<sup>52</sup> Nonspecific blood esterases that metabolize remifentanyl are mature at birth.<sup>53</sup>

## MATURATION

Allometry alone is insufficient to predict clearance in neonates and infants from adult estimates for most drugs.<sup>54,55</sup> The addition of a model describing maturation is required. The sigmoid hyperbolic or Hill model<sup>56</sup> has been found useful for describing this maturation process ( $MF$ ).

$$MF = \frac{PMA^{Hill}}{TM_{50}^{Hill} + PMA^{Hill}} \quad (\text{Eq. 16})$$

The  $TM_{50}$  describes the maturation half-time, while the Hill coefficient relates to the slope of this maturation profile. Maturation of clearance begins before birth, suggesting that postmenstrual age ( $PMA$ ) would be a better predictor of drug elimination than postnatal age.<sup>51</sup> Figure 6-4 shows the maturation profile for dexmedetomidine, expressed as both the standard per-kilogram model and by using allometry. Clearance is immature in infancy. Clearance, expressed as per kilogram, is greatest at 2 years of age, decreasing subsequently with age. This “artifact of size” disappears with use of the allometric model.

## ORGAN FUNCTION

Changes associated with normal growth and development can be distinguished from pathologic changes describing organ function.<sup>49</sup> Morphine clearance is reduced in neonates because of immature glucuronide conjugation, but clearance was lower in critically ill neonates than healthier cohorts,<sup>57-59</sup> possibly attributable to reduced hepatic function. The impact of organ function alteration may be concealed by another covariate. For example, positive pressure ventilation may be associated with reduced clearance. This effect may be attributable to a consequent reduced

**FIGURE 6-4** The clearance (CL) maturation profile of dexmedetomidine, expressed using the per-kilogram model and the allometric  $\frac{3}{4}$ -power model. This maturation pattern is typical of many drugs cleared by the liver or kidneys. (Data extracted from Potts AL, Anderson BJ, Warman GR, et al. Dexmedetomidine pharmacokinetics in pediatric intensive care—a pooled analysis. *Pediatr Anesth* 2009;19:1119-29.)

hepatic blood flow with a drug that has perfusion limited clearance (e.g., propofol, morphine).

Pharmacokinetic parameters ( $P$ ) can be described in an individual as the product of size ( $Fsize$ ), maturation ( $MF$ ) and organ function ( $OF$ ) influences, where  $Pstd$  is the parameter value in a standard size adult without pathologic changes in organ function<sup>49</sup>:

$$P = Pstd \cdot Fsize \cdot MF \cdot OF \quad (\text{Eq. 17})$$

## Pharmacodynamic Models

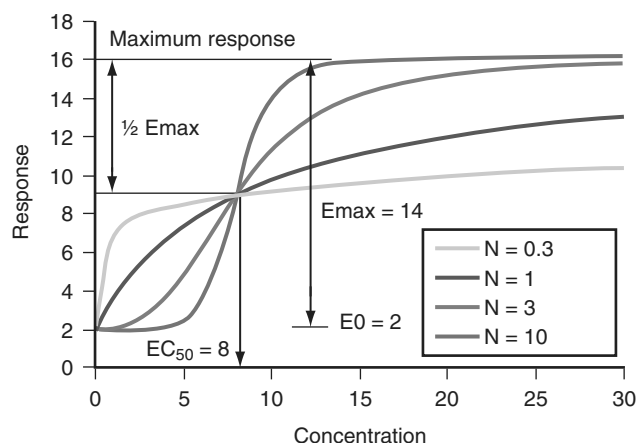

Pharmacokinetics is what the body does to the drug, while *pharmacodynamics* is what the drug does to the body. The precise boundary between these two processes is ill defined and often requires a link describing movement of drug from the plasma to the effect-site and its target. Drugs may exert effects at nonspecific membrane sites, by interference with transport mechanisms, by enzyme inhibition or induction, or by activation or inhibition of receptors.

### SIGMOID Emax MODEL

The relation between drug concentration and effect may be described by the Hill equation or Emax model (see maturation model above)<sup>56</sup>:

$$\text{Effect} = E0 + \frac{(Emax \cdot Ce^N)}{(EC_{50}^N + Ce^N)} \quad (\text{Eq. 18})$$

where  $E0$  is the baseline response,  $Emax$  is the maximum effect change,  $Ce$  is the concentration in the effect compartment,  $EC_{50}$  is the concentration producing 50%  $Emax$ , and  $N$  is the Hill coefficient defining the steepness of the concentration-response curve (Fig. 6-5). Efficacy is the maximum response on a dose or concentration-response curve.  $EC_{50}$  can be considered a measure of potency relative to another drug, provided  $N$  and  $Emax$  for the two drugs are the same. A concentration-response relationship for acetaminophen has been described using this model. An  $EC_{50}$  of 9.8 mg/L,  $N = 1$ , and an  $Emax$  of 5.3 pain units (on a visual analog scale [VAS] of 0 to 10) was reported.<sup>60</sup> Midazolam PD in adults have been similarly defined using electroencephalographic (EEG) responses.<sup>61,62</sup>

**FIGURE 6-5** The sigmoid Emax model is commonly used to describe the relationship between drug response and concentration. Changing the Hill coefficient ( $N$ ) dramatically alters the shape of the curve.

### QUANTAL EFFECT MODEL

The potency of anesthetic vapors may be expressed by minimum alveolar concentration (MAC), and this is the concentration at which 50% of subjects move in response to a standard surgical stimulus. MAC appears, at first sight, to be similar to  $EC_{50}$ , but is an expression of quantal response rather than magnitude of effect. There are two methods of estimating MAC. Responses can be recorded over the clinical dose range in a large number of subjects and logistic regression applied to estimate the relationship between dose and quantal effect; the MAC can then be interpolated. Large numbers of subjects may not be available, so an alternative is often used. The “up and down” method described by Dixon<sup>63,64</sup> estimates only the MAC rather than the entire sigmoid curve. It usually involves a study of only one concentration in each subject and, in a sequence of subjects, each receives a concentration depending on the response of the previous subject; the concentration is either decreased if the previous subject did not respond or increased if they did. The MAC is calculated either as the mean concentration of equal numbers of responses and no-responses or is the mean concentration of pairs of “response–no response.”

### LOGISTIC REGRESSION MODEL

When the pharmacologic effect is difficult to grade, then it may be useful to estimate the probability of achieving the effect as a function of plasma concentration. Effect measures, such as movement/no movement or rousable/nonrousable, are dichotomous. Logistic regression is commonly used to analyze such data and the interpolated  $EC_{50}$  value refers to the probability of response. For example, an  $EC_{50}$  of 0.52 mg/L for arousal after ketamine sedation in children has been estimated using this technique.<sup>65</sup>

## Linking Pharmacokinetics with Pharmacodynamics

A simple situation in which drug effect is directly related to concentration does not mean that drug effects parallel the time course of concentration. This occurs only when the concentration is low in relation to  $EC_{50}$ . In this situation the half-life of the drug may correlate closely with the half-life of drug effect.

Observed effects may not be directly related to serum concentration. Many drugs have a short half-life but a long duration of effect. This may be attributable to induced physiologic changes (e.g., aspirin and platelet function) or may be a result of the shape of the Emax model. If the initial concentration is very high in relation to the  $EC_{50}$ , then drug concentrations five half-lives later, when we might expect a minimal concentration, may still exert considerable effect.

There may also be a delay as a result of transfer of the drug to the effect site (e.g., neuromuscular blockers), a lag time (e.g., diuretics), physiologic response (e.g., antipyresis), active metabolite (e.g., propacetamol), or synthesis of physiologic substances (e.g., warfarin). A plasma concentration-effect plot can form a hysteresis loop because of this delay in effect. Hull and Sheiner introduced the effect compartment concept for neuromuscular blockers.<sup>66,67</sup> A single first-order parameter ( $T_{1/2keo}$ ) describes the equilibration half-time. This mathematical trick assumes that the concentration in the central compartment is the same as that in the effect compartment at equilibration, but that a time delay exists before drug reaches the effect compartment. The concentration in the effect compartment is used to describe the concentration-effect relationship.<sup>68</sup>

Adult  $T_{1/2keo}$  values are well described (e.g., morphine, 16 minutes; fentanyl, 5 minutes; alfentanil, 1 minute; propofol, 3 minutes). This  $T_{1/2keo}$  parameter is commonly incorporated into target controlled infusion pumps in order to achieve a rapid effect-site concentration. The adult midazolam  $T_{1/2keo}$  of 5 minutes may be prolonged in the elderly, resulting in overdose if this is not recognized during dose titration.<sup>66</sup>

The  $T_{1/2keo}$  for propofol in children has been described. As expected, a shorter  $T_{1/2keo}$  with decreasing age based on size models has been described.<sup>67,69</sup> Similar results have been demonstrated for sevoflurane and changes in the EEG.<sup>70</sup> If the effect-site is targeted and peak effect ( $T_{peak}$ ) is anticipated to be later than it actually is because it was determined in a teenager or adult, this will result in excessive dose in a young child.

## Drug Distribution

### PROTEIN BINDING

Acidic drugs (e.g., diazepam, barbiturates) tend to bind mainly to albumin while basic drugs (e.g., amide local anesthetic agents) bind to globulins, lipoproteins and glycoproteins. In general, plasma protein binding of many drugs is decreased in the neonate relative to the adult in part because of reduced total protein and albumin concentrations (Fig. 6-6).<sup>71</sup> Many drugs that are highly protein bound in adults have less of an affinity for protein in neonates (E-Fig. 6-1).<sup>71-75</sup> Reduced protein binding increases the free fraction of medications, thus providing more free medication and greater pharmacologic effect.<sup>1,3,12,14,17</sup> This effect is particularly important for medications that are highly protein bound, because the reduced protein binding increases the free fraction of the medication to a greater extent than for low protein bound drugs. For example, phenytoin is 85% protein bound in healthy infants but only 80% in those who are jaundiced. This equates to a 33% increase in the free fraction of phenytoin when jaundice occurs (E-Fig. 6-2). Differences in protein binding may have considerable influence on the response to medications that are acidic and are, therefore, highly protein bound (e.g., phenytoin, salicylate, bupivacaine, barbiturates, antibiotics, theophylline, and diazepam).<sup>17</sup> In addition, some medications, such as phenytoin, salicylate, sulfisoxazole, caffeine, ceftriaxone, diatrizoate

**E-FIGURE 6-1** Altered protein binding may affect the clinical response to any medication; note the much lower protein binding of phenobarbital and penicillin in the neonate and fetus compared with the adult. This reduced protein binding may partially account for the prolonged pharmacologic effects of barbiturates in neonates, because more unbound drug is able to be pharmacologically active. (Data from Ehrnebo M, Agurell S, Jalling B, et al. Age differences in drug binding by plasma proteins: studies on human foetuses, neonates and adults. *Eur J Clin Pharmacol* 1971;3:189-93.)

**E-FIGURE 6-2** Note that in the presence of hyperbilirubinemia, many drugs that are protein bound compete with bilirubin for binding sites, resulting in both elevated unbound bilirubin and unbound drug. This interaction may lead to an increased propensity for the development of kernicterus as well as more drug available for clinical effect. This effect is particularly important for drugs that normally are highly protein bound (e.g., phenytoin) but would be of minimal importance for drugs that have low protein binding (e.g., ampicillin). (Data from Ehrnebo M, Agurell S, Jalling B, et al. Age differences in drug binding by plasma proteins: studies on human foetuses, neonates and adults. *Eur J Clin Pharmacol* 1971;3:189-93.)

**E-FIGURE 6-10** MAC (minimum alveolar concentration) of desflurane in neonates, infants and children. MAC in full-term neonates of 9.2% increased slowly during infancy, reaching a zenith in infants 6 to 12 months of age of 9.9% and decreased thereafter with increasing age to adulthood. All MAC measurements were performed with desflurane in oxygen using a single skin incision. (Data from Taylor RH, Lerman J. Minimum alveolar concentration of desflurane and hemodynamic responses in neonates, infants, and children. *Anesthesiology* 1991;75:975-9.)

32 weeks gestation ( $1.28 \pm 0.17\%$ ) is 10% less than it is in neonates of 32 to 37 weeks gestational age ( $1.41 \pm 0.18\%$ ), which in turn is 12% less than it is in full-term neonates ( $1.60 \pm 0.03\%$ ).<sup>241</sup> The etiology of these age-dependent changes in MAC remains elusive. Several possible causes have been proposed, including maturational changes in the CNS and neurohumoral factors, but none of them have been confirmed.

Other factors are known to affect MAC. The melanocortin-1 receptor gene has been shown to affect the MAC of desflurane. That is, 90% of adults who were either homozygous or heterozygous for mutations of this gene (i.e., redheads) required 20% more anesthesia than those who had no mutations (brunettes).<sup>343</sup> A similar relationship should hold true for children with these mutations. Hypothermia decreases MAC. In children 4 to 10 years, the MAC of isoflurane decreases 5% per degree Celsius.<sup>344</sup>

Cerebral palsy and severe cognitive impairment reduce the MAC of halothane approximately 25% compared with healthy children.<sup>345</sup> Although tetanic stimulation was used to elicit a pain response, this stimulus underestimates the MAC compared with skin incision.<sup>346</sup> Nonetheless, the MAC of halothane in healthy children was similar to published data with skin incision.<sup>337</sup> Chronic anticonvulsant therapy decreased the MAC of halothane in handicapped children by 15%, compared with those without anticonvulsants, from  $0.71\% \pm 0.10\%$  to  $0.62\% \pm 0.03\%$ .<sup>345</sup> Several factors may account for the decrease in MAC in children with cognitive impairment, including central sensory impairment, increased pain threshold or insensitivity, and a disequilibrium of inhibitory and excitatory regulatory neurons within the spinal cord in these children.<sup>347,348</sup> Although the acute administration of barbiturates and benzodiazepines decreases MAC,<sup>349,350</sup> chronic administration of similar medications does not.<sup>351</sup> The effects of specific anticonvulsants, such as valproic acid and phenytoin, on the MAC of inhalational anesthetics in children remain unclear.

The MAC for nitrous oxide has been estimated to be 104% in adults<sup>352</sup>; comparable data do not exist in children. The additivity of MAC fractions of inhalational anesthetics (as well as nitrous oxide) is well established. For example, the total anesthetic delivered when 0.5 MAC of one agent and 0.5 MAC of a second agent are administered is 1 MAC. In adults, the concept of additivity has been confirmed for all inhalational anesthetics, including sevoflurane and desflurane, in combination with nitrous oxide.<sup>353,354</sup> In children, the concept of MAC additivity holds true when nitrous oxide is combined with halothane or isoflurane<sup>355,356</sup> but not when nitrous oxide is combined with sevoflurane or desflurane.<sup>219,220,238</sup> Nitrous oxide 60% decreases the MAC of sevoflurane only 20% and that of desflurane 26% (Table 6-7).<sup>339,340,357</sup> The MAC response to tracheal intubation during sevoflurane anesthesia in children is also attenuated with nitrous oxide.<sup>358</sup> The explanation for the differential additivity effect of nitrous oxide in children remains unclear.

The MAC for xenon in middle-aged adults is about 70%.<sup>359,360</sup> The MAC of xenon in children has not been determined.

The MAC responses to stimuli other than skin incision have also been determined in children (Table 6-8). The MAC for tracheal intubation is 10% to 50% greater than the MAC for skin incision for halothane,<sup>361,362</sup> enflurane,<sup>363</sup> and sevoflurane,<sup>358,364,365</sup> whereas the MAC for tracheal extubation is 10% to 25% less than the MAC for skin incision for isoflurane,<sup>366</sup> desflurane,<sup>367</sup> and sevoflurane.<sup>368,369</sup> The MAC values for laryngeal mask airway insertion and removal during sevoflurane differ by 15%.<sup>362,370</sup> The MAC response to tracheal intubation during sevoflurane

anesthesia in children is attenuated in the presence of adjuvants, such as clonidine (E-Table 6-1).<sup>365</sup> Conflicting evidence exists regarding the relative potencies of stereoisomers or enantiomers of chiral inhalational anesthetics.<sup>371-373</sup> Studies in animals suggest that the (+)S optical enantiomer may be more potent than the (−)R enantiomer, as evidenced by its ability to enhance potassium conductance in neurons.<sup>371,372</sup> In adults, the (−)R enantiomer of isoflurane was nominally (17%) more potent than the (+)S enantiomer.<sup>373</sup>

### Central Nervous System

All potent inhalational anesthetics depress the central nervous system (CNS), as evidenced by dose-dependent decreases in the cerebral vascular resistance and the cerebral metabolic rate for oxygen (CMRO<sub>2</sub>). The decrease in vascular resistance causes a reciprocal increase in cerebral blood flow (CBF) that begins at approximately 0.6 MAC.<sup>374</sup> The extent of the increase in CBF, however, depends on the inhalational anesthetics: halothane > enflurane ~ desflurane > isoflurane > sevoflurane.<sup>374-377</sup> In adults, the cerebral vasculature remains responsive to CO<sub>2</sub> under general

anesthesia but decreases with increasing MAC, disappearing at 1.5 MAC in the case of desflurane.<sup>378</sup> The net effect of inhalational anesthetics is a dose-dependent increase in the ratio of the CBF to CMRO<sub>2</sub>.

The effects of inhalational anesthetics on the CNS in children have not been fully elucidated. Autoregulation of CBF does not appear to vary with age in children up to 1.5 MAC sevoflurane.<sup>379,380</sup> CBF velocity in children varies directly with the end-tidal CO<sub>2</sub> during halothane and isoflurane anesthesia.<sup>381</sup> CBF velocity increases as the concentrations of halothane<sup>382</sup> and desflurane<sup>383</sup> increase. Compared with halothane, however, sevoflurane does not increase CBF velocity, suggesting it may be the preferred anesthetic.<sup>384</sup> Based on current evidence, sevoflurane and isoflurane remain the preferred inhalational anesthetics for neuroanesthesia in children at low MAC values (less than 1 MAC) and in the presence of mild hyperventilation (see Chapter 24).

In children, the EEG activity during halothane anesthesia differs substantially from that of sevoflurane. In the case of halothane, the EEG is characterized by slow waves superimposed on fast rhythms ( $\alpha$  and  $\beta$  waves), whereas in the case of sevoflurane, the EEG is characterized by mainly sharp slow waves.<sup>385</sup> Furthermore, the shift of power of the EEG from low (1 to 4 Hz) to medium frequencies (8 to 30 Hz) is greater for halothane than it is for sevoflurane. The clinical relevance of these EEG differences remains unclear at this time, but may explain in part the inconsistencies reported with processed EEG monitoring in children anesthetized with various inhalation anesthetics (see later discussion).

Enflurane was the first inhalational anesthetic to be associated with seizure activity both clinically and electroencephalographically in humans.<sup>386,387</sup> High concentrations of enflurane and a respiratory alkalosis were associated with seizure activity.

Both myoclonic movement of the extremities and transient spike and wave complexes on EEG have been reported during sevoflurane anesthesia in children.<sup>385,388-391</sup> Diffuse spike and wave complexes were noted on EEG at 5% and 7% inspired concentrations in two children with histories of epilepsy.<sup>389</sup> In a third child without a history of seizures, a 30-second burst of spike and wave complexes was recorded during sevoflurane anesthesia, but identified only after the event resolved.<sup>392</sup> The EEG data were analyzed in children who were premedicated with midazolam and then anesthetized with halothane or sevoflurane. There was no evidence of seizure activity.<sup>385</sup> Cortical epileptiform EEG activity has been reported during 1 to 2 MAC sevoflurane in adults with one episode of seizures that occurred with a pCO<sub>2</sub> of 34 mm Hg.<sup>393</sup> This prompted some to recommend limiting the depth of anesthesia with sevoflurane to minimize epileptiform EEG activity or even clinically evident seizure activity.<sup>394</sup> However, the co-administration of other anesthetic medications, such as midazolam, nitrous oxide, and opioids, may attenuate epileptiform EEG activity.<sup>393</sup> Furthermore, the notion of limiting the depth of sevoflurane anesthesia by reducing the concentration of sevoflurane as soon as the eyelash reflex is lost has not been shown to benefit children, and may actually increase the risk of awareness (see later discussion).

The association between myoclonic movement and seizures during induction of sevoflurane anesthesia remains tenuous. To prevent involuntary movements during induction, we recommend that the inspired concentration of sevoflurane be increased in a single stepwise manner from 0% to 8% (see Induction, earlier). If apnea occurs, ventilation should be assisted gently, while avoiding hyperventilation.

Awareness during inhalational anesthesia has been reported to occur with an incidence of 0.2% to 1.2% during sevoflurane anesthesia in children,<sup>395-397</sup> which exceeds that in adults. The reason(s) for this discrepancy remains unclear. These studies do suggest that children who experience awareness do not develop long-term sequelae.<sup>398</sup> Concerns over awareness during anesthesia has increased interest in the use of processed EEG monitoring in children.<sup>399</sup> Processed EEG monitoring during anesthesia has been evaluated using a number of EEG signals and techniques, processing signals in a “black box” and displaying a single numerical result. The most widely studied monitor to date is the BIS monitor, which displays the value on a scale between 0 and 100 (see Chapter 51). In adults, BIS readings below 60 are thought to be associated with a small risk of awareness and recall, whereas readings greater than 70 are associated with a large risk for awareness. The BIS value has been studied in children to a limited degree to date, but its validity and role in the anesthetic management of infants and children under 5 years of age remain in question. One concern is that the EEG algorithm in current BIS software is derived from adult EEG data, not from children. Despite use of an algorithm derived from adults, BIS measurements in children appear, for the most part, to track the depth of anesthesia, and these values correlate with the end-tidal concentration of the anesthetic. However, several unexplained curiosities have been reported. The BIS readings for halothane in children exceed those for isoflurane, desflurane, and sevoflurane at equipotent anesthetic concentrations.<sup>255,256,400</sup> This has been attributed to the differential effects of anesthetics on the EEG. The BIS readings for a specific sevoflurane concentration decreases with increasing ages.<sup>252,255,401</sup> The validity of processed EEG monitoring in children younger than 5 years has not been established. In children, the BIS values actually increased between 3% and 4% with sevoflurane, a paradoxical response to date unexplained.<sup>401</sup> A further concern is the enormous interindividual variability in processed EEG monitoring, making it difficult to define thresholds for awareness or lack thereof.<sup>401</sup> Interestingly, spontaneous ventilation increases the variability in the BIS readings.<sup>402</sup> The issue is further complicated by the fact that ketamine, nitrous oxide, and opioids do not depress the EEG in a dose-dependent manner. Discrepant BIS readings have been reported from the right and left sides of the brain<sup>403</sup> as well as in the prone position.<sup>404</sup> The BIS readings in children with cognitive impairment are reported to be 28 points less than those in unimpaired children at the same anesthetic concentration, although the authors failed to account for the reduced MAC in the impaired group.<sup>405</sup> Had they done so, the BIS readings may have been identical. The aggregate of this evidence undermines the validity of processed EEG monitoring in children.

### Cardiovascular System

Inhalational anesthetics (with the exception of xenon) affect the cardiovascular system either directly (by depressing myocardial contractility, altering the conduction system, or by dilating the peripheral vasculature) or indirectly (by affecting the balance of parasympathetic and sympathetic nervous systems and neurohumoral, renal, or reflex responses). The cardiovascular responses to inhalational anesthetics in children are further complicated by maturational changes in the cardiovascular system and its responsiveness to these anesthetics. When all of these developmental changes are taken into consideration there is a reduced margin of safety between adequate anesthesia and severe cardiopulmonary depression in infants and children compared with adults.

The salient features of the immature cardiovascular system in infants and children at both the macroscopic and microscopic levels have been reviewed.<sup>406</sup>

Assessment of cardiovascular variables in infants and children presents a challenge for clinicians. Although blood pressure (BP) and electrocardiography are standard monitors of hemodynamics in infants and children of all ages, measures of cardiac output and myocardial contractility are much more difficult to quantitate accurately. Two-dimensional echocardiography and impedance cardiometry have been used to estimate cardiac output and myocardial contractility in infants and children,<sup>407-410</sup> although the echocardiographic measurements are subject to variability depending on the preload and afterload. Load-independent derived echocardiographic variables (stress-velocity and stress-shortening indices) have improved the accuracy of echocardiographic estimates of myocardial function and are used with increasing frequency.<sup>411</sup> Transesophageal echocardiography is used much more frequently in children, although its use is limited to children with congenital heart disease undergoing cardiac surgery.

In children, several factors determine the BP responses to inhalational anesthetics, including the particular anesthetic studied, the dose, the presence of a premedication, the level of preoperative anxiety, and the systemic pressure measured: systolic, diastolic, or mean. Most studies demonstrate modest, dose-dependent decreases in BP with all of the inhalational anesthetics, although the magnitudes of the changes vary. In a direct comparison of sevoflurane and halothane, systolic BP decreased 7.5% at 1 MAC sevoflurane and 12.5% at 1 MAC halothane, but returned to awake values at 1.5 MAC with both anesthetics.<sup>411</sup> In children older than 1 year of age, systolic BP decreased 0% to 11% at 1 MAC sevoflurane, and 22% to 28% at 1 MAC desflurane, compared with awake values.<sup>339,340</sup> At 1 MAC, mean BP in children decreased 15% to 25% with isoflurane and sevoflurane.<sup>408,410</sup> All of the inhalational anesthetics (in concentrations up to 1.5 MAC) modestly depress the systemic BP in children.

Myocardial contractility decreases to a greater extent during halothane (up to 1.5 MAC) than during isoflurane or sevoflurane anesthesia, as evidenced by decreases in cardiac output and ejection fraction in healthy children.<sup>409,410,412</sup> Cardiac index decreased to similar extents with halothane and sevoflurane at 1 and 2 MAC: 10% at 1 MAC and 20% to 35% at 2 MAC.<sup>410</sup> Ejection fraction decreased 30% at 0.5 and 1.5 MAC halothane compared with awake values, but is unchanged at equipotent concentrations of isoflurane.<sup>408</sup> The addition of nitrous oxide to halothane or isoflurane in infants and small children depresses myocardial function to a similar extent as equipotent anesthetic concentrations of halothane or isoflurane in oxygen.<sup>412</sup> In children, halothane decreases myocardial contractility in a dose-dependent manner and to a greater extent than the ether anesthetics. Isoflurane and sevoflurane decrease myocardial contractility to a lesser extent than halothane and are preferred for children with limited cardiovascular reserves. IV atropine restores the decrease in myocardial function, in part, associated with halothane anesthesia,<sup>412-415</sup> whereas IV balanced salt solution restores the decrease in myocardial function associated with isoflurane anesthesia.<sup>409</sup>

The mechanism by which inhalational anesthetics depress myocardial function remains controversial. Studies in both animal and human myocardial cells suggest that halothane, isoflurane, and sevoflurane directly depress myocardial contractility by decreasing intracellular  $\text{Ca}^{2+}$  flux. Inhalational anesthetics

decrease the  $\text{Ca}^{2+}$  flux by their action on the calcium channels themselves, ion exchange pumps, and the sarcoplasmic reticulum.<sup>406</sup> Evidence suggests that inhalational anesthetics attenuate contractility of ventricular myocytes via voltage-dependent L-type calcium channels (which are responsible for release of large amounts of calcium from the sarcoplasmic reticulum).<sup>416,417</sup>

That neonates and infants are more sensitive to the depressant actions of inhalational anesthetics than are older children is supported by experimental evidence of maturational differences between neonatal and adult rat, rabbit, and feline myocardium.<sup>417-420</sup> Structural differences that may account, in part, for the changes in myocardial sensitivity to inhalational anesthetics with age, include a reduction in contractile elements, immature sarcoplasmic reticulum, and functional differences in calcium sensitivity of the contractile elements, calcium channels, and the sodium-calcium pump in the neonatal myocardium.<sup>406,416-418,420-423</sup> The determinants of  $\text{Ca}^{2+}$  homeostasis in neonatal ventricular myocardial cells depend on transsarcolemmic  $\text{Ca}^{2+}$  flux to a far greater extent than on the sarcoplasmic reticulum.<sup>406</sup> This is based on a growing body of experimental evidence that includes the finding that the concentration of the  $\text{Na}^+-\text{Ca}^{2+}$  exchange protein in the neonatal myocardium, a protein that regulates transsarcolemmic flux of  $\text{Ca}^{2+}$ , exceeds that in adult cells by 2.5-fold and that its concentration decreases with age as the concentration of L-type voltage-dependent calcium channels increases.<sup>418</sup> Furthermore, halothane reversibly inhibits the  $\text{Na}^+-\text{Ca}^{2+}$  exchange protein in immature myocardial cells.<sup>418</sup> The sarcoplasmic reticulum is poorly developed in neonatal myocardial cells, and this finding weighs heavily against the sarcoplasmic reticulum being the major source of  $\text{Ca}^{2+}$  required for myocardial contractility. Further research is required before the contribution of each aspect of  $\text{Ca}^{2+}$  homeostasis to myocardial contractility in the neonate can be confirmed.

Ever since the introduction of halothane into clinical practice, clinicians have been aware of a greater incidence of hypotension and bradycardia in neonates who were anesthetized with halothane than in adults. However, this was not the case when *equi-potent* concentrations (approximately 1 MAC) of halothane<sup>337,414</sup> were administered to neonates and older infants 1 to 6 months of age. Subsequent studies demonstrated that isoflurane,<sup>424</sup> sevoflurane,<sup>340</sup> and desflurane<sup>339</sup> all decreased systolic pressure in neonates to similar extents as in older infants 1 to 6 months of age. Interestingly, systolic BP decreased 30% in response to 1 MAC sevoflurane in neonates and infants 1 to 6 months of age, which was substantially greater than the 5% decrease in older infants and children up to 12 years of age.<sup>340</sup> In the case of desflurane, systolic BP decreased 30% in response to 1 MAC desflurane across all age groups.<sup>339</sup> These data suggest that systolic BP decreases up to 30% in response to 1 MAC of all inhalational anesthetics in infants and children, and that caution should be exercised when administering these anesthetics to infants and children who are at risk for hemodynamic instability, or in whom greater concentrations of inhaled anesthetics are required. On the basis of echocardiographic determinations, cardiac output and ejection fraction decrease in a dose-dependent fashion from awake to 1.5 MAC halothane and isoflurane in neonates and infants.<sup>407</sup> In a comparison of sevoflurane and halothane up to 1.5 MAC in infants, sevoflurane maintained cardiac index but decreased BP and systemic vascular resistance.<sup>425</sup> Myocardial contractility decreased in a dose-dependent manner with halothane as well as with sevoflurane, although the decrease with the former exceeded that with the latter.

The baroreceptor reflex response is also depressed in infants with either halothane<sup>426</sup> or isoflurane,<sup>427</sup> albeit to a greater extent with halothane. In view of the greater incidence of hypotension in neonates and infants than older children, an intact baroreceptor reflex could offset in part, the cardiovascular consequences. However, inhalational anesthetics blunt this response, leaving the infant vulnerable to the direct cardiodepressant actions of the anesthetics. Prophylactic anticholinergics augment the cardiac output by increasing the heart rate.

Two studies evaluated the effects of inhalational anesthesia on the hemodynamics of children with congenital heart disease undergoing cardiac surgery.<sup>428,429</sup> Sevoflurane maintained cardiac index and heart rate with less hypotension and negative inotropic effect than halothane. Isoflurane maintained cardiac index and ejection fraction, increased heart rate, and caused less depression of mean arterial pressure than halothane.<sup>428</sup> Sevoflurane was also associated with fewer episodes of severe hypotension and reduced need for vasopressors and chronotropes during emergence than halothane.<sup>429</sup>

Inhalational anesthetics also vary in their effect on cardiac rhythm. Halothane slows the heart rate, in some cases leading to junctional rhythms, bradycardia, and asystole. This response is dose dependent. Three mechanisms have been proposed to explain the genesis of halothane-associated dysrhythmias: a direct effect on the sinoatrial node, a vagal effect, or an imbalance in the parasympathetic and sympathetic tone. It has also been suggested that the etiology of the bradycardia during halothane anesthesia may be a withdrawal of sympathetic tone. Bradycardia is particularly marked in the neonate, presumably because parasympathetic influences predominate over the sparse sympathetic innervation of the myocardium in this age group. Junctional rhythms are also common during halothane anesthesia. Atrial or ventricular ectopic beats are rare, except in the presence of hypercapnia.<sup>430</sup> In infants and children anesthetized with halothane, 10 µg/kg atropine increases heart rate by 50% or more and promotes sinus rhythm.<sup>431</sup> This dose of atropine also increases BP in infants and children 2 years of age and older.

Halothane also sensitizes the myocardium to catecholamines, particularly in the presence of hypercapnia and "light anesthesia."<sup>430</sup> Halothane decreases the threshold for ventricular extrasystoles during epinephrine administration threefold.<sup>432-434</sup> In contrast, isoflurane, desflurane, and sevoflurane maintain or increase heart rate during the early induction period of anesthesia,\* although a slowing of the heart rate has been reported during sevoflurane anesthesia. When bradycardia occurs in an anesthetized child, hypoxia must be considered first before other causes, such as a direct drug effect (i.e., high concentration of halothane). Isoflurane, desflurane, and sevoflurane do not sensitize the myocardium to catecholamines to the same extent as does halothane, and ventricular arrhythmias are rare.<sup>432,433,438</sup> The mechanism by which the sinus node controls automaticity is incompletely understood but may include K<sup>+</sup> currents, hyperpolarization-activated current, and T and L forms of Ca<sup>2+</sup> currents.<sup>406</sup> Moreover, developmental changes in these channels likely account, in part, for the differential effects of inhalational anesthetics on heart rate with age.<sup>421</sup>

Recent concerns of a relationship between inhalational anesthetics and prolonged QT interval that progressed to induce cardiac arrest or torsades de pointes have emerged. Although the

ether inhalational anesthetics prolong the QTc interval (with greater than 500 milliseconds being abnormal),<sup>439,440</sup> this alone appears to be insufficient to induce torsades de pointes. Torsades de pointes also requires the transmural dispersion of repolarization. This is defined as the variability in the rate of repolarization across the myocardium, from epi- to endocardium. The rate of repolarization may be estimated by the interval in the peak to end of the T wave on a 12-lead electrocardiogram. Evidence has demonstrated that the risk of torsades de pointes during sevoflurane anesthesia is minimal because the transmural dispersion of repolarization is limited.<sup>441</sup>

Paroxysmal increases in BP (both systolic and diastolic pressures) and heart rate have been reported in adults after a rapid increase in the inspired concentration of isoflurane or desflurane.<sup>442</sup> This occurs as a result of a massive sympathetic response, mediated by norepinephrine and/or epinephrine, that culminates in tachycardia and hypertension.<sup>443,444</sup> Further increases in the inspired concentration of the inciting anesthetic while attempting to attenuate the tachycardia and hypertension are ineffective and may perpetuate or augment the response. In order to restore vital signs to normal, the inciting anesthetic should be discontinued and replaced with another anesthetic. Repetitive small increases (1%) in the inspired concentration of the putative anesthetic produces transient but attenuated catecholamine bursts and cardiovascular responses compared with larger increases in concentration.<sup>445,446</sup> Fentanyl (2 µg/kg), esmolol, and clonidine have all been shown to be effective in preventing, attenuating, or eliminating these responses.<sup>447-449</sup> The origin of these responses is unknown, although the rapidity of the response points to the lung.<sup>450</sup> Others, however, dispute this notion, contending that two sites must be responsible for triggering the sympathetic discharge; the lung and the VRG,<sup>451</sup> with the latter mediating the greater response.<sup>451,452</sup> Neuroexcitatory responses have not been reported in children with isoflurane, desflurane, or sevoflurane.<sup>453</sup>

Xenon offers an immense advantage over the ether-based inhalational anesthetics in that it maintains circulatory stability. This anesthetic may have a niche role when anesthetizing infants and children with congenital and acquired heart disease. However, the effects of xenon on the hearts in children have not been studied. Although the MAC of xenon in adults is very large (see Table 6-3), MAC for xenon in children may be even greater. If the MAC exceeds the adult values, this may limit not only the dose that may be administered to children (e.g., much less than 1 MAC) but it may limit the inspired concentration of oxygen as well. Notwithstanding the MAC of xenon in children, this anesthetic will certainly be much less effective in children with cyanotic congenital heart disease, as it is the least soluble anesthetic and its large MAC restricts the MAC multiple that may be administered.

### Respiratory System

During spontaneous ventilation, both tidal volume and respiratory rate vary with the specific anesthetic, depth of anesthesia, and nociception. The increased respiratory rate during inhalational anesthesia in children has been attributed to sensitization of the stretch receptors within the lung as well as possible central effects. Inhalational anesthetics significantly affect respiration in infants and children in a dose-dependent fashion via effects on the respiratory center, chest wall muscles, and reflex responses. Halothane depresses minute ventilation by decreasing tidal volume and attenuating the response to carbon dioxide.<sup>454-457</sup>

\*References 324, 339, 340, 408, 410, 424, 425, 435-437.

This depression is offset, in part, by an increase in the respiratory rate.<sup>454,457</sup> These ventilatory responses to halothane are age dependent; minute ventilation in infants decreases to a greater extent than in children.<sup>456</sup> In infants and young children anesthetized with halothane, intercostal muscle activity is attenuated before the diaphragm.<sup>454,458</sup> This effect is most pronounced in preterm and full-term neonates and infants, and when a tracheal tube is used in place of a laryngeal mask airway.<sup>459</sup> The movement of the chest and abdomen during the respiratory cycle is one of synchronized protrusion of the abdomen and collapse of the chest wall during inspiration (with some intercostal indrawing) and indrawing of the abdomen and flattening of the chest wall during expiration. This is commonly referred to as the “rocking horse” movement of the chest (similar to the phenomenon that occurs during upper airway obstruction in infants and children). This results in loss of FRC and is of particular concern in infants younger than 2 years of age who have decreased type I muscle fibers in both the diaphragm and intercostal muscles (see Fig. 12-11). This explains why infants fatigue easily and why positive end-expiratory pressure is useful in this age group. Isoflurane, enflurane, sevoflurane, and desflurane also depress ventilatory drive, decrease tidal volume, and attenuate the response to carbon dioxide.<sup>455,457,460-466</sup> The increase in respiratory frequency that follows respiratory depression (decreased tidal volume) may not restore minute ventilation to preanesthetic levels.

Sevoflurane depresses respiration to a similar extent as halothane up to 1.4 MAC but depresses respiration to a greater extent at concentrations greater than 1.4 MAC.<sup>460</sup> This results from a direct effect of sevoflurane on respiratory frequency.<sup>463</sup> Although respiratory effort may decrease rapidly during sevoflurane or desflurane anesthesia, their low blood solubilities and rapid wash-out profiles in part ensure that this is a self-limiting phenomenon during spontaneous respirations. Sevoflurane decreases the tone of the intercostal muscles to a lesser extent than halothane.<sup>458,462</sup> The compensatory changes in respiratory rate differ among the anesthetics; respiratory rate increases at 1.4 MAC or more with halothane, is unchanged with isoflurane, but decreases at 1.4 MAC or less with sevoflurane and enflurane.<sup>455,457</sup> This inadequate compensatory response to respiratory depression with sevoflurane and enflurane suggests that when children are anesthetized with those anesthetics, spontaneous ventilation must be monitored carefully to avoid hypopnea or apnea. Sevoflurane maintains or decreases airway resistance in children with normal airways, and those with asthma or a recent upper respiratory tract infection. Insertion of a tracheal tube during sevoflurane anesthesia increases airway resistance without sequelae.<sup>467,468</sup>

Desflurane depresses respiration in children during spontaneous respiration at greater than 1 MAC by decreasing tidal volume.<sup>466</sup> However, desflurane does increase airway resistance in children with asthma and respiratory tract infections to a greater extent than sevoflurane.<sup>468</sup> Desflurane is probably best avoided in these children.

Studies of the upper airway in children anesthetized with inhalational anesthesia have sought to explain the pathophysiology of airway obstruction. Sevoflurane at 1 MAC causes more upper airway obstruction than halothane.<sup>469</sup> In escalating doses between 0.5 and 1.5 MAC, sevoflurane decreased the cross-sectional area of the airway by one third, predominantly in the anteroposterior dimension.<sup>470</sup> This effect primarily results from pharyngeal wall collapse, which can be easily offset with positive end-expiratory pressure (see Chapter 12).

**TABLE 6-9 In Vivo Metabolism of Inhalational Anesthetics**

Inhalational Agent	Percent Metabolized	Reference
Methoxyflurane	50	1911
Halothane	20	1912
Sevoflurane	5	486
Enflurane	2.4	1913
Isoflurane	0.2	1914
Desflurane	0.02	1915

### Renal System

Potent inhalational anesthetics may affect renal function via four possible mechanisms: cardiovascular, autonomic, neuroendocrine, and metabolic. Although the first three mechanisms pose no direct threat to renal function, the fourth mechanism, metabolic, is a serious clinical concern that has resulted in renal dysfunction after inhalational anesthesia.

Inhalational anesthetics are metabolized in vivo by the CYP isozyme system to varying extents (Table 6-9). Metabolism of inhalational anesthetics may release both inorganic and organic fluoride moieties.<sup>471</sup> It is the inorganic fluoride that is released from these ether anesthetics that has stimulated interest in renal dysfunction after inhalational anesthesia.

Isoflurane and desflurane undergo limited metabolism in vivo, resulting in very small plasma concentrations of inorganic fluoride, even after 131 MAC hours of isoflurane.<sup>472</sup> In contrast, halothane is metabolized to a substantially greater extent but releases most of the fluoride in an organic form, trifluoroacetate. Trifluoroacetate has, however, been linked to halothane hepatitis (see later discussion). The metabolism of enflurane, sevoflurane, and methoxyflurane yields greater plasma concentrations of inorganic fluoride than isoflurane. The metabolism of sevoflurane yields both inorganic and organic fluoride moieties.<sup>473</sup> The organic form, hexafluoroisopropanol, is rapidly conjugated and excreted by the kidneys<sup>473</sup> and poses no threat to humans. Peak plasma concentrations of inorganic fluoride after exposure to inhalational anesthetics follow a similar order to that in Table 6-9: methoxyflurane > sevoflurane > enflurane > isoflurane > halothane ~ = desflurane.<sup>474-478</sup> In the case of methoxyflurane, two metabolites are produced: inorganic fluoride and oxalic acid. Both were implicated in the pathogenesis of renal dysfunction, although, clinically, the renal injury was more consistently associated with inorganic fluoride.<sup>479</sup> Subsequent studies demonstrated that subclinical nephrotoxicity occurred after more than 2.5 MAC hours of methoxyflurane, provided the plasma concentration of inorganic fluoride exceeded 50  $\mu\text{mol/L}$ ; nephrotoxicity occurred after more than 5 MAC hours if the concentration of inorganic fluoride exceeded 90  $\mu\text{mol/L}$ .<sup>480</sup> These clinical concerns led to the voluntary withdrawal of methoxyflurane from clinical practice.

In contrast to adults, renal dysfunction was not a feature after methoxyflurane anesthesia in children. The peak plasma concentrations of inorganic fluoride in children anesthetized with methoxyflurane were significantly less than in adults after an equivalent anesthetic exposure.<sup>481</sup> The reduced plasma concentrations of fluoride in children were attributed to several causes, including a decreased metabolism of methoxyflurane, greater uptake of fluoride by bone, increased excretion of fluoride ions, or a reduced renal sensitivity to fluoride.<sup>481</sup>

That the plasma concentrations of inorganic fluoride in children who were anesthetized with sevoflurane were similar to or

greater than those after enflurane<sup>482-484</sup> raised concerns about possible renal dysfunction after prolonged exposure. However, inorganic fluoride concentrations after relatively brief anesthetics in children are similar to those in adults: less than 20  $\mu\text{mol/L}$  after about 1 MAC hour, which decreases to less than 10  $\mu\text{mol/L}$  by 4 hours after discontinuation of anesthesia.<sup>465</sup> Nonetheless, the peak plasma concentrations of inorganic fluoride paralleled the MAC hour exposure to sevoflurane in both children and adults.<sup>484</sup> Concerns regarding the risk of renal dysfunction after sevoflurane were heightened after reports that the peak plasma concentration of inorganic fluoride in some adults exceeded the purported threshold for nephrotoxicity (50  $\mu\text{mol/L}$ ).<sup>485</sup> Despite the high plasma concentrations of inorganic fluoride after sevoflurane anesthesia, there was no evidence of renal dysfunction. These reports, together with a dearth of evidence in the toxicology literature, suggested that fluoride-mediated nephrotoxicity may be independent of the plasma concentration of inorganic fluoride.

Kharasch and colleagues postulated that inhalational anesthetic-induced nephrotoxicity might be anesthetic specific. They determined that the primary isozyme responsible for the degradation of enflurane, isoflurane, sevoflurane, and methoxyflurane anesthetics was CYP450 2E1,<sup>471,486-488</sup> with secondary isozymes including CYP450 2A6 and 3A.<sup>489</sup> Subsequently, they reported large quantities of CYP450 2E1 not only within the liver, but also within the kidneys.<sup>486</sup> They also noted that the affinity of renal CYP450 2E1 for methoxyflurane was fivefold greater than it was for sevoflurane.<sup>489</sup> This provided further evidence that the renal dysfunction after ether inhalational anesthetics resulted from the local production of inorganic fluoride within the renal medulla rather than extrarenal production, and that certain anesthetics were more prone to release of inorganic fluoride than others (e.g., methoxyflurane much more so than sevoflurane). Because CYP450 2E1 has a greater affinity for methoxyflurane than sevoflurane, we now understand why renal dysfunction occurs after methoxyflurane and not after sevoflurane.<sup>489</sup> The lack of an association between sevoflurane, plasma inorganic fluoride concentration, and renal dysfunction in children and adults supports this new understanding of the mechanism of renal dysfunction after inhalational anesthesia. Consequently, the risk of renal dysfunction after sevoflurane is independent of the duration of exposure to sevoflurane. Sevoflurane does not pose any greater risk for perioperative renal disease than other maintenance anesthetics.<sup>490</sup> A second theoretical cause of sevoflurane-associated renal dysfunction is compound A, a product of alkaline hydrolysis of sevoflurane in the presence of carbon dioxide absorbents (see later discussion).

### Hepatic System

In vivo metabolism of inhalational anesthetics varies with age, increasing to adult values within the first 2 years of life. The developmental changes in metabolism may be attributed to several factors, including reduced activity of the hepatic microsomal enzymes, reduced fat stores, and more rapid elimination of inhalational anesthetics in infants and children compared with adults. Halothane, isoflurane, enflurane, sevoflurane, and desflurane have all been associated with postoperative liver dysfunction and/or liver failure in adults, although the relationship between sevoflurane and desflurane and liver dysfunction remains tenuous.<sup>491-494</sup> In children, halothane and sevoflurane have been associated with transient hepatic dysfunction.<sup>495-498</sup> Indeed, several pediatric cases of transient postoperative liver failure and one case of fulminant hepatic failure and death have

been attributed to "halothane hepatitis" that was confirmed serologically with antibodies to halothane-altered hepatic cell membrane antigens.<sup>495</sup> The exact mechanism of the hepatic dysfunction after halothane exposure remains unclear, although some clinicians have speculated that it is caused by an immunologic response to a metabolite of halothane. This putative toxic metabolite, a trifluoroacetyl halide compound, is produced during oxidative metabolism of halothane. It is thought that this compound induces an immunologic response in the liver by binding covalently to hepatic microsomal proteins, thereby forming an immunologically active hapten. A subsequent exposure to halothane then incites an immunologic response in the liver.<sup>499</sup> Hepatic enzymes may also be induced by previous administration of drugs, such as barbiturates, phenytoin, and rifampin. Although some have admonished clinicians for administering repeat anesthetics with halothane in children, it is our opinion that, in view of the millions of uneventful repeat halothane anesthetics in infants and children worldwide, insufficient evidence exists to support such an admonition.

### CLINICAL EFFECTS

#### Induction Techniques

Although the physicochemical characteristics of the ether series of anesthetics would predict that anesthesia could be induced smoothly and more rapidly with these agents than with halothane,<sup>308,310</sup> this has not proved to be the case. All of the ether anesthetics (except sevoflurane) irritate the upper airway in children, resulting in a high incidence of breath holding, coughing, salivation, excitement, laryngospasm, and hemoglobin-oxygen desaturation.<sup>435,500-509</sup> Clinical studies with desflurane in children demonstrated a high incidence of breath holding, laryngospasm, and desaturation during inhalational induction (approximately 50%).<sup>435,509</sup> As a result, a "black box" warning was issued against the use of desflurane for induction of anesthesia in infants and children. Before the introduction of desflurane, some advocated inducing anesthesia in children with isoflurane.<sup>502-506</sup> For example, it has been suggested that the quality and speed of induction of anesthesia with isoflurane in oxygen in infants and children is similar to that with halothane.<sup>503</sup> However, airway reflexes were commonly triggered with isoflurane despite the use of a number of strategies to attenuate them,<sup>507,509,510</sup> including slowly increasing the inspired concentration, and scented masks. Given the smooth induction characteristics, economy, and availability of sevoflurane, there are no reasons to consider other anesthetics for induction of anesthesia in infants and children.

In contrast to the noxious effects of the methyl ethyl ether series of anesthetics on the airway, sevoflurane does not irritate the upper airway and is well tolerated when administered by mask to infants and children at any concentration.\* The introduction of sevoflurane has challenged and displaced halothane as the induction agent of choice in children in most countries. The incidences of coughing, breath holding, laryngospasm, and hemoglobin-oxygen desaturation during induction with sevoflurane, whether by slow incremental increases in concentration or a single breath, are similar to those that occur during halothane (Table 6-10). The observation that the airway reflex responses are infrequent after a single-breath induction with 8% sevoflurane or 5% halothane casts doubt on the adage that high concentrations of inhalational anesthetics trigger airway reflex responses.<sup>515-517</sup> In fact, the induction is so smooth with sevoflurane that adjuvants,

such as a premedication, concurrent use of nitrous oxide, or other strategies to prevent airway reflex responses, are unnecessary.

Induction of anesthesia with xenon has not been studied in children. In adults, inhalational induction with xenon at equi-MAC with sevoflurane resulted in a more rapid induction with stability of respirations with xenon.<sup>518</sup> These data suggest that xenon may be an excellent induction anesthetic in children, provided its characteristics are upheld in well-designed clinical trials.

There is no single ideal approach to induce anesthesia by inhalation for all children. However, we advocate empowering children as much as possible to minimize fear. After appropriate preoperative preparation (involving premedication or parental presence or distraction techniques), the child is seated on the bed and encouraged to breathe through a face mask scented with a favorite flavor (to disguise the plastic odor of the mask) that is held over the nose and mouth. A fresh gas composed of 70% nitrous oxide in oxygen is breathed (while the pop-off value is completely open for 1 to 2 minutes). As soon as the child becomes “silly” or ceases to respond verbally, 8% sevoflurane is administered. Induction of anesthesia with halothane was performed with stepwise increments in the inspired concentration of 0.5% to 1.0% every three to four breaths until an adequate depth of anesthesia was achieved. This slow increase in the inspired concentration of halothane was thought to attenuate the incidence of airway reflex responses, although this is not evidence based. In fact, when a single breath vital capacity induction was performed in children older than 6 years of age with 5% halothane, the incidence of airway reflex responses was surprisingly small.<sup>515</sup> Initially, sevoflurane was also administered in slow increments of 1% to 1.5% until 8%, but this caused transient agitation and involuntary movement of the extremities, frequently and sometimes violently, particularly in adolescents.<sup>340</sup> This was attributed to an exaggerated excitement phase. To minimize the excitement phase, we recommend that the inspired concentration of sevoflurane be increased as rapidly as possible, from 0% to 8% in a single-step increase.<sup>515</sup> This is based on a study of single-breath induction with 8% sevoflurane and 5% halothane in which the incidence of involuntary movement and need for restraint was significantly less with sevoflurane than it was with halothane.<sup>515</sup> Recently, induction of anesthesia with 12% sevoflurane was reported to be more rapid than with 8%.<sup>519</sup> This is not a surprising finding, although 12% sevoflurane vaporizers should not be used in clinical practice because inspired concentrations of sevoflurane (in a laboratory setting) of 11% in oxygen and 10% in nitrous oxide support combustion.

Although some studies report more rapid induction of anesthesia with sevoflurane than with halothane, others have not. This inconsistency in the relative speed of induction reflects

differences in study design that likely failed to take advantage of the 8% sevoflurane vaporizer and the differences in MAC. For children who are unable to perform a single-breath vital capacity induction, a rapid increase in the inspired concentration of sevoflurane has been a very effective alternative, with results comparable to the single-breath technique.<sup>329,513-515</sup>

Sevoflurane does not trigger airway reflex responses either alone or in combination with other agents, such as nitrous oxide. One study suggested that sevoflurane is the least irritating to the airway of all the inhalational anesthetics.<sup>520</sup> Previous studies suggested that airway irritability and excitement during sevoflurane anesthesia were similar whether nitrous oxide was present or absent, although others have disputed these findings.<sup>515,521</sup> The lack of effect of nitrous oxide on the speed of induction in the single-breath study was attributed to its concentration-reducing effect on sevoflurane.<sup>515</sup>

Although halothane has been the preferred agent for induction of anesthesia because of its lack of airway irritability, arrhythmias occur more frequently during halothane than during anesthesia with the ether anesthetics. Halothane-induced arrhythmias occur more frequently during spontaneous ventilation and in association with high levels of circulating catecholamines. Most of these arrhythmias are unifocal or multifocal premature ventricular beats, nodal rhythm, bigeminy, or supraventricular arrhythmias.<sup>330,430,508</sup> Despite their appearance, most of these arrhythmias are benign and preserve the blood pressure; ventricular tachycardia, however, may cause hypotension. Management of arrhythmias during halothane anesthesia includes inflating the lungs with large tidal volumes, hyperventilation to decrease the arterial carbon dioxide tension, increasing the concentration of halothane if there is evidence of “light” anesthesia (i.e., sweating, hypertension), and substituting another inhalational anesthetic for halothane.<sup>430,522</sup> Lidocaine has no role in the treatment of these arrhythmias because the myocardium is not intrinsically irritable. Moreover, a rapid IV bolus of lidocaine (2 mg/kg) may cause profound bradycardia.<sup>523</sup> Arrhythmias are rare during anesthesia with the ether series of anesthetics, but when they occur they are usually nodal in origin.\* Arrhythmias during anesthesia with the ether anesthetics are usually self-limiting, resolving spontaneously or with parenteral administration of an anticholinergic. If the arrhythmias persist, then a cardiology consultation should be sought, particularly in a child with a history of congenital heart disease. Both IV and inhalational anesthetics have been used for induction and maintenance of anesthesia in children with congenital heart disease. (See cardiovascular section earlier and Chapter 21 for a more detailed discussion.)

\*References 330, 426, 427, 505, 508, 515, 524.

Once an adequate depth of anesthesia has been achieved, it is prudent to maintain spontaneous respirations with the maximal inspired concentration of sevoflurane that is tolerated until IV access has been achieved. If hypopnea or apnea occurs, then ventilation should be assisted while avoiding hypocapnia. The reason to recommend this practice is to prevent awareness from occurring in the early induction period.<sup>395,396</sup> Discontinuing or decreasing the inspired concentration of nitrous oxide or sevoflurane individually or together may predispose to awareness, particularly if the child is stimulated at a light plane of anesthesia. This may occur in situations where anesthesia is induced in one location (induction room) and the child is then transferred to another (operating room) without continuously supplying sevoflurane. Appreciating the limited solubility of nitrous oxide and sevoflurane will help to understand how rapidly these anesthetics egress from the body, particularly after a brief exposure. Once IV access is established, some practitioners administer propofol or another IV anesthetic before discontinuing the nitrous oxide to facilitate insertion of a laryngeal mask airway or tracheal intubation. The concentration of sevoflurane can then be decreased.

### Emergence

Emergence or recovery has been arbitrarily divided into early (extubation, eye opening, following commands) and late (drinking, discharge time from postanesthesia care unit or hospital). Although most studies have demonstrated a more rapid early recovery after less soluble anesthetics,<sup>326-328,331,334</sup> few have demonstrated a more rapid late recovery.<sup>324,334,524,525</sup>

The speed of emergence and recovery from anesthesia are discussed above. The incidence of complications, such as airway reflex responses and vomiting during emergence from anesthesia, after mask anesthesia or tracheal intubation, are similar with most inhalational agents.\* However, the incidence of airway responses of any severity after desflurane were significantly greater than after isoflurane. Moreover, the incidence of airway adverse responses after removing a laryngeal mask airway (LMA) deep during desflurane anesthesia was significantly greater than was the incidence after removal of an LMA following recovery from desflurane (awake) or after isoflurane anesthesia.<sup>527</sup>

### Emergence Delirium

*Emergence delirium* is defined as a dissociated state of consciousness in which children are inconsolable, irritable, uncompromising, and/or uncooperative (see Videos 46-1, 46-2).<sup>528,529</sup> Children experiencing emergence delirium often demand that all monitors, IV lines, and bandages be removed and that they be dressed in their own clothing. Many of these children fail to recognize and respond appropriately to their parents. Parents who witness this transient state usually volunteer that this behavior is unusual and uncustodial for their child. The core behaviors identified as being associated with emergence delirium after anesthesia in children include nonpurposeful action, and averting eyes or staring.<sup>530</sup>

Emergence delirium is not a new phenomenon, having been reported after the introduction of almost every new anesthetic, including most inhalational anesthetics,<sup>†</sup> and IV agents, including midazolam, remifentanyl, and propofol.<sup>533,534</sup> The incidence

of emergence delirium after inhalational anesthesia in children ranges from 2% to 80%.<sup>327,328,331,525,528</sup>

The prevalence of emergence delirium depends on several factors, including the choice of inhalational anesthetic, age of the child, adjuvant medications, presence of pain, and the scale used for diagnosis.<sup>528,529</sup> The prevalence of emergence delirium is similar after desflurane, sevoflurane, and isoflurane, but less after halothane anesthesia.<sup>535,536</sup> The greatest incidence of emergence delirium occurs in children 1 to 5 years of age.<sup>528,537</sup> Fortunately, these episodes usually last only 10 to 20 minutes and resolve spontaneously without sequelae. The mechanism by which emergence delirium occurs remains unknown.

Emergence delirium has been reported in adults as well as infants, although the incidence is much less in both age groups than in children. Diagnosing emergence delirium after anesthesia and surgery has been complicated by our inability to distinguish it from pain. In one study, ketorolac decreased the incidence of emergence delirium threefold to fourfold after myringotomy with either halothane or sevoflurane anesthesia.<sup>526</sup> Because ketorolac does not sedate children, it is likely that pain was confused with emergence delirium. Subsequent studies in children demonstrated that emergence delirium occurs after sevoflurane anesthesia even in the presence of neuraxial blocks.<sup>528,537</sup> The frequency of delirium is independent of the speed of awakening from anesthesia,<sup>538,539</sup> the duration of a deep level of anesthesia,<sup>540</sup> the duration of general anesthesia,<sup>541</sup> and the presence of parents.<sup>536</sup>

The definitive study regarding the incidence of emergence delirium was undertaken in healthy children who required anesthesia for magnetic resonance imaging (MRI) and who did not undergo surgery.<sup>536</sup> The incidence of emergence delirium was twofold greater after sevoflurane than it was after halothane.

However, in most published studies, the metric used to diagnose emergence delirium had not been validated. To address this deficiency, the Pediatric Anesthesia Emergence Delirium (PAED) scale was developed.<sup>529</sup> The threshold PAED score to diagnose emergence delirium was thought to be greater than 10 but more recently a value greater than 12 was suggested.<sup>542</sup> When the PAED scale was compared with two nonvalidated scales,<sup>542</sup> the three appeared to be comparable, although the comparison was biased because the PAED scale was assessed first, followed by the other two scales (Table 6-11).

Pharmacologic interventions to treat emergence delirium were recently summarized in a meta-analysis.<sup>543</sup> Effective inter-

**TABLE 6-11** Development and Psychometric Evaluation of the Pediatric Anesthesia Emergence Delirium Scale

1. The child makes eye contact with the caregiver.
2. The child's actions are purposeful.
3. The child is aware of his/her surroundings.
4. The child is restless.
5. The child is inconsolable.

Items 1, 2, and 3 are reverse scored as follows: 4 = not at all, 3 = just a little, 2 = quite a bit, 1 = very much, 0 = extremely. Items 4 and 5 are scored as follows: 0 = not at all, 1 = just a little, 2 = quite a bit, 3 = very much, 4 = extremely. The scores of each item were summed to obtain a total Pediatric Anesthesia Emergence Delirium (PAED) scale score. The degree of emergence delirium increased directly with the total score.

ventions included fentanyl,<sup>544</sup> ketamine,<sup>545</sup> a propofol infusion or a bolus at the end of anesthesia, clonidine,<sup>546,547</sup> and dexmedetomidine.<sup>548</sup> In contrast, a single dose of propofol at induction of anesthesia, midazolam, and flumazenil were not effective.<sup>543,549-553</sup> Additional studies using assessment with a validated delirium scale are needed to clarify the contribution of anesthetics to emergence delirium during pain-free surgery.

### Neuromuscular Junction

All inhalational anesthetics potentiate the actions of nondepolarizing muscle relaxants<sup>554-556</sup> and decrease neuromuscular transmission,<sup>557</sup> the latter, however, only at increased concentrations. The mechanism of the reduced neuromuscular transmission is unknown but is likely attributable to actions of these anesthetics at the synaptic junction rather than PK or CNS effects. The potentiation of action of nondepolarizing relaxants follows the order: isoflurane ~ desflurane ~ sevoflurane > enflurane > halothane > nitrous oxide–opioid technique.<sup>554,558</sup> However, this potentiation may depend on the type of nondepolarizing relaxant studied (longer-acting relaxants are affected to a greater extent than intermediate-acting relaxants)<sup>554,555,559</sup> and the concentration of anesthetic (reduced concentrations may yield small or no differences between anesthetics, whereas greater concentrations may demonstrate substantive differences).<sup>555</sup> In two parallel studies of atracurium infusions in children,<sup>559,560</sup> halothane and isoflurane decreased the atracurium requirements similarly in the first, whereas enflurane markedly decreased the requirements compared with halothane in the second. These observations suggest that inhalational anesthetics potentiate intermediate-acting relaxants as they do long-acting relaxants.

### Malignant Hyperthermia

All potent inhalational anesthetics, except xenon,<sup>561</sup> trigger malignant hyperthermia (MH) reactions in susceptible adults and children.<sup>562-571</sup> Studies indicate that the relative capabilities of the four inhalational anesthetics to augment caffeine-induced contractures in MH-susceptible muscle *in vitro* are halothane > enflurane > isoflurane > methoxyflurane.<sup>572</sup> Using the surrogate marker of the time interval from administration of anesthesia until a reaction was detected to estimate the relative potency of the modern anesthetics to trigger MH, the order was halothane > sevoflurane > isoflurane ~ enflurane.<sup>573</sup> Currently, all inhalational anesthetics should be avoided in children who are MH susceptible (see Chapter 40).

The wash-out of inhalational anesthetics from anesthetic machines before anesthetizing a child with MH requires an understanding of the PK of these anesthetics in the specific anesthetic workstation. See Chapter 40 for a full discussion.

### Stability and Toxicology of Breakdown Products

Inhalational anesthetics may be degraded via several pathways in the presence of most CO<sub>2</sub> absorbents to form several potentially toxic byproducts. Enflurane, isoflurane, and desflurane (but not halothane and sevoflurane) react with desiccated soda lime to produce carbon monoxide. Halothane and sevoflurane react with soda lime to yield several organic compounds that are potentially organ toxic. In contrast, xenon is completely inert with CO<sub>2</sub> absorbents, thereby posing no risk from the genesis of metabolites or degradation products in humans.

Two strategies to address the clinical risks associated with the degradation of ether inhalational anesthetics are molecular sieves<sup>574</sup> and new CO<sub>2</sub> absorbents.<sup>575-579</sup> While molecular sieves

were thought to have great promise, they have not reached the market for clinical use. In contrast, a number of new CO<sub>2</sub> absorbents have been developed to absorb CO<sub>2</sub> from the breathing circuit without degrading inhalational anesthetics to carbon monoxide and compound A (E-Table 6-2).<sup>575,576</sup> The previous generation of CO<sub>2</sub> absorbents differed in their composition and, therefore, in their affinity to degrade inhalational anesthetics. Soda lime contained 95% calcium hydroxide, either sodium or potassium hydroxide, and the balance as water. Baralyme, which is no longer available, contained 80% calcium hydroxide, 20% barium hydroxide, and the balance as water. E-Table 6-2 compares the compositions of the older with the newer CO<sub>2</sub> absorbents, which do not contain a strong base. Most recently, Amsorb Plus and Drägerorb Free were formulated for minimal degradation of inhalational anesthetics, as well as to address efficient CO<sub>2</sub> absorption.<sup>580</sup>

Carbon monoxide may be produced when a methyl ethyl ether inhalational anesthetic is incubated with a desiccated CO<sub>2</sub> absorbent (most commonly soda lime or Baralyme). The absorbent within a CO<sub>2</sub> canister may become desiccated if dry fresh gas flows through the canister at a rate sufficient to remove most of the moisture (i.e., more than 5 L/min continuously through the absorbent canister for 24 hours or longer while it is not in service). If the circuit reservoir bag is detached from the canister while fresh gas is flowing, then fresh gas may flow retrograde through the canister and exit primarily where the reservoir bag is normally placed. This cannot occur in anesthetic machines in which the fresh gas enters distal to the inspiratory flow valve. If the fresh gas flows retrograde through the canister for a sufficient time, it desiccates the absorbent and increases the risk of degradation of subsequently administered inhalational anesthetics. If one of the methyl ethyl ether inhalational agents (desflurane, isoflurane, or enflurane) is administered through a desiccated absorbent, carbon monoxide may be generated.<sup>579,581,582</sup> The magnitude of the carbon monoxide production for a specific absorbent follows the order: desflurane = enflurane > isoflurane >> halothane = sevoflurane. Other factors that determine the magnitude of the carbon monoxide concentration produced include the concentration of the inhalational agent, the dryness of the absorbent, the type of absorbent (Baralyme > soda lime > newer absorbents), and the temperature of the absorbent.<sup>581</sup> As the newer absorbents reflect, the removal of the strong alkalis, NaOH and KOH, which are essential for the production of carbon monoxide, virtually eliminates this risk (E-Table 6-3).<sup>583</sup>

Small concentrations of carbon monoxide (up to 18 ppm) have been detected in children who were anesthetized with desflurane or sevoflurane using fresh carbon dioxide absorbent that includes KOH and NaOH.<sup>584</sup> Carbon monoxide concentration correlated well with the fresh gas flow to minute ventilation ratio (less than 0.68) and weakly with the type of anesthetic agent (desflurane) and age.<sup>584</sup> Carbon monoxide has been detected in concentrations up to 3 ppm during and after anesthesia, even spinal anesthesia.<sup>585</sup> One may question whether a minimum fresh gas flow with desflurane and other nonsevoflurane anesthetics is warranted. The presence of carbon monoxide in the exhaled breath has been attributed to heme metabolism, inflammation, and sepsis, although the authors did not use fresh soda lime in their breathing circuits.<sup>585</sup>

Carbon monoxide is not detectable by any freestanding anesthetic agent analyzers, pulse oximetry, or blood gas analyzers (with the exception of co-oximeters), although it is detectable by mass spectrometry. A carbon monoxide analyzer is currently

marketed for use during anesthesia. The solution to this problem is prevention: turn off the anesthetic machine at the end of the day, disconnect the fresh gas hose to the absorbent canister, always have the reservoir bag connected to the canister, and avoid passing desflurane, enflurane, and isoflurane through a desiccated absorbent. Others have suggested that high-flow anesthesia should be avoided whenever a circle circuit is used to prevent inadvertent desiccation of absorbent. If the absorbent is desiccated, some have suggested “rehydrating” the absorbent, although this, too, is fraught with potential problems (including clumping of the absorbent).<sup>586</sup> If there is suspicion that the absorbent is desiccated, we strongly recommend replacing the absorbent before introducing an inhalational anesthetic. Alternatives to conventional absorbents, such as the molecular sieve and the newer absorbents, may very well obviate degradation of the ether anesthetics, provided the absorbent is not desiccated.<sup>575,576,578,579</sup> When methyl ethyl ether anesthetics are incubated with desiccated Amsorb, carbon monoxide is not produced, although it may be produced with other desiccated absorbents (see E-Table 6-3).<sup>575,576,579</sup> The incidence of carbon monoxide poisoning during anesthesia remains extremely rare even when soda lime is used as the absorbent. In contrast, the potential for carbon monoxide poisoning is zero if Amsorb or one of the absorbents that does not include strong metal alkali is used.

Halothane is degraded in the presence of carbon dioxide absorbents to the unsaturated vinyl compound, 2-bromochloroethylene, which is lethal in mice.<sup>587</sup> Although 2-bromochloroethylene is potentially nephrotoxic, it poses very little risk in humans, even under low flow conditions, because its maximal concentration in the circuit is less than 3% of its lethal concentration.<sup>588</sup>

Sevoflurane is both absorbed and degraded via the Cannizzaro reaction in the presence of absorbent, resulting in five degradation products.<sup>589,590</sup> Although the degradation of sevoflurane by the absorbent was initially posited to delay its wash-in, evidence suggests that this effect is trivial.<sup>591</sup> Of the five degradation products produced when sevoflurane is degraded in either soda lime or Baralyme, compounds A and B appear in the greatest concentrations. Compound A, fluoromethyl-2,2-difluoro-1-(trifluoromethyl)vinyl ether (also known as PIFE), is nephrotoxic in rats at concentrations of 100 ppm or greater, and has a lethal concentration (LC<sub>50</sub>) of 1100 ppm. Compound B, a methoxyethyl ether compound that is minimally volatile at room temperature, is present in closed circuits at less than 5 ppm and poses no serious risk to animals or humans. The remaining three metabolites, compounds C, D, and E, are present in such low concentrations in the breathing circuit that they are inconsequential. In a low-flow closed circuit model with an inspired concentration of 2.5% sevoflurane, the concentration of compound A peaks at 20 to 40 ppm after several hours of anesthesia.<sup>591-595</sup> In children, compound A concentrations reach 16 ppm after 5.6 MAC hours of sevoflurane in a semi-closed circuit with 2 L/min fresh gas flow.<sup>596</sup> Factors that are known to increase the production of compound A include an increase in the inspired concentration of sevoflurane, Baralyme greater than soda lime, and an increase in the temperature of the absorbent.<sup>590,591</sup> The newer formulation of CO<sub>2</sub> absorbents degrade sevoflurane to a lesser degree compared with the previous absorbents (see E-Table 6-2 and E-Table 6-3). As in the case of carbon monoxide production, monovalent bases are important ingredients for the degradation of sevoflurane to compound A and their absence reduced the extent of degradation of sevoflurane.<sup>577,583,597</sup> In rats under low flow

conditions, compound A is nephrotoxic.<sup>598-600</sup> In contrast, studies in humans have been far from conclusive.<sup>592-594,601</sup> Commonly used indicators, such as albuminuria, have yielded inconsistent evidence of renal dysfunction.<sup>592-595,601</sup> One mechanism to explain compound A-induced nephrotoxicity is the  $\beta$ -lyase-dependent metabolism to nephrotoxic fluorinated compounds. However, this has been the subject of intense debate.<sup>602,603</sup> If compound A-associated nephrotoxicity were proven to depend on the  $\beta$ -lyase metabolic pathway, the limited concentration of this enzyme system in the renal cytoplasm and mitochondria of humans would make nephrotoxicity an unlikely outcome. Indeed, the inconsistency in the evidence of nephrotoxicity associated with compound A between rats and humans has been attributed to an 8- to 30-fold greater concentration of  $\beta$ -lyase in rats compared with that in humans.<sup>604</sup> To date, there have been no complications related to compound A and kidney damage in humans.

At the present time, sevoflurane is the only inhalational agent for which authorities have recommended a minimum fresh gas flow when it is administered in a closed circuit with soda lime or Baralyme. The minimal fresh gas flow is 2 L/min, although this has been adopted in a limited number of countries.

## Nitrous Oxide

Nitrous oxide confers several properties that differ substantively from the potent inhalational anesthetics that merit consideration. Nitrous oxide has a very limited solubility in blood,  $\lambda_{\text{blood/gas}}$  being 0.47. The MAC for nitrous oxide is 104% in adults; MAC has not been determined in children. Its chemical structure is N–N–O.

Nitrous oxide diffuses into gas cavities that are filled with nitrogen more rapidly than nitrogen egresses because it is 34 times more soluble in blood than nitrogen ( $\lambda_{\text{blood/gas}}$  for nitrogen 0.014). Consequently, the volume of the cavity expands. However, the magnitude of the increase in the volume of the cavity depends, in part, on the concentration of nitrous oxide administered, as determined by the formula  $100/(100 - \%N_2O)$ . The rate at which the cavity expands also depends on the source of the blood supply: those cavities in which the blood supply decreases as the volume of the cavity increases (e.g., a loop of obstructed bowel) will expand slower and to a smaller overall volume than a cavity in which the blood supply is independent of the cavity volume (e.g., a pneumothorax). By using a model of these conditions the time to double the volume of a loop of obstructed bowel with nitrous oxide was estimated to be 120 minutes, whereas the time to double the volume of a pneumothorax was one tenth, or 12 minutes.<sup>605</sup> Any gas-filled cavities within the body are vulnerable for expansion if nitrous oxide is administered, including obstructed bowel,<sup>605</sup> pneumothorax, gas cavities within the eye, endotracheal tube cuffs,<sup>606</sup> laryngeal mask airways,<sup>607,608</sup> bubbles in veins,<sup>609</sup> and pneumoencephalography.<sup>610</sup> Theoretically, nitrous oxide should be avoided during laparoscopic surgery, to avoid expanding CO<sub>2</sub> bubbles that reach the venous circulation (see Chapter 27).

Inhalational anesthetics confer a very low risk for postoperative nausea and vomiting. In contrast, nitrous oxide is considered to be an emetogenic anesthetic. In a large meta-analysis of the impact of nitrous oxide on the incidence of postoperative nausea and vomiting in adults, the authors determined that for emetogenic surgery, eliminating nitrous oxide was salutary (number needed to treat of six) whereas for nonemetogenic surgery there

was no benefit from omitting nitrous oxide.<sup>611</sup> Hence, avoiding nitrous oxide in surgery that is emetogenic is reasonable. However, the authors of that study also reported that the number needed to harm, in the form of intraoperative awareness when nitrous oxide was omitted from the anesthetic, was 46, or more than 2%! Hence, omitting nitrous oxide from the anesthetic prescription requires very careful consideration, assessment, and monitoring for awareness.

A number of studies investigated the contribution of nitrous oxide to postoperative vomiting in children. Although there is some evidence that avoiding nitrous oxide reduces the incidence of postoperative vomiting in children,<sup>612</sup> the preponderance of evidence shows no benefit.<sup>613-617</sup> In part, this may be attributed to the multiplicity of factors that contribute to postoperative vomiting, as well as the salutary effects of other factors, such as the use of propofol and/or antiemetics. In none of the studies in which nitrous oxide was omitted in children was awareness reported.

The inclusion of nitrous oxide in remifentanyl-propofol anesthesia in children has been associated with a reduction in postoperative hyperalgesia.<sup>618</sup>

## Environmental Impact

Currently, the National Institute for Occupational Safety and Health (NIOSH) recommendations limit the chronic exposure to nitrous oxide to 25 ppm and to inhalational anesthetics to 10 ppm. The basis for these recommendations is uncertain but may be attributed to the risk of teratogenicity and end-organ dysfunction. In pediatric anesthesia, mask anesthesia and/or uncuffed tracheal tubes and laryngeal mask airways in children leak inhalational anesthetics into the environment. As a result there is local exposure to inhaled anesthetics during anesthesia in children that should be considered.

Concern over the pollution of the stratosphere and ozone layer depletion by polyhalogenated anesthetics has raised further questions for the long-term use of these agents and the need to fully recycle or adsorb the waste gases.<sup>619</sup> The polyhalogenated compounds are produced in extremely low concentrations; and although they have a high molecular weight, atmospheric winds likely facilitate their transfer to the stratosphere, where they do harm to the ozone layer. However, the most compelling data of their limited impact on the environment relate to their half-lives. The half-lives of these polyhalogenated anesthetics in the stratosphere are approximately 5 years. Contrast these to nitrous oxide, a compound with a very small molecular weight (in comparison with potent inhalational anesthetics), which is administered in high concentrations (50% to 70%) and which has a half-life in the stratosphere of 120 years! Nitrous oxide is a known greenhouse gas and depletes the ozone layer. The case for banning the polyhalogenated anesthetics pales in comparison with the enormous potential environmental impact of nitrous oxide. Although nitrous oxide is a serious greenhouse pollutant, agriculture and industry account for the vast majority of the nitrous oxide released into the atmosphere, with medical sources accounting for a trivial, unidentified fraction.<sup>620</sup> Highly efficient scrubbers and absorbers are being developed to prevent atmospheric pollution and recycle expensive anesthetics (e.g., xenon) but their use remains experimental at this time. To preserve the ozone layer, all anesthetic practices should limit the fresh gas flow and concentration of polyhalogenated anesthetics and nitrous oxide.

## Oxygen

The concentration of oxygen for each anesthetic should be carefully titrated to the child's needs. Requirements are monitored by inspired oxygen concentration measurement, oxygen-hemoglobin saturation (pulse oximetry), and arterial blood gas determinations. Oxygen is often liberally administered in excess of the child's metabolic needs. However, potential dangers in this excess should be noted,<sup>621</sup> particularly in two areas: (1) Pulmonary oxygen toxicity is well documented; despite the fact that it develops slowly, general recommendations are to use an air/oxygen combination for prolonged procedures when nitrous oxide is contraindicated.<sup>622</sup> (2) Of additional concern is the remote possibility of adverse effects on the immature neonatal retina leading to retinopathy of prematurity (ROP).<sup>623-634</sup> Several cases of ROP have been reported in infants whose only known exposure to supplemental oxygen occurred in the OR; it should be noted that no new cases related to OR management have been reported since 1981!<sup>635,636</sup> Many factors contribute to the development of ROP; it has been reported in children with cyanotic congenital heart disease, infants not exposed to exogenous oxygen, and even in stillborn infants.<sup>637,638</sup> A possible relationship of the development of ROP to arterial carbon dioxide variations, hypercarbia, hypotension, candida sepsis, inflammatory response, red blood cell transfusions, corticosteroid therapy, duration of ventilation, elevated blood glucose values, low gestational age, chronic lung disease, a deficiency of insulin-like growth factor, and vascular endothelial growth factor, as well as hypoxemia and fluctuating levels of oxygen, have all been suggested.<sup>639-659</sup> Other factors, such as exogenous bright light, maternal diabetes, maternal chorioamnionitis, and maternal antihistamine use within 2 weeks of delivery, have been found to be risk factors; the evidence for vitamin E deficiency is less convincing.<sup>660-663</sup> The possibility of a genetic predisposition, that is, a genetic polymorphism altering control of neovascularization, has also been proposed.<sup>653,664-666</sup> The use of continuous transcutaneous oxygen tension monitoring was not found to reduce the risk of ROP in infants weighing less than 1000 g, compared with controls.<sup>667</sup> It appears the major risk factor for developing ROP is extreme prematurity; *oxygen therapy represents only part of this complex problem.*<sup>626,627,629</sup> The incidence of ROP is predominantly limited to infants weighing 1000 g or less, but it is a concern in infants with a birth weight less than 1500 g born at less than 28 weeks gestation.<sup>668-670</sup> It should be noted that new treatments may involve systemic administration of propranolol (improves neovascularization) and intravitreal injections of anti-vascular endothelial growth factors are being examined; both these treatments may have anesthetic implications.<sup>671,672</sup> The evidence implicating hyperoxia as contributing to the development of ROP must be recognized but placed in perspective. Although it was thought that tight control of oxygen saturation and minimizing exposure to exogenous oxygen would reduce the incidence of ROP,<sup>673</sup> a multicenter study, the Supplemental Therapeutic Oxygen Prethreshold Retinopathy of Prematurity study (STOP-ROP), failed to support that hypothesis.<sup>674</sup> In fact, the conclusion reached stated, *"Although the relative risk-benefit of supplemental oxygen for each infant must be individually considered, clinicians need no longer be concerned that supplemental oxygen, as used in this study, will exacerbate active prethreshold ROP."*<sup>674</sup> This study suggests that anesthesiologists should take practical precautions to protect an infant's retinas from hyperoxemia without unnecessarily endangering the infant. No comprehensive epidemiologic studies have yet examined anesthetic risk factors, but, given the

many cofactors that are associated with this entity, it appears that anesthesia management, although very important, is a small piece of this puzzle.

Bearing in mind the possible role of hyperoxia and hypercarbia, intraoperative management must include careful monitoring of inspired oxygen and expired carbon dioxide concentrations. Maintaining the oxygen saturation at 93% to 95% results in a  $\text{PaO}_2$  of approximately 70 mm Hg, with values exceeding 80 mm Hg on occasion.<sup>628,675,676</sup> Unfortunately, individual oximeters may vary considerably in terms of their accuracy, so practitioners must be familiar with their equipment.<sup>677</sup> The use of air blended with oxygen can be used to further reduce the inspired oxygen concentration. A transport system equipped with an air-oxygen blender is desirable to continue the titration of oxygen therapy from the OR to the ICU. (When using portable oxygen tanks, a good rule of thumb to determine the capacity of an E-cylinder is as follows: the minutes of oxygen delivery left in the tank = pounds of pressure [in pounds per square inch]  $\times$  0.3 divided by gas flow [in liters per minute].) While avoiding hyperoxia, one must never lose sight of the importance of *avoiding hypoxemia; hypoxemia is life-threatening whereas hyperoxia is not*. One cannot be faulted if ROP should occur, provided a reasonable and safe approach to oxygen administration and ventilation has been made.

## Intravenous Anesthetic Agents

The anesthetic effects of IV agents are primarily reflected by brain concentrations; to achieve anesthesia, it is necessary to obtain an adequate cerebral blood concentration. Each drug administered is rapidly redistributed from vessel-rich well perfused areas (brain, heart, lung, liver, and kidneys) to muscle, and finally to vessel-poor less well perfused areas (bone, fat). Thus, termination of the effect of a single drug dose is primarily determined by redistribution. The much slower tertiary distribution to relatively underperfused tissues of the body is noted with long-term drug infusions. Protein binding, body composition, cardiac output, distribution of cardiac output, metabolism, and excretion all alter the PK and PD of IV drugs. Anesthetic depth may be altered if a constant cerebral blood level is not maintained. The changes in body composition and the blood-brain barrier that occur during maturation may also greatly affect the duration of action of IV drugs, especially in neonates. In addition to perinatal circulatory changes (e.g., ductus venosus, ductus arteriosus), there are maturational differences in relative organ mass and regional blood flow while a symptomatic patent ductus arteriosus may also result in differences in distribution. Blood flow, as a fraction of the cardiac output, to the kidney and brain increases with age, whereas that to the liver decreases through the neonatal period.<sup>678</sup> Cerebral and hepatic mass, as proportions of body weight in the infant, are much greater than in the adult.<sup>679</sup> Whereas onset times are generally faster for neonates than adults (a size effect), reduced cardiac output and cerebral perfusion in neonates means that the expected onset time after an IV induction is slower in neonates, although reduced protein binding may counter this observation for some drugs. Offset time is also delayed because redistribution to well-perfused and deep under-perfused tissues is more limited.

### BARBITURATES

#### Methohexital

Methohexital (Brevital) is a short-acting barbiturate for the IV induction of anesthesia (1 to 2 mg/kg). Administered

intravenously as a 1% solution (10 mg/mL), it produces pain at the injection site; hiccups, apnea, and seizure-like activity may also be occasionally observed.<sup>680,681</sup> Methohexital has minimal effects on cardiovascular function (increased heart rate) in children.<sup>682</sup> Methohexital may be contraindicated in children with temporal lobe epilepsy.<sup>680</sup> Slow IV titration averts apnea. A possible advantage of methohexital (clearance 0.76 L/min/70 kg) over thiopental (clearance 0.24 L/min/70 kg) is that its mature rate of metabolism is greater while the volumes of distribution at steady state are similar (170 L/70 kg),<sup>684</sup> suggesting a more rapid recovery when large doses have been administered.<sup>685-687</sup> Anesthesia is achieved at plasma concentrations of  $3.12 \pm 0.99$  mg/L.<sup>688</sup>

Rectal methohexital in a 10% solution (20 to 30 mg/kg) is a safe and atraumatic method of induction with an acceptably small incidence of undesired adverse effects (hiccups 13%, defecation 10%),<sup>689</sup> although this technique is no longer commonly used. It was particularly suited for brief radiologic procedures, such as computed tomographic scans, with a single rectal administration of a 10% solution (100 mg/mL given through a well-lubricated catheter), as well as for minor outpatient surgery.<sup>690,691</sup> Absorption by this route is quite variable and may account for an occasional child with prolonged or rapid onset of sedation.<sup>685,692</sup> This technique and dosage have been used safely in children from 3 months to 6 years of age. It is a useful adjunct to induction of anesthesia in older cognitively impaired children, or in those who are excessively fearful of the anesthesia mask or an IV needle. It is also an alternative for children who are still in diapers and who are not candidates for other premedicants, such as midazolam (e.g., a child taking erythromycin).<sup>693,694</sup>

Oxygen desaturation occurs in approximately 40% of cases and is usually related to airway obstruction; this is generally readily corrected by repositioning the head.<sup>689,695</sup> Methohexital should be administered only under the supervision of a physician trained in airway management to ensure adequacy of the airway and ventilation, because airway obstruction, seizures, or apnea may rarely occur.<sup>696</sup> *Children must not be left unobserved after administration.*

#### Thiopental

The most likely mechanism of action of thiopental is via binding to GABA<sub>A</sub> receptors, which increases the duration of GABA-activated chloride channel opening. The median effective dose ( $\text{ED}_{50}$ ) of thiopental varies with age: 3.4 mg/kg in neonates, 6.3 mg/kg in infants, 3.9 mg/kg in children aged 1 to 4 years, 4.5 mg/kg in children 4 to 7 years, 4.3 mg/kg in children 7 to 12 years and 4.1 mg/kg in adolescents aged 12 to 16 years.<sup>697,698</sup> Children aged 13 to 68 months given rectal thiopental (44 mg/kg) 45 minutes prior to surgery were either asleep or adequately sedated with plasma concentrations above 2.8 mg/L.<sup>699</sup> The effect-site concentration of thiopental for induction of anesthesia in neonates may be less than that in infants because the neonate has relatively immature cerebral cortical function, rudimentary dendritic arborization, and relatively few synapses.<sup>700</sup>

The hypotensive response in neonates given thiopental appears not as dramatic as that associated with propofol, although it still may occur with reversion to fetal circulation.<sup>701,702</sup> Thiopental has little direct effect on vascular smooth muscle tone. Cardiovascular depression is centrally mediated by inhibition of sympathetic nervous activity and direct myocardial depression through effects on transsarcolemmic and sarcoplasmic reticulum calcium flux. Although doses of 6 mg/kg have been given as

premedication before intubation in term infants without physiologic consequences,<sup>703</sup> the mean dose required for satisfactory induction in neonates is less, at  $3.4 \pm 0.2$  mg/kg.<sup>697</sup>

The duration of the clinical effect of thiopental depends primarily on redistribution rather than metabolism (10% per hour). As a result, repeated doses of thiopental may accumulate, causing prolonged sedation. Children 5 months to 13 years of age, however, metabolize thiopental almost twice as rapidly as adults when expressed as per kilogram (see E-Fig. 6-3).<sup>704-706</sup> The elimination half-life of thiopental in neonates is greater than that in adults and children<sup>707,708</sup> because of the reduced clearance in neonates. Clearance, expressed using a  $\frac{3}{4}$  allometric model, at 26 weeks PMA was 0.015 L/min/70 kg and increased to 0.119 L/min/70 kg by 42 weeks PMA.<sup>709</sup> Maturation of the CYP2C19 pathway increases rapidly after birth in term neonates<sup>710</sup> and the mature clearance of 0.24 L/min/70 kg is achieved within 3 months of age.

Acute tolerance to thiopental, well demonstrated in adults, may also occur in children.<sup>711</sup> A total IV dose of 10 mg/kg is generally the upper limit; however, with this dose, it is common to have a prolonged period of sedation after brief surgical procedures. Thiopental is a weak vasodilator and a direct myocardial depressant; both of these effects may cause significant systemic hypotension in the *hypovolemic* state (e.g., dehydration resulting from prolonged fasting or trauma).<sup>712</sup>

Thiopental in a 10% solution (20 to 30 mg/kg) may also be used for induction of anesthesia by rectal instillation when methohexital is contraindicated (temporal lobe epilepsy).<sup>680</sup> The period of sedation may be longer for thiopental than for methohexital, partly because of the reduced rate of metabolism.<sup>713</sup>

Thiopental has also been used in the pediatric critical care setting as a continuous high-dose infusion (approximately 2 to 4 mg/kg/hr) to control intracranial hypertension. Monitoring the blood concentration of thiopental may be useful during such therapy to avoid depressing myocardial function. The elimination half-life of thiopental after a continuous infusion may be markedly prolonged compared with that after a single bolus (11.7 vs 6.1 hours).<sup>705,706</sup> These findings may, in part, be attributed to the underlying illness, intercurrent drug treatment, and zero-order kinetics at higher concentrations (Michaelis constant 28.3 mg/L).<sup>709,714</sup>

## PROPOFOL

Propofol (Diprivan) is a sedative-hypnotic agent useful for both the induction and maintenance of anesthesia.<sup>715</sup> Diprivan is formulated with 1% propofol, 10% soybean oil, 1.25% egg yolk phosphatide (ovolecithin), 2.25% glycerol, EDTA (ethylenediaminetetraacetic acid), and sodium hydroxide to maintain a pH of 7.0 to 8.5. This formulation has a white milky appearance because it is a lipid macroemulsion with average droplet size of 0.15 to 0.3  $\mu$ mol/L (where 5 to 7  $\mu$ mol/L is required to pass through capillaries).<sup>716</sup> These droplets remain distinct in suspension owing to the negative surface charges on the phosphate moieties in the ovolecithin phospholipids in the aqueous outer layer. These droplets may coalesce if the negative surface charges on the emulsion droplets dissipate, which is a slow, naturally occurring process, but which may also be precipitated by physical maneuvers (freeze-thawing, high temperatures, or agitation) or by changes in the chemical composition of the emulsion, such as by decreasing pH or the addition of electrolytes (i.e., sodium, potassium, calcium, or magnesium) or medications (i.e., lidocaine [see later discussion]).<sup>716</sup> Soybean oil is composed of

long-chain triglycerides (LCT), defined by the 12 to 22 carbon atoms in their skeletons: linoleic acid (54%), oleic acids (26%), linolenic acid (7.8%), and stearic acid (2.6%). EDTA was added to Diprivan after 1998 as an antimicrobial agent. Generic formulations of propofol are available; these contain sulfites or metabisulfite as the antimicrobial agent.

Propofol is a highly lipophilic drug that is rapidly distributed into vessel-rich organs, accounting for its rapid onset and usefulness as an induction agent. Termination of this effect is achieved by the combination of rapid redistribution and rapid hepatic and extrahepatic clearance.<sup>717-719</sup> The rapidity of the redistribution from vessel-rich organs accounts for its brief action and the need for repeated small boluses or a constant infusion to maintain a stable plane of anesthesia and sedation. PK studies demonstrated a larger  $V_{dss}$  (9.7 L/kg) in children compared with adults, and more rapid redistribution, but a clearance (34 mL/min/kg) that is similar to or greater than that reported in adults.<sup>720-723</sup> Clearance, standardized to a 70 kg person using allometry, is immature in preterm neonates (0.4 L/min/70 kg at 30 weeks PMA); there is rapid maturation around term (1 L/min/70 kg), achieving 90% of mature clearance (1.8 L/min/70 kg) by 5 months postnatal age (see Fig. 6-10).<sup>178,724-727</sup> Clearance is limited by the hepatic blood flow and is consequently reduced in children in low cardiac output states.<sup>728</sup> Although interindividual variability in the PK in neonates is large, the reduced clearance suggests that recovery after propofol in neonates may be prolonged and that repeat doses may not be required as frequently as in older children and adults. Propofol is conjugated to a water-soluble glucuronide in the liver and excreted in the urine.<sup>720</sup> Propofol also undergoes extrahepatic metabolism (in lung, kidney), as evidenced by the similar PK in infants with biliary atresia and healthy controls.<sup>729</sup>

Although measuring the concentration of propofol in blood has been the sole means to assess its disposition *in vivo*, alternate noninvasive techniques have been sought to provide online measurements. Mass spectrometry of the exhaled breath from adults and children, a technique that is similar to end-tidal gas monitoring of inhalational anesthetics, has proven to provide stable estimates of the concentration of propofol in blood.<sup>730,731</sup> It may soon be possible to guide administration of propofol in the OR by the measurement of expired propofol.<sup>732,733</sup>

In children who have not been premedicated, the dose of propofol required for loss of the eyelash reflex generally increases with decreasing age.<sup>734-738</sup> The  $ED_{50}$  for loss of the eyelash reflex in infants (1 to 6 months) is  $3 \pm 0.2$  mg/kg, which decreases in children (1 to 12 years) to 1.3 to 1.6 mg/kg, and increases in older children (10 to 16 years) to  $2.4 \pm 0.1$  mg/kg. A more linear decrease in propofol dosing with increasing age between infants and children 12 years of age was determined in Chinese children.<sup>737</sup> A 10% decrease in the propofol dose for the  $ED_{95}$  between children younger than age 2 years, 2 to 5 years, and 6 to 12 years was noted. The  $ED_{90-95}$  for loss of eyelash reflex for all age groups is 50% to 75% greater than the  $ED_{50}$ .<sup>734,735</sup> Larger doses may be required for acceptance of the face mask.<sup>735,739</sup> The dose of propofol in neonates has not been clearly established. In one study, a dose of 2.5 mg/kg permitted tracheal intubation in the majority of neonates, although the exact dose used was not specified.<sup>740</sup> Successful insertion of an LMA in unpremedicated children requires an even larger dose of propofol (5.4 mg/kg [4.7 to 6.8 mg/kg, 95% confidence interval]).<sup>741</sup> After induction of anesthesia with sevoflurane and nitrous oxide, excellent conditions for tracheal intubation are achieved with 1.5 to 2 mg/kg in

children.<sup>742-745</sup> Propofol is widely used as a continuous infusion or in intermittent doses in children undergoing brief radiologic procedures, during medical procedures, such as oncology and gastroenterology, and for children with MH.<sup>39,746-749</sup> Although early evidence suggested that 100 µg/kg/min propofol was required after a halothane induction to maintain immobility during MRI,<sup>746</sup> subsequent studies showed that much larger doses are required in unpremedicated children or after sevoflurane inductions.<sup>39</sup> Specifically, initial infusion rates of propofol of 200 to 250 µg/kg/min (12 to 15 mg/kg/hr) or even greater may be required (up to 500 µg/kg/min for the first 15 minutes and then tapered) to prevent nonpurposeful limb movement during scans. The initial rate may have to be increased for younger children (e.g., infants) and for those who are cognitively impaired. Midazolam premedication may reduce the propofol requirements, but it delays emergence after brief procedures. Some advocate intermittent boluses of propofol whereas others advocate continuous infusions. Once movement has abated, the infusion rate of propofol may be titrated approaching 200 µg/kg/min in infants and 150 µg/kg/min in older children. In one study, systolic BP decreased more and the total dose of propofol was greater when continuous infusions were used, compared with intermittent boluses.<sup>749</sup> If minor movement can be tolerated (e.g., medical procedures), then intermittent boluses may be preferred for brief procedures, whereas if immobility is required (radiation oncology and radiologic procedures), then infusions are preferred. In some clinical scenarios, such as radiation oncology, burns, and oncology procedures, repeated sedation with propofol over a prolonged period is required. There is no evidence that tolerance to propofol develops.<sup>750</sup>

Integrated PK-PD studies in neonates are lacking, partly because of a lack of consistent effect measures. The equilibration half-time ( $T_{1/2keo}$ ) for the effect compartment is unknown, but is assumed to be smaller<sup>251</sup> than the 3 minutes described in adults.<sup>751,752</sup> Reduced GABA<sub>A</sub> receptor numbers in the neonatal brain may contribute to a reduced target concentration, but this hypothesis remains untested. A circadian night-rhythm effect has been noted in an investigation of infant propofol sedation after major craniofacial surgery,<sup>753</sup> but such an effect is unlikely in neonates who do not have established day-night sleep cycles.<sup>754</sup>

Propofol affects a number of organ system responses in vivo. Systolic BP decreases approximately 15% in children,<sup>721,739,755,756</sup> which is similar to what occurs in adults.<sup>757</sup> Most studies reported similar decreases in BP after propofol and thiopental in children.<sup>756,758</sup> The incidence of apnea after an induction bolus of either propofol or thiopental is similar.<sup>739,755,756,758</sup> The major clinical disadvantage of propofol in children is pain when it is injected intravenously in a small vein.<sup>759</sup> This pain can be diminished by using any one of a number of strategies, including injecting propofol into a large vein; pretreatment with IV lidocaine (0.5 mg/kg), meperidine, nitrous oxide, metoprolol, or tramadol; and combining a small dose of lidocaine (0.5 to 1.0 mg/kg) with the propofol.\* The most effective method to eliminate pain is to apply a “mini-Bier block” by manually occluding the IV flow by squeezing the extremity proximal to the IV site for 45 to 60 seconds and injecting IV lidocaine (0.5 to 1.0 mg/kg). As soon as the Bier block is released, the desired dose of propofol is administered painlessly (E-Fig. 6-11). The average number of patients who need to be treated to benefit from this maneuver

to prevent pain (*number needed to treat*) in adults is less than two,<sup>763</sup> indicating that this technique is extremely effective,<sup>759</sup> which should make this a routine practice.<sup>765</sup> Parenthetically, any parenteral form of lidocaine, including those that contain preservative, may be administered intravenously, combined with or before propofol, without triggering an anaphylactoid reaction.

The mechanism by which IV propofol causes pain has been attributed to the nociceptive effects of trace concentrations of propofol (15 to 20 µg/mL) in the outer aqueous layer of the Diprivan soybean-oil micelles. When the concentration of propofol in the aqueous outer layer coating the micelles was reduced (i.e., by increasing the concentration of medium-chain triglycerides in the formulation), irritation of the nociceptive nerve endings in the veins and the severity of the pain during injection were attenuated.<sup>766</sup>

Indicators for recovery from anesthesia, such as time to eye opening and time to extubation, are more rapid in children when anesthesia was induced with propofol compared with thiopental.<sup>767-772</sup> Recovery of psychomotor function is more rapid after a propofol induction and maintenance of anesthesia compared with thiopental-isoflurane anesthesia.<sup>773</sup> Recovery room stay and time to hospital discharge are reduced with propofol.<sup>767,769</sup> Emergence delirium rarely occurs after propofol anesthesia in children.<sup>538,774-777</sup> Propofol reduces the incidence of nausea and vomiting when used as an induction agent or when used for the maintenance of anesthesia.<sup>769,778-784</sup> However, there have been conflicting results for particular procedures, such as strabismus repair and tonsillectomy, and when the drug is combined with opioids.<sup>785-788</sup> Nausea and vomiting may be considered surrogate endpoints for serious adverse outcomes after surgery in children. No studies have demonstrated clinically important abbreviated times to discharge or decrease in overnight admission rate for vomiting and/or dehydration in children treated with propofol. Short-term infusions of propofol for surgical or medical procedures have shown that the depth of sedation is easily controlled by adjusting the infusion rate while still ensuring rapid and complete recovery.<sup>789-793</sup> Compared with thiopental, propofol is less irritating to the airway, which translates into a reduced incidence of laryngospasm.<sup>758,794-796</sup> Insertion of a laryngeal mask airway is substantially easier and more successful after a propofol induction compared with thiopental.<sup>718,741,797,798</sup>

Propofol compromises airway patency and respiration in children; the upper airway narrows particularly in the hypopharyngeal region, but it does remain patent.<sup>799</sup> If airway obstruction occurs, the chin lift maneuver augments the patency of the upper airway.<sup>800,801</sup> Theoretically, collapse of the upper airway increases in parallel with the dose of propofol by direct inhibition of genioglossus muscle activity, as well as an inhibition of centrally mediated airway dilatation and airway reflexes.<sup>802</sup> All of these upper airway changes are reversed on emergence from anesthesia.<sup>803</sup> When propofol is given as an IV bolus, transient apnea may occur.<sup>737,742,756</sup> Concerns over atelectasis and airway obstruction have prompted some to insert a tracheal tube or laryngeal mask airway in children sedated with propofol during medical procedures. However, evidence suggests that the incidence of atelectasis in children who are breathing spontaneously with an unprotected airway is less than in those whose tracheas are intubated.<sup>804</sup>

Diprivan and the current lipid-based generic formulations of propofol must be handled with aseptic techniques, because the lipid is a culture medium.<sup>805</sup> Propofol 1% can support the growth of at least four well-known organisms: *Staphylococcus aureus*,

*Pseudomonas aeruginosa*, *Escherichia coli*, and *Candida albicans*.<sup>806-808</sup> When Diprivan was first introduced, it was prepared (as are all lipid emulsions) under strict aseptic conditions, with a layer of nitrogen above the liquid emulsion in each vial.<sup>716</sup> Once opened, external contamination of the vials, however, resulted in severe sepsis and several deaths before antimicrobial agents were mandated to be added to the propofol formulations to prevent or retard bacterial growth. In very small concentrations, EDTA inhibits bacterial growth by chelating vital trace metals without affecting the emulsion droplet size or stability. Other formulations of propofol contain sulfite or metabisulfites, which release sulfur dioxide that prevents bacterial growth. Sulfites are more effective at reduced pH values, but there is a limit to how acidic the emulsion can become because this destabilizes the emulsion droplets. To further prevent any risk of bacterial contamination, all opened vials of propofol should be discarded after 6 hours. These strategies have eliminated concerns of bacterial contamination of propofol and episodes of sepsis.

Long-term propofol infusions were used extensively for sedation in ICUs after recognizing that its favorable PK would facilitate a rapid wake-up.<sup>717</sup> However, a report of five deaths in infants and children (4 weeks to 6 years of age) who were sedated with Diprivan raised serious doubts about the safety of such a practice.<sup>809</sup> The syndrome, now known as propofol infusion syndrome (PRIS), occurs primarily, but not exclusively, in children who are sedated for prolonged periods in ICUs.<sup>809-813</sup> Clinical experience indicates that PRIS is most common when propofol is infused continuously at more than 5 mg/kg/hr (70 µg/kg/min) for more than 48 hours. Manifestations of PRIS include the insidious onset of lipemia, metabolic acidosis, hyperkalemia, and rhabdomyolysis that may precipitously transform into profound myocardial instability and cardiovascular collapse that is refractory to all resuscitative efforts. Manifesting signs may be subtle, with the sudden onset of bradycardia that is refractory to the usual interventions. PRIS was suspected in a 5-year-old undergoing an arteriovenous malformation resection when an unexplained metabolic acidosis was detected after a 6-hour infusion of propofol.<sup>814</sup> When propofol was discontinued, the signs of PRIS abated. In an adult neurosurgical ICU where propofol sedation was used, a retrospective review determined that for every 1 mg/kg/hr that the propofol infusion exceeded 5 mg/kg/hr, the odds ratio of death was 1.93.<sup>815</sup> After a total of at least 28 deaths in children and 14 adults, the FDA cautioned against the use of propofol for long-term sedation. Predisposing risk factors include concomitant catecholamine inotrope infusions or high-dose corticosteroids and sepsis. Mortality currently ranges from 30% to 80%, although early institution of hemodialysis or extracorporeal membrane oxygenation may improve survival.<sup>816</sup>

Unraveling PRIS has proved to be difficult. Early investigations noted that during PRIS, the blood concentrations of malonylcarnitine and C5-acylcarnitine increased. These compounds are known to inhibit carnitine palmitoyl transferase and the transfer of LCT into mitochondria.<sup>817,818</sup> Propofol may also directly inhibit carnitine palmitoyl transferase to impede flux of LCT into the mitochondria. Within the mitochondria, propofol uncouples the  $\beta$  oxidation spiral at complex II in the respiratory chain, which, in turn, inhibits transmembrane flux of LCT into mitochondria, strangling the mitochondria from a much needed source of energy. To reduce the risk of PRIS, new formulations of propofol are being developed that contain less or no LCT. Medium-chain triglycerides are replacing LCTs in propofol. The

clinical importance of these developments requires further investigations with multicenter studies.<sup>819</sup>

The safety of propofol in the neonatal period has raised concerns after reports of profound episodes of cardiorespiratory collapse in neonates.<sup>820,821</sup> In these cases, precipitous and severe decreases in systolic BP, heart rate, and oxygenation were observed after a single induction dose of propofol (1 to 7 mg/kg) in neonates without evidence of congenital heart defects or cardiomyopathy. Resuscitation was extremely difficult in all cases despite intervention with both inotropic and chronotropic agents. A myriad of causes of bradycardia associated with propofol administration have been proposed.<sup>822</sup> In a comprehensive review of bradycardia after propofol in children and adults, the authors concluded that "propofol carries a finite risk for bradycardia with potential for major harm."<sup>823</sup> Whether these responses reflect acute right-to-left shunting, a return to fetal circulation, or another, as yet undisclosed, cause in neonates has not been confirmed; caution should be exercised when propofol is used to induce anesthesia in neonates.<sup>702</sup>

Although anaphylactoid reactions have been reported after propofol administration in children, specific causes for the allergic reaction have not been identified.<sup>824</sup> In some instances, the "reactions" were primarily respiratory and attributed to preservatives, such as metabisulfites.<sup>825</sup> However, 13 of 14 adults who developed anaphylactoid reactions after their first exposure to propofol displayed a hypersensitivity response to propofol with at least one test during immunologic testing.<sup>826</sup> Similar findings in children have not been reported. It has been proposed that first exposure reactions suggest a previous sensitization possibly arising from isopropyl epitopes similar to propofol in cosmetics, detergents and cough medicines.

The package insert for Diprivan cautions against its use in all patients with "egg allergy." However, children with egg allergy (including severe allergy) have received measles-mumps-rubella vaccine, which is derived from eggs, without untoward experience,<sup>827-829</sup> although isolated reactions have been reported. In the past 2 decades, no immunologically verified anaphylactic reactions have been reported in children with egg allergy who received Diprivan. In fact, Diprivan contains egg lecithin which is derived from heated egg yolk. Egg lecithin is a phospholipid and has not been reported to trigger allergic reactions, although trace concentrations of egg yolk, of which only 2 of 9 proteins present, Gal d 5 and Gal d 6, are possibly immunogenic. When propofol was given 43 times to 28 children with egg allergy, only one experienced a mild nonanaphylactoid reaction, which led to their recommendation to avoid propofol only in children with documented anaphylaxis to eggs.<sup>830</sup>

Soy protein allergy is primarily a gastrointestinal allergy that dissipates by 5 to 6 years of age because of repeated exposure to soy protein in foods. Very rarely is soy allergy a systemic disease. Although propofol is a soy based emulsion, the Astra-Zeneca web site states that all protein moieties are removed during the manufacturing process rendering soy an exceedingly unlikely epitope to trigger an immunologically based anaphylactic reaction. The reader should note that there is an approximately 5% cross-reactivity between soy and peanut allergy.<sup>831</sup> In children with both soy allergy and peanut anaphylaxis, it may be prudent to avoid propofol, especially if administering generic formulations.

In an effort to divest propofol of its lipid carrier and pain during IV administration, alternate formulations of propofol have been under development for parenteral use. New

formulations of propofol must satisfy a number of conditions: easy to administer, stable formulation, no or minimal pain on injection, no infectious risk, and rapid PK. Unfortunately, many of the formulations that have been developed to date have failed in one or more of the above criteria. Most recently, a prodrug (fospropofol [Lusedra]) and nonlipid excipients (cyclodextrin, nanoparticle carriers) have shown promise. Clinical trials with fospropofol for sedation in adults have shown promise.<sup>832,833</sup>

Fospropofol, a phosphate-modified prodrug of propofol, undergoes enzymatic hydrolysis in approximately 8 minutes in blood to remove the phosphate moiety yielding the active form of propofol.<sup>834-838</sup> Fospropofol displays similar kinetics to the parent compound, without pain on injection. With the delayed onset of sedation with this prodrug, the slow increase in blood concentrations should reduce adverse respiratory and cardiovascular side effects, but this also slows induction of anesthesia. This formulation carries a minimal risk of microbial infection because there is no lipid excipient. The release of formaldehyde and formate as metabolites of fospropofol are concerns that require further investigation.<sup>832,839</sup> A frequent adverse effect of fospropofol is transient perianal and perineal pain or burning, for which no preventative measure has been forthcoming.<sup>839</sup> There are no published data with fospropofol in children. Currently, further development of fospropofol by the manufacturer has been suspended.

Regarding the nonlipid formulation using  $\beta$ -cyclodextrins, human studies show a large incidence of pain on IV injection that make it a nonviable alternative.<sup>840</sup> In adults, this formulation produced more pain during injection than Diprivan, rendering this formulation unlikely to reach the marketplace. Another formulation of propofol is Aquafol (Daewon Pharmaceutical Co, Ltd, Seoul, Republic of Korea), a nanoparticle microemulsion that contains two polyethylene glycol-based compounds to stabilize the microemulsion.<sup>841</sup> The PD and safety of Aquafol were similar to those of Diprivan in adults, although differences were noted in the PK. In adults, this formulation yielded more pain during IV administration than Diprivan.<sup>842</sup> Unless this issue is addressed, this formulation is unlikely to be used widely in clinical practice.

Finally, some recommend supplanting long-chain triglycerides in propofol with medium-chain triglycerides to reduce the risk of PRIS and pain during injection. When 1% propofol with long-chain triglycerides was compared with 1% propofol in a mixture of medium and long-chain triglycerides, both with 1 mL of 2% lidocaine, the frequency of pain and its intensity during injection were similar.<sup>843</sup>

## KETAMINE

Ketamine (Ketalar) is a derivative of phencyclidine that similarly antagonizes the *N*-methyl-D-aspartate (NMDA) receptor.<sup>844</sup> Its action is related to central dissociation of the cerebral cortex, and it also causes cerebral excitation. The latter property may be responsible for precipitating seizures in susceptible children and the reason that processed EEG monitoring devices do not work with ketamine sedation or anesthesia.<sup>263-265,845,846</sup>

Ketamine is available as a mixture of two enantiomers; the *S*(+) enantiomer has four times the potency of the *R*(-) enantiomer. *S*(+)-ketamine has approximately twice the potency of the other enantiomer. The metabolite norketamine, has a potency that is one-third that of its parent compound. Plasma concentrations associated with anesthesia are approximately 3  $\mu\text{g/mL}$ ,<sup>847</sup> whereas concentrations for hypnosis and amnesia during surgery

**FIGURE 6-18** The relationship between effect compartment concentration and level of ketamine sedation (purple line). The concentration producing 50% of the maximum effect ( $EC_{50}$ ) was 0.562 mg/L. Categorical data are shown as crosses. The brown and blue lines demonstrate the 5% and 95% confidence intervals. (Reproduced with permission from Herd DW, Anderson BJ, Keene NA, Holford NH. Investigating the pharmacodynamics of ketamine in children. *Paediatr Anaesth* 2008;18:36-42.)

are reported to be 0.8 to 4  $\mu\text{g/mL}$ ; awakening usually occurs at concentrations less than 0.5  $\mu\text{g/mL}$ . Pain thresholds are increased at 0.1  $\mu\text{g/mL}$ .<sup>848</sup> The concentration-response curve for ketamine sedation is steep.<sup>65,849</sup> This means that small serum concentration changes will have dramatic effect on the degree of sedation observed (Fig. 6-18).

Ketamine is very lipid soluble with rapid distribution and the onset of anesthesia after IV administration is approximately 30 seconds. This is usually heralded by horizontal or vertical nystagmus (Video 6-1).<sup>850,851</sup> Studies separating equivalent anesthetic doses of ketamine isomers identified a reduced incidence of side effects, more potent analgesia, and fewer cardiovascular effects with the dextro isomer rather than the levo isomer<sup>850,852-855</sup>; acute tolerance has been reported.<sup>856</sup> Children require greater doses of ketamine (per kilogram) than adults because of greater clearance (per kilogram); however, there is considerable patient-to-patient variability.<sup>262,848,850,852</sup>

Ketamine undergoes N-demethylation to norketamine; metabolized mainly by CYP3A4, although CYP2C9, CYP2B6 also have a role. Elimination of racemic ketamine is complicated by the *R*(-)-ketamine enantiomer, which inhibits the elimination of the *S*(+)-ketamine enantiomer.<sup>857</sup> Clearance is immature in neonates but matures to reach adult rates (80 L/hr/70 kg, i.e., liver blood flow) within the first 6 months of life, when described using allometric size models.<sup>858</sup> Clearance in neonates is reduced (26 L/hr/70 kg)<sup>859-861</sup> while  $V_{dss}$  is increased (3.46 L/kg at birth, 1.18 L/kg at 4 years, 0.75 L/kg at adulthood).<sup>859</sup> This larger  $V_{dss}$  in neonates contributes to the observation that neonates require a fourfold greater dose than 6-year-old children to prevent gross motor movement.<sup>862</sup>

Bioavailability after intramuscular (IM) administration is approximately 93% in adults and even greater in children.<sup>848,863,864</sup> There is a high hepatic extraction ratio and the relative bioavailability of oral, nasal, and rectal formulations is 20% to 50% (Table 6-12).<sup>864-866</sup> Children presenting for burn surgery had slow absorption (absorption half-time [ $T_{1/2abs}$ ] was 59 min) with large between-subject variability.<sup>865</sup>

Ketamine is an excellent analgesic and amnestic; the recommended dose for induction of anesthesia is 1 to 3 mg/kg intravenously or 5 to 10 mg/kg intramuscularly.<sup>854,867</sup> The duration of action of a single IV dose is 5 to 8 minutes, with an  $\alpha$ -elimination half-life of 11 minutes, and a  $\beta$ -elimination half-life of 2.5 to 3.0 hours.<sup>868-870</sup> Further supplementary doses of 0.5 to 1.0 mg/kg are administered when clinically indicated. Atropine or another antisialagogue accompanying the initial dose diminishes the production of copious secretions that occur with ketamine.<sup>871,872</sup> Ketamine may also be administered in very low doses intravenously (0.25 to 0.5 mg/kg) or intramuscularly (1 to 2 mg/kg), either alone or in combination with low-dose midazolam (0.05 mg/kg [50  $\mu$ g/kg]), along with atropine (0.02 mg/kg) for sedation, for a variety of procedures, such as oncology evaluations, suture of lacerations, or radiologic interventions.<sup>854,867,873-878</sup> If an antisialagogue is not administered, there is a greater risk for laryngospasm,<sup>879</sup> although guidelines for emergency departments suggest that supplementation with atropine or a benzodiazepine may not be necessary with doses of 1 to 1.5 mg/kg.<sup>880,881</sup> Larger doses of ketamine will produce a state of general anesthesia.<sup>882-884</sup> Even after small doses there is potential for apnea or airway obstruction, particularly when combined with other sedating medications.<sup>882,885,886</sup>

Ketamine has also been administered orally, nasally, and rectally, both as a premedication before general anesthesia and for procedural sedation.<sup>683,683,887-902</sup> Oral ketamine administered as a

The use of ketamine is increasing for postoperative pain management when administered in small doses as an opioid-sparing drug<sup>854,867,919-922</sup>; although a recent meta-analysis documented reduced pain scores and nonopioid sparing effects, it failed to substantiate its efficacy in opioid-sparing (see later discussion). Ketamine has also been used topically to treat mucositis and other painful conditions.<sup>293,923-929</sup> Ketamine increases heart rate, cardiac index, and systemic BP; it also increases pulmonary artery pressure in adults but has a small effect on respiration.<sup>850,930</sup> In children, there is apparently no effect on pulmonary artery pressure provided that ventilation is controlled.<sup>931</sup> If a child is sedated with ketamine but allowed to breathe spontaneously, increases in end-tidal CO<sub>2</sub> could increase pulmonary artery pressures.<sup>932</sup> Ketamine sedation has been shown to maintain peripheral vascular resistance, thus affecting intracardiac shunting less than propofol in children sedated for cardiac catheterization.<sup>933</sup> However, the combination of ketamine and propofol might be superior to either drug alone in this circumstance.<sup>934,935</sup> Ketamine has negative inotropic effects in those who depend on vasopressors.<sup>936</sup> The effect of ketamine on the musculature of the upper airway differs from that of midazolam; in adults, ketamine does not cause airway obstruction, whereas midazolam does.<sup>937</sup> Ketamine has one of the best safety profiles of any anesthetic agent. After unintended overdoses as great as 56 mg/kg IM and 15 mg/kg IV,<sup>938</sup> the duration of sedation persisted for 3 to 24 hours; respiratory depression occurred in four children, whereas tracheal intubation was required in two. When the children who received an overdose were monitored and their airways were maintained, recovery occurred without incident. This report, combined with the minimal effect of ketamine on airway patency, may explain, in part, the successful widespread use of this anesthetic by non-anesthesiologists. However, there remains a small but consistent incidence of adverse airway-related events, such as laryngospasm, apnea, and airway obstruction associated with ketamine, underscoring the need to ensure that the personnel responsible for administering ketamine are trained in advanced airway management. Ketamine also relaxes the smooth musculature of the airway stimulated by histamine<sup>939</sup>; treatment of acute asthma with subanesthetic doses has yielded mixed results.<sup>940-942</sup>

The most common adverse reaction to ketamine is postoperative vomiting, which occurs in 33% of children after anesthesia.<sup>851</sup> Intraoperative and postoperative dreaming and hallucinations occur more commonly in older than in younger children.<sup>851</sup> The incidence of these latter adverse effects may be reduced when ketamine is supplemented with a benzodiazepine.<sup>943,944</sup> One clinical report described two children, each 3 years of age, who had recurrent nightmares and abnormal behavior persisting for 10 months after a single ketamine administration.<sup>945</sup> A soporific environment may reduce the incidence of emergence phenomena.<sup>946</sup>

### Indications

Ketamine is useful for children who are developmentally delayed, or those who become combative because they are too frightened to come to the OR. Ketamine can be used in very low doses (0.25-0.5 mg/kg) for short-term procedures, such as diagnostic spinal punctures and bone marrow aspiration, and in larger doses for angiography and cardiac catheterization. Ketamine may be particularly valuable for burn-dressing changes, suture removal, induction of anesthesia in hypovolemic children, children for whom application of a face mask may prove hazardous (such as with epidermolysis bullosa), and children who require invasive

monitoring before induction of general anesthesia.<sup>850,852,947-949</sup> Ketamine has been successfully used even in neonates with less apparent cardiovascular depression than occurs with halothane or isoflurane.<sup>950</sup>

The role of ketamine for postoperative pain has been recently reviewed using meta-analysis. Administration of ketamine in the OR was associated with decreased postoperative pain intensity and nonopioid analgesic requirement in the postoperative care unit, but failed to exhibit a postoperative opioid-sparing effect in the subsequent 6 to 24 hours.<sup>951</sup>

### Contraindications

Ketamine may produce increases in intracranial pressure (ICP) as a result of cerebral vasodilation; it also increases CMRO<sub>2</sub>. Ketamine may be contraindicated in children with intracranial hypertension.<sup>952,953</sup> This concern regarding ICP has been challenged<sup>954,955</sup>; adult patients whose lungs were mechanically ventilated and who were sedated with a ketamine infusion demonstrated a decrease in ICP after bolus doses of 1.5, 3.0, and 5.0 mg/kg.<sup>956</sup> The caveat is that the tracheas were already intubated, ventilation was controlled, and they were sedated. There may be a use for ketamine sedation in the ICU where there is meticulous attention to airway management and control of ventilation.<sup>955</sup>

A 30% increase in intraocular pressure (IOP) has also been noted; thus, ketamine may be potentially dangerous in the presence of a corneal laceration.<sup>957</sup> In children with active upper respiratory tract infections, copious secretions caused by ketamine may well exacerbate an already irritable airway and result in laryngospasm.<sup>871,879</sup> Ketamine may cause an incompetent gag reflex and thus should not be administered in anesthetic induction doses to children with a full stomach without appropriate airway management. Ketamine may not be useful as the sole anesthetic agent in any surgical procedure in which total control of the child's position is necessary, because purposeless movements frequently occur. Ketamine may be inappropriate in any child with a history of psychiatric or seizure disorder because of its psychotropic and epileptogenic effects.<sup>845,850</sup> In addition, studies in newborn rodents and nonhuman primates correlated ketamine treatment with increased neuronal apoptosis during rapid synaptogenesis.<sup>844,958,959</sup> In neonatal rhesus monkeys, infusions of ketamine (20 to 50 µg/kg/hr) yielded apoptosis after 24 hours but not after 3 hours.<sup>960</sup> At this time, the clinical importance of these findings to humans is unclear, because apoptosis has been studied only in laboratory animals. It is unclear whether these data can be extrapolated from animals to developing humans (see Chapter 23). Similar observations in rodents have been made with isoflurane, nitrous oxide, benzodiazepines, propofol, and other medications commonly used to provide sedation or analgesia and anesthesia to infants. However, current anesthetic practice should not change until rigorous scientific investigations are carried out.<sup>961</sup> Although the administration of ketamine appears simple, its side effects are potentially dangerous. *Ketamine must be administered only by physicians experienced with managing a compromised airway.* We urge that it not be used as a premedication unless given in the presence of continuous supervision by properly trained personnel.

### ETOMIDATE

Etomidate (Amidate) is a steroid-based hypnotic induction agent. It is metabolized principally by hepatic esterases. Concentrations associated with anesthesia are 300 to 500 µg/L. As with most

induction agents, offset of effect is by redistribution; clearance is approximately 1000 mL/min/70 kg in children and adults. Children require a 30% increased bolus dose because of an increased V<sub>1</sub>.<sup>962</sup>

Etomidate is painful when administered intravenously. However, concerns regarding the risks of anaphylactoid reactions and suppression of adrenal function have resulted in most anesthesiologists avoiding this agent in routine cases.<sup>963</sup> Etomidate is very useful in children with head injury and those with an unstable cardiovascular status, such as children with a cardiomyopathy, because of the virtual absence of adverse effects on hemodynamics or cardiac function.<sup>964,965</sup> It is often used by emergency department physicians for management of the airway.<sup>966-968</sup> Commonly used doses include 0.2 to 0.3 mg/kg before administration of a low-dose opioid and a muscle relaxant. Etomidate is often used to facilitate tracheal intubation in critically ill children, that is, those in whom it would seem to offer the most advantage. Because a very large proportion of critically ill children, particularly those resistant to vasopressors, suffer from relative adrenal insufficiency, corticosteroid supplementation may be indicated in such patients in whom etomidate is deemed necessary for their safe airway management.<sup>969,970</sup> (See later discussion, New Drugs in the Pipeline.)

## Neuromuscular Blocking Drugs

### NEUROMUSCULAR MONITORING

The measurement of evoked responses after an electrical stimulus is the standard method for evaluating neuromuscular function. This method allows nearly instantaneous evaluation of the degree of neuromuscular blockade in the unconscious individual. The force of contraction of the thumb, the accelerometer, or the electromyogram may be used to make this assessment.<sup>971</sup> Twitch tension measurements use the force of contraction of the adductor pollicis. This muscle is the only thumb muscle supplied by the ulnar nerve; measurements therefore approach the single-muscle precision of the experimental nerve muscle preparation.<sup>554</sup> The evoked tension of the adductor pollicis in response to stimulation of the ulnar nerve can be recorded by a force displacement transducer (E-Fig. 6-12, *A*). With the electromyogram, the compound muscle action potential is recorded by surface or needle electrodes applied to any muscle, usually the adductor pollicis brevis, the abductor digiti minimi, or the first dorsal interosseous muscle of the hand (see E-Fig. 6-12, *B*). To achieve reproducibility and to ensure full activation of all stimulated nerve and muscle fibers, the stimuli should be supramaximal in intensity, square wave in nature, and no longer than 0.2 millisecond in duration.

Clinically, three types of stimulation are used (E-Fig. 6-13):

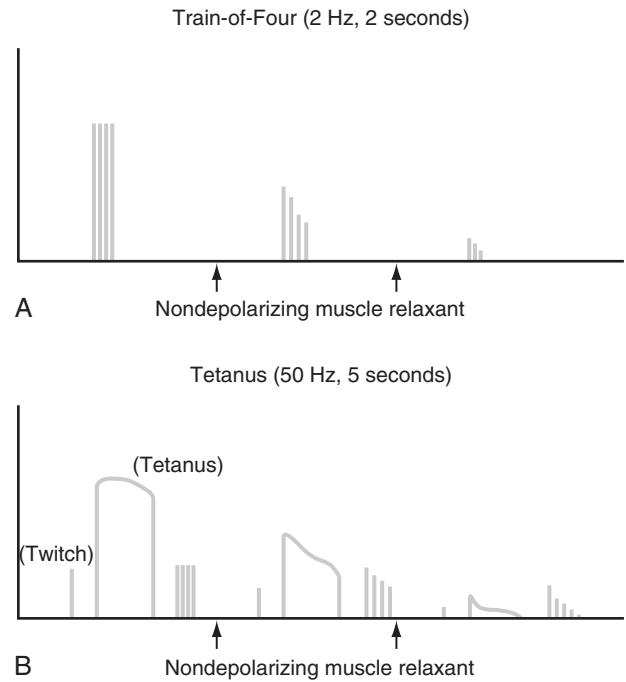

1. Single twitch (0.1 to 0.25 Hz [cycles/second])
2. Train-of-four (2 Hz for 2 seconds)
3. Tetanus (50 Hz, usually for 5 seconds)

*Single-twitch* rates are useful whenever there is an observable control response. By comparing the percentage change of twitch tension before and after administration of the neuromuscular blocking agent, one can assess the degree of paralysis. Single stimuli detect relatively high degrees of neuromuscular blockade. In fact, depression of the twitch response can be observed only if more than three fourths of the postsynaptic receptors are blocked.<sup>972</sup>

The *train-of-four* is the most commonly used method for assessing nondepolarizing neuromuscular blockade. It consists of

**E-FIGURE 6-12** **A**, Arrangement used for studying evoked tensions in infants and children. **B**, Position of electrodes for recording an evoked electromyogram. In a clinical setting and in the absence of recording apparatus, feeling the twitch response is adequate.

**E-FIGURE 6-13** Idealized recording of the effect of nondepolarizing muscle relaxants on the train-of-four and tetanic stimulation. Note in **A** the four equal twitches before the administration of a nondepolarizing muscle relaxant (arrows). After curare, the fourth twitch is less in amplitude than the first (train-of-four). The last sequence indicates greater neuromuscular blockade because only three of the four twitches are observed. **B**, Corresponding single twitch, train-of-four, and tetanus observations at a lower amplification. Note the marked fade and posttetanic facilitation after the second dose of nondepolarizing muscle relaxant (arrows).

four supramaximal stimuli applied to the ulnar nerve at a frequency of 2 cycles/sec. The ratio of the amplitude of the fourth twitch to the first is an indicator of the degree of neuromuscular blockade. The main advantage of the train-of-four is that it does not require a control measurement. Furthermore, the train-of-four technique can be repeated every 10 seconds, thus allowing rapid changes in neuromuscular blockade to be closely monitored.<sup>554</sup> In general, when the train-of-four is zero, the conditions for tracheal intubation are satisfactory (excellent or good).<sup>973</sup> Preterm infants younger than 32 weeks postconceptional age (PCA) have reduced train-of-four fourth-response values ( $83\% \pm 2\%$ ) compared with more mature neonates (E-Fig. 6-14).<sup>974</sup> In full-term infants younger than 1 month of age, the height of the fourth evoked response of the train is about 95%.<sup>975</sup> The change to the greater value during the first month of life probably indicates maturation of the myoneural junction. In children 2 months of age and older, all components of the train-of-four are nearly equal (100%).<sup>974</sup>

*Tetanic stimulation* is usually obtained by supramaximally stimulating the nerve for 5 seconds or more. During tetanic stimulation, synthesis of acetylcholine increases; however, this increase is limited. If the duration of stimulation is too prolonged or the frequency of stimulation is too great, fade occurs; that is, a decrement in the height of tetanus is noted. The usual explanation for the occurrence of fade is that during repetitive stimulation, the acetylcholine output-per-impulse wanes. Under normal circumstances, the diminution of acetylcholine output does not affect transmission because of the continuing excess of both acetylcholine and receptors at the myoneural junction (safety factor). During partial receptor blockade with a nondepolarizing relaxant, the progressive diminution of acetylcholine output eventually results in a decreased number of stimulated receptors and a consequent decrease in the amplitude of contraction. An alternative notion holds that fade is not simply the consequence of a spontaneously occurring decrease in the transmitter action but is, in fact, because of a different and separate action of the drug. This suggests that the relaxant has a prejunctional effect.<sup>976</sup> In infants and children anesthetized with halothane, the percent of fade during tetanic stimulation for 5 seconds at 20 cycles/sec is 5% and at 50 cycles/sec it is 9%.<sup>975</sup> These values are comparable to those for adults.<sup>977</sup> If the duration of stimulation is prolonged, an even greater degree of fade may be noted. In small infants, a more than 50% decrement in the height of tetanus has been observed during 15 seconds of tetanic stimulation; this decrement is even more marked in preterm infants.<sup>978,979</sup> These findings suggest that small infants can indeed sustain short periods of tetanic stimulation, but their musculature becomes fatigued more quickly than that of older children.

The integrity of the myoneural junction can also be analyzed by evaluation of posttetanic facilitation. The increased synthesis and release of acetylcholine that occur during tetanic stimulation continue for a short interval after the stimulation has stopped. This increased production normally does not result in facilitation because all the muscle fibers are excited by the stimulus. In the presence of nondepolarizing (competitive) neuromuscular blockade, however, the increased posttetanic acetylcholine release stimulates a greater number of muscle fibers, producing the characteristic posttetanic facilitation.<sup>977</sup>

The posttetanic count has been used to evaluate intense neuromuscular blockade in children.<sup>980,981</sup> This is a measure obtained by applying a 50 cycle/sec tetanic stimulus to the ulnar nerve for 5 seconds, followed by single-twitch stimulation at 1 cycle/sec;

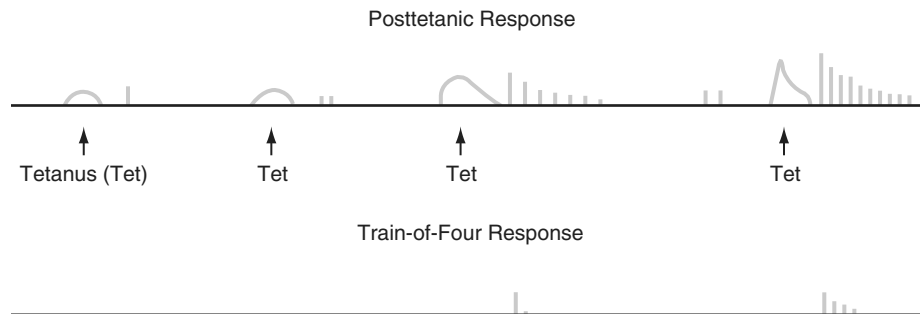

the number of twitches observed in the posttetanic period is known as the posttetanic count (E-Fig. 6-15). Because tetanus and posttetanic responses are indicators of deep neuromuscular blockade, they can usually be elicited during recovery before the reappearance of the train-of-four. At very deep levels of blockade, no tetanus or posttetanic effect can be seen; as the patient recovers, a single posttetanic response eventually manifests itself. The number of posttetanic counts increases as recovery proceeds until, at posttetanic counts of six to seven, the first twitch of the train-of-four reappears. It has been shown that during recovery, the first posttetanic response precedes the first response of the train-of-four by 5 to 10 minutes with intermediate relaxants and by 20 to 30 minutes with long-acting relaxants.<sup>980,981</sup> In a clinical situation in which neuromuscular recording instruments are not available, the number of contractions during train-of-four are counted. This technique depends on the fact that the number of twitches in the train-of-four usually correlates well with the degree of blockade. When the height of the first twitch is about 21% of control, three contractions are usually detected during train-of-four stimulation; at a single-twitch height of 14% of control, two contractions are in evidence, and when the single-twitch height is about 7%, only one contraction is detected.<sup>982</sup> During procedures in which a child's hand is covered by surgical drapes, palpating the number of contractions provides a satisfactory alternative. The number of contractions during train-of-four stimulation thus yields a practical assessment of neuromuscular blockade. For more profound blockade, the posttetanic counts can be used intermittently. However, repeated tetanic stimulation is not ideal because it is painful and can lead to posttetanic exhaustion.

Although twitch monitoring is the standard method of evaluating neuromuscular blockade, the neuromuscular blockade in one group of muscles can differ substantively from that in another. For example, 1.7 times more relaxant is required to block the diaphragm and the vocal cords than the adductor pollicis.<sup>983,984</sup> Nonetheless, recovery of the twitch response is also approximately 50% more rapid in these central muscles. Accordingly, it is conceivable that children could cough or react during intubation in the absence of the twitch response when it is measured peripherally. Perhaps more importantly, when the peripheral twitch response has recovered at the end of the procedure, it is a clear indication that the diaphragm and the vocal cords are in a more advanced stage of recovery. Monitoring the orbicularis oculi contraction (as an estimate of the relaxation of central muscles) to predict whether the conditions for tracheal intubation are suitable, is preferred because it occurs before the twitch response of the adductor muscle of the thumb.<sup>985</sup>

Another method for monitoring neuromuscular blockade is acceleromyography, which uses a piezoelectric sensor to quantify the movement of the thumb, converting this to an electrical signal. There is considerable disagreement in the published literature as to which of these techniques is most accurate.<sup>986-988</sup> Monitors based on acceleromyography are becoming more commonly available; however, these are not "user friendly" and are difficult to use in infants because of the small arc of the displaced thumb. Some consider this monitor to be more accurate than standard mechanomyography based train-of-four monitors.<sup>989,990</sup> Others think that mechanomyography is more accurate because it is "less influenced by external disturbances," i.e., it does not go out of calibration.<sup>991</sup> Therefore, at present, for clinical purposes in infants and children, mechanomyography still seems to be the

**E-FIGURE 6-14** The train-of-four values and tetanus to twitch ratios of critically ill infants younger than 42 weeks developmental age in the neonatal intensive care unit and term infants anesthetized with halothane. Note the evidence of maturation of the myoneural junction in the older children. *mo*, Month; *wk*, week; *yr*, year. (Redrawn from Goudsouzian NG, Crone RK, Todres ID. Recovery from pancuronium blockade in the neonatal intensive care unit. *Br J Anaesth* 1981;53:1303-9.)

**E-FIGURE 6-15** The recovery pattern of train-of-four and posttetanic response after treatment with a nondepolarizing muscle relaxant. Note that despite deep neuromuscular blockade (absent train-of-four) the posttetanic response is evident. The less intense the neuromuscular blockade, the greater the number of posttetanic counts (see text).

simplest and most helpful clinical monitor during the use of nondepolarizing competitive blockers.

### NEUROMUSCULAR JUNCTION

Adult postjunctional acetylcholine receptors possess five subunits—two  $\alpha$  and one  $\beta$ ,  $\delta$ , and  $\epsilon$  subunits. Preterm neonates (less than 31 weeks PMA) have a  $\gamma$  subunit instead of an  $\epsilon$  subunit in their neuromuscular receptor.<sup>992</sup> Fetal receptors have a greater opening time than adult receptors, allowing more sodium to enter the cell, with a consequent larger depolarizing potential. The resulting increased sensitivity to acetylcholine is at odds with the observed increased sensitivity to NMBDs, but may compensate for reduced acetylcholine stores in the terminal nerve endings.<sup>993</sup>

Neuromuscular transmission is immature in neonates and infants until the age of 2 months.<sup>975,994</sup> Neonates deplete acetylcholine vesicle reserves more quickly than do infants older than 2 months, in response to tetanic nerve stimulation.<sup>975</sup> Data from phrenic nerve–hemidiaphragm preparations from rats aged 11 to 28 days suggest this is the result of a low quantal content of acetylcholine in neonatal endplate potentials.<sup>243</sup> Neonates display an increased sensitivity to NMBDs. An alternative proposal to explain this increased sensitivity is based on NMBD synergism observations.<sup>995,996</sup> Neonates display poor synergism and this has been explained on the basis that NMBDs occupy only one of the two  $\alpha$ -subunit receptor sites in neonates as opposed to two in children and adults.<sup>996</sup> If this is true, then neonates may use NMBDs more efficiently than children.

Preterm infants tolerate respiratory loads poorly. The diaphragm in the preterm neonate contains only 10% of the slowly contracting type I fibers. This proportion increases to 25% at term, and to 55% by 2 years of age.<sup>245</sup> A similar maturation pattern has been observed for the intercostal muscles.<sup>245</sup> Type I fibers tend to be more sensitive to NMBDs than type II fibers, and consequently the diaphragmatic function in neonates may be better preserved and recover earlier than peripheral muscles.<sup>984,997-999</sup>

Total body water and extracellular fluid (ECF)<sup>1000</sup> are greatest in preterm neonates and decrease throughout gestation and postnatal life, whereas fat as a percentage of body weight increases with postnatal age. Muscle contributes only 10% of body weight in neonates, and 33% by the end of childhood. Polar drugs, such as depolarizing and nondepolarizing NMBDs, distribute rapidly into the ECF, but enter cells more slowly. Consequently, a larger initial dose of such drugs is required in infants compared with children or adults. Increasing the muscle bulk contributes new acetylcholine receptors. This greater number of receptors requires a greater amount of drug to block activation of receptor ion channels.

### PHARMACODYNAMICS

There is age-related variability in the dose required to achieve a predetermined level of neuromuscular blockade during balanced thiopental–N<sub>2</sub>O–fentanyl anesthesia. The ED<sub>95</sub> of vecuronium was 47  $\pm$  11  $\mu$ g/kg in neonates and infants, 81  $\pm$  12  $\mu$ g/kg in children between 3 and 10 years of age and 55  $\pm$  12  $\mu$ g/kg in children aged 13 years or older (Fig. 6-19).<sup>1001</sup>

Similar profiles have been reported for other NMBDs.<sup>984,1002-1005</sup> In addition, duration of neuromuscular blockade is greater in neonates than in children.<sup>1006</sup> The reduced dose requirement in neonates is attributable to immaturity of the neuromuscular junction. The increased Vd from an expanded ECF in neonates means

**FIGURE 6-19** Dose changes with age for vecuronium during balanced anesthesia. ED<sub>50</sub> is the dose that achieves 50% of the maximum response; ED<sub>95</sub> is the dose that achieves 95% of the maximum response. (Data extracted from Meretoja OA, Wirtavuori K, Neuvonen PJ. Age-dependence of the dose-response curve of vecuronium in pediatric patients during balanced anesthesia. *Anesth Analg* 1988;67:21-6.)

a similar initial dose (per kilogram) is given to neonates and teenagers. Children tend to require larger doses than adults; the reason for the larger dose requirement in children is unclear but it may be the result of increased muscle bulk.

Investigation of concentration–response relationships is more revealing. The plasma concentration required in neonates to achieve the same level of neuromuscular block as in children or adults is 20% to 50% less, consistent with immaturity of the neuromuscular junction.<sup>85,1007-1010</sup> Plasma concentration requirements are reduced by volatile anesthetic agents.<sup>559,1011,1012</sup>

The onset time for NMBDs in neonates is faster than it is in older children and adults. Onset time (time to maximal effect) after vecuronium 70  $\mu$ g/kg was most rapid for infants (1.5  $\pm$  0.6 min) compared with that for children (2.4  $\pm$  1.4 min) and adults (2.9  $\pm$  0.2 min).<sup>1006</sup> These observations are similar to those reported for other intermediate- and long-acting NMBDs.<sup>999</sup> The more rapid onset of these drugs in neonates has been attributed to a greater cardiac output seen with the per-kilogram model.<sup>999</sup>

Cardiac output is used as a surrogate measure for muscle perfusion. Onset time is a function of size. An onset time standardized to a 70 kg person using an allometric  $\frac{1}{4}$ -power model is around 3 minutes for most long acting NMBDs. In children with low cardiac output or decreased muscle perfusion, onset times are prolonged. The onset time of neuromuscular paralysis is proportional to  $T_{1/2keo}$ . An increase in the  $T_{1/2keo}$  of *d*-tubocurarine with increasing inspired halothane concentration has been demonstrated.<sup>267</sup> The reason for the delayed action of tubocurarine may be that halothane is a negative inotrope<sup>268</sup> and decreases muscle blood flow.<sup>1013</sup>

### PHARMACOKINETICS

The dose of NMBDs at different ages depends on the complex interweaving of PD and PK factors. The Vd mirrors ECF changes and can be predicted using either an allometric  $\frac{3}{4}$ -power model or the surface area model ( $\frac{2}{3}$ -power model), both of which approximate ECF changes with weight.<sup>67</sup>

The clearance of *d*-tubocurarine, standardized to an allometric or surface area model, is reduced in neonates and infants

compared with older children and adults.<sup>85</sup> These age-related clearance changes follow age-related maturation of glomerular filtration in the kidney,<sup>175</sup> which is the elimination route of *d*-tubocurarine. Total plasma clearance of other nondepolarizing muscle relaxants cleared by renal (alcuronium) and/or hepatic pathways (pancuronium, pipecuronium, rocuronium, and vecuronium) are all reduced in neonates.<sup>1007,1009,1014-1016</sup> In contrast, the clearances of atracurium and cisatracurium are neither renal- nor hepatic-dependent but rather depend on Hofmann elimination, ester hydrolysis, and other unspecified pathways.<sup>1017</sup> Clearance of these drugs is increased in neonates when expressed as per kilogram.<sup>1018-1020</sup> When clearance is standardized using allometric  $\frac{3}{4}$ -power scaling, the clearances for atracurium and cisatracurium are similar throughout all age groups. The clearance of succinylcholine, expressed as per kilogram, also decreases as age increases.<sup>209,210</sup> Succinylcholine is hydrolyzed by butyrylcholinesterase. These observations are consistent with that observed for the clearance of remifentanyl,<sup>52</sup> which is also cleared by plasma esterases. These clearance pathways are mature at birth.<sup>53</sup>

Conversion of *d*-tubocurarine half-times from chronologic time to physiologic time is revealing.  $T_{1/2\alpha}$  increases with age in chronologic time, but in physiologic time it is the same at all ages, as we would expect from a distribution phase standardized by allometry.  $T_{1/2\beta}$  decreases with age in physiologic time, consistent with reduced clearance related to the greater  $V_d$  in the very young. The  $T_{1/2\text{keo}}$  is large in neonates and infants, reduced in children, and further reduced in adults, possibly because of increased muscle bulk and concomitant increased muscle perfusion in older children and adults.

## SUCCINYLCHOLINE

Succinylcholine is the only depolarizing relaxant used in children. Infants are more resistant to its neuromuscular effects than adults.<sup>1021</sup> Early studies demonstrated that the degree of neuromuscular blockade achieved by 1 mg/kg IV in infants is about equal to that produced by 0.5 mg/kg in older children.<sup>1022</sup> The increase in dose requirement in younger children is thought to result, in part, from the drug's rapid distribution into the infant's large ECF volume (E-Table 6-4 and Table 6-13).

Succinylcholine remains the NMBD with the most rapid onset. The onset time of a paralyzing dose (1.0 mg/kg) of succinylcholine is 35 to 55 seconds in children and adolescents; the onset time after 3 mg/kg in neonates is faster (30 to 40 sec).<sup>1023</sup> Onset time is dependent on both age and dose; the younger the child and the greater the dose, the shorter the onset time.

As in adults, administration of a continuous infusion of succinylcholine in infants and children can result in tachyphylaxis (increased requirement). In addition, phase II block may be produced, as evidenced by a train-of-four less than 50% (blockade similar to that produced by nondepolarizing muscle relaxants). In children, tachyphylaxis generally develops after administration of about 3 mg/kg of succinylcholine, and phase II block develops during tachyphylaxis after 4 mg/kg.<sup>210,1024</sup>

Succinylcholine is effective when administered by the IM route; in this instance, complete paralysis is achieved in 3 to 4 minutes. Evidence of relaxation of the respiratory muscles, as manifest by decreased positive pressure required to ventilate by face mask, can be detected before the abolishment of the twitch response. A dose of 2 mg/kg IM does not achieve satisfactory relaxation in all children, whereas the higher dose of 3 mg/kg IM produces a mean twitch depression of 85%; 4 mg/kg produces

**TABLE 6-13** Suggested Standard Intubating Doses of Commonly Used Relaxants in Infants and Children

	Infants (mg/kg)	Children (mg/kg)
Succinylcholine	3	1.5-2
Cisatracurium	0.1	0.1-0.2
Atracurium	0.5	0.5
Rocuronium*	0.25-0.5	0.6-1.2
Pancuronium	0.1	0.1
Vecuronium	0.07-0.1	0.1

(See text for source data.)

\*Low-dose rocuronium (0.3 mg/kg) allows tracheal intubation after 3 minutes during inhalational anesthesia in children, but then is easily antagonized in about 20 minutes. Large-dose rocuronium (1.2 mg/kg) may be used as a substitute for succinylcholine for rapid intubation in children.

profound relaxation in all children, but its effects may last up to 20 minutes.<sup>1025</sup> In infants younger than 6 months of age, a dose of 5 mg/kg IM is required to achieve profound relaxation; maximal twitch depression occurred a mean of  $3.3 \pm 0.4$  minutes.<sup>1026</sup> Recovery from the neuromuscular effect of IM succinylcholine is faster in infants than in children. Changes in the heart rate after IM succinylcholine are not pronounced. Consequently, routine IM administration of atropine with IM succinylcholine is not generally indicated.<sup>1027</sup> Succinylcholine has also been administered intralingually.<sup>1028,1029</sup> One study examined the time to clinical apnea in 60 children younger than 10 years of age. Succinylcholine (1.1 mg/kg) resulted in apnea in  $75 \pm 4$  seconds when administered intralingually, in  $35 \pm 1$  seconds when administered intravenously, and in  $210 \pm 17$  seconds when administered intramuscularly.<sup>1029</sup> In that study, 8 of 10 children given intralingual succinylcholine who did not receive concomitant atropine developed an arrhythmia (primarily bradycardia).

In an emergency, an alternate route for administration of succinylcholine (3 mg/kg) when an IV line is not in place should offer a fairly rapid onset of relaxation. Intralingual administration with an onset of 133 sec, is significantly more rapid than after IM injection, 295 sec.<sup>1028</sup> Caution should be exercised, however, when administering sublingual or intralingual medications. To preclude an intralingual hematoma, it is advised that a 25-gauge needle be used and the blood vessels on the undersurface of the tongue identified to minimize the risk of puncture. Sublingual succinylcholine is an alternative to the IV route, but it should be preceded by a vagolytic agent to avoid arrhythmias. The submental approach would seem to avoid the potential for causing bleeding from the tongue.

## Cholinesterase Deficiency

Plasma cholinesterase (pseudocholinesterase) is a circulating glycoprotein that metabolizes succinylcholine into succinylmonocholine. Activity of plasma cholinesterase may decrease as a result of a congenital enzyme variant or an acquired cause. This enzyme codes at the E1 locus of the long arm of chromosome 3. Ninety-six percent of the population is homozygous for the "usual" cholinesterase enzyme and 4% are homozygous or heterozygous for the variant alleles.<sup>1030</sup> Five alleles code for the majority of cholinesterase enzyme: (1) normal cholinesterase enzyme, which is designated by "usual" ( $E^u$ ); (2) decreased cholinesterase activity or quantity, which is designated as atypical ( $E^a$ ) (homozygote in 1:3000 to 1:10,000); (3) fluoride resistant allele ( $E^f$ )

**E-TABLE 6-4** Effective Doses ( $ED_{95}$ ,  $\mu\text{g/kg}$ ) of Commonly Used Relaxants in Neonates, Infants, Children, and Adults

	Neonates	Infants	Children	Adults
Succinylcholine	620	729	423	290
Atracurium	120	156-175	170-350	110-280
Vecuronium	47	42-47	56-80	27-56
Rocuronium	ND	255	402	350
Cisatracurium	ND	ND	41	32-50

See text for details.  
 $ED_{95}$ , Dose that achieves 95% of the maximum response; *ND*, no published data at the time of writing this chapter.

(homozygote in 1:150,000); (4) silent allele ( $E^s$ ) (homozygote 1:10,000); and (5) the Cynthiana ( $C_s$ ) or Neitlich variant, which is associated with an increase in (or rapid) cholinesterase activity.<sup>1031</sup> Variations on the silent gene have been detected in Eskimo populations with three variants labeled: S for silent, T for trace, and R for residual. The duration of succinylcholine in children who are homozygous for the silent gene may be up to 6 to 8 hours. Additional genetic variants of pseudocholinesterase have been identified, including types H, J, and K, which represent a 60%, 66%, and 30% reduction in enzyme activity, respectively.<sup>1030</sup> Evidence suggests that K variant occurs in 13% of the random population and that K/K homozygous variant may be present in 1:63 population, one of the most common variants with a duration of prolonged blockade of less than 1 hour. Moreover, K variants have occurred in the presence of other mutations suggesting that multiple mutations may be present in the same patient.

Heterozygote atypical ( $E^uE^a$ ), which occurs in 1:30 of the population, may prolong neuromuscular blockade by only a few minutes and may go undetected. In contrast, homozygote atypical ( $E^uE^a$ ), which occurs in approximately 1:3000 population, may cause paralysis for up to 1 hour after a single dose of succinylcholine. Of the genetic variants of cholinesterase, silent gene ( $E^s$ ) confers the least plasma cholinesterase activity and therefore the most prolonged duration of paralysis. Homozygote ( $E^sE^s$ ) occurs in 1:10,000 population and may result in 8 hours of paralysis. Plasma cholinesterase activity is more often diminished when a genetic variant is present, but a number of clinical conditions may also reduce its activity. These include severe liver disease, malnutrition, organophosphate poisoning, severe burns, renal failure, plasmapheresis, and medications (cyclophosphamide, echothiophate iodide, oral contraceptives).<sup>1030,1032,1033</sup> Several conditions are associated with increases in plasma cholinesterase activity, including thyroid disease, obesity, nephrotic syndrome, and cognitively challenged children.<sup>1030,1034-1036</sup>

Plasma cholinesterase activity is determined by the percent inhibition of benzyl choline degradation by the amide local anesthetic dibucaine when it is incubated with a sample of plasma. With the homozygous normal allele ( $E^uE^u$ ), dibucaine profoundly inhibits plasma cholinesterase activity (approximately 80%), whereas with the homozygous atypical allele ( $E^uE^a$ ), it inhibits the activity by only 20%. When fluoride is added to the plasma, fluoride inhibits  $E^uE^u$  60% but inhibits  $E^uE^a$  only 36%. Thus, a low dibucaine number indicates a deficiency of plasma cholinesterase.

### Adverse Effects of Succinylcholine

#### Temporomandibular Joint Stiffness

IV succinylcholine is infrequently associated with an increase in masseter muscle tone that limits mouth opening (trismus), particularly when given during halothane anesthesia. The incidence of isolated trismus when IV succinylcholine is administered during halothane anesthesia, 0.3% to 1%, is severalfold greater than that after IV thiopental and succinylcholine, 0/4457 (upper 95% confidence of 7/10,000).<sup>1037,1038</sup> The increase in masseter muscle tone after succinylcholine is transient, lasting for only a few minutes and occurring despite abolition of the evoked twitch response in the masseter and peripheral muscles. The increase in masseter muscle tone is usually mild and can be overcome by manually distracting the mandible.<sup>1039</sup> However, on rare occasions, the increase in muscle tone may be so severe that mouth opening is impossible, thus interfering or preventing tracheal

intubation. Whether this increased tone is related to the “trismus” (so-called “jaws of steel”) (see Fig. 40-2) encountered in children with MH remains a matter of debate.<sup>1040</sup> Prospective studies designed to evaluate masseter muscle tone have failed to demonstrate a child with a marked increase in masseter tone who later developed evidence of MH.<sup>1041,1042</sup> In several retrospective reports, however, a number of children experienced severe trismus and did develop or have a positive test response for MH.<sup>1043-1045</sup> These studies failed to clarify how best to proceed when severe trismus occurs. Some advocate canceling the surgical procedure, treating the child as susceptible to MH, and recommending a muscle biopsy.<sup>1045,1046</sup> This recommendation is based on a 50% incidence of positive muscle biopsies for MH in children who developed severe trismus after succinylcholine. Others advocate continuing the procedure, avoiding further exposure to triggering agents by changing the anesthetic technique to one that is free of triggers, observing for signs of MH (e.g., increased  $CO_2$  production or tachycardia), and, if indicated, initiating arterial and central venous blood gas sampling, as well as early treatment.<sup>1047,1048</sup> Finally, others have advocated continuing with the original triggering anesthetic while monitoring for signs of MH.<sup>1037</sup> For the most part, this entire issue has become moot because sevoflurane has supplanted halothane as the primary inhaled anesthetic in children and the FDA issued a “black box” warning regarding the routine use of succinylcholine for tracheal intubation in children. Curiously, the now widespread use of nondepolarizing relaxants has generated several purported reports of masseter muscle rigidity after use of these agents. Whether these cases actually represent nondepolarizing relaxant-induced masseter spasm or a combination of light anesthesia and incomplete muscle relaxation is unclear.<sup>1049-1051</sup>

#### Arrhythmias

The molecular structure of succinylcholine resembles that of two acetylcholine molecules joined by an ester linkage. The consequent stimulation of cholinergic autonomic receptors can be associated with cardiac arrhythmias, increased salivation, and bronchial secretions. Changes in heart rate are frequently observed after treatment with succinylcholine. Heart rate usually increases transiently and this response appears to be more pronounced in the presence of sevoflurane than halothane.<sup>1052</sup> Succinylcholine-associated arrhythmias are rarely a result of ventricular irritability. Prior IV administration of an anticholinergic agent (e.g., atropine) markedly decreases, but does not completely abolish, the incidence of these arrhythmias.<sup>1053</sup> As in adults, the incidence and severity of these irregularities in heart rate increase after a second dose.<sup>1029,1054</sup> Of greater concern is the occasional bradycardia and asystole after a single dose in children.<sup>1053</sup> Accordingly, it is recommended that a vagolytic agent precede the IV administration of succinylcholine unless there is a contraindication to such medications.

#### Hyperkalemia

Succinylcholine-induced muscle fasciculation is also associated with mild hyperkalemia, increased intragastric and intraocular pressure, and skeletal muscle pains; rhabdomyolysis and myoglobinemia may occur in those patients suffering neuromuscular disorders. These disorders are not always diagnosable in neonates. Congenital myotonic dystrophy, for example, may present with mild respiratory dysfunction or feeding difficulty in the neonate. The response to succinylcholine in these neonates, however, remains dramatic, with sustained muscle contraction.<sup>1055</sup>

The serum potassium concentration increases 1 mEq/L or less after IV succinylcholine in normal children; this increase does not cause arrhythmias.<sup>1056</sup> However, life-threatening hyperkalemia can occur after a single IV dose of succinylcholine in children with burns (more than 8% body surface area burn), those who are immobile, or who have chronic infections (including intra-abdominal sepsis and *Clostridium*), upper motor neuron lesions (e.g., paraplegia, encephalitis), lower motor neuron lesions (e.g., tetanus, neuropathy complicating nephropathy), crush injuries, and neuromuscular diseases (including Werdnig-Hoffman disease).<sup>1057-1064</sup> In these situations, direct denervation injury or a pseudo-denervation state (immobilization) leads to a proliferation of extrajunctional normal acetylcholine receptors, as well as proliferation of immature (containing  $\gamma$  subunits) and nicotinic (neuronal) acetylcholine receptors, along the muscle membrane, so that the entire muscle becomes capable of releasing potassium during depolarization.<sup>1064</sup> These immature and nicotinic acetylcholine receptors release more intracellular potassium and for a longer period after the channels open, than do the usual acetylcholine receptors. The presence of extrajunctional receptors has been documented within several hours of injury, although clinically significant hyperkalemia does not seem to occur until 1 to 3 days after injury. Thus, administration of succinylcholine to children with these injuries may result in a massive efflux of intracellular potassium, leading to a cardiac arrest.<sup>1065</sup> In contrast to these acquired conditions, children who are born spastic quadriparetic from cerebral palsy or those with a myelomeningocele respond with a normal increase in serum potassium concentration (less than 1 mEq/L) after IV administration of succinylcholine.<sup>1065-1067</sup> The definitive treatment of succinylcholine-induced hyperkalemia is IV calcium (10 mg/kg calcium chloride or 30 mg/kg calcium gluconate or more). This restores the gap between the resting membrane potential of the cardiac cells and the threshold potential for depolarization. Repeated doses of calcium may be required, together with cardiopulmonary resuscitation, epinephrine, sodium bicarbonate, hyperventilation, inhaled albuterol (or intravenous salbutamol), or glucose and insulin, until the arrhythmias abate. Defibrillation of the heart has no role in this circumstance. Successful treatment of hyperkalemia might require a very prolonged resuscitation. Sodium polystyrene sulfonate by nasogastric or rectal administration may be required for leaching potassium after acute redistribution between extracellular and intracellular spaces by the above measures (see Chapters 8, 26, and 39).

### Biochemical Changes

Serum creatine kinase concentrations may increase after administration of succinylcholine in the presence of inhalational agents, especially halothane.<sup>1068</sup> This increase is less pronounced during a thiopental-nitrous oxide anesthetic but more pronounced in children with neuromuscular disease.<sup>1069</sup> After a malignant hyperthermia reaction, creatine kinase reaches its peak 12 to 18 hours after the onset of the reaction. It may also be found in association with a “jaws of steel” response to succinylcholine.

### Rhabdomyolysis

Rhabdomyolysis can occur after halothane or sevoflurane,<sup>1070</sup> even in the absence of succinylcholine as in the case of Duchenne and Becker muscular dystrophy. Isolated rhabdomyolysis or rhabdomyolysis in combination with hyperkalemia as in the case of Duchenne muscular dystrophy, requires hyperhydration with alkalinization of the urine to prevent acute tubular necrosis from deposition of myoglobin.

### Myoglobinemia

Myoglobinemia, another sensitive indicator of muscle injury, may occur after succinylcholine treatment, but rarely leads to myoglobinuria (i.e., “cola”-colored urine).<sup>1071</sup> If it occurs, it should be aggressively treated as described previously for rhabdomyolysis.

### Fasciculations

Fasciculations are usually observed in adolescents and children but rarely in infants; in children 1 to 3 years old they are described as gross muscle movements.<sup>1068,1072</sup> Pretreatment with small doses of succinylcholine (100  $\mu$ g/kg), pancuronium (20  $\mu$ g/kg), fentanyl (1 to 2  $\mu$ g/kg), or alfentanil (50  $\mu$ g/kg) may decrease the frequency and intensity of the fasciculations and the consequent rise of intragastric pressure.<sup>1068,1072-1075</sup> This increase in intragastric pressure, however, is offset by the increase in skeletal muscle tone of the crura of the diaphragm, thereby actually increasing the barrier to regurgitation.

### Intraocular Pressure

Intraocular pressure increases transiently in children after IV succinylcholine independent of the presence of fasciculations.<sup>1076</sup> The exact mechanism of this increase in IOP is not clear. Initially, the increase in IOP was attributed to tonic contractions of extraocular muscles but it is probably because of the cycloplegic action of succinylcholine, with deepening of the anterior chamber and increased outflow resistance. The IOP usually increases by about 10 mm Hg, peaks in 2 to 3 minutes, and then returns to baseline in 5 to 7 minutes.<sup>1076</sup> It is advisable to perform applanation tonometry before succinylcholine, or wait at least 7 minutes after succinylcholine before performing tonometry in children. Although the use of succinylcholine in children with open eye injuries has not resulted in further damage to the eye,<sup>1077</sup> it is nonetheless prudent to refrain from its use in situations of penetrating ocular wounds unless the eye is not salvageable. High-dose rocuronium (1.2 mg/kg) is a reasonable substitute for succinylcholine rapid-sequence intubation in these circumstances.<sup>1078</sup>

### Clinical Uses of Succinylcholine

The use of succinylcholine for routine surgical procedures in children has been abandoned, primarily because of the rare but life-threatening possibility of cardiac arrest in male children with undiagnosed muscular dystrophy.<sup>1079,1080</sup> On the other hand, succinylcholine does have the most rapid onset and brief duration of action of all currently available muscle relaxants. Consequently, succinylcholine is desirable for rapid-sequence tracheal intubation for brief procedures and for the treatment of laryngospasm.<sup>1023,1081,1082</sup> Because the rapidity of onset is dose related, 1.5 to 2.0 mg/kg IV succinylcholine should be administered to children to depress the neuromuscular twitch 95% within 40 seconds; the smaller dose of 1.0 mg/kg would achieve the same degree of depression in about 50 seconds.<sup>1023,1081</sup> In infants younger than 1 year of age, 3 mg/kg IV would be an appropriate dose because of the larger Vd. These doses provide excellent intubating conditions in all children.<sup>1023</sup> To decrease the incidence of arrhythmias after succinylcholine (particularly after a second dose), atropine 0.01 to 0.02 mg/kg IV should precede the succinylcholine.

In 1993 the FDA issued a “black box” warning against the routine use of succinylcholine in children and adolescents except for emergency airway management. This was based on several

case reports of hyperkalemic cardiac arrests, primarily in children with undiagnosed Duchenne muscular dystrophy.<sup>1083</sup> The disturbing observation about this complication was the staggering mortality rate of 55%. Almost all of these cases, however, occurred in male children 8 years old and younger. In many instances the arrhythmias were misdiagnosed as MH and not treated with IV calcium in a timely manner. Subsequently, the FDA and the manufacturer revised the product label (package insert) to read:

*Since there may be no signs or symptoms to alert the practitioner to which patients are at risk, it is recommended that the use of succinylcholine should be reserved for emergency intubation or in instances where immediate securing of the airway is necessary, e.g., laryngospasm, difficult airway, full stomach, or for intramuscular route when a suitable vein is inaccessible.*

In cases in which the child has eaten and is at risk for a hyperkalemic response to succinylcholine, a standard rapid-sequence intubation with equivalent intubation conditions may be performed using high-dose rocuronium (1.2 mg/kg).<sup>1078</sup> The main disadvantage of using a nondepolarizing relaxant is that the duration of the nondepolarizing relaxant may exceed the duration of the planned procedure. A new agent that antagonizes rocuronium (sugammadex) will likely solve the dilemma and allow rapid intubation with rocuronium, even for brief emergency procedures, while avoiding the need to use succinylcholine (see later discussion).<sup>1084-1087</sup>

## Intermediate-Acting Nondepolarizing Relaxants

### ATRACURIUM

Chemically, atracurium (Tracrium) is an imidazoline bisquaternary compound that undergoes spontaneous decomposition into inactive metabolites. At physiologic (alkaline) pH, it undergoes enzymatic hydrolysis independent of plasma cholinesterase (Hofmann elimination), ester hydrolysis, and other unspecified pathways.<sup>1017</sup> In blood and other tissue fluids, the quaternary ammonium compound breaks down primarily into laudanosine and a related quaternary acid (methylacrylate). The elimination half-life of atracurium is similar in infants and children (14 to 20 minutes). The steady state plasma concentration resulting in 50% neuromuscular block (EC<sub>50</sub>) did not differ between infants, children, or adults (363, 444, or 436 ng/mL, respectively).<sup>1008</sup>

For intubating purposes, two to three times the ED<sub>95</sub> (300 to 600 µg/kg) is given to produce effective blockade in most children.<sup>1088,1089</sup> Such doses provide satisfactory conditions for intubation within 2 minutes. The period of absence of twitch response after an intubating dose of atracurium usually lasts 15 to 30 minutes. Hence, in clinical situations, an intubating dose should provide complete neuromuscular blockade for such an interval, followed by another 20 minutes of intermediate blockade (twitch height 5% to 25%); complete recovery usually occurs within 40 to 60 minutes. Comparison of data from children and adults demonstrate that children require more atracurium per kilogram and generally recover faster. This difference, however, is relatively small and is masked in most cases by the wide range of individual patient responses.

Because atracurium is degraded spontaneously, and its metabolites do not have neuromuscular blocking properties, it can be

easily administered by continuous infusion. The infusion requirement to maintain 90% to 99% twitch depression in children is 6 µg/kg/min during isoflurane anesthesia, 7 to 8 µg/kg/min with halothane, and 9 µg/kg/min with a N<sub>2</sub>O:O<sub>2</sub> opioid technique.<sup>559,560</sup> No significant differences in the Vd, clearance, or half-lives have been detected for atracurium between normal infants and children with impaired hepatic function.<sup>1018</sup> Plasma laudanosine concentrations tend to be greater in children with hepatic impairment than in children with normal hepatic function.<sup>1018</sup>

The side effects of atracurium are minimal. At clinical doses of up to 600 µg/kg, the compound does not significantly alter the heart rate or BP in children. Mild cutaneous flushing reactions are sometimes observed.<sup>1088</sup> Extremely rare instances of anaphylactoid reactions or bronchospasm have been reported.

### CISATRACURIUM

Cisatracurium (Nimbex) is one of the 10 stereoisomers of atracurium (1*R*-cis, 1'*R*-cis). Cisatracurium is three times more potent than atracurium, with the same duration of action.<sup>1090</sup> Similar to other nondepolarizing relaxants, its onset can be accelerated by increasing the dose (see E-Table 6-4 and Table 6-13); as with the other relaxants, this will increase the duration of the action. Cisatracurium, like atracurium, is a noncumulative agent with recovery occurring during the elimination phase rather than during the distribution phase.

Cisatracurium has a slightly slower onset of action than atracurium, consistent with its relative potency. Twice the ED<sub>95</sub> dose (80 µg/kg) of cisatracurium leads to complete suppression of the twitch response in 2.5 minutes. The recovery to 25% and 95% of control response occurs in 31 and 53 minutes, respectively.<sup>1090-1093</sup> Its histamine-releasing effects are minimal; its duration and recovery profile are essentially the same as atracurium.

The distribution and elimination half-lives of cisatracurium in children are 3.5 and 23 minutes, respectively. The Vdss and the total body clearance are greater (expressed as mg/kg, see Fig. 6-4) than in adults, thus explaining the faster recovery in children.<sup>1019</sup> In adults with renal failure, the clearance of cisatracurium is reduced by 13%; plasma laudanosine levels were greater but were only about 10% of those reported with atracurium.<sup>1094</sup> The duration of action of cisatracurium in renal failure patients is not significantly prolonged.<sup>1095</sup> It should be noted that patients receiving chronic anticonvulsant therapy (carbamazepine or phenytoin) can develop a moderate resistance to the action of cisatracurium.<sup>1096</sup>

### VECURIUM

Vecuronium is the monoquaternary homologue of pancuronium in which the methyl group of the 2β-nitrogen atom is absent. The Vd is greater in infants than in children (357 ± 70 vs. 204 ± 116 mL/kg), whereas plasma clearances are similar (5.6 ± 1.0 vs. 5.9 ± 2.4 mL/kg/min).<sup>1007</sup>

Its primary advantage is the absence of any adverse cardiovascular effects even in doses several times greater than the usually recommended clinical doses (see E-Table 6-4 and Table 6-13).<sup>1097</sup> Vecuronium is primarily metabolized by the liver and excreted in bile.<sup>1098</sup> Dose requirements according to age groups are much more pronounced (more than 50%), with a biphasic distribution of the dose requirement and duration of action; infants younger than 1 year of age are significantly more sensitive to the action of vecuronium than are older children. As adolescence is reached, the requirement diminishes to that of adults.<sup>1001,1006,1099,1100</sup>

However, on rare occasions there may be resistance to vecuronium in neonates.<sup>1101</sup>

Neuromuscular blockers are often administered to critically ill children. Vecuronium has been popular because of the absence of cardiovascular side effects and because its metabolites do not seem to have CNS effects. However, adult and pediatric patients in ICUs have had residual weakness after the discontinuation of vecuronium, possibly contributed by active 3-OH metabolite or its steroid-like structure.<sup>1102-1104</sup> In one study in which the rate of infusion was adjusted by accelerometry, all children recovered within 1 hour. Of note in these children, the requirements of neonates and small infants was 45% less than those of older children.<sup>1105</sup> In this respect, cisatracurium seems to offer an advantage because its recovery from prolonged infusion in children is faster than that of vecuronium.<sup>1106</sup>

## ROCURONIUM

Rocuronium (Zemuron) is a monoquaternary steroidal muscle relaxant similar to vecuronium. It has the fastest onset of action of the intermediate-acting nondepolarizing relaxants because of its low potency and greater dose requirements.<sup>1107</sup> The onset time of rocuronium is 1 to 1.5 minutes following a  $2 \times \text{ED}_{95}$  dose; this is 20 to 70 seconds faster than vecuronium, although its duration of action is similar.<sup>1108</sup> Rocuronium is eliminated primarily by the liver; the kidney excretes about 10%.<sup>1109-1114</sup> Renal failure does not affect the onset of rocuronium-induced neuromuscular blockade in adults or children. However, it may prolong the duration of action of rocuronium in adults, a finding not shared for children older than 1 year of age.<sup>1109,1111,1114</sup>

Rocuronium has an  $\text{ED}_{95}$  of 303  $\mu\text{g}/\text{kg}$  in children during halothane anesthesia,<sup>1115</sup> with slightly greater doses required during  $\text{N}_2\text{O}/\text{O}_2$  opioid anesthesia.<sup>1116-1118</sup> After the administration of 600  $\mu\text{g}/\text{kg}$  rocuronium ( $2 \times \text{ED}_{95}$ ), 90% and 100% neuromuscular block occurred in 0.8 and 1.3 minutes (see E-Table 6-4 and Table 6-13). At this dose, heart rate increased by approximately 15 beats per minute in children. The mean time to recover to 25% of control was approximately 28 minutes, and recovery to 90% of control was 46 minutes.<sup>1118</sup>

For brief cases in which children are anesthetized with 8% inspired sevoflurane, 0.3 mg/kg rocuronium yields satisfactory intubating conditions within 2 to 3 minutes.<sup>1119</sup> This dose of rocuronium can be antagonized within approximately 20 minutes of administration.<sup>1114</sup> The intubating conditions after rocuronium (600  $\mu\text{g}/\text{kg}$ ) have been compared with those after vecuronium (100  $\mu\text{g}/\text{kg}$ ), atracurium (500  $\mu\text{g}/\text{kg}$ ), and succinylcholine (1 mg/kg). It was found that tracheal intubation could be performed within 60 seconds in all the children who had received rocuronium or succinylcholine, but not until 120 seconds after vecuronium and 180 seconds after atracurium.<sup>1120,1121</sup> The intubating conditions at 60 seconds are improved by increasing the dose<sup>1122</sup>; by increasing the dose to 1.2 mg/kg ( $3$  to  $4 \times \text{ED}_{95}$ ), the intubating conditions are similar to those after treatment with succinylcholine.<sup>1078,1118</sup> At the larger doses, heart rate increases transiently, while systolic and diastolic pressures are unchanged.<sup>1115,1123</sup> It is unclear whether this increase in heart rate after rocuronium is the result of pain on injection or an inherent chronotropic effect.<sup>1086</sup> Dosing studies in infants 2 to 11 months of age demonstrated a slightly faster onset of neuromuscular blockade than in older children with the same dose (600  $\mu\text{g}/\text{kg}$ ). The times to 90% and 100% twitch depression were 37 and 64 seconds, respectively. In infants, the rate of

onset of neuromuscular blockade 60 seconds after rocuronium is comparable to that after succinylcholine.<sup>1115,1124</sup> Neonates appear to be more sensitive to rocuronium than older infants.<sup>1125</sup> In neonates, the duration of action of 600  $\mu\text{g}/\text{kg}$  is approximately 90 minutes and there is marked patient-to-patient variability. Consequently, 450  $\mu\text{g}/\text{kg}$  rocuronium provides adequate intubating conditions, with a duration of action of approximately 1 hour.<sup>1125</sup>

In a PK study, the clearance of rocuronium in infants was less than in children (4 vs 7 mL/kg/min), whereas the  $V_d$  was greater in infants. The mean residence time was 56 minutes in infants versus 26 minutes in children, thus explaining the prolonged duration of action of rocuronium in infants compared with children. In a steady-state target-controlled infusion study, the potency of rocuronium was greatest in infants, least in children, and intermediate in adults.<sup>1126</sup> The greater plasma clearance and smaller  $V_d$  of rocuronium in children compared with infants and adults result in a markedly smaller mean residence time and a decreased duration of neuromuscular blockade.<sup>1009</sup> Consistent with the dose-response effects of curare and vecuronium in infants, smaller plasma concentrations of rocuronium are required in the effect compartment in infants than in children to produce the same degree of neuromuscular blockade.<sup>85</sup> Sevoflurane markedly potentiates the effects of rocuronium.<sup>1127</sup>

If an IV route is unavailable, the IM route for rocuronium is a reasonable alternative; IM rocuronium (1.8 mg/kg,  $3 \times$  the IV intubating dose) provided poor intubating conditions 4 minutes after administration in most children. Neuromuscular blockade (greater than 98%) was achieved in 6 to 8 minutes.<sup>1128</sup> The bioavailability of IM rocuronium at these doses is approximately 80%<sup>1129</sup>; IM rocuronium appears to be a viable alternative to IM succinylcholine although the time of onset of neuromuscular blockade is very slow and may not be appropriate for emergent situations. The duration of IM rocuronium effect (approximately  $80 \pm 22$  minutes) is much greater than that after IM succinylcholine.<sup>1128</sup>

## CLINICAL IMPLICATIONS WHEN USING SHORT- AND INTERMEDIATE-ACTING RELAXANTS

Short- and intermediate-acting relaxants have great utility in infants and children because of the large number of brief surgical procedures performed. Because of their short duration of action, these drugs can be given in one intubating dose (atracurium [500  $\mu\text{g}/\text{kg}$ ]; cisatracurium [200  $\mu\text{g}/\text{kg}$ ]; vecuronium [100  $\mu\text{g}/\text{kg}$ ]; rocuronium [600  $\mu\text{g}/\text{kg}$ ]) and a light anesthetic level maintained throughout the procedure. If more than 45 minutes elapse since the last dose of one of these neuromuscular blockers, one may reasonably assume that neuromuscular function has nearly recovered, but safe practice would recommend confirming *recovery of neuromuscular integrity by clinical signs or by assessment with a neuromuscular blockade monitor. We recommend antagonism in all infants despite clinical signs of recovery.*

The benzyisoquinoliniums and organosteroidal NMBDs are acidic compounds (pH 3 to 4) that can precipitate thiopental (pH 10 to 11) if admixed.<sup>1130</sup> Consequently, when these drugs are administered in tandem, the IV tubing should be thoroughly flushed between the thiopental and these relaxants. Vecuronium and rocuronium are painful when administered intravenously in a small vein during the light stages of anesthetic. This pain is usually demonstrated by withdrawal of the hand. Pain can be

attenuated by deepening the level of anesthesia or pretreating with fentanyl, lidocaine, or ketamine.<sup>1131,1132</sup>

## Long-Acting Nondepolarizing Relaxants

For almost half a century the mainstay of muscle relaxants was curare (*d*-tubocurarine). After the development of intermediate relaxants, its use diminished because its duration of action was too great for most surgeries, and large doses released histamine. Curare is no longer available.

Following curare, several long-acting relaxants with minimal adverse effects were developed. These included metocurine, pipercuronium, and doxacurium, which are two, four, and ten times as potent as curare, respectively. The only long-acting relaxant that is still used in some institutions is pancuronium.

### PANCURONIUM

Pancuronium bromide (Pavulon) is a bisquaternary ammonium steroidal compound with nondepolarizing neuromuscular blocking properties. Pancuronium undergoes partial (15% to 20%) hepatic deacetylation to produce 3-OH, 17-OH, and 3,17-di-OH metabolites. A prolongation of effect can be expected in patients with renal or hepatic failure because a major proportion of pancuronium is excreted in the urine (40% to 60%) and in the bile (11%). Vd ( $203 \pm 36$  mL/kg) and plasma clearance ( $1.7 \pm 0.2$  mL/kg/min) of pancuronium (0.1 mg/kg) are associated with a long elimination half-life ( $103 \pm 23$  min) in children (3 to 6 years) under halothane anesthesia.<sup>1133</sup> It is more potent than curare, metocurine, and gallamine, with a slightly shorter duration of action.<sup>1134</sup> It induces mild tachycardia by blocking presynaptic noradrenaline uptake (increased cardiac output in infants) but has no histamine-releasing properties. As a result, systolic BP tends to increase.<sup>1135</sup> Pancuronium (100 µg/kg) provides satisfactory conditions for tracheal intubation in 70% to 90% of infants and children within 150 seconds of administration. Increasing the initial dose to 150 µg/kg provides satisfactory intubating conditions in all children within 80 seconds (see E-Table 6-4 and Table 6-13).<sup>1081,1136</sup>

Pancuronium is frequently advocated for cardiac surgery and other high-risk procedures in infants and children. The anesthetic technique of combining a high-dose opioid with air-oxygen-pancuronium is well tolerated by infants, from a cardiovascular perspective. The vagolytic effect (tachycardia) of pancuronium counteracts the vagotonic effect (bradycardia) of potent opioids, and its relaxant properties counteract opioid-induced chest wall and glottic rigidity.<sup>1137</sup> Pancuronium has been used to facilitate ventilation in preterm infants in neonatal ICUs.<sup>1138</sup> Because pancuronium increases the heart rate, BP, and plasma epinephrine and norepinephrine levels in neonates, there is some concern that it may contribute to the risk of an intracerebral hemorrhage.<sup>1139</sup> Accordingly, it would seem prudent to administer pancuronium with either general anesthesia or with adequate sedation, to blunt adverse cardiovascular responses. Vecuronium may offer an advantage over pancuronium because it does not significantly increase the BP.<sup>1140-1144</sup> Nasotracheal intubation or intratracheal suctioning in neonates who are paralyzed with pancuronium results in smaller increases in intracranial pressure than in neonates who are not paralyzed.<sup>1144,1145</sup> By abolishing fluctuations in cerebral blood flow through the use of muscle relaxants, the incidence and severity of intraventricular hemorrhages should theoretically be reduced.

## Antagonism of Muscle Relaxants

### GENERAL PRINCIPLES

In children and especially infants, oxygen consumption is greater than it is in adults. Therefore, a slight diminution in respiratory muscle power may lead to hypoxemia and CO<sub>2</sub> retention. Consequently, it is very important that neuromuscular function is returned to normal at the end of the surgical procedure. Neonates are at greater risk for residual neuromuscular blockade than adults for several reasons, including (1) immaturity of the neuromuscular system, (2) greater elimination half-life of relaxants, (3) the reduced number of type I muscle fibers in the ventilatory musculature (thus being more susceptible to fatigue [see Chapter 12, Fig. 12-11]),<sup>245</sup> and (4) the closing lung volume of a neonate overlaps with the tidal volume (i.e., airway closure occurs at the end of expiration).<sup>1146</sup> If respiration is mildly impaired as a result of residual muscle paralysis, even more alveoli will collapse. The result may be hypoxemia as well as hypercarbia and acidosis, which may potentiate and prolong the duration of action of the muscle relaxant, thus creating a vicious cycle.

When monitoring neuromuscular blockade in infants and children, train-of-four monitoring of the adductor pollicis overestimates the degree of neuromuscular blockade in the diaphragm.<sup>984</sup> Larger doses of muscle relaxants are required to block the diaphragm than the adductor pollicis train-of-four would suggest. Therefore, if the train-of-four of the adductor has fully recovered, one can assume that the diaphragm has fully recovered.

Clinical evaluation of the adequacy of antagonism in infants is more difficult than in children or adults. Neither grip strength nor voluntary head lifting can be elicited; rather, it is important when working with infants to observe the clinical conditions preoperatively (muscle tone, depth of respiration, vigor of crying) and to aim for a comparable level of activity in the postantagonism period. Useful clinical signs that the neuromuscular blockade has been antagonized include the ability to flex the hips, flex the arm, lift the legs, and the return of abdominal muscle tone.<sup>1147</sup> Inspiratory force may be measured; a negative force of  $-25$  cm H<sub>2</sub>O or greater indicates adequate antagonism.<sup>1148</sup> A crying vital capacity greater than 15 mL/kg indicates an adequate respiratory reserve. The train-of-four is a valuable aid because it can be used in the smallest of infants in whom the force of contraction can easily be palpated (four equal contractions indicating adequate antagonism).

Although edrophonium may establish a faster onset of effect, final recovery is invariably greater with neostigmine, which is why the latter is recommended for routine pediatric practice.<sup>1149,1150</sup> The distribution volumes of neostigmine are similar in infants (2 to 10 months), children (1 to 6 years), and adults (Vdss 0.5 L/kg), whereas the elimination half-life is less in children.<sup>1151</sup> Clearance decreases as age increases (13.6, 11.1, 9.6 mL/min/kg in infants, children, and adults 29 to 48 years, respectively).<sup>1151</sup> The dose requirement of anticholinesterase agents to antagonize neuromuscular blockade in children is less than adults.<sup>1151</sup> However, the speed of antagonism depends on the extent of neuromuscular blockade at the time of the antagonism, as well as the type and dose of antagonizing agent. In the presence of train-of-four responses with fade, 20 to 25 µg/kg of neostigmine, preceded by 10 to 20 µg/kg of atropine or 5 to 10 µg/kg of glycopyrrolate, is sufficient to achieve full recovery of muscle strength. This dose of neostigmine can be repeated if required (up to 70 µg/kg).

Doses of neostigmine in excess of 100 µg/kg may induce a paradoxical weakness from excessive acetylcholine at the neuromuscular junction. The dose of edrophonium for children is greater than it is for adults; at least 0.3 mg/kg is needed, but 0.5 to 1.0 mg/kg is most common.<sup>1150,1152-1155</sup>

Some have suggested that it is not necessary to antagonize intermediate-acting relaxants, particularly if a lengthy time interval has elapsed since the last dose. With the advent of reliable neuromuscular monitors and their use in conjunction with clinical observations and measurements of respiratory adequacy, clinicians are more confident that antagonism was not always required. This may be particularly appropriate for the short- and intermediate-acting relaxants, particularly atracurium or cisatracurium, which are hydrolyzed in plasma. Children have the additional advantage of recovering from neuromuscular blockade more rapidly than adults.<sup>1154,1155</sup> In infants, the elimination of all muscle relaxants might be delayed, necessitating antagonism of any neuromuscular blockade. Most importantly, if there is any concern that some degree of neuromuscular blockade persists, then the blockade must be antagonized.

Hypothermia potentiates the action of most nondepolarizing muscle relaxants and delays their elimination.<sup>1156</sup> This effect can create a special problem at the end of a surgical procedure when the children attempt to resume spontaneous respirations. Shivering increases oxygen consumption and augments the load on the respiratory system. If the respiratory muscles are unable to match this increased load, hypoxemia and CO<sub>2</sub> retention may occur, which, in turn, may lead to acidosis, which, again, may potentiate the relaxant. To avoid the extra cardiorespiratory load in a post-surgical infant, it is reasonable to warm the infant if the temperature is less than 35° C (95° F). Once the core temperature is above this level, antagonism of neuromuscular blockade may be attempted.

Theoretically, all antibiotics have neuromuscular depressing properties when administered in association with relaxants.<sup>1157</sup> Among the antibiotics, aminoglycoside derivatives, such as gentamicin, tobramycin, and neomycin, have the greatest effect. A single clinical dose of antibiotic will likely have minimal effect on the neuromuscular blockade.<sup>1158</sup> This factor alone does not rule out the possibility that large concentrations of antibiotics, especially in the presence of other potentiating factors, may augment the neuromuscular blockade. The clinical importance of the interaction of antibiotics with muscle relaxants to prolong neuromuscular blockade has diminished with the introduction of intermediate-acting neuromuscular blocking agents.

## SUGAMMADEX

Sugammadex (Org 25969), a member of the cyclodextrin family, is a cyclic oligosaccharide<sup>1159</sup> with hydrophobic molecules within the center (Fig. 6-20).<sup>1160,1161</sup> This compound encapsulates

rocuronium, and vecuronium to a lesser degree, and forms a stable complex that prevents further action of the relaxants; the complex is then excreted unchanged by the kidneys. The chemical encapsulation decreases the plasma concentration of rocuronium, thus promoting the dissociation of rocuronium from the acetylcholine receptor, speeding recovery of muscle strength. As more rocuronium dissociates from the receptor, it, too, is encapsulated, thus reversing even very intense neuromuscular blockade from rocuronium. Three minutes after 0.6 mg/kg rocuronium produced profound neuromuscular block in adult volunteers, a single dose of sugammadex, 2 mg/kg or greater, reversed the neuromuscular block within 2 minutes.<sup>1162</sup> An early sugammadex study in children suggests that sugammadex, at 2 mg/kg, reverses a rocuronium-induced moderate neuromuscular blockade in infants, children, and adolescents.<sup>1085</sup> The average time to recover a train-of-four ratio of 0.9 at the time of appearance of the second twitch response was 1.2, 1.1, and 1.2 minutes in children, adolescents, and adults, respectively. If further clinical trials confirm the safety and efficacy of this new concept, and studies in children demonstrate safety and efficacy, then sugammadex may be effective in antagonizing large doses of rocuronium rapidly, efficiently, and soon after the onset of neuromuscular blockade.<sup>1163-1167</sup> Sugammadex rapidly antagonizes even intense neuromuscular blockade in adults, in whom no twitches were observed.<sup>1164,1168</sup> The rapidity of the reversal depends on both the intensity of the block and the dose of sugammadex.<sup>1084,1086,1169</sup> Under these circumstances, rocuronium might then supplant succinylcholine in many circumstances, including rapid-sequence intubations for brief procedures in children.<sup>1087,1170</sup>

However, two impediments have prevented the widespread use of sugammadex. First, there is some evidence that sugammadex may trigger allergic or anaphylactic reactions.<sup>1171</sup> This has halted the approval of sugammadex in North America. Second, sugammadex is not used for routine reversal because it is extremely expensive. This is quite unfortunate, as the incidence of hyperkalemia or MH induced by succinylcholine would likely have decreased to near zero if we could routinely substitute high-dose rocuronium without fear of prolonged neuromuscular blockade. The expense of sugammadex has put this medication out of financial practicality for routine use in nearly every health-care facility in the world.<sup>1172</sup> Table 6-14 illustrates the approximate cost for reversal of various levels of blockade for several weight ranges. In contrast, reversal with current medications costs very little compared with the expense for similar antagonism with sugammadex. This renders sugammadex a rescue drug only. Data suggest that this drug could be used for rescue of a cannot-intubate/cannot-ventilate situation after administration of a rapid intubating dose of rocuronium (1.2 mg/kg) within 2 minutes, compared with the time for the effects of succinylcholine to abate.<sup>1087,1164</sup>

**FIGURE 6-20** X-ray crystallography of (A) the rocuronium molecule (shown in blue) and (B) sugammadex (green ring). C, The 3-D conformation of the rocuronium molecule complements the conformation of the inner ring of sugammadex. The rocuronium–sugammadex complex is stable, without a dissociation constant, and is excreted unchanged via the kidneys. (Redrawn from Gijzenbergh F, Ramael S, Houwing N, van IT. First human exposure of Org 25969, a novel agent to reverse the action of rocuronium bromide. *Anesthesiology* 2005;103:695-703.)

**TABLE 6-14** Approximate Cost (USD) for Sugammadex Reversal of Rocuronium by Weight and Density of Block\*

Depth of Block	WEIGHT (kg)			
	3	10	20	70
Mild (4 twitches with fade) 2 mg/kg	\$1.46	\$9.75	\$19.50	\$67.90
Moderate (1-2 twitches) 4 mg/kg	\$1.95	\$19.50	\$39.00	\$135.80
Profound (no twitches) 8 mg/kg	\$3.90	\$39.00	\$78.00	\$271.60
Wasted drug (single patient use profound blockade)	\$93.60	\$58.50	\$19.50	\$68.03 <sup>†</sup>

(Personal communication from Neil Morton, MD. UK prices converted to USD as of June 2011.)

\*This drug is not yet approved by the US FDA, so price is determined on UK basis.

<sup>†</sup>Assumes one large vial and one small vial for complete dosing.

In another application of the use of sugammadex, two recent reports describe its effectiveness to stop anaphylactic reactions to rocuronium that were resistant to standard treatment.<sup>1173,1174</sup>

If neuromuscular blockade must be reinstituted after administration of sugammadex, the dose of rocuronium that would be required for neuromuscular blockade is unclear. Although this is feasible,<sup>1133</sup> it would seem much more prudent to switch to a benzyliisoquinolinium muscle relaxant that is unaffected by the presence of sugammadex.

## Relaxants in Special Situations

Of the many drug combinations possible, that of succinylcholine after a halothane induction seems to be most likely to trigger MH<sup>1175</sup> (see Chapter 40). The use of depolarizing neuromuscular blocking agents in combination with halogenated agents should be avoided in children at risk for this syndrome.<sup>1176</sup> The safest general anesthetic technique for children at risk for MH is an opioid plus N<sub>2</sub>O plus O<sub>2</sub> combination, together with benzodiazepines, propofol, and a nondepolarizing relaxant. Nondepolarizing agents devoid of cardiovascular side effects may offer an advantage in not causing tachycardia, an early sign of MH.<sup>1177</sup> There has been some concern of the potential association between mitochondrial disease and MH. A major review, along with evidence from pathology specimens from patients who had a family member with MH, suggest that this is not at all clear and may be a case of “fortuitous association.”<sup>1178</sup> Because many of these children are bedridden, it would seem prudent to avoid succinylcholine, although there are “*inadequate data to support the recommendation ... that the anesthetic plan for patients with mitochondrial disease should routinely include MH precautions.*”<sup>1179</sup>

The use of NMBDs in children with neuromuscular and mitochondrial diseases has been the subject of debate.<sup>1180</sup> Rhabdomyolysis has been reported after succinylcholine in children with Duchenne and Becker muscular dystrophy (see Chapters 22 and 40). It is prudent to avoid succinylcholine in any child with

a suspicious neuromuscular or mitochondrial disease (see earlier). The response of children with neuromuscular disease to nondepolarizing relaxants is variable. Most are relatively sensitive to the NMBDs, particularly those with muscular dystrophy, because of muscle wasting.<sup>1181,1182</sup> The duration of neuromuscular blockade is often prolonged. Rarely, resistance may be evident as a result of chronic immobilization. Of all the nondepolarizing relaxants, we recommend cisatracurium because of its multiple sites of degradation that are independent of organ function.<sup>1183-1185</sup> The dose requirement of atracurium in children with Duchenne muscular dystrophy is similar to that in unaffected children, although the duration of action may be prolonged.<sup>1183</sup> The dose response of rocuronium in children with Duchenne muscular dystrophy shows marked prolongation of both the onset and recovery times (two to three times normal).<sup>1186</sup> Thus, NMBDs should be administered with caution in children with severe preexisting respiratory dysfunction, because even a small dose of a NMBD may cause profound muscle weakness and the need for ventilatory support. Similarly, it is important to antagonize any residual neuromuscular blockade at the end of surgery. *If there is any doubt about the competence of the neuromuscular junction, the trachea should remain intubated until muscle strength has recovered.*

Succinylcholine can cause hyperkalemia in children with burns, which may cause a cardiac arrest.<sup>1187</sup> The more extensive the burn, the more likely and the greater the hyperkalemic response. An 8% burn is the smallest burn that has been associated with hyperkalemia. Although most instances of cardiac arrest have occurred 20 to 50 days after the burn injury, exaggerated increases in the plasma concentration of potassium after succinylcholine can occur within a few days of the burn. However, hyperkalemia after succinylcholine has not been reported in the first 24 to 48 hours after a burn. Hyperkalemia is thought to result from the upregulation of acetylcholine receptors along the surface of the muscle membrane in the postburn phase (see Chapter 34).<sup>1188</sup>

Children with burns may require two to three times the usual IV dose of nondepolarizing relaxants. This resistance peaks about 2 weeks after the burn, persists for many months in those with major burns, and decreases gradually as the burns heal. The degree of resistance appears to correlate with both the extent of the burn and the period of healing. The resistance can be explained, in part, by an increase in the V<sub>d</sub> of the relaxant (including binding to an increased plasma concentration of  $\alpha$ 1-acid glycoprotein) and an increase in number, sensitivity, and type of extrajunctional acetylcholine receptors (see Chapter 34).

## Opioids

### MORPHINE

Morphine is the most frequently used opioid to treat postoperative pain in children and is the standard against which all other opioids are compared. Morphine's main analgesic effect is by supraspinal  $\mu_1$ -receptor activation. The  $\mu_2$ -receptor in the spinal cord plays an important analgesic role when the drug is administered by the intrathecal or epidural route.<sup>1189</sup> Morphine is soluble in water, but lipid solubility is poor compared with other opioids. Morphine's low oil-water partition coefficient of 1.4 and its pK<sub>a</sub> of 8 (10% to 20% un-ionized drug at physiologic pH) contribute to delayed onset of peak action, with slow CNS penetration. The T<sub>1/2keo</sub> for morphine is approximately 17 minutes in adults<sup>1190</sup> and is estimated to be 8 minutes in the full-term neonate.<sup>1191</sup>

Target analgesic plasma concentrations are thought to be 10 to 20 ng/mL after major surgery in neonates and infants.<sup>1192,1193</sup> The large PK and PD variability suggests that morphine be titrated to effect using small incremental doses (0.02 mg/kg) in neonates and infants suffering postoperative pain.<sup>1194</sup>

Morphine is primarily metabolized by the hepatic enzyme UGT2B7 to morphine-3-glucuronide (M3G) and morphine-6-glucuronide (M6G); both have pharmacologic activity. Sulfation and renal clearance are minor pathways in adults but are more dominant in neonates. Contributions to both the desired effect (analgesia) and the undesired effects (nausea, respiratory depression) of M6G are the subject of clinical controversy.<sup>1195</sup> It has been suggested that M3G antagonizes morphine and contributes to the development of tolerance.<sup>1196</sup>

Clearance increases from 3.2 L/hr/70 kg at 24 weeks PMA to 19 L/hr/70 kg at term, reaching adult values (80 L/hr/70 kg) at 6 to 12 months (see Fig. 6-10).<sup>57</sup> These developmental factors for morphine metabolism explain in part the prolonged duration of action in neonates. The maturation profile also suggests that older infants are able to exceed the reported clearance (in L/hr/kg) of morphine in adults (see Fig. 6-4). Clearance is perfusion-limited, with a high hepatic extraction ratio. Oral bioavailability is approximately 35% because of this first pass effect. The metabolites are cleared by the kidney and, in part, by biliary excretion. Impaired renal function leads to M3G and M6G accumulation. Clearance is reduced in critically ill neonates compared healthier cohorts and in those undergoing cardiac surgery (Fig. 6-21).<sup>57-59,1192</sup>

Morphine PK parameters show large interindividual variability contributing to the range of morphine serum concentrations observed during constant infusions. Protein binding of morphine is small in preterm neonates and has minimal impact on the disposition changes with age.

Although morphine is usually administered intravenously to neonates, other routes have been used. A large variability in the analgesic effect of morphine has been observed after rectal administration; this is a major disadvantage of this route. Although this route is used,<sup>1197</sup> delayed absorption with multiple doses causing respiratory arrest has been reported.<sup>1198</sup> Morphine (25 to 50 µg/kg) can also be given via the caudal route and subarachnoid spaces (see Chapters 41 and 43).<sup>1199,1200,1200-1209</sup> Although systemic absorption is slow, morphine spreads within the CSF to the brainstem where it may cause respiratory depression lasting from 6 to more than 18 hours.<sup>1195</sup>

Morphine may be administered intravenously by intermittent bolus, continuous infusion, or patient-controlled analgesia (see Chapter 43).<sup>1210-1212</sup> The usual initial IV dose is 0.05 to 0.2 mg/kg. A reduced dose is indicated in children who are critically ill, are receiving supplemental analgesics or hypnotics, and/or have nocturnal hemoglobin desaturation during obstructive sleep apnea.<sup>1213-1215</sup>

The major risk associated with opioid use in infants and children is respiratory depression.<sup>234,1182</sup> Morphine infusion rates of 10 to 30 µg/kg/hr provide adequate postoperative analgesia without respiratory depression.<sup>1216</sup> Postoperative analgesia is achieved at reduced infusion rates in infants 4 weeks of age or older (~5 µg/kg/hr for neonates, ~8.5 µg/kg/hr at 1 month, ~13.5 µg/kg/hr at 3 months, ~18 µg/kg/hr at 1 year, and slightly less than 16 µg/kg/hr for 1- to 3-year-olds).<sup>233</sup> Respiratory depression may occur at concentrations of 20 ng/mL in infants and children,<sup>231</sup> but concentration-response relationships in neonates, particularly preterm neonates prone to physiologic apnea, are

**FIGURE 6-21** Morphine clearance versus postconceptional age in normal postoperative infants and infants undergoing cardiac surgery. Note that there is a rapid increase in an infant's ability to metabolize morphine in the first several weeks of life and that some infants achieve adult values by 1 month of age. Also note that after cardiac surgery infants have a marked impairment of morphine metabolism, which may reflect the use of vasopressors and/or decreased cardiac output to the liver. There is extreme patient-to-patient variability at all ages; preterm infants have the lowest clearance of any age group. (Data from Lynn A, Nespeca MK, Bratton SL, et al. Clearance of morphine in postoperative infants during intravenous infusion: the influence of age and surgery. *Anesth Analg* 1998;86:958-63 and Mikkelsen S, Feilberg VL, Christensen CB, Lundstrom KE. Morphine pharmacokinetics in preterm and mature newborn infants. *Acta Paediatr* 1994;83:1025-8.)

unknown. When respiratory depression from morphine occurs, it results from both diminished tidal volume and respiratory rate. Whether morphine causes a parallel shift in the CO<sub>2</sub> response curve or a change in the slope, as well as a parallel shift, has not been clearly established. Morphine appears to depress respiration in neonates to a greater extent than meperidine,<sup>1217</sup> although the mechanism behind this is uncertain and may relate to altered PK, an immature blood-brain barrier,<sup>223</sup> altered regional blood flow, or an increased cerebral uptake. In neonatal rats, the brain uptake of morphine is two to three times that in adult rats.<sup>223</sup> This may explain the fivefold reduced LD<sub>50</sub> of morphine in neonatal versus adult animals.<sup>221-223</sup> This immaturity of the blood-brain barrier may account, in part, for the increased sensitivity of the neonate to morphine compared with meperidine or fentanyl; because of their lipophilicity, the latter two opioids rapidly cross an adult's or infant's blood-brain barrier, that is, there is essentially no blood-brain barrier.<sup>1219</sup> Alternatively, reduced clearance could lead to drug accumulation in some infants given repeat doses.<sup>171</sup> Another possibility is a maturation of the PD effects on respiration rather than altered PK, that is, a maturation of the sensitivity of the respiratory center to morphine, rather than a change in brain equilibrium.<sup>1220</sup> Whether one or more of these mechanisms is relevant, morphine must be used with caution in preterm infants and in infants younger than 1 year of age. Significant histamine release may follow a rapid IV bolus of morphine and,

**TABLE 6-15** Relative Comparison of Commonly Used Oral and Parenteral Opioids in an Adult

Drug	Parenteral Dose (mg)	Oral Dose (mg)	Half-Life (hour)
Morphine	10	30-40	2.0-3.5
Hydromorphone	1.5-2.0	6.0-7.5	2-4
Oxycodone		15-30	2-4
Methadone	7.5-10.0	15	22-25
Meperidine	75-100	300	3-5
Codeine	120-130	200	3
Fentanyl	0.1	0.1	0.5

on rare occasions, may result in systemic hypotension.<sup>1221</sup> Urticaria over the course of the vein in which morphine was infused is a local, not systemic, allergic reaction.

The incidence of vomiting in postoperative children is related to the morphine dose. Morphine doses in excess of 0.1 mg/kg are associated with a greater than 50% incidence of vomiting in children.<sup>1222,1223</sup> Withdrawal symptoms may be observed in neonates after cessation of a continuous morphine infusion for more than 2 weeks, and after infusion periods less than 2 weeks if the morphine infusion rate is greater than 40 µg/kg/hr. Strategies to prevent withdrawal from morphine include the use of neuraxial analgesia, nurse-controlled sedation management protocols, ketamine or naloxone mixed with morphine infusion, and the use of alternate agents (e.g., methadone) with lower potential for tolerance.<sup>1224,1225</sup> Table 6-15 summarizes the relative doses of opioids administered via the parenteral and oral routes.

### MEPERIDINE

Meperidine (Pethidine, Demerol) has been traditionally considered a potent opioid to treat severe pain, although in the past decade, meperidine is no longer indicated as an analgesic (because of its side effects and complications), leaving it indicated only for shivering.

Meperidine is a weak opioid, primarily µ-receptor, agonist that has a potency approximately one-tenth that of morphine. The analgesic effects are detectable within 5 minutes of IV administration, and peak effect is reached within 10 minutes in adults ( $T_{1/2keo}$  of approximately 7 to 8 minutes).<sup>1226,1227</sup> Meperidine is metabolized by N-demethylation to meperidinic acid and normeperidine. Meperidine clearance in infants and children is approximately 8 to 10 mL/min/kg.<sup>1228,1229</sup> Elimination in neonates is greatly reduced, and elimination half-time in neonates who have received meperidine by placental transfer may be 2 to 7 times greater than that in adults.<sup>1230</sup> The elimination half-life of meperidine in children after IV administration is approximately 3 ± 0.5 hours,<sup>1228</sup> with a variable half-life in neonates between 3.3 and 59.4 hours.<sup>1229</sup> The  $V_{dss}$  in infants, 7.2 (3.3 to 11) L/kg,<sup>1229</sup> is greater than that in children 2 to 8 years (2.8 ± 0.6 L/kg).<sup>1228</sup>

In children, meperidine is indicated only to stop shivering, not for analgesia. Although its onset time is more rapid than morphine, the risk of seizures after repeated dosing in children has all but removed it from routine clinical use. The impression that meperidine causes less histamine release than morphine has been questioned.<sup>1231</sup> Meperidine is no more effective for treating biliary or renal tract spasm than comparative µ opioids.<sup>1232</sup> The

purported benefits of substituting meperidine for morphine in children who are hypovolemic or asthmatic are questionable.

The dose of meperidine is 1 to 2 mg/kg (see Table 6-15), although reduced doses should be used in critically ill children. Peak plasma values after IV, IM, and rectal administration are 5 minutes, 10 minutes, and 60 minutes, respectively.<sup>1233,1234</sup> Rectal administration of meperidine in children results in wide variations in systemic blood values (32% to 81% of administered dose) and is not recommended.<sup>1228</sup>

Respiratory depression in infants after meperidine appears to be less than after morphine.<sup>1217</sup> The  $LD_{50}$  of meperidine in the neonatal animal is only 20% less than in the adult animal, corresponding with the human clinical response.<sup>221</sup> This is consistent with the reduced respiratory depression with meperidine compared with the equivalent dose of morphine. As with any opioid, the use of meperidine in very young infants must be accompanied by careful observation for respiratory depression and airway obstruction because the PK vary considerably.<sup>1229</sup> Meperidine was used for a number of years as a component of various "lytic cocktails" that provided sedation. It was administered rectally, orally and intramuscularly. The safety of these admixtures, especially in neonates, is dubious and its use in sedation mixtures has fallen into disfavor.<sup>1235</sup> Meperidine's local anesthetic properties have been found useful for epidural techniques in adults.<sup>1236</sup>

Because repeated doses of meperidine may result in the accumulation of normeperidine, which causes seizures,<sup>1237,1238</sup> this drug has been removed from the formulary in many children's hospitals. We do not recommend the use of this opioid other than for a single dose administration.

### HYDROMORPHONE

Hydromorphone (Dilaudid) is a semisynthetic congener of morphine with a potency of around 5 to 7.5 times that of morphine.<sup>1239</sup> IV and IM dose is 10 to 20 µg/kg with a continuous IV infusion of hydromorphone of 1-4 µg/kg/hr. Its bioavailability is about 55% after nasal and oral (30 to 80 µg/kg every 3 to 4 hours) administration and about 35% after rectal administration (not recommended)<sup>1240-1242</sup>; there is high first-pass metabolism.<sup>1243</sup> A clearance of 51.7 (range, 28.6 to 98.2) mL/min/kg is reported in children, with a half-life of 2.5 ± 0.9 hours.<sup>1240,1244</sup> Hydromorphone is metabolized to hydromorphone-3-glucuronide (95%) and to other metabolites.<sup>1245</sup>

Hydromorphone is commonly used when prolonged analgesia is required.<sup>1246-1249</sup> Morphine is often changed to hydromorphone to reduce the adverse effects or because of concern of accumulation of morphine metabolites, particularly in the presence of renal failure.<sup>1218</sup> Hydromorphone is commonly administered IV, orally, in the epidural space, and more recently through the nasal mucosa.<sup>1239,1246,1247,1250-1253</sup> Hydromorphone is used for chronic cancer pain, and plasma concentrations of around 4.7 ng/mL (range 1.9 to 8.9 ng/mL) relieve mucositis in children given patient-controlled analgesia devices.<sup>1239,1244</sup>

### OXYCODONE

Oxycodone (OxyContin) is another long-acting semisynthetic opioid that is usually administered orally and is available in a controlled-release formulation.<sup>1254-1256</sup> The relative bioavailability in adults of intranasal, oral, and rectal formulations was approximately 50% that of the IV route. The buccal and sublingual absorption of oxycodone is similar in young children.<sup>1244</sup> The bioavailability after various routes is IM, 68%; buccal, 55%; and

orogastric, 37%.<sup>1257,1258</sup> Oxycodone may also be administered rectally, with a similar bioavailability, although absorption can be prolonged, so that route is not recommended.<sup>1259</sup> The IV formulation of oxycodone significantly depresses respiration; 0.1 mg/kg in children after ophthalmic surgery caused greater ventilatory depression than other opioids.<sup>1260,1261</sup> As with many medications, interindividual variability in the elimination half-life of oxycodone in the neonate is extreme.<sup>1262,1263</sup> In children, the elimination half-life after IV, buccal, IM, or orogastric administration is 2 to 3 hours.<sup>1257</sup> Mean values for clearance and  $V_{dss}$  were  $15.2 \pm 4.2$  mL/min/kg and  $2.1 \pm 0.8$  L/kg, respectively, in children after ophthalmic surgery.<sup>1260</sup> This opioid is commonly used to transition from patient-controlled analgesia and to treat chronic painful conditions (see Chapters 43 and 44).

### METHADONE

Methadone is a synthetic opioid with an analgesic potency similar to that of morphine but with a more rapid distribution and a slower elimination. Methadone is used as a maintenance drug in opioid-addicted adults to prevent withdrawal. Methadone might have beneficial effects because it is a long-acting synthetic opioid with a very high bioavailability (80%) by the enteral route. It also has NMDA receptor antagonistic activity and this may be beneficial in chronic pain treatment because agonism of this receptor is associated with opioid tolerance and hyperalgesia. Methadone is a racemate and clinical effect is a result of the *R*-methadone isomer. Methadone is 2.5-20 times more analgesic than morphine.<sup>1264</sup>

The primary indication for methadone in children is to wean from long-term opioid infusions to prevent withdrawal, and to provide analgesia when other opioids have failed or have been associated with intolerable side effects.<sup>1224,1225,1254,1264-1271</sup> IV methadone has been shown to be an effective analgesic for postoperative pain relief (the minimum effective analgesic concentration of methadone in opioid naïve adults is 58 µg/L),<sup>1272</sup> and oral administration has been recommended as the first-line opioid for severe and persistent pain in children.<sup>1269</sup> It seems also to be a safe enteral alternative for IV opioids in palliative pediatric oncologic patients.<sup>1273</sup>

Methadone has high lipid solubility with a large  $V_d$  of 6 to 7 L/kg in children and adults.<sup>1274-1277</sup> It is metabolized by N-demethylation, and clearance in adults is  $2.7 \pm 1.7$  mL/min/kg with higher rates reported in children 1-18 years.<sup>1277</sup> The clearances of each racemate (*R* and *S*) are similar (approximately 1.4 to 1.7 mL/min/kg) in adolescents.<sup>1278</sup> There are few PK data available for infants under 1 year of age. The few neonatal data on methadone PK show a slow elimination half-life with enormous interindividual variability (3.8 to 62 hours).<sup>1225</sup> In adults, the mean elimination half-life after oral administration is prolonged, 33 to 46 hours.

### FENTANYL

Fentanyl (Sublimaze) offers greater hemodynamic stability than morphine, a rapid onset ( $T_{1/2keo}$  of 6.6 minutes in adults) a short duration of effect. Its relative increased lipid solubility and small molecular conformation enables efficient penetration of the blood-brain barrier and redistribution. It is the most commonly used opioid during general anesthesia in infants and children. It is particularly effective in the care of high-risk preterm and term neonates, as well as in infants and children during cardiac surgical procedures. High doses of fentanyl (10 to 100 µg/kg) are often administered to maintain cardiovascular

homeostasis.<sup>1137,1279-1289</sup> Fentanyl may be administered intravenously, intramuscularly, as a supplement to epidural analgesia, orally (trans-oral mucosal absorption), and transdermally—both passively and by iontophoresis.<sup>1290-1295</sup>

Fentanyl is metabolized by oxidative N-dealkylation (CYP3A4) into norfentanyl and hydroxylated. All metabolites are inactive and a small amount of fentanyl is eliminated via the kidneys unchanged. Compared with term neonates, the clearance of fentanyl in preterm infants is markedly reduced (mean elimination half-life is  $17.7 \pm 9.3$  hours) contributing to prolonged respiratory depression in preterm neonates. Clearance matures with gestational age; 7 mL/min/kg at 25 weeks PMA, 10 mL/min/kg at 30 weeks PMA, and 12 mL/min/kg at 35 weeks PMA.<sup>1296</sup> The clearance of fentanyl is reduced to 70% to 80% of adult values in term neonates and, when standardized to a 70 kg person, reaches adult values (approx. 50 L/hr/70 kg) within the first 2 weeks of life.<sup>858</sup> Clearance of fentanyl in older infants (more than 3 months of age) and children is greater than that in adults when expressed as per kilogram (30.6 mL/kg/min vs 17.9 mL/kg/min, respectively), resulting in a reduced elimination half-life (68 minutes vs 121 minutes, respectively).<sup>1279,1282,1297-1299</sup>

Fentanyl's  $V_{dss}$  is approximately 5.9 L/kg in term neonates, and decreases with age to 4.5 L/kg during infancy, 3.1 L/kg during childhood, and 1.6 L/kg in adults.<sup>1300</sup> This increased  $V_{dss}$  results in a lower blood concentration after bolus administration in neonates and infants. Administration of fentanyl 3 µg/kg by slow IV push in term infants (1 to 7 months age) intra-operatively neither depressed respiration nor caused hypoxemia in a placebo-controlled trial.<sup>1301,1302</sup> Slow administration and both an increased  $V_{dss}$  and an increased clearance (per kilogram) in this age group contributed to these results. Fentanyl clearance may be impaired with decreased hepatic blood flow (e.g., from increased intra-abdominal pressure in neonatal omphalocele repair), although a maldistribution of blood away from regions of concentrated cytochrome enzyme activity in the liver may also play a role.<sup>1303</sup>

Infants with cyanotic heart disease had reduced  $V_{dss}$  and greater plasma concentrations of fentanyl with infusion therapy.<sup>1281</sup> These greater plasma concentrations resulted from a reduced clearance (34 L/hr/70 kg), that was attributed to hemodynamic disturbance and consequent reduced hepatic blood flow.<sup>1304</sup> Hypothermia has also been shown to reduce fentanyl clearance.<sup>1305</sup> Profound hypotension has been reported after a bolus of midazolam in neonates in whom fentanyl was infused and vice versa.<sup>1306</sup> Other drugs metabolized by CYP3A4 (e.g., cyclosporine, erythromycin) may compete for clearance and result in increased fentanyl plasma concentrations.

Fentanyl is a potent  $\mu$ -receptor agonist with a potency 70 to 125 times greater than that of morphine. A plasma concentration of 15 to 30 ng/mL is required to provide total IV anesthesia in adults, whereas the  $EC_{50}$ , based on EEG evidence, is 10 ng/mL.<sup>1307,1308</sup> Fentanyl has been shown to effectively prevent preterm neonates from surgical stress responses and to improve postoperative outcome.<sup>1309</sup> Single doses of fentanyl (3 µg/kg) can reduce the physiologic and behavioral measures of pain and stress associated with mechanical ventilation in preterm infants.<sup>1310</sup> Fentanyl has similar respiratory depression in infants and adults when plasma concentrations are similar.<sup>1311</sup>

The PK of fentanyl in critically ill children receiving long-term infusions is also quite variable, with a mean terminal elimination half-life of 21 hours and a range of 11 to 36 hours.<sup>1312</sup> The infusion rates of fentanyl that are required to achieve a similar level of sedation and analgesia may vary as much as 10-fold.<sup>1312</sup> This

**FIGURE 6-22** This figure is a simulation of the time required for a 50% reduction in the effective site concentration of remifentanyl (yellow circles), sufentanil (purple circles), alfentanil (brown triangles), and fentanyl (blue triangles) after an infusion (duration of 0 to 240 minutes) designed to maintain a constant effect-site concentration. Note that there is a completely flat curve for remifentanyl, suggesting that a plateau effect is rapidly reached with remifentanyl compared with the other opioids, such that even after a long infusion, the time to 50% reduction in effect-site concentration is still under 4 minutes. (Redrawn and modified with permission from Westmoreland CL, Hole JF, Sebel PS, et al. Pharmacokinetics of remifentanyl [GI87084B] and its major metabolite [GI90291] in patients undergoing elective inpatient surgery. *Anesthesiology* 1993;79:893-903.)

variability in PK and PD strongly reinforces the need to titrate the dose to effect and to be prepared to provide postoperative ventilatory support as needed. Children who receive a chronic infusion of fentanyl are at risk of rapidly developing tolerance; on discontinuance of the infusion, these children may demonstrate signs of withdrawal. All long-term infusions should be tapered slowly over days rather than discontinuing them abruptly.<sup>1298,1313,1314</sup>

With low-dose fentanyl, the termination of action is primarily a combination of redistribution and rapid clearance by the liver.<sup>1298,1315</sup> The CSHT after a 1 hour infusion of fentanyl is approximately 20 minutes, which increases to 270 minutes after an 8 hour infusion in adults (Fig. 6-22).<sup>38</sup> Although the CSHT is reduced in children, there are no data in neonates.<sup>1299</sup> High-dose fentanyl, accumulates in muscle and fat and is therefore released (recirculated) more slowly, thus accounting in part for the prolonged respiratory depression after high doses. There is no evidence of dose-dependent kinetics; that is, there is no tissue or enzyme saturation in the clinically used ranges.<sup>1315</sup> In some respects, the pharmacology of opioids is very similar to thiopental: at low doses their clinical effect is terminated by redistribution, whereas at high doses their clinical effect is terminated by metabolism.<sup>1311,1316-1319</sup>

The usual initial dose of fentanyl is 1 to 3  $\mu\text{g}/\text{kg}$ , a dose that may be supplemented as clinically indicated. Fentanyl is highly lipid soluble and rapidly crosses the blood-brain barrier. This characteristic may, in part, explain why the  $\text{LD}_{50}$  for fentanyl in neonatal animals is 90% of that in adult animals. Continuous intraoperative and postoperative infusions of fentanyl are common in children of all ages.<sup>1281,1319,1320</sup> Fentanyl is also used to provide patient-controlled analgesia (see Chapter 43).<sup>1321,1322</sup>

Chest wall and glottic rigidity have been reported after IV administration of opioids, although most often after fentanyl. The reason for this is not clear.<sup>1323-1328</sup> Glottic rigidity may account for the inability to ventilate by bag and mask after IV fentanyl.<sup>1328</sup>

This adverse response can be minimized by administering the opioid slowly, and it can be reversed by administering either a muscle relaxant or naloxone. One other concern is the rare association of increased vagal tone with bolus administration; bradycardia may have profound effects on the cardiac output of neonates. Additionally, fentanyl markedly depresses the baroreceptor reflex control of heart rate in neonates.<sup>1329</sup> It is for these reasons that the combination of pancuronium and fentanyl became popular.

Oral transmucosal fentanyl (Fentanyl Oralet) was one of only several medications approved by the FDA for premedication of children, although this formulation is no longer marketed. A new formulation (Actiq) has been approved for adults and children 16 years of age or older, and is currently under investigation in children for the treatment of breakthrough pain.<sup>1330,1331</sup> Fentanyl is rapidly absorbed through the oral mucosa, which bypasses the liver.<sup>787,1291,1292,1332-1336</sup> Nonetheless, approximately half the absorption is gastrointestinal. The bioavailability of this formulation in children (33%) is less than that in adults (50%).<sup>1291,1292</sup> Uptake continues for a period of time after consumption, which potentially can provide analgesia for several hours.<sup>787,1291,1292</sup> The use of this formulation will likely be limited to the treatment of breakthrough pain.

The fentanyl patch was developed to provide an extended release of fentanyl similar to that provided with a continuous IV infusion.<sup>1290,1337-1346</sup> *This formulation was not designed to be administered to treat postsurgical pain, but rather for those who require opioids chronically.* This fentanyl transdermal therapeutic system (TTS) is available with a drug release rate of 12.5  $\mu\text{g}/\text{hr}$  and matches the lower dosing requirements of cancer pain control in children.<sup>1347</sup> An approximate conversion factor of 45 mg/day oral morphine to 12.5  $\mu\text{g}/\text{hr}$  fentanyl TTS is used for initial dose estimation in children on chronic morphine therapy. This is conservatively low to avoid respiratory depression. In adults, uptake of fentanyl begins within 1 hour and achieves therapeutic levels within 6 to 8 hours and peak levels at 24 hours.<sup>1343,1346,1348</sup> In children, the peak occurs earlier, at about 18 hours.<sup>1349</sup> The skin acts as a reservoir, and even after removal of the patch, uptake continues for several hours, with a consequent apparent elimination half-life of  $14.5 \pm 6$  hours.<sup>1349</sup> Fentanyl uptake is markedly affected by skin blood flow, skin thickness, location of the patch, and adherence to the skin.<sup>1350-1353</sup> Alterations in skin blood flow (e.g., fever) may increase absorption.<sup>1354</sup> Alterations to skin blood flow caused by warming devices (increased absorption) or hypothermia (decreased absorption) during anesthesia should be considered in children with chronic pain who present with TTS fentanyl.

The use of TTS medication should be limited to pain specialists who have familiarity with the unusual PK of this drug delivery system.<sup>1355</sup> One study suggests that the PK of fentanyl by this route in children and adult patients are similar.<sup>1349</sup> A multicenter study in children 2 to 16 years of age reported satisfactory chronic analgesia. However, it should be noted that the data submitted to the FDA revealed plasma concentrations of fentanyl in children 1.5 to 5 years of age that were twice those in adults.<sup>1356</sup> These data are consistent with another study that found a negative correlation between fentanyl concentrations and age, that is, greater concentrations in younger children.<sup>1349</sup> Children may be particularly vulnerable to the rapid drug absorption compared with adults because they have thinner skin and better skin blood flow.<sup>906</sup> Accordingly, it seems prudent to begin with the smallest size patch and gradually increase as indicated (see Chapters 43

and 44). Finally, all patches, including those that have already been used, still contain large amounts of fentanyl that may cause a fatal intoxication if accidentally ingested by a child.<sup>1357,1358</sup> Proper disposal of these opioid-containing patches is required.

Epidural fentanyl is widely combined with an amide local anesthetic for provision of postoperative analgesia, although the use of such combinations continues to be debated. Pruritus, nausea, and vomiting may be exacerbated by the addition of fentanyl. The combination remains popular with bupivacaine as the amide anesthetic, although there is no evidence to support a levobupivacaine combination.<sup>1359</sup> Spread beyond the site of administration is dose-dependent but limited, and respiratory depression is uncommon.<sup>1254,1360</sup>

### ALFENTANIL

Alfentanil (Alfenta) is a fentanyl analogue whose main advantage is its reduced lipid solubility and smaller Vd compared with fentanyl.<sup>1361</sup> It has a rapid onset ( $T_{1/2\text{keo}}$  of 0.9 minutes in adults), a brief duration of action, and one-fourth the potency of fentanyl. A target plasma concentration of 400 ng/mL is used in anesthesia. Metabolism is through oxidative N-dealkylation by CYP3A4 and O-dealkylation and then conjugation to metabolites that are excreted renally.<sup>1362</sup> Studies indicate that brain concentrations of alfentanil are sevenfold to ninefold less, the Vd is four times less, and protein binding is greater than fentanyl.<sup>1363</sup> Alfentanil is more rapidly eliminated from the body than fentanyl, resulting in more frequent dosing. Clearance in neonates (20 to 60 mL/min/70 kg) is one-tenth that in adults (250 to 500 mL/min/70 kg) with rapid maturation.<sup>67</sup> In preterm neonates, the half-life is as long as 6 to 9 hours.<sup>1364,1365</sup> The Vd in children and adults are similar, but increased in preterm neonates (Vd  $1.0 \pm 0.39$  vs  $0.48 \pm 0.19$  L/kg). Clearance is greater in children, expressed as per kilogram ( $11.1 \pm 3.9$  mL/kg/min vs  $5.9 \pm 1.6$  mL/kg/min). As a result, the elimination half-life in children is less ( $63 \pm 24$  vs  $95 \pm 20$  minutes).<sup>1366-1369</sup> The Vd and elimination half-life in infants 3 to 12 months of age and older children are similar.<sup>1368</sup> Because clearance is markedly diminished in children with hepatic disease, clinical effects are prolonged in those with reduced hepatic blood flow (e.g., children with increased intraabdominal pressure, children receiving vasopressors, and those with some forms of congenital heart disease).<sup>1361,1370,1371</sup> Renal failure has little effect on its elimination.<sup>1372</sup> Because less alfentanil is bound to  $\alpha 1$ -acid glycoprotein in preterm infants (65%) than in term infants (79%), an increased fraction of alfentanil is available for biologic effect in the former.<sup>78</sup>

The PK and PD of alfentanil suggest potential applications for the rapid control of analgesia and awakening from anesthesia. Alfentanil (10  $\mu\text{g/kg}$ ) has been combined with propofol (2.5 mg/kg) for tracheal intubation without a NMBD.<sup>1373</sup> High-dose alfentanil is also used for cardiac procedures. Alfentanil should be used with caution without NMBDs in neonates because of the frequency of chest wall or glottic rigidity.<sup>1229,1374</sup>

### SUFENTANIL

Sufentanil (Sufenta) is a potent synthetic narcotic that in many respects is similar to fentanyl and alfentanil. Sufentanil is 5 to 10 times more potent than fentanyl, with a  $T_{1/2\text{keo}}$  of 6.2 minutes in adults.<sup>1375</sup> A concentration of 5 to 10 ng/mL is required for total IV anesthesia, and 0.2 to 0.4 ng/mL for analgesia. PD differences are suggested in neonates. The plasma concentration of sufentanil at the time of additional anesthetic supplementation to suppress hemodynamic responses to surgical stimulation

was 2.51 ng/mL in neonates, significantly greater than the concentrations of 1.58, 1.53, and 1.56 ng/mL observed in infants, children, and adolescents, respectively.<sup>1376</sup>

Elimination of sufentanil has been suggested by O-demethylation and N-dealkylation in animal studies. As with fentanyl and alfentanil, the CYP3A4 enzyme is responsible for the N-dealkylation.<sup>1377</sup> The majority of studies of IV sufentanil in children have focused on those undergoing cardiac surgery. Evidence has shown age-dependent PK in which neonates have a larger Vdss, reduced clearance, and a greater and more variable elimination half-life than older children and adults (E-Fig. 6-16).<sup>1376,1378,1379</sup> Clearance in neonates undergoing cardiovascular surgery ( $6.7 \pm 6.1$  mL/kg/min), is reduced compared with values of  $18.1 \pm 2.7$ ,  $16.9 \pm 3.2$ , and  $13.1 \pm 3.6$  mL/kg/min in infants, children, and adolescents, respectively.<sup>1376</sup>, consistent with rapid development of hepatic metabolic pathways.<sup>1378</sup> Clearance maturation standardized to a 70 kilogram person using allometry is similar to that of other drugs that depend on CYP3A4 for metabolism (e.g., levobupivacaine, fentanyl, alfentanil) (see Fig. 6-10).<sup>156</sup> Clearance rates in infants ( $27.5 \pm 9.3$  mL/kg/min) were greater, expressed as per kilogram, than those in children ( $18.1 \pm 10.7$  mL/kg/min) in another study of children undergoing cardiovascular surgery.<sup>1379</sup> Clearance in healthy children (2 to 8 years) was greater ( $30.5 \pm 8.8$  mL/kg/min) than those undergoing cardiac surgery.<sup>1380</sup> Decreased hepatic blood flow reduces clearance.<sup>1380</sup> The elimination of sufentanil is unaffected by renal failure but markedly altered by factors that influence hepatic blood flow; cirrhosis apparently has little effect on its elimination.<sup>1361,1381,1382</sup>

The Vdss was  $4.15 \pm 1.0$  L/kg in neonates; greater than the values of  $2.73 \pm 0.5$  and  $2.75 \pm 0.5$  L/kg observed in children and adolescents, respectively.<sup>1376,1380</sup>

Bradycardia and asystole have been observed after a bolus administration of sufentanil, suggesting that the simultaneous administration of a vagolytic agent (atropine, glycopyrrolate, or pancuronium bromide) may be sensible with rapid administration.<sup>1383,1384</sup> Nasal sufentanil may have a role for sedation in children although data in neonates are lacking and there are concerns about the risk of respiratory depression.<sup>1385-1390</sup> Several studies demonstrated that children are more likely to accept nasal sufentanil compared with nasal midazolam, although there was a greater incidence of vomiting after sufentanil and several children experienced decreased chest wall compliance after or during induction of anesthesia. The dose of sufentanil that is most effective when administered intranasally is 2 to 3  $\mu\text{g/kg}$ .<sup>1386,1388</sup> Epidural sufentanil (0.7 to 0.75  $\mu\text{g/kg}$ ) has been effective in children, lasting more than 3 hours, although pruritus can be bothersome.<sup>1391-1393</sup>

### REMIFENTANIL

Remifentanil (Ultiva) is the newest in the family of synthetic opioids.<sup>1394,1395</sup> Its brief elimination half-life of 3 to 6 minutes means that it is usually given as an infusion.<sup>205,1396-1398</sup> This opioid is unique because an ester linkage in the molecule allows rapid degradation to a carboxylic acid metabolite by blood and tissue esterases.<sup>1399</sup> Metabolism is unaffected by hepatic or renal function.<sup>1400</sup> The active metabolite of remifentanil that is eliminated by the kidneys has approximately 1/300th to 1/1000th the opioid activity of the parent compound and, theoretically, could accumulate and cause clinical manifestations in children with impaired renal function.<sup>1401</sup> One study in adults failed to demonstrate any residual opioid effects after a 12-hour infusion in patients with renal failure.<sup>1402</sup> Perhaps the most important

**E-FIGURE 6-16** Pharmacokinetics for sufentanil versus age. Note that the  $\beta$ -elimination half-life ( $T_{1/2\beta}$ ) and volume of distribution at steady state ( $V_{dss}$ ) are inversely related to age; clearance is the lowest in neonates. Children and adolescents have sufentanil pharmacokinetics similar to that of adults. (Data from Greeley WJ, de Bruijn NP, Davis DP. Sufentanil pharmacokinetics in pediatric cardiovascular patients. *Anesth Analg* 1987;66:1067-72.)

**FIGURE 6-23** The effect of age on the dose (infusion rate) of remifentanyl tolerated during spontaneous ventilation under anesthesia in children undergoing strabismus surgery.<sup>257</sup> Superimposed on this plot is estimated remifentanyl clearance determined using an allometric model.<sup>12</sup> There is a mismatch between clearance and infusion rate for those individuals still in infancy. The higher infusion rates recorded in those infants can be attributed to greater suppression of respiratory drive in this age group than with the older children during the study; a respiratory rate of 10 breaths per minute in an infant is disproportionately slow compared to the same rate in a 7-year-old child, suggesting excessive dose. (Reproduced with permission from Anderson BJ. Pediatric models for adult target-controlled infusion pumps. *Pediatr Anesth* 2010;20:223-32; Rigby-Jones AE, Priston MJ, Sneyd JR, et al. Data extracted from Ross AK, Davis PJ, del Dear G, et al. Pharmacokinetics of remifentanyl in anesthetized pediatric patients undergoing elective surgery or diagnostic procedures. *Anesth Analg* 2001;93:1393-401.

CL, Clearance; C<sub>max</sub>, peak plasma concentration; V<sub>dss</sub>, volume of distribution at steady state.

\*Significantly different from other groups.

characteristic of remifentanyl is its very brief half-life and the associated rapid recovery within about 10 minutes. Clearance in patients with butyrylcholinesterase deficiency is unaffected. The nonspecific blood esterases that metabolize remifentanyl are mature at birth.<sup>53</sup>

A target plasma concentration of 2 to 3 µg/L is adequate for laryngoscopy, 6 to 8 µg/L for laparotomy and 10 to 12 µg/L might be sought to ablate the stress response associated with cardiac surgery.<sup>1403</sup> Analgesic concentrations are 0.2 to 0.4 µg/L. The T<sub>1/2keo</sub> is 1.16 minutes in adults,<sup>204</sup> but the neonatal T<sub>1/2keo</sub> has not been reported. Analgesic alternatives should be available for when the short-duration analgesic effect from remifentanyl has dissipated. Reports of a rapid development of µ-receptor tolerance with remifentanyl are in conflict; activity at δ-opioid receptors may contribute.<sup>1404</sup> Remifentanyl clearance can be described in all age groups by simple application of an allometric model.<sup>52</sup> This standardized clearance of 2790 mL/min/70 kg is similar to that reported by others in children<sup>205,1405</sup> and adults.<sup>204,1395</sup> The smaller the child, the greater the clearance when expressed as mL/min/kg. Clearance decreases with increasing age, with rates of 90 mL/kg/min in infants under 2 years of age, 60 mL/kg/min

in children 2 to 12 years of age, and 40 mL/kg/min in adults (Fig. 6-23 and Table 6-16).<sup>52,205,1405</sup> The steady-state V<sub>d</sub> was greatest in infants under 2 months age (452 mL/kg) and decreased to 308 mL/kg in children 2 months to 2 years, and to 240 mL/kg in children more than 2 years of age.<sup>205</sup> Elimination half-life appears to be constant, approximately 3 to 6 minutes, independent of dose or duration of the infusion<sup>205,1396</sup>; the CSHT is constant (see Fig. 6-22).<sup>1401</sup> For example, when the infusions of remifentanyl differed as much as 20-fold, the time to return to spontaneous respirations varied by only 1 to 3 minutes.<sup>1400,1406</sup> For opioids, its effect on respiration is an excellent reflection of its PD effects.<sup>1407</sup> After 3-hour infusions of alfentanil and remifentanyl in adults, the elimination half-lives were 47.3 ± 12 minutes for alfentanil, compared with 3.2 ± 0.9 minutes for remifentanyl. The time to recover 50% of the minute ventilation, a PD effect of opioids, was 54.0 ± 48.1 minutes for alfentanil, compared with 5.4 ± 1.8 minutes for remifentanyl.<sup>1407</sup>

Although covariate effects, such as cardiac surgery, appear to have a muted effect on PK, cardiopulmonary bypass (CPB) does have an impact. Remifentanyl dosage adjustments are required during and after CPB because of marked changes in its V<sub>d</sub>.<sup>1408</sup>

response.<sup>1435,1436</sup> However, because the plasma half-life is so brief, there is rarely a need for a bolus, because a steady-state opioid concentration occurs within three to five half-lives. Conversely, this negative chronotropic effect and the concomitant reduction in BP can be used to induce controlled hypotension.<sup>1437,1438</sup>

Remifentanyl would seem to be the ideal opioid to provide a deep analgesic effect that allows spinal cord-evoked motor and sensory monitoring.<sup>1439</sup> Nonetheless, anesthesia is not produced by opioids alone. An anxiolytic must be administered to ensure that amnesia occurs. The half-lives of all anxiolytics exceed that of remifentanyl, and this needs to be considered during recovery. Remifentanyl complements propofol for short-term analgesia during total IV anesthesia for a variety of surgical and nonsurgical procedures, as well as analgesia and sedation in the ICU.\* We have commonly used a fixed combination of remifentanyl (5 µg/mL) in propofol (10 mg/mL), starting at a propofol infusion rate of 150 µg/kg/min for upper and lower gastrointestinal endoscopic procedures in children under 10 years, and a lower concentration of remifentanyl in teenagers (2.5 µg/mL in propofol [10 mg/mL]) because of the hypotension and bradypnea in older children.<sup>1446</sup> Remifentanyl seems to cause less respiratory depression in younger children.<sup>1411</sup> For upper endoscopy, topicalizing the tongue and pharynx with lidocaine helps blunt responses to passing the endoscope through the oropharynx. The infusion rate is adjusted according to the child's responses.

Remifentanyl has also been used to supplement propofol to facilitate endotracheal intubation without the use of a muscle relaxant. Two dose-response studies found that about 3 µg/kg of remifentanyl combined with 4 mg/kg propofol provided the best intubating conditions. Intubating conditions were the same as with mivacurium or succinylcholine. Resumption of spontaneous respirations after a remifentanyl-propofol combination was similar to that after succinylcholine.<sup>1447,1448</sup> It would seem that this combination is a reasonable alternative to succinylcholine to facilitate endotracheal intubation in children in whom succinylcholine is contraindicated, when the duration of intubation is anticipated to be brief, or when spontaneous ventilation is desired.

#### **BUTORPHANOL AND NALBUPHINE**

Butorphanol (Stadol) and nalbuphine (Nubain) are synthetic narcotic agonist-antagonist analgesics that are apparently equianalgesic.<sup>1449-1452</sup> They are effective through κ-receptor agonism and partial µ-receptor antagonism, have 0.5 to 0.7 times morphine's potency, and an antagonist effect 25 times weaker than naloxone. An appealing PD effect is sedation, particularly when compared with midazolam.<sup>1449,1452-1455</sup> Nalbuphine's elimination half-life is significantly shorter in children 1.5 to 5 years of age (0.9 hour) than it was in children 5 to 8.5 years of age

route may offer particular advantage for children without IV access.<sup>1464,1471-1474</sup> One report suggests a lower rate of postoperative vomiting after butorphanol compared with morphine.<sup>1465</sup> Another describes the use of rectal administration; as expected, the authors found irregular absorption, but peak blood levels were relatively rapidly achieved ( $25 \pm 11$  minutes) and the elimination half-life was  $2.7 \pm 0.7$  hours.<sup>1475</sup> We do not recommend the rectal route of administration. What must be remembered is that these agents may reverse  $\mu$ -receptor-mediated analgesic effects of the more potent opioids and should therefore be used as the initial or the sole opioid.

This family of drugs has had mixed results in reversing or preventing opioid-induced pruritus.<sup>1476,1477</sup> Nalbuphine does not reverse respiratory depression after morphine,<sup>1478</sup> but may be effective after fentanyl.<sup>1479</sup> Butorphanol has also been administered by the caudal epidural route ( $25 \mu\text{g/kg}$ ).<sup>1480,1481</sup>

### CODEINE

Codeine, or methylmorphine, is a morphine-like opioid with 10% of the potency of morphine. It is mainly metabolized by glucuronidation, but minor pathways are by N-demethylation to norcodeine and O-demethylation to morphine. However, a full accounting of the metabolism of codeine has remained elusive. Approximately 10% of codeine is metabolized to morphine. As the affinity of codeine for opioid receptors is very low, the analgesic effect of codeine is believed to be a result of its morphine metabolite.<sup>1482</sup> Evidence suggests that up to 11% of codeine is metabolized to hydrocodone,<sup>196</sup> which may provide an alternate mechanism of analgesia to its metabolism to morphine. The continued use of this minor opium alkaloid for pediatric analgesia remains baffling and is subject to debate, because it is effectively a prodrug analgesic.<sup>1483</sup>

The primary routes for delivery of codeine are the oral and IM routes, although the rectal route has also been advocated.<sup>1484</sup> The dose of codeine by all three routes is similar, 0.5 to 1.5 mg/kg. IV codeine was used in the past, but serious life-threatening adverse effects, including transient but severe cardiorespiratory depression<sup>1485-1487</sup> and seizures,<sup>1488</sup> led to proscription of this route of delivery.

Codeine's popularity as a perioperative analgesic in children is based in part on its favorable PK. When given orally, it is rapidly and completely absorbed, with 50% undergoing first-pass hepatic metabolism. Bioavailability after oral codeine is 90%, although after surgery the bioavailability may be quite variable.<sup>1482,1489</sup> Blood concentrations after oral codeine reach a peak by 1 hour. Its terminal elimination half-life is 3 to 3.5 hours. When given by the IM and rectal routes, peak blood concentrations are achieved rapidly, within 0.5 hour, with the blood concentrations after the rectal route being less than after the IM route. The duration of action after these two routes of administration is 1 to 2 hours. The elimination half-life after rectal administration in children is approximately 2.6 hours in children, but 4.6 hours in infants,<sup>1490</sup> suggesting the need for a much greater interval between subsequent doses in infants. A Vd of 3.6 L/kg and a clearance (CL) of 0.85 L/hr have been described in adults but there are few data detailing the developmental changes in children.

In vivo, 5% to 15% of codeine is excreted unchanged in the urine. The remaining 85% to 95% undergoes metabolism in the liver by one of three routes: glucuronidation (principal route), O-demethylation, and N-demethylation.<sup>1482</sup> Five percent to 15% of codeine undergoes O-demethylation to morphine. This

metabolic pathway depends on CYP2D6, an enzyme responsible for the metabolism of more than 20% of prescribed medications. The N-demethylation pathway depends on the CYP3A enzyme system.

CYP2D6 activity in fetal liver microsomes is either absent or less than 1% of adult values.<sup>1490</sup> O-demethylation begins postnatally with rapid maturation of this enzyme system irrespective of the gestational age at birth, although activity may remain less than 25% of adult values at 5 years of age. Interestingly, CYP2D6 is a noninducible enzyme whose activity, however, may vary with certain disease states, including malignancy, cigarette smoking, and some chronic inflammatory diseases (rheumatoid arthritis).<sup>1482</sup> Glucuronidation is immature at birth but develops throughout infancy, whereas N-demethylation is fully mature at birth. Variability in the clinical response to codeine prompted investigations into genetic variants or polymorphisms of CYP2D6. This enzyme is mapped to chromosome 22 at 22q13.1. Fifty-five polymorphisms of CYP2D6 with a frequency that exceeds 1% of the population have been described.<sup>1491</sup> These include both functional and nonfunctional polymorphisms, as well as gene duplication. The polymorphisms are numbered with \*1 being the normal or wild allele (the \* denotes an allele). The mutant alleles, \*3, \*4, \*5, \*6, and \*9, for example, confer no CYP2D6 activity.<sup>1482,1491,1492</sup> The latter polymorphisms account for more than 90% of the poor metabolizers (see later discussion). Variants \*2, \*10, and \*17 have modestly reduced activity and are referred as intermediate metabolizers.<sup>1482</sup> To further complicate the genetic pattern, multiple copies of the same genes<sup>1492</sup> may be present in some individuals, resulting in bizarre phenotypes. The wide array of CYP2D6 polymorphisms of codeine may be summarized into three broad categories: poor metabolizers (PM, negligible morphine produced), extensive metabolizers (EM, normal) and ultraextensive metabolizers (UM, rapid production and large amounts of morphine produced). Up to 10% of Caucasians and 30% of Hong Kong Chinese are PM, rendering codeine an ineffective analgesic for these children.<sup>1482</sup> Alternately, 29% of the Ethiopian and 1% of Swedish, German, and Chinese populations are UM.<sup>1482</sup> Recent evidence suggested that the frequency of CYP2D6 polymorphisms, particularly children who are PM, may be more common and more varied than previously thought. Children with these polymorphisms who also have upregulated opioid receptors as a result of chronic intermittent nocturnal hypoxia may be particularly vulnerable to a mishap after a usual or subclinical dose of codeine.<sup>200,1492a</sup> Consequently, the wide clinical response to a standard (or less than standard) dose of codeine necessitates careful monitoring in those with compromised cardiorespiratory status. Several deaths or near deaths have been reported with "standard" doses of oral codeine in children later found to be UM.<sup>1493,1494,1492a</sup>

Codeine may be effective for pain control, although its limited conversion to morphine likely makes it suitable for only mild and moderate forms of pain. The limited conversion to morphine and fewer adverse effects of codeine has made it popular for infants and young children, particularly when a single dose is involved. There is some evidence that codeine is associated with less nausea and vomiting than morphine.<sup>1495</sup> Codeine is often used in combination with acetaminophen or NSAIDs. The addition of codeine to acetaminophen has been shown to improve postoperative pain relief in infants.<sup>1496</sup> One study found that the analgesic effect of the combination of acetaminophen (10 to 15 mg/kg) and codeine (1 to 1.5 mg/kg) was comparable to that of ibuprofen (5 to 10 mg/kg) in children after tonsillectomy.<sup>1497</sup>

In poor metabolizers, codeine confers little or no analgesia, although adverse effects persist.<sup>1498</sup> In ultra-rapid metabolizers on the other hand, a large incidence of adverse effects might be expected, including apnea, because of large plasma morphine concentrations. Administration (especially of codeine preparations with an antihistamine and a decongestant) in the neonate may cause intoxication.<sup>1499</sup> A mother who ingested codeine while breastfeeding is thought to have transferred morphine in the breast milk, resulting in a fatality in her neonate. The mother, a UM, produced morphine more rapidly from the codeine, which resulted in respiratory depression in the neonate.<sup>1493,1500</sup> Because there is unpredictable variability in the conversion of codeine to morphine, we recommend alternative medications be considered; with codeine, if the child is a PM, they will receive very little analgesia, whereas, if a UM, they could sustain a life-threatening event because of increased conversion to morphine.

### TRAMADOL

Tramadol (Ultram) is a weak opioid with minimal effects on respiration and causes monoaminergic spinal cord inhibition of pain.<sup>1501-1504</sup> This formulation is structurally related to morphine and codeine.<sup>1504</sup> Two enantiomers provide analgesia; one is a opioid  $\mu$ -receptor agonist, and the other inhibits neuronal reuptake of serotonin and inhibits norepinephrine uptake, thus producing "multimodal antinociception."<sup>1504</sup> It is primarily metabolized into *O*-desmethyltramadol (M1) by CYP2D6, which, because of its extensive polymorphism poses the same concerns as in the case of codeine.<sup>1505</sup> Poor metabolizers have both reduced analgesia and nausea.

Prostaglandin H<sub>2</sub> synthetase (PGHS) is the enzyme responsible for metabolism of arachidonic acid to the unstable prostaglandin H<sub>2</sub>. The two major forms of this enzyme are the constitutive PGHS-1 (COX-1) and the inducible PGHS-2 (COX-2). PGHS comprises two sites, a cyclooxygenase (COX) site and a peroxidase (POX) site. The conversion of arachidonic acid to prostaglandin G<sub>2</sub>, the precursor of the other prostaglandins (E-Fig. 6-17), depends on a tyrosine-385 radical at the COX active site. Acetaminophen acts as a reducing cosubstrate on the POX site. Alternatively, acetaminophen effects may be mediated by an active metabolite (*p*-aminophenol). *p*-Aminophenol is conjugated with arachidonic acid by fatty acid amide hydrolase and exerts its effect through cannabinoid receptors.<sup>1524</sup>

The ED<sub>50</sub> for rectal acetaminophen to avoid any supplemental opioids after day-stay surgery is 35 mg/kg.<sup>1525</sup> Further studies are required before regular doses greater than 40 mg/kg can be recommended because of concerns about hepatotoxicity,<sup>1525-1527</sup> which can occur even after single doses of 250 mg/kg.<sup>1528</sup> Time delays of approximately 1 hour between peak concentration and peak effect have been reported.<sup>1529,1530</sup> An estimate of a maximum effect was 5.17 (the greatest possible pain relief [VAS 0 to 10] would equate to an Emax of 10 out of 10 pain units) and an EC<sub>50</sub> of 9.98 mg/L. The T<sub>1/2</sub>keo of the analgesic effect compartment was 53 minutes.<sup>60,1529</sup> A target effect compartment concentration of 10 mg/L was associated with a pain reduction of 2.6/10.<sup>60</sup>

The relative bioavailability of rectal to oral acetaminophen formulations (rectal/oral) is approximately 0.5 in children but the relative bioavailability is greater in neonates and approaches unity.<sup>96</sup> There are two IV paracetamol formulations available, and caution must be exercised with the choice of formulation.<sup>1531</sup> One is an acetaminophen formulation, whereas the other, propacetamol (*N*-acetyl-*para*-aminophenoldiethyl aminoacetic ester), is a water-soluble prodrug of acetaminophen that can be administered intravenously over 15 min. It is rapidly hydroxylated into acetaminophen (1 g propacetamol = 0.5 g acetaminophen).<sup>1532</sup>

The T<sub>1/2</sub>abs of acetaminophen from the duodenum is rapid (4.5 minutes) in children who were given acetaminophen as an elixir.<sup>1533</sup> The T<sub>1/2</sub>abs in infants under the age of 3 months was delayed (16.6 minutes), consistent with delayed gastric emptying in young infants.<sup>96,1533</sup> In contrast, rectal absorption is slow and erratic with large variability. For example, absorption parameters for the triglyceride base were a T<sub>1/2</sub>abs of 1.34 hours (coefficient of variation [CV] = 90%) with a lag time before absorption began of 8 minutes (CV = 31%). The T<sub>1/2</sub>abs for rectal formulations was prolonged in infants less than 3 months (1.51 times greater) compared with those in older children.<sup>1534</sup>

Sulfate metabolism is the dominant route of elimination in neonates, while glucuronide conjugation (via UGT1A6) is dominant in adults. A total body clearance of 0.74 L/hr/70 kg at 28 weeks PMA and 4.9 L/hr/70 kg (CV = 38%) in full-term neonates after enteral acetaminophen has been reported using an allometric  $\frac{3}{4}$ -power model.<sup>1534</sup> Clearance increases over the first year of life (see Fig. 6-10) and reaches 80% of that in older children (16 L/hr/70 kg) by 6 months postnatal age.<sup>96,173</sup> Similar clearance estimates are reported in neonates after IV formulations of acetaminophen.<sup>1535,1536</sup> The relative bioavailability of the oral formulation is 0.9.

The Vd for acetaminophen is 49 to 70 L/70 kg. The Vd decreases exponentially, with a TM<sub>50</sub> of 11.5 weeks, from 109.7 L/70 kg at 28 weeks PCA to 72.9 L/70 kg by 60 weeks, reflective of fetal body composition and water distribution changes over the first few months of life.<sup>96</sup>

**E-FIGURE 6-17** The conversion of arachidonic acid to prostaglandin  $G_2$  ( $PGG_2$ ), the precursor of the prostaglandins, is controlled by prostaglandin  $H_2$  synthetase. Prostaglandin  $H_2$  synthetase comprises two sites, a cyclooxygenase site and a peroxidase site.  $PGE_2$ , Prostaglandin  $E_2$ ;  $PGF_2$ , Prostaglandin  $F_2$ .

The toxic metabolite of acetaminophen, *N*-acetyl-*p*-benzoquinone imine (NAPQI), is formed by CYP2E1, 1A2, and 3A4. This metabolite binds to intracellular hepatic macromolecules to produce cell necrosis and other damage. Infants less than 90 days postnatal age have decreased expression of CYP2E1 activity in vitro compared with older infants, children, and adults,<sup>1537</sup> CYP3A4 appears during the first week after birth, whereas CYP1A2 appears later.<sup>8</sup> Neonates can produce hepatotoxic metabolites (e.g., NAPQI), but the reduced activity of CYP in neonates may explain the rare occurrence of acetaminophen-induced hepatotoxicity in neonates. Nonetheless, two massive 10-fold overdoses of paracetamol were reported in infants and underscore the need for extreme care when administering IV forms of acetaminophen.<sup>1538</sup> Neither infant progressed to acute

coefficient, see Fig. 6-5) of the concentration-response curve was steeper than that for acetaminophen (Hill = 2 for ibuprofen, Hill = 1 for acetaminophen) indicating a more rapid onset of analgesia. NSAIDs are rapidly absorbed in the gastrointestinal tract after oral administration in children. The relative bioavailability of oral preparations approaches unity. The rate and extent of absorption after rectal administration of NSAIDs such as ibuprofen, diclofenac, flurbiprofen, indomethacin, and nimesulide, are less than after the oral routes.

The Vd is small in adults (less than 0.2 L/kg) but larger in children. Preterm neonates (22 to 31 weeks gestational age) given IV ibuprofen had a Vd of  $0.62 \pm 0.04$  L/kg.<sup>1553</sup> One paper reported a dramatic reduction in ibuprofen central volume after closure of the PDA in preterm neonates (0.244 vs 0.171 L/kg).<sup>1554</sup> The NSAIDs, as a group, are weakly acidic, lipophilic, and highly protein bound. The impact of altered protein binding is probably minimal with routine dosing, because NSAIDs cleared by the liver have a low hepatic extraction ratio.<sup>81</sup>

NSAIDs undergo extensive phase I and phase II enzyme biotransformation in the liver, with subsequent excretion into urine or bile. Renal elimination is not an important elimination pathway for the commonly used NSAIDs. PK parameter variability is large, in part attributable to covariate effects of age, size, and pharmacogenomics. Ibuprofen, for example, is metabolized by the CYP2C9 and CYP2C8 subfamily. Considerable variation exists in the expression of CYP2C activities among individuals, and functional polymorphism of the gene coding for CYP2C9 has been described.<sup>1555</sup> CYP2C9 activity is low immediately after birth (21% of adult values), subsequently increasing progressively to reach a peak activity within 3 months, when expressed as mg/kg/hr.<sup>1556</sup>

Clearance (L/hr/kg) is generally greater in children than it is in adults, as we might expect when the linear per kilogram model is used. Ibuprofen clearance maturation follows the similar pattern to other drugs (Fig. 6-4). Clearance increases from 2.06 mL/hr/kg in extreme preterm neonates 22 to 31 weeks PMA,<sup>1553</sup> to 9.49 mL/hr/kg in preterm neonates 28 weeks PMA,<sup>1554</sup> peaking at 140 mL/hr/kg in preschool children, before decreasing again during late childhood and adolescence (71 mL/hr/kg).<sup>1557</sup> Similar data exist for indomethacin.<sup>1549,1558,1559</sup>

Many NSAIDs exhibit stereoselectivity.<sup>1560</sup> Ibuprofen stereoselectivity is reported in preterm neonates (less than 28 weeks gestation). *R*- and *S*-ibuprofen half-lives were about 10 hours and 25.5 hours, respectively. The mean clearance of *R*-ibuprofen (12.7 mL/hr) was about 2.5-fold greater than that of *S*-ibuprofen (5.0 mL/hr).<sup>1561</sup>

During pregnancy, there is relatively little transfer of NSAIDs from maternal to fetal blood. Very small quantities of NSAIDs are secreted into breast milk. Similarly, infant exposure to ketorolac via breast milk is estimated to be only 0.4% of maternal exposure.<sup>1562</sup>

NSAIDs undergo drug interactions through altered clearance and competition for active renal tubular secretion with other organic acids. A high fractional protein binding has been proposed to explain drug interactions between NSAIDs and oral anticoagulant agents, oral hypoglycemics, sulfonamides, bilirubin, and other protein bound drugs. One paper<sup>1563</sup> showed that warfarin administered with phenylbutazone increased both plasma warfarin concentrations and the prothrombin time in normal volunteers. However, while phenylbutazone displaces warfarin from its albumin binding sites in vitro, this observation does not explain changes in prothrombin time. The increased prothrombin time is a result of increased serum warfarin

concentrations attributed to reduced clearance, and not from changes in protein binding.<sup>81</sup> Both warfarin and phenylbutazone

The PK, standardized using allometry, are similar in adults and children (E-Table 6-5). The terminal elimination half-life in children 4 to 8 years of age is approximately 6 hours, although there is considerable variability.<sup>1587-1589</sup> PK may also be influenced by chronobiology<sup>754</sup> and many NSAIDs exhibit stereoselectivity. Ketorolac is supplied and administered as a racemic mixture that contains a 1 : 1 ratio of the *R*(+) and *S*(-) stereoisomers. Pharmacologic activity resides almost exclusively with the *S*(-) stereoisomer.<sup>1560,1590</sup> Clearance of the *S*(-) enantiomer was four times that of the *R*(+) enantiomer (6.2 vs 1.4 mL/min/kg) in children 3 to 18 years.<sup>1591</sup> Terminal half-life of *S*(-)-ketorolac was 40% that of the *R*(+) enantiomer (107 vs 259 min), and the Vd of the *S*(-) enantiomer was greater than that of the *R*(+) form (0.82 vs 0.50 L/kg). Recovery of *S*(-)-ketorolac glucuronide was 2.3 times that of the *R*(+) enantiomer. Because of the greater clearance and shorter half-life of *S*(-)-ketorolac, PK predictions based on racemic assays may overestimate the duration of pharmacologic effect.<sup>1591</sup>

One of the major concerns with ketorolac is the inhibition of platelet function through inhibition of cyclooxygenase, and the consequent potential for postsurgical bleeding. Ketorolac has been shown to have minimal effect on prothrombin and partial thromboplastin times but has been shown to cause modest increases in the bleeding time.<sup>1575,1592-1595</sup> Unlike aspirin, the ketorolac antiplatelet effect is reversible and, therefore, the effect is dependent on the presence of ketorolac within the body.<sup>1596</sup> This effect on platelet function has been of most concern in children undergoing adenotonsillectomy.<sup>1597-1600</sup> In the studies reporting posttonsillectomy bleeding, most involved administration of the ketorolac during or at the beginning of the surgical procedure, before hemostasis was achieved. In addition, the increased incidence of bleeding appears to be primarily during the first 24 hours, which corresponds to the several half-lives it would take to eliminate ketorolac from the body. The incidence of bleeding after the first 24 hours does not appear to be different.<sup>1601</sup> It would therefore be reasonable to not administer this medication until the end of surgery, after hemostasis is achieved. Some practitioners eschew this issue altogether and only administer ketorolac when the potential for a life-threatening hemorrhage is less.<sup>1473</sup> Concerns regarding the possibility of postoperative hemorrhage appear to be valid, but the true frequency of life-threatening bleeding due exclusively to ketorolac is quite small.<sup>1583,1602-1605</sup> One paper reported a dose-response relationship for this bleeding propensity; the risk associated with the drug was larger and clinically important when ketorolac was used in higher doses, in older subjects, and for more than 5 days.<sup>1606</sup> Safety assessment showed no changes in renal or hepatic function tests, surgical drain output, or continuous oximetry between groups given placebo, 0.5 mg/kg, or 1 mg/kg at 6 to 18 hours after surgery.<sup>1560,1590</sup> Many clinicians discuss the possible use of ketorolac with the surgeon before administering it and document the conversation in the anesthesia record. Ketorolac can be used to treat pain after congenital heart surgery without an increased risk of bleeding complications.<sup>1603</sup> Ketorolac has been safely used to provide analgesia for preterm and term infants, but the PK in this age group has not been described.<sup>1607</sup>

Another concern is the potential for adverse effects on bone healing, particularly spinal fusion.<sup>1608,1609</sup> Evidence suggests that nonunion of the spine is associated only with large-dose and not low-dose ketorolac. Ketorolac has been used safely to provide analgesia for other types of orthopedic conditions as well.<sup>1610,1611</sup> One other concern is the report of sudden and profound

Target-Controlled Infusion

## Total Intravenous Anesthesia

### INDICATIONS

The most common indications for total intravenous anesthesia (TIVA) techniques in children are the following: those at risk for malignant hyperthermia (in whom volatile agents are to be avoided); children with a high risk of postoperative nausea and vomiting; brief radiologic or painful procedures, when rapid recovery is needed (e.g., magnetic resonance imaging, bone marrow aspiration, gastrointestinal endoscopy); frequent repeated anesthesia (e.g., radiation therapy); major surgery to control the stress response; neurosurgical procedures to assist with control of intracranial pressure and for cerebral metabolic protection, spinal instrumentation, and when evoked motor and auditory brain potentials are needed; and children in need of airway procedures (e.g., bronchoscopy).<sup>1-4</sup> Total intravenous sedation and anesthesia are used in pediatric intensive care, but propofol is specifically contraindicated for prolonged use with high infusion rates in very sick or young children, because of the propofol infusion syndrome risk.<sup>5-14</sup>

### DRUGS AND TECHNIQUES

The most commonly used medications include propofol, remifentanyl, alfentanil, and sufentanil; ketamine is occasionally used.<sup>15</sup> Delivery can be by a manual infusion scheme (Table 7-1) or by using pharmacokinetic model-driven infusion devices with software developed specifically for use in children. Unfortunately, the commercially available software packages usually limit the applicable age from 1 to 3 years or older, or weight from 10 to 15 kg or greater, and the pharmacokinetic (PK) parameters are derived from studies of a relatively few healthy children. Propofol programs that allow for age-, weight-, and gender-related changes in central compartment volume, clearance, and distribution have been developed and perform well in healthy children.<sup>16,17</sup> However, there are considerable gaps in knowledge for some drugs, for ill children, and for young children, infants, and neonates, so caution is needed when applying such programs to these populations. Therefore, the anesthesiologist can use these preprogrammed devices as a basis for initiating a TIVA technique but must also use skill, knowledge, and experience to titrate the intravenous (IV) agents to avoid awareness, pain, and adverse effects.

### PRINCIPLES

Healthy children often need a relatively high dose of IV agent per unit of body weight, and maintenance infusion rates need to

be higher than the weight-corrected dose for adults.<sup>18</sup> Conversely, the immature neonate, the critically ill child, or those with major organ failure need considerably smaller doses of IV anesthetic agents; care is particularly needed in children receiving vasoactive medication and those with congenital heart disease.<sup>19</sup> Titration is advisable to allow for wide interindividual variation in PK and pharmacodynamics (PD). Electronic monitoring of depth of anesthesia (processed electroencephalography) has not been sufficiently well-validated in infants and children, and is yet to be used as the sole guide to dosing. After IV injection, it is assumed that the drug rapidly and evenly distributes throughout the body. However, the drug is delivered into the venous side of the systemic circulation, passes through the pulmonary circulation, and then distributes to the major organs and other tissues, all of which have variable blood flow, metabolic enzyme activity, and composition (in terms of proportions of fat and water). Because regional blood flow, body composition, and body proportions vary during development, the PK and PD of drugs are even more complex in children than in adults.

The apparent volume into which drugs distribute therefore varies among children, within the same individual at different stages of development, and among drugs. A drug that is very lipid soluble will have a very large *volume of distribution* ( $V_d$ ), as will one that is highly bound to plasma proteins.

*Elimination* of medications and their metabolites commonly occurs by metabolism in the liver and subsequent excretion of water-soluble metabolites via the kidneys. Thus, conditions such as young age and hepatic and renal dysfunction, which are characterized by immature or reduced hepatic and renal functions, will attenuate the elimination of these medications. A measure of elimination of the medication is the *clearance*, which is the volume of blood from which the drug is eliminated per unit of time. Prolongation of the elimination of a drug reflects either an increase in the  $V_d$  or a reduction in clearance or both.

For a fixed infusion rate in a single compartment model, it takes five half-lives to reach a steady-state concentration (greater than 96% of the target) in the blood (Fig. 7-1). To more rapidly achieve steady-state conditions, a bolus dose or loading infusion may be administered. This rapidly fills the  $V_d$ , after which a new rate of infusion is calculated to maintain the blood concentration (Fig. 7-2). This is the dilemma of manual infusions; this loading dose has to pass the central volume and is usually so large that it will cause adverse effects, hemodynamic instability, and/or toxicity. Even a remifentanyl bolus should be administered over several minutes to reduce the risk of bradycardia, hypotension, and/or difficult mask ventilation.

TABLE 7-1 Manual Infusion Schemes

Drug	Loading Dose	Maintenance Infusion	Notes
Propofol <sup>26</sup>	1 mg/kg	10 mg/kg/hr for 10 minutes, then 8 mg/kg/hr for 10 minutes, then 6 mg/kg/hr thereafter	Adult regimen to achieve blood concentration of 3 µg/mL. Underdelivers to children and achieves lower blood concentration of 2 µg/mL.
Propofol <sup>25</sup>	1 mg/kg	13 mg/kg/hr for 10 minutes, then 11 mg/kg/hr for 10 minutes, then 9 mg/kg/hr thereafter	Concurrently with alfentanil infusion.
Alfentanil <sup>49</sup>	10-50 µg/kg	1-5 µg/kg/min	Results in blood concentration of 50-200 ng/mL.
Remifentanil <sup>1</sup>	0.5 µg/kg/min for 3 minutes	0.25 µg/kg/min	Produces blood concentrations of 6-9 ng/mL.
Remifentanil <sup>1</sup>	0.5-1.0 µg/kg over 1 minute	0.1-0.5 µg/kg/min	Produces blood concentrations of 5-10 ng/mL.
Sufentanil <sup>1,40</sup>	0.1-0.5 µg/kg	0.005-0.01 µg/kg/min	Results in blood concentration of 0.2 ng/mL for sedation and analgesia.
Sufentanil <sup>1,40</sup>	1-5 µg/kg	0.01-0.05 µg/kg/min	Results in blood concentrations of 0.6-3.0 ng/mL for anesthesia.
Fentanyl <sup>49</sup>	1-10 µg/kg	0.1-0.2 µg/kg/min	
Ketamine <sup>49</sup>	1-2 mg/kg	0.1-2.5 mg/kg/hr	Smaller dose and infusion rate for analgesia and sedation. Larger dose and infusion rate for anesthesia titrated to effect.
Midazolam <sup>49</sup>	0.05-0.1 mg/kg	0.1-0.3 mg/kg/hr	

FIGURE 7-1 Fixed rate infusion of propofol at 10 mg/kg/hr with no bolus dose in a healthy 10-kg, 1-year-old infant. Steady state is not reached after 1 hour. There is a lag of effect-site concentration behind blood concentration both during infusion and after stopping infusion. Effect-site concentration reaches blood concentration at about 1 hour. Context-sensitive half-time is 9 minutes. (Simulated using Tivatrain. Available at [www.eurosiva.org/TivaTrainer/tivatrain\\_main.htm](http://www.eurosiva.org/TivaTrainer/tivatrain_main.htm))

FIGURE 7-2 Manual infusion in a healthy 70-kg 40-year-old subject. Bolus dose was 1 mg/kg, then 10 mg/kg/hr for 10 minutes, 8 mg/kg/hr for 10 minutes, then 6 mg/kg/hr thereafter until 60 minutes, when infusion is discontinued. Maximum blood concentration is 4.5 µg/mL. Effect-site concentration reaches 3 µg/mL after around 10 minutes but drifts down to around 2.6 µg/mL and then very gradually rises. Context-sensitive half-time after 1 hour is 7 minutes. (Data from the Diprifusor pharmacokinetic data set.)

To more clearly understand the disposition of drugs after an IV dose, it is useful to consider a three-compartment model. The drug is delivered and eliminated from a central compartment, V1 (which includes the blood), but also distributes to and redistributes from two peripheral compartments, one representing well-perfused organs and tissues (fast compartment, V2), and the other representing more poorly perfused tissues, such as fat (slow compartment, V3) (Table 7-2). The transfer of the drug between the

central compartment (V1) and the two peripheral compartments (V2, V3), and also the elimination of the drug from the central compartment, is described by a series of clearances indicating the distribution back and forth between paired compartments, such as V1 to V2 and then V2 back to V1. The primary target organ that IV anesthetic agents affect is the brain. Therefore, an additional rate constant (keo) is added to describe the equilibration between the central compartment and the effect site in the brain.

**TABLE 7-2** Nomenclature for TCI Systems

Term	Meaning	Units
TCI	Target-controlled infusion	
Vc or V1	Central compartment volume	L
V2	Fast compartment volume (vessel rich group) = $V1 \times k_{12}/k_{21}$	L
V3	Slow compartment volume (vessel poor group) = $V3 \times k_{13}/k_{31}$	L
CL1	Elimination clearance = $V1 \times k_{10}$	L/hr
CL2 or Q2	Clearance between V1 and V2 = $V2 \times k_{21}$	L/hr
CL3 or Q3	Clearance between V1 and V3 = $V3 \times k_{31}$	L/hr
Cp	Blood concentration	
Ce	Effect-site concentration	
T	Target concentration	
CALC	Concentration calculated by TCI software	
MEAS	Concentration measured	
$k_{10}$	Elimination rate constant	/min
keo	Rate constant for equilibration between blood and effect-site	/min
$T_{1/2\text{keo}}$	Half-time for equilibration between blood and effect-site $T_{1/2\text{keo}} = L_N(2)/\text{keo}$	min
$k_{12}, k_{21}$	Rate constants for movement between V1 and V2	/min
$k_{13}, k_{31}$	Rate constants for movement between V1 and V3	/min

This compartment is not represented by a volume but rather by the time required to equilibrate. Consequently, there is a time lag before changes in the blood concentration are reflected in the effect site (see Figs. 7-1 and 7-2).

A hydraulic model is useful for understanding these concepts. The central compartment is connected to the peripheral compartments and effect site by a series of pipes of different diameters, and also to a drainage pipe to represent elimination (Fig. 7-3, *A* through *F*). The heights of the columns of fluid, which represent concentrations of drug, illustrate the gradient down which drug travels between the central and peripheral compartments, and this can be animated over time to show filling and emptying of compartments relative to each other. The diameter of the interconnecting pipes between the central and peripheral compartments represents the intercompartment clearances, and size of the drainage channel represents elimination. This hydraulic analogy is used in the Tivatrainer PK simulation program.<sup>20</sup>

### Fixed Infusion Rate and a Three-Compartment Model

When a fixed infusion rate is started (see Fig. 7-1), the blood concentration will increase but, almost simultaneously, distribution of drug to the fast compartment and elimination both begin. Distribution of drugs throughout the body contributes more to the removal of drug from blood than elimination for most medications. For remifentanyl, extremely rapid esterase clearance dominates. As the concentrations within each compartment equilibrate, the concentration gradient between compartments lessens (slowing drug transfer between compartments) but distribution to the slow compartment continues along with elimination. The net effect is that the blood concentration continues to increase, albeit at a slower rate. As the blood concentration increases toward equilibrium, elimination becomes relatively

**TABLE 7-3** Context-Sensitive Half-Times of Opioids in Children

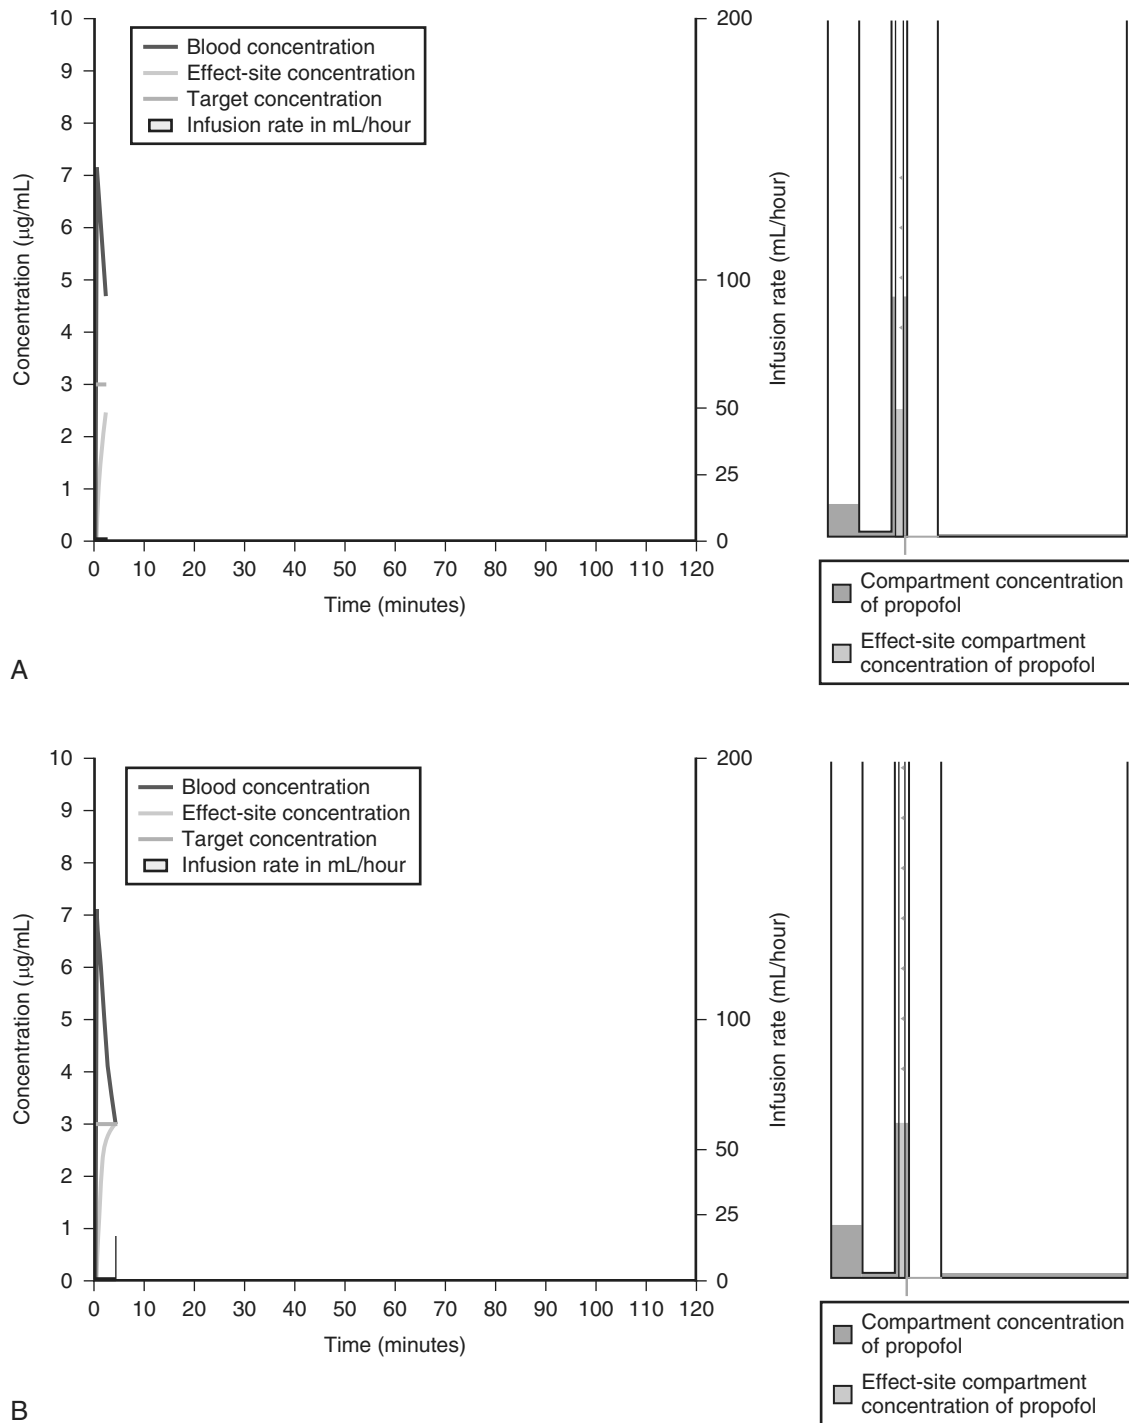

Opioid	INFUSION DURATION (minutes)				
	10	100	200	300	600
Remifentanyl	3-6	3-6	3-6	3-6	3-6
Alfentanil	10	45	55	58	60
Sufentanyl		20	25	35	60
Fentanyl	12	30	100	200	

Data from Absalom A, Struys MMRF. An overview of TCI and TIVA. Gent, Belgium: Academia Press; 2005.

more important; Figure 7-1 illustrates how far behind the effect-site concentration lags. Eventually, after several hours (or in some cases, days), a steady state is reached where infusion rate is directly proportional to clearance.

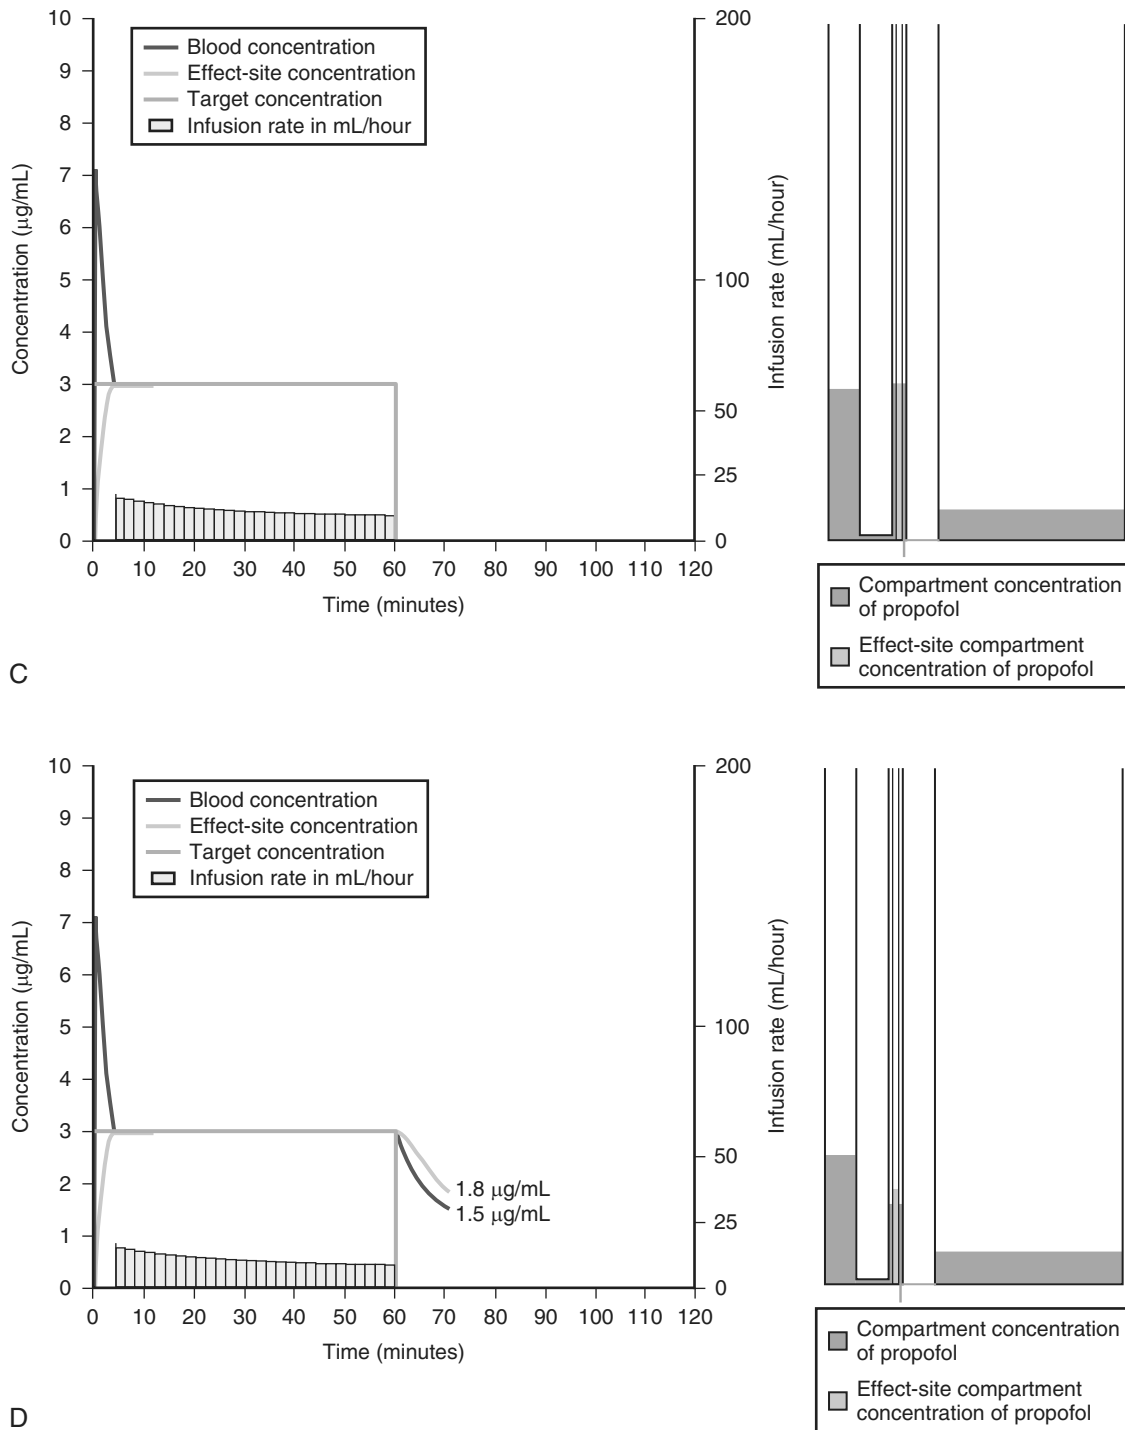

### Bolus and Variable Rate Infusion in a Three-Compartment Model

A loading dose can start to fill the central compartment and ideally should be aiming to create an effect-site concentration at a specific target concentration without overshoot. Then the rate of infusion should decrease in a stepwise manner to maintain a constant effect-site concentration until a steady state is reached. As drug is delivered into the central compartment, it continuously distributes to the peripheral compartments while it is continuously eliminated. The infusion rate must vary because it has to match the changes in the contribution of distribution and elimination with time (Figs. 7-4 and 7-5). When the infusion is stopped, then elimination will continue to drain the central compartment, and drug will continue to distribute to V2 and V3 along concentration gradients from V1 for some time. Equilibrium may be reached, but the drug now begins to move back from the peripheral compartments into the central compartment, maintaining the central compartment drug concentration for a period of time. This can continue for a protracted interval, particularly for highly lipid-soluble drugs that have a very large slow compartment V3 and a reservoir or depot effect (see Fig. 7-3, *F*). Eventually the central compartment concentration will decrease. For most anesthetics, the longer the duration of an infusion, the more the drug has distributed into the peripheral compartments, and the larger the reservoir of drug to be redistributed back into the central compartment and eliminated, once the infusion ceases. The half-time of the decrease in drug concentration in blood, therefore, is related to the duration of the infusion for most drugs (except remifentanyl [see later discussion]). This is termed the *context-sensitive half-time* (CSHT), where the context is the duration of the infusion and relates to a pseudo-steady-state maintained by a target-controlled infusion (see later discussion). For an individual drug in an individual patient, CSHT can be plotted against the duration of the infusion (Fig. 7-6, *A* and *B*). The CSHT graph will eventually become parallel to the time axis and this is when the pseudo-steady-state becomes a true steady-state. At that time, the infusion has become context *insensitive*. This pattern is observed for nearly all IV anesthetics. The exception is remifentanyl, whose half-time becomes context insensitive almost immediately after initiation of the infusion, because its elimination is rapid and complete; the capacity of the red cell, plasma, and tissue esterase enzyme systems are enormous (Table 7-3). The relevant PK parameters for remifentanyl, alfentanil, and sufentanyl are summarized in Table 7-4.<sup>1</sup> The

**FIGURE 7-3 A,** Hydraulic model representation of effect-site target-controlled infusion. Compartment volumes ( $V_1$ ,  $V_2$ , and  $V_3$ ) and intercompartmental clearance values ( $CL_1$ ,  $CL_2$ , and  $CL_3$ ) for Paedfusor model in a healthy 10-kg, 1-year-old infant: lean body mass 9.0 kg, body surface area 0.46 m<sup>2</sup>, are  $V_1 = 4.6$  L,  $V_2 = 9.5$  L,  $V_3 = 58.2$  L,  $CL_1 = 21.1$  L/hr;  $CL_2 = 31.4$  L/hr,  $CL_3 = 11.5$  L/hr. In the first few minutes the central compartment to effect-site concentration gradient is marked to "overpressure" the transfer of propofol to the effect site. The peak blood concentration is 7.1 µg/mL. Distribution from compartment 1 ( $C_1$ ) to  $C_2$  occurs rapidly also, which slows the rise in effect-site concentration and blood concentration. Elimination from  $C_1$  and distribution from  $C_1$  to  $C_3$  is also occurring. **B,** At 4.5 minutes, the effect-site concentration has reached the target of 3 µg/mL and has equilibrated with the concentration in  $C_1$ . The infusion device, which has been off after the initial loading infusion, now switches back on to maintain the effect-site target concentration at 3 µg/mL.

*Continued*

**FIGURE 7-3, cont'd C,** After 1 hour of maintenance at an effect-site concentration of 3 µg/mL, the target is set to 0 µg/mL and the pump switches off. A total of 14 mL of propofol (1%) has been administered, or 14 mg/kg. There is now a considerable accumulation of propofol in compartment 2 (C2) and C3, while C1 and the effect site are still in equilibrium. **D,** Some 10 minutes after the effect-site target concentration is set to 0, the blood concentration has halved; thus the context-sensitive half-time is 10 minutes. The lag in the decline in effect-site concentration is clearly seen, and there is now a gradient between effect site and C1. There is now also a concentration gradient from C2 to both C1 and C3, and this slows the decline in the concentration in C1.

**FIGURE 7-3, cont'd E,** One hour after the infusion is stopped the blood and effect-site concentrations have fallen to one fifth of the maintenance effect-site concentration. There are still considerable quantities of propofol in compartments C2 and C3 that slow the decline of the concentration of C1 and effect-site concentrations. **F,** Even after 4 hours, the depot of propofol in C2 and C3 is considerable, although blood and effect-site concentrations are extremely low. However, these low concentrations may still be exerting significant antiemetic and anxiolytic effects. (Data from the Paedfusor pharmacokinetic data set.)

**FIGURE 7-4** Manual infusion of propofol in a 1-year-old, 10-kg child. Bolus dose of 1 mg/kg, then 10 mg/kg/hr for 10 minutes, then 8 mg/kg/hr for 10 minutes, then 6 mg/kg/hr thereafter. Infusion stopped at 60 minutes. Effect-site concentration does not equilibrate until 11 minutes. Blood and effect-site concentrations stabilize around 1.8 µg/mL. However, this is unlikely to represent a sufficient depth of anesthesia for surgery. Context-sensitive half-time after 1 hour is 9 minutes. (Data from the Paedfusor pharmacokinetic data set.)

**FIGURE 7-5** Manual infusion of propofol in 1-year-old, 10-kg child. Bolus dose of 1 mg/kg, then 13 mg/kg/hr for 10 minutes, then 11 mg/kg/hr for 10 minutes, then 9 mg/kg/hr thereafter. Infusion stopped at 60 minutes. Effect-site concentration does not equilibrate until 20 minutes. Blood and effect-site concentrations stabilize around 2.4  $\mu\text{g/mL}$ , but gradually rise over the subsequent hour to 2.6  $\mu\text{g/mL}$ . (Data from the Paedfusor pharmacokinetic data set.)

**FIGURE 7-6** **A**, Context-sensitive half-times (CSHTs) after short-duration infusions. **B**, CSHTs after longer-duration infusions. For very lipid-soluble drugs such as fentanyl and propofol, V3 is very large compared with V1. Intercompartmental clearance between V1 and V3 is given by the equation  $V1 \times k_{13} = V3 \times k_{31}$ , which implies that if V1 is much smaller than V3, rapid distribution from V1 to V3 is associated with very slow redistribution from V3 to V1. This is indeed seen with propofol and fentanyl, which have slow offset of effects after prolonged infusion. Propofol has a CSHT that varies from around 3 minutes for a short-duration infusion to 18 minutes after a 12-hour infusion. This is because elimination is quite rapid compared with the rate of redistribution from V3. For alfentanil, the concentration of the un-ionized form is 100 times greater than that of fentanyl (pKa alfentanil 6.4, fentanyl 8.5). Alfentanil therefore has a more rapid onset time and shorter effect-site equilibration half-life, a smaller V1, lower volume of distribution at steady-state, and lower clearance than fentanyl. Fentanyl does, however, have a shorter CSHT than alfentanil after a short-duration infusion lasting less than 2 hours (**A**); but for longer-duration infusions, alfentanil reaches a maximum CSHT after about 90 minutes, whereas for fentanyl, the CSHT continues to increase after 12 hours (**B**). This is because fentanyl has a huge V3, and redistribution back to V1 maintains the blood concentration when the infusion stops. (Simulated using Tivatrain. Available at: [www.eurosva.org/TivaTrainer/tivatrain\\_main.htm](http://www.eurosva.org/TivaTrainer/tivatrain_main.htm).)

**TABLE 7-4** Pharmacokinetic Parameters for Short-Acting Opioids

	Remifentanyl <sup>50,51</sup>	Alfentanil <sup>52</sup>	Sufentanil <sup>53</sup>
V1	$5.1 - 0.0201 \times (\text{age} - 40) + 0.072 \times (\text{LBM} - 55)$	Male: $0.111 \times \text{weight}$ Female: $1.15 \times 0.111 \times \text{weight}$	$0.164 \times \text{weight}$
V2	$9.82 - 0.0811 \times (\text{age} - 40) + 0.108 \times (\text{LBM} - 55)$	12.0	$0.359 \times \text{weight}$

Age in years; weight in kilograms; LBM, lean body mass.

differences in CSHTs are illustrated in Table 7-3 and Figure 7-6, **A** and **B**. Fentanyl has a small CSHT when given by infusion for a short time, but this dramatically increases as the duration of the infusion increases. Alfentanil's CSHT reaches a plateau after approximately 90 minutes of infusion. Clearances of fentanyl, alfentanil, and sufentanil are reduced in neonates and young infants because of the immaturity of hepatic enzyme systems, whereas clearance of remifentanyl is relatively age-independent because esterases are ubiquitous throughout the body and are fully mature in neonates.

Administration of propofol can affect its own distribution and elimination by altering regional blood flow. Both fentanyl and alfentanil increase the volume of V1 and clearance of propofol, whereas propofol and midazolam inhibit the metabolism of alfentanil by the cytochrome P-450 enzyme isoform CYP3A4. Recent evidence in adults suggests that both sevoflurane and remifentanyl can significantly increase the plasma concentrations of propofol.<sup>21,22</sup> In addition to these PK interactions there are important synergistic PD interactions between agents that suppress central nervous system activity.<sup>23,24</sup> For TIVA techniques in children, concurrent administration of opioids has a significant "propofol-sparing" effect, while providing analgesia and stress

**FIGURE 7-7** Target-controlled infusion modeled using the Paedfusor pharmacokinetic data set. Blood-targeted infusion of propofol in a healthy 1-year-old, 10-kg child. Blood target is 3 µg/mL. Bolus dose of 1.4 mg/kg delivered, then stepwise-reducing infusion of from 19.1 mg/kg/hr to 9.5 mg/kg/hr at 1 hour. Infusion stopped at 60 minutes (i.e., blood target to 0 µg/mL). Effect-site concentration does not reach 3 µg/mL until 15 minutes 44 seconds. Total dose of propofol is 13.6 mg/kg. Context-sensitive half-time is 10 minutes.

control.<sup>24,25</sup> It is especially important to take advantage of this synergism to avoid excessive propofol and long-chain triglyceride load, particularly with concerns about propofol infusion syndrome. *Remifentanyl provides the most effective propofol-sparing effect, but fast recovery means alternative techniques of analgesia must be well established before the remifentanyl is discontinued.* Fentanyl, alfentanil, and sufentanil are effective in this regard; local and regional analgesia techniques also allow significant propofol dose reduction once the block becomes established. Nitrous oxide and low concentrations of inhalational anesthetics also act synergistically with propofol and opioids.

**MANUAL INFUSION SCHEMES**  
**Propofol**

A simple scheme was devised to maintain a blood concentration of propofol in healthy adults of 3 µg/mL.<sup>26</sup> A bolus IV dose of 1 mg/kg is followed by a continuous infusion of 10 mg/kg/hr for 10 minutes, then 8 mg/kg/hr for 10 minutes, then 6 mg/kg/hr thereafter. When this “10, 8, 6” regimen is modeled and verified using the Marsh model for an adult patient, the estimated blood concentration slightly exceeds 3 µg/mL, but remains reasonably stable.<sup>27</sup> This simple dosing regimen is very effective in adults (see Fig. 7-2). However, when the same regimen is modeled using the “Paedfusor” PK data set for a child 1 year old and weighing 10 kg, the blood concentration achieved is approximately 2 µg/mL, but decreases slowly over time. Thus, this regimen delivers a sub-therapeutic blood concentration of propofol in children. The subtherapeutic concentrations of propofol occurred because of a larger central compartment and an increased clearance of propofol in children compared with adults (see Fig. 7-4, Table 7-5). When the Paedfusor is used to calculate the dose of propofol that is required to achieve a blood concentration of 3 µg/mL, the bolus dose needed is 50% greater than in adults (1.5 mg/kg) and the infusion rates needed are approximately “19, 15, 12” each for 10-minute infusion. In addition, it takes approximately 15 minutes for the effect-site concentration to reach 3 µg/mL (Fig. 7-7). These data from the Paedfusor support the notion that the dosing of propofol infusions in young children is approximately twice that in adults. Similar results are predicted using the PK data set of Kataria et al<sup>28</sup> for children 3 to 11 years,<sup>29</sup> and in clinical adaptations of PK models.<sup>30</sup> This increased dose requirement can cause problems, because propofol is formulated in lipid and the lipid load can be considerable, particularly in young patients (Fig. 7-8). Propofol formulations are now available in concentrations varying from 5 mg/mL to 20 mg/mL (0.5% to 2%), and the

**TABLE 7-5** Differences between Adult and Pediatric Pharmacokinetic Parameters

Age	Vd (mL/kg)	Elimination Half-life (minutes)	Clearance (mL/min/kg)
1-3 yr	9500	188	53
3-11 yr	9700	398	34
Adult	4700	312	28

Notes: The apparent volume of distribution (Vd) of propofol in the child is twice that of adults. The clearance of propofol in young children is twice that of adults and elimination is much more rapid.  
Data from Absalom A, Struys MMRF. An overview of TCI and TIVA. Gent, Belgium: Academia Press; 2005.

**FIGURE 7-8** Lipid load after 480 minutes of a blood targeted propofol 1% infusion (formulated in a vehicle containing 0.1 g/mL lipid) with target concentration of 3 µg/mL. Note the smaller infants have almost twice the lipid load and so a 2% propofol formulation is recommended to halve the relative lipid exposure; other propofol-sparing and lipid-sparing measures should also be used. (Simulated using Tivatrainner. Available at: [www.eurosiva.org/TivaTrainer/tivatrainner\\_main.htm](http://www.eurosiva.org/TivaTrainer/tivatrainner_main.htm))

most effective “lipid-sparing” strategy for infusions is to use 20 mg/mL propofol (2%), as this immediately decreases the lipid load.

**Opioids**

Simple manual infusion regimens can be used for the opioids fentanyl, alfentanil, remifentanyl, and sufentanil. The manual

infusion regimens for these opioids in children are summarized in Table 7-1. Transitioning to maintenance analgesia after infusions of these opioids is a significant issue, and it is important to ensure either adequate regional or local anesthesia techniques are established or that adequate doses of systemic analgesia are given well before the infusion is discontinued. Transitioning is somewhat smoother after sufentanil than after alfentanil or remifentanyl in children. The problem of acute tolerance to ultra-short-acting opioids has been noted after use of remifentanyl in surgery for pediatric scoliosis.<sup>31</sup>

### Ketamine

Ketamine can be used in a simple basic manual regimen as a loading dose of 1 to 2 mg/kg and a maintenance infusion of 0.1–2.5 mg/kg/hr, depending on whether the target state is analgesia, sedation, or anesthesia (see Table 7-1).

### Midazolam

Slow bolus dosing of up to 0.1 mg/kg followed by an infusion rate of 0.1 mg/kg/hr provides baseline sedation with adjustments and additional bolus doses often needed. Caution is required, with bolus dosing in neonates and infants and in the critically ill because hypotension may occur and the depth of sedation achieved with midazolam is tremendously variable (see Table 7-1).

## Target-Controlled Infusion

A target-controlled infusion (TCI) is controlled by a computer that performs rapid sequential calculations every 8 to 10 seconds to determine the infusion rate required to produce a user-defined drug concentration in the central compartment (which includes the blood) or at the effect site of action of the drug in the brain.<sup>1</sup> *Thus, TCI may be blood targeted or effect-site targeted.* The standard nomenclature for TCI systems is listed in Table 7-2. Modern TCI systems are computer-controlled syringe drivers capable of infusion rates up to 1200 mL/hr, with a precision of 0.1 mL/hr. They incorporate a user interface and display and a range of safety alarms, monitoring functions, and warning systems. For most programs, the user has to choose a drug and its concentration from a menu and one must also select a PK parameter set (referred to as a “model”). The models suitable for use in children are quite limited, and some models are not suitable for all age groups. Others may be suitable but have not been validated in younger children; neonatal and infant models are quite rare. Experience with the various models may be gained by running simulation programs, such as Tivatrainner ([www.eurosva.org/TivaTrainer/tivatrainner\\_main.htm](http://www.eurosva.org/TivaTrainer/tivatrainner_main.htm)) or Rugloop (<http://www.demed.be/rugloop.htm>), on a personal computer. Tivatrainner now allows uploading of new models via a central website and server, and contains details and simulations of pediatric models for propofol, and neonatal and pediatric models for sufentanil, in addition to a wide range of adult models for propofol, alfentanil, remifentanyl, fentanyl, ketamine, and midazolam. The simulation shows animated graphs of blood and effect-site concentrations against time, infusion rates, volumes, compartment sizes, and many other features.

The models within TCI systems are derived from studies of small numbers of healthy patients, and are only a guide to drug administration for an individual patient.<sup>17</sup> The accuracy of TCI propofol has been assessed in children.<sup>17,27</sup> TCI propofol has been incorporated into a modified version of the commercial “Diprifusor” device; it is known as the Paedfusor<sup>32</sup> and has been evaluated

**TABLE 7-6 Paedfusor Pharmacokinetic Parameter Set**

1-12 years	$V1 = 0.4584 \times \text{weight}$ ; $V2 = V1 \times k_{12}/k_{21}$ ; $V3 = V1 \times k_{13}/k_{31}$ $k_{10} = 0.1527 \times \text{weight}^{-0.3}$ $k_{12} = 0.114$ ; $k_{21} = 0.055$ $k_{13} = 0.0419$ ; $k_{31} = 0.0033$ $keo = 0.26$

\*This is the value for adults, but Munoz and colleagues<sup>38</sup> have studied these two models to define a more accurate  $keo$  for children 3 to 11 years of age, and the values are 0.91 for Paedfusor and 0.41 for Kataria. Jeleazcov<sup>39</sup> has derived age-related  $keo$  values by the formula  $keo = 1.03 \times e^{-(0.12 \times \text{age})}$ .

clinically and found to perform well (Table 7-6).<sup>27,33,34</sup> In children undergoing cardiac surgery, the model performed significantly better than the adult model in adults.<sup>32,35,36</sup> Several pediatric propofol models have been validated<sup>17,28</sup> (Table 7-7), but all models have problems.<sup>37</sup> Experience shows that clinicians need to learn how to use each model to optimize levels of anesthesia, to ensure stability during induction and maintenance phases, and to enhance recovery speed and quality. Most pediatric models overestimate the initial Vd<sup>17</sup> which risks too large an initial bolus dose.<sup>17</sup> The Paedfusor model makes an allowance for the steady increase of clearance with age in younger children,

**FIGURE 7-9** Target-controlled infusion modeled using the Paedfusor pharmacokinetic data set. Effect-site-targeted infusion of propofol in a healthy 1-year-old, 10-kg child. Effect-site target is 3  $\mu\text{g/mL}$ . Bolus dose of 3.4 mg/kg is delivered at 45.5 mL/hr to accentuate the gradient from blood to effect site, then infusion switches off for 4 minutes. Peak blood concentration after bolus dose is 7.1  $\mu\text{g/mL}$ . Stepwise-reducing infusion of from 15.7 mg/kg/hr to 9.5 mg/kg/hr at 1 hour was done. Infusion stopped at 60 minutes (i.e., effect-site target is 0  $\mu\text{g/mL}$ ). Effect-site concentration reaches 3  $\mu\text{g/mL}$  at 3 minutes 39 seconds. Total dose of propofol is 14 mg/kg. Context-sensitive half-time is 10 minutes 37 seconds.

**TABLE 7-8** Example of Target-Controlled Infusion (5  $\mu\text{g/mL}$ ) Based on Calculated Blood-Concentration Targeting Compared with Calculated Effect-Site Concentration Targeting for a Healthy 1-Year-Old (Weight 10 kg), Using the Paedfusor Pharmacokinetic Parameters

	Blood Concentration Targeting	Effect-Site Concentration Targeting
Loading dose	1.7 mg/kg	5.7 mg/kg*
Maximum blood target reached	5 $\mu\text{g/kg}$	12 $\mu\text{g/kg}$ *
Total propofol infused after 60 minutes	23.2 mg/kg	23.3 mg/kg
Time to achieve effect site target of 5 $\mu\text{g/mL}$	17.5 minutes	4.5 minutes†

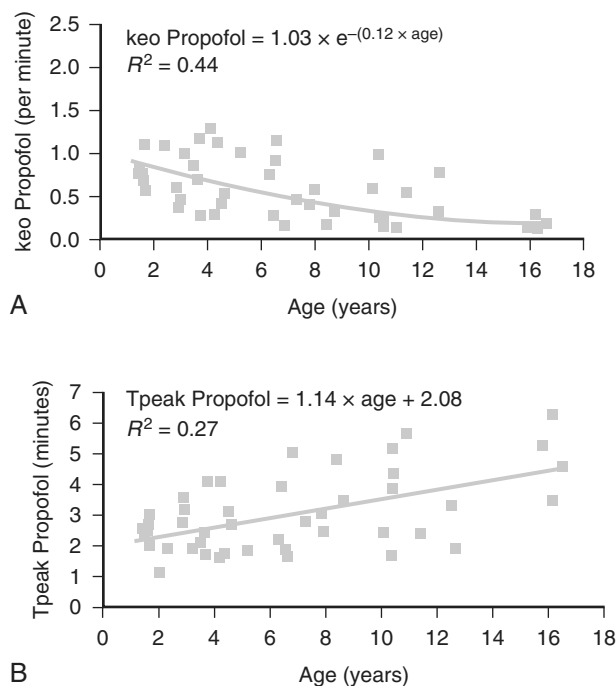

\*Potential for hemodynamic changes due to high peak blood concentration from larger bolus dose.

†Very much shorter time to achieve effect-site target.

particularly those below 30 kg in weight (see Tables 7-6 and 7-7, Fig. 7-9). The minimum age and weight limits for each model also differ, with 1 year of age and 5 kg for the Paedfusor system, and 3 years of age and 15 kg for the Kataria system. Below a weight of 12.5 kg and an age of 2 years, the second compartment becomes negative with the Kataria model, which means that model cannot be used clinically in such young patients. For simulation using the Paedfusor parameters, the adult value for keo of 0.26 per minute ( $T_{1/2\text{keo}}$  2.7 minutes) can be used (see Table 7-7). This means effect-site targeting may be simulated with Paedfusor (Table 7-8), and it may be possible to display a predicted concentration for an effect-site while using a pump in blood-targeted TCI mode, as with Diprifusor. Attempts have been made by Munoz to define a more accurate keo for children,

in an ingenious study using auditory evoked responses with both the Paedfusor and Kataria models.<sup>38</sup> For children 3 to 11 years of age, the median extrapolated keo values for the Paedfusor models was 0.91 per minute ( $T_{1/2\text{keo}}$  0.8 minutes), and for the Kataria model, 0.41 per minute ( $T_{1/2\text{keo}}$  1.7 minutes). The bispectral index (BIS) was used to derive a value for the time to peak effect, and hence keo.<sup>39-41</sup> It was concluded that the time to peak effect after a bolus dose was shorter in children than adults, as the extrapolated  $T_{1/2\text{keo}}$  values were considerably smaller, although this extrapolation may be flawed when considering a TCI system.<sup>37</sup> Similar findings were reported by Hahn and colleagues using state entropy monitoring.<sup>42</sup> This has enabled calculation of an age-specific range of values for the keo (Fig. 7-10), which should allow more accurate effect-site targeting using propofol in the future. It must be stressed that compartmental values are highly specific to a single model, and are not interchangeable.<sup>17,37</sup> It can be argued that these calculations and extrapolations are a trick to get around imperfect PK values.<sup>17,37</sup> Integrating PK and PD into models appropriate for use in children is challenging not least because of doubts about the sensitivity and specificity of depth of anesthesia monitoring in children.<sup>42-45</sup>

Effect-site targeting offers the advantages of more rapid achievement of desired depth of anesthesia and less titration of the target depth in practice, but whilst it has been used in research in children, it has yet to become a clinical tool.<sup>46</sup> Table 7-8 shows how the behavior of the TCI differs between blood and effect-site targeted infusion using the adult keo of 0.26 per minute ( $T_{1/2\text{keo}}$  2.7 minutes). It can be expected that effect-site targeting may have more profound cardiovascular and respiratory effects than blood targeting, because of the larger initial bolus doses and resultant higher peak blood propofol concentrations attained.<sup>46</sup> It is known that slower administration of propofol preserves spontaneous respiration in children.<sup>47</sup> However, use of age-appropriate keo and  $T_{1/2\text{keo}}$  values and careful titration from

**FIGURE 7-10** **A**, Equilibration rate constant (*keo*) of propofol and **B**, time to peak propofol effect (*Tpeak*) as a function of age. (Data from Jelezov C, Ihmsen H, Schmidt J, et al. Pharmacodynamic modelling of the bispectral index response to propofol-based anaesthesia during general surgery in children. *Br J Anaesth* 2008;100:509-16.)

**FIGURE 7-11** The predicted propofol doses at induction, 20, and 60 minutes are shown for Paedfusor in plasma-targeted mode, for the Munoz derived *keo* values in effect-site targeted mode for Paedfusor (PF) and Kataria (Kat), and for Jelezov in effect-site targeted mode. The effect of the variable age-related *keo* value of Jelezov can be seen in the higher bolus and maintenance doses for infants. A propofol target concentration of 5 µg/mL was used for all simulations. (Data from Limb J, Morton NS. Age-specific effect-site TCI in children: modelling using TivaTrainer. *Anaesthesia* 2010;65:542)

a low initial target value may ameliorate these adverse effects. However, the variable *keo* of the Jelezov dataset, derived from using BIS, means adverse effects may be more marked in infants (Fig. 7-11 and 7-12).<sup>39,46</sup> Although the use of BIS remains uncertain in children,<sup>48</sup> particularly those less than 2 years old, the use

**FIGURE 7-12** Predicted context-sensitive half-time (CSHT) of propofol depends on the pharmacokinetic model. The Jelezov model uses age-appropriate *keo* values and this results in the shortest predicted CSHTs for all infusion durations. This has clinical importance as it predicts a shorter recovery time for a given target concentration. (Data from Limb J, Morton NS. Age-specific effect-site TCI in children: modelling using TivaTrainer. *Anaesthesia* 2010;65:542 and Absalom A. A hitch-hiker's guide to the intravenous PK/PD galaxy. *Pediatr Anesth* 2011;21:915-8)

**FIGURE 7-13** The peak plasma concentrations attained in simulations in Figure 7-12 for an effect-site target of 5 µg/mL are shown. The high boluses noted in Table 7-8 do not necessarily equate to high peak plasma concentrations because of the variable volumes of distribution in the pediatric models at different ages. (Data from Limb J, Morton NS. Age-specific effect-site TCI in children: modelling using TivaTrainer. *Anaesthesia* 2010;65:542 and Absalom A. A hitch-hiker's guide to the intravenous PK/PD galaxy. *Pediatr Anesth* 2011;21:915-8)

of the Jelezov model in TCI systems gives the prospect of more accurate and efficient propofol delivery to children.<sup>46</sup> This has safety implications in terms of reducing lipid load and clinical utility by increasing speed of recovery (Fig. 7-13).

**ELECTROLYTE DISTURBANCES ARE COMMON** in children because of their small size, large ratio of surface area to volume, and immature homeostatic mechanisms. As a result, fluid management can be challenging. On the ward, in the operating room, or in the intensive care unit (ICU), additional difficulties may result when fluid management is not tailored to the individual or when therapeutic decisions are based on extrapolations from adult data. To better understand the former and to limit the latter, this chapter reviews the basic mechanisms underlying fluid and electrolyte regulation, the developmental anatomy and physiology of fluid compartments, and the management of selected pediatric disease states relevant to anesthesia and critical care.

## Regulatory Mechanisms: Fluid Volume, Osmolality, and Arterial Pressure

Water is in thermodynamic equilibrium across cell membranes, and it moves only in response to the movement of solutes (E-Fig. 8-1). Movement of water is described by the Starling equation:

$$Q_f = K_f[(P_c - P_i) - \sigma(\pi_c - \pi_i)]$$

where  $Q_f$  is fluid flow;  $K_f$  is the membrane fluid filtration coefficient;  $P_c$ ,  $P_i$ ,  $\pi_c$ , and  $\pi_i$  are hydrostatic and osmotic pressures on either side of the membrane; and  $\sigma$  is the reflection coefficient for the solute and membrane of interest. The reflection coefficient gives a measure of a solute's permeability and, consequently, its contribution to osmotic force after equilibration. Across the blood-brain barrier, for example, the  $\sigma$  for sodium approaches 1.0,<sup>1</sup> whereas in muscle and other cell membranes,  $\sigma$  is on the order of 0.15 to 0.3.<sup>2</sup> Therefore, when isotonic

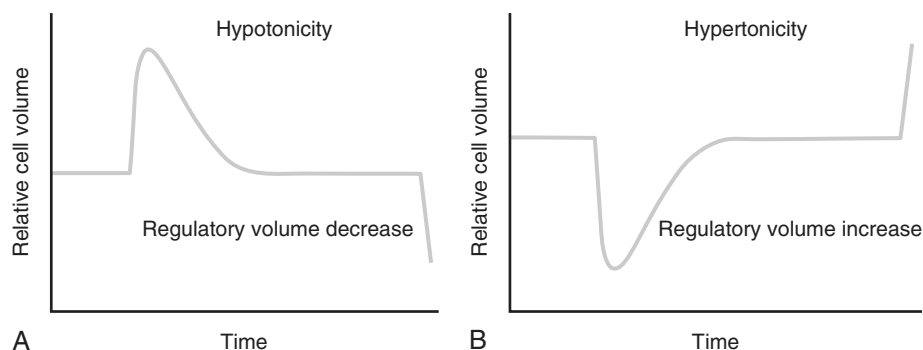

sodium-containing solutions are given intravenously, usually only 15% to 30% of administered salt and water remains in the intravascular space while the remainder accumulates as interstitial edema.<sup>3,4</sup> In contrast, hypertonic solutions permit greater expansion of circulating blood volume with smaller fluid loads and less edema.<sup>5-7</sup>

Both the amount and the concentration of solute are tightly regulated to maintain the volumes of intravascular and intracellular compartments. Because sodium is the primary extracellular solute, this ion is the focus of homeostatic mechanisms concerned with maintenance of intravascular volume. When osmolality is held constant, water movement follows sodium movement. As a result, total body sodium (although not necessarily serum  $\text{Na}^+$ ) and total body water (TBW) generally parallel one another. Because sodium "leak" across membranes limits its contribution to the support of intravascular volume, this compartment is also critically dependent on large, impermeable molecules such as proteins. In contrast to sodium, albumin molecules, for example, follow the Starling equilibrium with a reflection coefficient in excess of 0.8.<sup>8</sup> Soluble proteins create the so-called *colloid oncotic pressure*, approximately 80% of which is contributed by albumin.

Although the presence of albumin supports intravascular volume, protein leak into the interstitium (and consequent water movement) may limit its effectiveness. It has been observed, for example, that the reflection coefficient for albumin decreases by as much as one third after mechanical trauma.<sup>9</sup> Furthermore, because of ongoing leakage, a slow continuous infusion of albumen is superior to bolus administration for increasing the serum albumen concentration in critically ill individuals.<sup>10</sup>

**E-FIGURE 8-1** Movement of water from the intracellular to extracellular compartments is described by the Starling equation. See text for details.

**FIGURE 8-1** Activation of mechanisms regulating cell volume in response to volume perturbations. Volume-regulatory losses and gains of solutes are termed *regulatory volume decrease* (A) and *regulatory volume increase* (B), respectively. The course of these decreases and increases varies with the type of cell and experimental conditions. Typically, however, a regulatory volume increase mediated by the uptake of electrolytes or a regulatory volume decrease mediated by the loss of electrolytes and organic osmolytes occurs over a period of minutes. When cells that have undergone a regulatory volume decrease (A) or increase (B) are returned to normotonic conditions, they swell above or shrink below their resting volume. This is due to volume-regulatory accumulation or loss of solutes, which effectively makes the cytoplasm hypertonic or hypotonic, respectively, as compared with normotonic extracellular fluid. (From McManus ML, Churchwell KB, Strange K. Regulation of cell volume in health and disease. *N Engl J Med* 1995;333:1260-6. ©Massachusetts Medical Society.)

Potassium is the primary intracellular solute, with approximately one third of cellular energy metabolism devoted to  $\text{Na}^+/\text{K}^+$  exchange. Sodium continuously leaks into cells along its concentration gradient, yet it is rapidly extruded in exchange for potassium. As the cell is exposed to varying osmolarity, water movement occurs, causing cell swelling or shrinkage. Because stable cell volume is critical for survival, complex regulatory mechanisms have evolved to ensure that stability is maintained.<sup>11,12</sup> The processes by which swollen cells return to normal size are collectively termed *regulatory volume decrease* processes, and those returning a shrunken cell to normal are termed *regulatory volume increase* processes (Fig. 8-1). With sudden, brief changes in osmolality, regulatory volume increase or decrease processes are activated after small (1% to 2%) changes in cell volume, returning cell volume to normal primarily through transport of electrolytes. If anisotonic conditions persist, chronic compensation occurs through the accumulation or loss of small organic molecules termed *osmolytes* or *idiogenic osmoles* (e.g., polyols, sorbitol, myoinositol), amino acids and their derivatives (e.g., taurine, alanine, proline), and methylamines (e.g., betaine, glycerylphosphorylcholine).

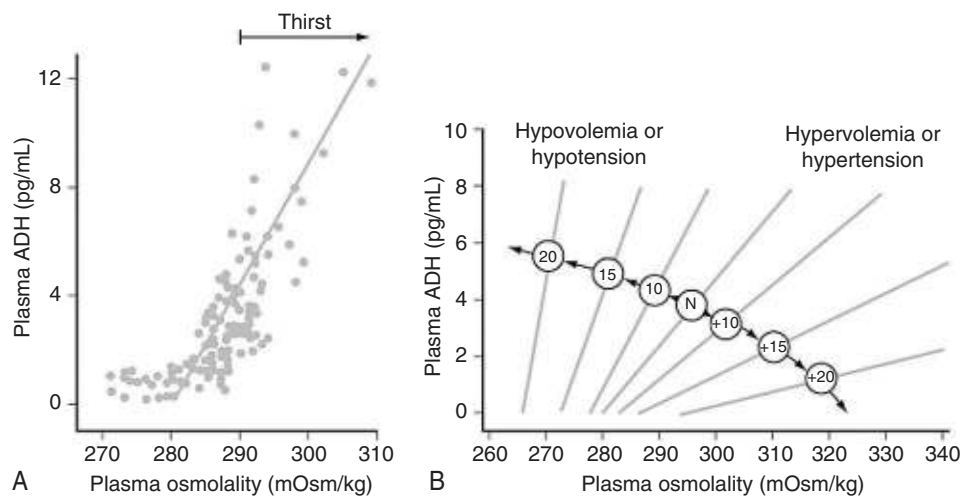

Like intracellular volume, circulating blood (intravascular) volume is also tightly controlled. Increases in intravascular volume result from increases in sodium and water retention, whereas decreases in intravascular volume result from increases in excretion of sodium and water. As noted earlier, serum osmolality must be maintained within a very narrow range if serum sodium is to be an effective focus of intravascular volume control. Serum osmolality is usually maintained between 280 and 300 mOsm/L. Changes in osmolality as small as 1% trigger compensatory mechanisms.

Serum osmolality is primarily regulated by antidiuretic hormone (ADH), thirst, and renal concentrating ability. Because the indirect aim of osmolar control is actually volume control, these same osmoregulatory mechanisms are also influenced by factors such as blood pressure (BP), cardiac output, and vascular capacitance.<sup>13,14</sup> In pathologic conditions such as ascites or hemorrhage, intravascular volume preservation takes precedence over osmolality and osmoregulatory mechanisms operate to restore intravascular volume, even at the expense of disrupting physiologic solute balance.

For example, ADH is released from neurons of the supraoptic and paraventricular nuclei in response to osmolar fluctuations in cell size. Solutes that readily permeate cell membranes, such as urea, increase the serum osmolality without triggering the release of ADH. Infusion of solutes with large actual or effective reflection coefficients ( $\sigma$ ) at the cell membrane (e.g., sodium, mannitol) elicits a robust ADH release. ADH release begins when the serum osmolality reaches a threshold of approximately 280 mOsm/L. Rapid increases in osmolality lead to a greater release of ADH than do slow increases. Hypovolemia and hypotension diminish the threshold for ADH release and increase the “gain” of the system by exaggerating the rate of increase in serum ADH concentrations (E-Fig. 8-2). Thus, in a volume-depleted or hypotensive child, brisk ADH release occurs in response to plasma osmolalities as low as 260 to 270 mOsm/L. It has been hypothesized that different populations of vasopressin-secreting cells are responsive to osmotic and baroreceptor-mediated input.

Intravascular fluid volume, salt and water intake, electrolyte balance, and cardiovascular status are interrelated at several levels.<sup>15</sup> For example, as the veins and arteries become replete with fluid and the systemic BP increases, ADH release wanes as both *pressure diuresis* and *natriuresis* commence.<sup>16</sup> The resulting relationship between urine output and arterial pressure is termed the *renal function curve*, and its intersection with salt and water intake determines the *equilibrium point* at which arterial BP ultimately stabilizes (Fig. 8-2). Equilibrium (chronic) BP is influenced only by shifts of the renal function or fluid intake curves. Transient changes in arterial pressure secondary to peripheral vascular resistance changes are always resolved by opposing shifts in total body salt and TBW.

In response to a decreasing arterial pressure, the renin-angiotensin system is also mobilized. With decreased renal perfusion, juxtaglomerular cells release renin, which in turn converts renin substrate (angiotensinogen) to angiotensin I. Angiotensin I is then rapidly converted to angiotensin II by angiotensin-converting enzyme present in lung endothelium. Angiotensin II supports arterial pressure in three ways: (1) direct vasoconstriction, (2) increased salt and water retention (via renal vasoconstriction and decreased glomerular filtration), and (3) stimulation of aldosterone secretion (Fig. 8-3).

**E-FIGURE 8-2** **A**, Relationship between plasma antidiuretic hormone (ADH) concentration and plasma osmolality in normal humans in whom the plasma osmolality was changed by varying the state of hydration. Notice that the osmotic threshold for thirst is a few milliosmoles per kilogram higher than that for ADH. **B**, The influence of hemodynamic status on the osmoregulation of ADH in otherwise healthy humans. The numbers in the *center circles* refer to the percentage change in volume or pressure; *N* (in the *center circles*) refers to the normovolemic normotensive subject. Notice that the hemodynamic status affects both the slope of the relationship between the plasma ADH and osmolality and the osmotic threshold for ADH release. (**A** adapted from Robertson GL, Aycinena P, Zerbe RL. Neurogenic disorders of osmoregulation. *Am J Med* 1982;72:339; **B** from Rose DB. *Clinical physiology of acid-base and electrolyte disorders*. 4th ed. New York: McGraw-Hill; 1994. p. 159, 163.)

ADH, pressure diuresis, and the renin-angiotensin system permit wide ranges in salt and water intake without large fluctuations in BP or volume status. All serve to support the systemic circulation when threatened and complement the more immediate activity of the sympathetic nervous system. In addition to high-pressure sensors such as aortic arch and carotid sinus baroreceptors, intravascular volume information is provided by low-pressure thoracic sensors. For this reason, effective increases or decreases in intrathoracic blood volume may mimic changes in whole-body volume status and produce natriuresis, diuresis, or fluid retention. Intravascular volume may also be sensed as the stretch of atrial muscle fibers, leading to release of atrial natriuretic peptide.<sup>17</sup> Although its complete physiologic role is uncertain, atrial natriuretic peptide may serve to “fine tune” volume status by causing modest vasodilation, gently increasing the glomerular filtration rate (GFR), and decreasing reabsorption of sodium. The combination of complex autoregulatory mechanisms with complementary actions operating on varying time scales, all responding to different, yet interrelated, effector stimuli, yields an elegant system by which the mature individual may maintain circulation amid a variety of challenges. In this context, it is interesting to observe that successful heart transplant

recipients, despite general cardiovascular stability, typically manifest fundamental derangements in body fluid homeostasis.<sup>18</sup>

## Maturation of Fluid Compartments and Homeostatic Mechanisms

### BODY WATER AND ELECTROLYTE DISTRIBUTION

Much of our understanding of the development of body water compartments is derived from deuterium oxide dilution studies performed in the 1950s.<sup>19</sup> In a series of 21 neonates, TBW was found to be approximately  $78 \pm 5\%$  of body weight. Subsequent measurements in fewer subjects showed that TBW decreased to approximately 60% in the second 6 months of life with most of the loss being extracellular. A smaller decrease (to about 57%) is observed late in childhood (Fig. 8-4).

The importance of the extracellular compartment, its relationship to the intracellular space, and much of the chemical anatomy of both were first described by Gamble in educational monographs issued during the first part of the 20th century (E-Fig. 8-3).<sup>20,21</sup> The chemical compositions of mature body fluid compartments are provided in Table 8-1.

### CIRCULATING BLOOD VOLUME

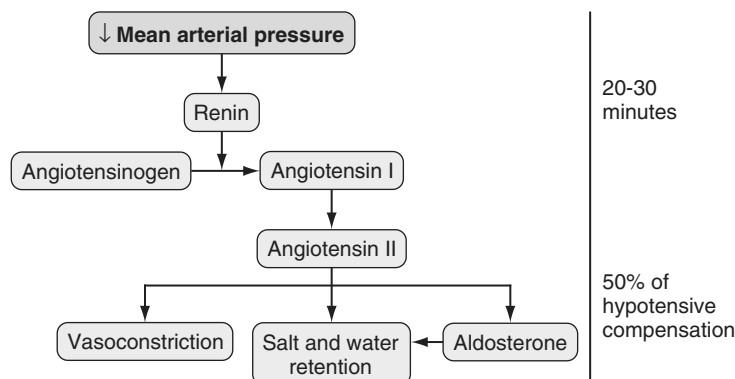

The blood volume in neonates was determined to be  $82 \pm 9$  mL/kg using an iodine 121-labeled human serum albumin technique, although substantial variability may result from the degree of placental-fetal transfusion.<sup>22</sup> In low-birth-weight (LBW), preterm, or critically ill infants, values as high as 100 mL/kg have been measured.<sup>23</sup> Blood volume increases slightly during the first few months of life, reaching its zenith at 2 months of age (approximately 86 mL/kg), then returns to near 80 mL/kg and finally stabilizes at 70 mL/kg by the end of the first year of life. In general, the ratio of blood volume to weight decreases with growth. The most accurate basis for prediction of blood volume is lean body mass, the consideration of which removes any male/female variation even into adulthood.<sup>24</sup> An estimate of the circulating blood volume is presented in Table 8-2.

### MATURATION OF HOMEOSTATIC MECHANISMS

Renal development begins at approximately 5 weeks of gestation and continues in a centrifugal pattern until the full complement of nephrons is in place by about the 38th week. In the outermost regions of the renal cortex, postnatal nephron differentiation may continue for several weeks to months. In the early stages of gestation, renal blood flow is approximately one fifth of normal.

**FIGURE 8-2** Analysis of arterial pressure regulation by equating the renal output curve with the salt and water intake curve. The equilibrium point describes the level to which the arterial pressure will be regulated. (That portion of the salt and water intake that is lost from the body through nonrenal routes is ignored in this figure.) (From Guyton AC, Hall JC, editors. *Textbook of medical physiology*. Philadelphia: WB Saunders; 1996. p. 221-37.)

**FIGURE 8-3** Physiologic responses to hypotension.

**E-FIGURE 8-3** Acid-base composition of body fluids. These diagrams are constructed from average values for the individual factors expressed in terms of acid-base equivalence—that is, as cubic centimeters of one-tenth normal solutions per hundred cubic centimeters of fluid. The base factors are superimposed in the left column and the acid factors are superimposed in the right column for each fluid. The diagrams represent, as is actually the case, a structure composed not of salt but of individually sustained concentrations of ions. The exact acid-base equivalence indicated by the equal height of the two columns is obtained by adjustability of the bicarbonate ion concentration ( $\text{HCO}_3^-$ ) to any change elsewhere in the structure. (From McIver MA, Gamble JL. Body fluid changes due to upper intestinal obstruction. JAMA 1928;92:1589-92. Copyright 1928, American Medical Association.)

**FIGURE 8-4** Total body water (blue circles), extracellular water (purple triangles), and intracellular water (orange circles) as percentages of body weight in infants and children, compared with corresponding values for the fetus and adults. (From Friis-Hansen B. Body water compartments in children: changes during growth and related changes in body composition. *Pediatrics* 1961;28:169-81.)

School age	75
Adults	70

Initially this is related to structural immaturity, and later it is due to increased renovascular resistance. By 38 weeks of gestation, renal blood flow is approximately one third of normal. High renovascular resistance protects the developing nephron from both pressure and volume overload. The resulting renal contribution to metabolic homeostasis in utero is limited.

As with the pulmonary bed, vascular resistance in the kidney decreases after birth, leading to abrupt increases in renal blood flow and GFR. In utero, despite a low GFR, urine output is brisk, owing to poor reabsorption of salt and water. Plasma renin activity is increased in utero, decreases immediately after birth, and then increases again as excess extracellular water is mobilized and excreted. Aldosterone levels are increased in cord blood and are maintained at this level for the first 3 days of life. The increased aldosterone may be necessary for sodium retention during periods of increased anabolism early in life.

Intrarenal gradients of NaCl and urea are less steep in the immature kidney, and full nephron length has yet to be achieved. Consequently, urine concentrating ability is limited in neonates, with maximum urine osmolality being about half that of the adult (700 to 800 mEq/L versus 1300 to 1400 mEq/L). In part, this also relates to low circulating ADH levels and decreased renal responsiveness to ADH. Although overall ADH production is not impaired, excessive secretion may occur in some disease states. Limited urine-concentrating ability necessitates large urine volumes for elimination of large solute loads.

In the first year of life, renal plasma flow and GFR are approximately one half the adult values of 350 and 70 mL/min/m<sup>2</sup>, respectively.<sup>25</sup> Consequently, serum creatinine is increased in term and preterm infants, yet normalizes in the second month

of life. Fractional excretion of sodium ( $FE_{Na}$ ) is markedly increased in preterm infants, decreases somewhat by term, and stabilizes at adult levels by the second month of life. Although the adult kidney may easily achieve  $FE_{Na}$  values as low as 0.5%, the 34-week-gestation infant is limited to no less than 2%.

These maturational features make it very difficult for the preterm or young infant to handle fluctuations in fluid and solute loads. Both sodium conservation and regulation of extracellular fluid volume are impaired relative to the older child and adult. Limited GFR makes excretion of a fluid challenge difficult. Excessive urinary sodium loss leads to increased maintenance requirements. Hyponatremia is common. Conversely, diminished concentrating ability increases free water losses during excretion of a solute load, whereas the high ratio of surface area to volume produces increased evaporative water loss. Consequently, fluid requirements are relatively high, and dehydration is common. Any errors in the fluid management are poorly tolerated. As a rule, the most severe impairment exists in preterm infants, and the majority of homeostatic mechanisms are fully developed after the first year of life.

## Fluid and Electrolyte Requirements

Holliday summarized the evolution of contemporary hydration therapy.<sup>20</sup> In 1831, Latta first reported the use of intravenous (IV) fluids in the resuscitation of patients dehydrated by cholera.<sup>26</sup> In 1918, growing information on the subject permitted Blackfan and Maxcy to successfully treat nine infants by intraperitoneal injection.<sup>27</sup> In 1923, Gamble and associates detailed the anatomy of fluid and electrolyte compartments, introducing the use of milliequivalents to clinical practice.<sup>21</sup> This paved the way for the development of the “deficit therapy” regimen of Darrow.<sup>28</sup>

In subsequent decades, various recipes to replace the extracellular and intracellular fluid losses were suggested. For the most part, these failed because of excessive potassium and insufficient sodium content. Hyponatremia was common. When the focus of the treatment shifted to replacing the extracellular fluid deficit, rapid restoration of extracellular fluid volume using solutions with sodium concentrations similar to those in blood became commonplace. This, along with oral rehydration, is the preferred method of treatment today.

The concept of “maintenance fluids” is a complex subject. Although water and salt are required to sustain life, it is fair to say that for an individual child at any particular time, the precise amounts necessary are unknown (and perhaps unknowable). Instead, fluids and electrolytes, like anesthetics, are titrated to effect with general guidelines provided by clinical assessment, basic physiologic principles, and limited published data. The term *maintenance fluids* is often more limiting than helpful, and in all cases it is less precise than other terms familiar to anesthesiologists, such as *minimal alveolar concentration* (MAC) or *median effective dose* ( $ED_{50}$ ).

Holliday and Segar provided calculations for a first approximation of “the maintenance need for water in parenteral fluid therapy” in 1957.<sup>29</sup> Integrating the relevant known physiology at that time, these authors observed that “insensible loss of water and urinary water loss roughly parallel energy metabolism and do not parallel weight.” However, because water utilization parallels energy metabolism, energy metabolism follows surface area, and surface area follows weight, it should be possible to estimate water requirement from weight alone. The authors then proceeded under a series of assumptions to extrapolate from limited

**FIGURE 8-5** The upper and lower curves were plotted from data from the study by Talbot.<sup>126</sup> Weights at the 50th percentile level were selected for converting calories at various ages to calories related to weight. The computed line for the average hospitalized child was derived from the following equations:

- 0-10 kg: 100 kcal/kg.
  - 10-20 kg: 1000 kcal + 50 kcal/kg for each kg over 10 kg
  - 20 kg and up: 1500 kcal + 20 kcal/kg for each kg over 20 kg
- (From Holliday MA, Segar WE. The maintenance need for water in parenteral fluid therapy. *Pediatrics* 1957;19:823-32.)

**TABLE 8-3** Relationship between Weight and Hourly or Daily Maintenance Fluid Requirements of Children as per the 4-2-1 Rule

Weight (kg)	MAINTENANCE FLUID REQUIREMENTS	
	Hour	Day
<10	4 mL/kg	100 mL/kg
10-20	40 mL + 2 mL/kg for every kg >10 kg	1000 mL + 50 mL/kg for every kg >10 kg
>20	60 mL + 1 mL/kg for every kg >20 kg	1500 mL + 20 mL/kg for every kg >20 kg

data to a “relationship between weight and energy expenditure that might easily be remembered.”

Assuming energy requirements of “hospitalized patients” to be “roughly midway between basal and normal levels,” they constructed a curve of caloric requirement versus weight.<sup>29</sup> This curve could be seen as comprising three linear sections: 0 to 10 kg, 10 to 20 kg, and 20 to 70 kg (Fig. 8-5). Viewing the curve in this manner, the authors reasoned that “fortuitously, the average need for water, expressed in milliliters, equals energy expenditure in calories”: 100 mL/kg/day for weights to 10 kg, an additional 50 mL/kg/day for each kilogram from 11 to 20 kg, and 20 mL/kg/day more for each kilogram beyond 20 kg. In anesthetic practice, this formula has been further simplified, with the hourly requirement referred to as the “4-2-1 rule” (4 mL/kg/hr for the first 10 kg of weight, 2 mL/kg/hr for the next 10 kg, and 1 mL/kg/hr for each kilogram thereafter; Table 8-3).

For decades, the simplicity and elegance of the Holliday and Segar formula has made it the starting point for fluid management in healthy children. As recently as 2006, the majority of

consultant anesthetists in the United Kingdom administered hyponatremic glucose-containing solutions intraoperatively and postoperatively to children undergoing elective surgery.<sup>30</sup> However, the uncritical use of these solutions was never intended, and their blind application in the operating room, or in any clinical situation, is unwarranted. Further, as Holliday and Segar have themselves pointed out, their original approach involved hyponatremic glucose-containing solutions rather than near-isotonic solutions such as 0.9% saline or lactated Ringer solution (LR).<sup>30a</sup> In addition, these requirements were assessed at a basal metabolic state and not when the child was acutely ill or under physiologic stress. As the authors cautioned that “understanding of the limitations and of exceptions to the system [is] required. Even more essential is the clinical judgment to modify the system as circumstances dictate.” General water losses for infants and children are summarized in Table 8-4.

More recently, Holliday revised the approach to fluid therapy in children that he and Segar enshrined with several caveats.<sup>30b</sup> In a related commentary, Holliday pointed out several problems with applying the original 4-2-1 rule to acutely ill children.<sup>30c</sup> Namely, dysregulation of ADH is a hallmark of critical illness because ADH secretion is affected by a variety of nonosmotic factors such as pain, stress, mechanical ventilation, and many medications. As a result, the choice of intravenous fluid and the rapidity of deficit replacement must be approached with care. The authors recommended a relatively simple strategy for healthy children undergoing elective surgery (including outpatients) to turn off ADH secretion and prevent perioperative water retention and subsequent hyponatremia. When a child (who is without significant heart or kidney disease) presents with marginal to moderate hypovolemia (e.g., after fasting for surgery), 20 to 40 mL/kg of isotonic fluids should be given during surgery and the postanesthesia care unit stay (as rapidly as 10 to 20 mL/kg/hr). Clinical judgment must always allow for modification of these recommendations if indicated for an individual child.<sup>31,32</sup> If hypovolemia is more severe (e.g., after an extensive bowel preparation), 40 to 80 mL/kg may be necessary during the perioperative period.

Postrecovery IV fluid therapy should consist of an isotonic solution infused at half the rate described in the original 4-2-1 fluid regimen (i.e., 2 mL/kg for the first 10 kg, 1 mL/kg for the next 10 kg, and 0.5 mL/kg for each additional kilogram thereafter). If the child does not or cannot tolerate oral intake after 6 to 12 hours, standard maintenance fluid therapy using hypotonic saline (e.g., 0.45% saline) should be initiated to avoid hyponatremia and fluid overload from prolonged administration of the isotonic solutions. This regimen should limit the ADH response and reduce the risk for postoperative hyponatremia and hypernatremia.<sup>31-33</sup> It remains essential, however, to monitor plasma electrolyte concentrations serially on the ward, regardless

of the fluid doctrine followed, to be certain that electrolyte concentrations remain within normal limits.<sup>34,35</sup>

## NEONATAL FLUID MANAGEMENT

In the first few days of life, isotonic losses of salt and water cause the normal neonate to lose 5% to 15% of body weight. Although GFR rises rapidly, urine output is initially low, and renal losses are modest. Day 1 fluid requirements of the wrapped neonate, therefore, are relatively low. Over the next few days of life, losses and requirements increase. In the poorly feeding infant, progression to hypernatremia and dehydration are common. When intake is appropriate, the term infant will regain body weight during the first week of life.

Three distinct phases of fluid and electrolyte homeostasis have been described in LBW<sup>36</sup> and very low-birth-weight (VLBW)<sup>37</sup> infants. In the first day of life, there is minimal urine output, and body weight is stable despite low fluid intake. In the second phase, days 2 and 3 of life, diuresis occurs irrespective of the amount of fluid administered. By the fourth and fifth days of life, urine output begins to vary with changes in fluid intake and state of health.

Prematurity increases neonatal fluid requirements significantly. Fluid requirements are therefore estimated and then titrated to the infant's changing weight, urine output, and serum sodium concentration.

No less important is glucose homeostasis. In the ninth month of gestation, the fetus begins to form glycogen stores at a rate of more than 100 kcal/day. In the unstressed, term infant, hepatic glycogen stores are 5% of body weight. Immediately after birth, glycogenolysis depletes most of these stores within the first 24 to 48 hours. Gluconeogenesis must then proceed to yield glucose at a rate of approximately 4 mg/kg/min.

At birth, fetal serum glucose is 60% to 70% of maternal concentrations. This may decrease within the first hours of life before recovering but should exceed 45 mg/dL to avoid neurologic injury. Symptoms of hypoglycemia may include jitteriness, lethargy, temperature instability, and convulsions. Ten percent dextrose in water (D<sub>10</sub>W) may be given as a bolus of 2 to 4 mL/kg followed by a continuous infusion (through a pump) providing 4 to 6 mg/kg/min. The serum glucose concentration is then analyzed frequently and the infusion adjusted as necessary to prevent hypoglycemia and hyperglycemia. It is important that the amount of glucose being provided be calculated in milligrams per kilogram per minute to avoid errors during fluid changes and to facilitate the diagnosis of persistent hypoglycemia.

Typical *day 1* infant fluid orders call for 70 to 80 mL/kg of D<sub>10</sub>W. Because D<sub>10</sub>W contains 10 g of glucose per deciliter, this dosage provides

$$10 \text{ g/dL} \quad 70-80 \text{ mL/kg/day} = 7-8 \text{ g/kg/day} = 0.333 \text{ g/kg/hr} \\ \equiv 5 \text{ mg/kg/min}$$

On *day 2*, fluids are routinely increased to at least 100 mL/kg/day, and sodium is added at 2 to 3 mEq/dL. After urine output is established, potassium is added at 1 to 2 mEq/dL. The final solution, containing 30 mEq Na<sup>+</sup> and 10 to 20 mEq K<sup>+</sup> per liter, approximates the 0.2% saline “maintenance” solution commonly used previously in older children.

In the neonatal ICU, fluid management focuses on provision of adequate nutrition, maintenance of electrolyte balance, and limitation of fluid overload. The last factor is of particular concern because plasma oncotic pressure is reduced in preterm

infants and the whole-body protein reflection coefficient is less than that in adults.<sup>38</sup> VLBW infants are at particular risk for fluid and electrolyte imbalances.<sup>39</sup> Even modest fluid overload may exacerbate pulmonary edema, prolong ductal patency, and more readily produce congestive heart failure. This perspective typically accompanies the infant to the operating room, where the primary considerations are routinely quite the opposite: restoration of circulating blood volume after third space accumulation, maintenance of intravascular volume amid ongoing blood loss, replacement of potentially massive evaporative losses, and maintenance of BP despite anesthetic-induced vasodilatation and increased venous capacitance. During surgery, these concerns must take precedence; yet unnecessary administration of fluid is best avoided.

## Intraoperative Fluid Management

### INTRAVENOUS ACCESS AND FLUID ADMINISTRATION DEVICES

In pediatrics, the first step toward intraoperative fluid management is often the most challenging: that is, gaining IV access. In general, simple procedures in healthy children are successfully approached using a single peripheral IV line. Although preferences vary among anesthesiologists, establishing IV access is most easily accomplished after induction of anesthesia. In young children, anesthesia is often induced by inhalation, and a catheter is inserted by an assistant into a hand or foot vein. In older children, or when IV access is desirable before anesthesia is induced, IV access may be facilitated by the use of topical anesthesia (e.g., EMLA cream, amethocaine, lidocaine infiltration) or sedation or both.

Complex surgeries in sicker children usually require at least two large-bore catheters. In pediatrics, however, “large bore” is a relative term, with 22-gauge catheters typically providing sufficient access in infants. Preferred sites for larger catheters include the antecubital and saphenous veins. In cases in which access to the central circulation is required (as for pressure monitoring, infusion of vasoactive medications, or prolonged access), longer catheters may be placed via the femoral, subclavian, or internal jugular vein (the latter usually via a high, anterior approach).<sup>40</sup> Although secure access may also be obtained via the external jugular vein, it is often difficult to negotiate the J-wire or catheter tip into the central circulation.<sup>41</sup> Peripherally inserted central catheter (PICC) lines are becoming increasingly used in hospitalized children. Although they represent a long-term means of delivering IV fluids and medications in children who require such treatment interventions, there are limitations to their utility intraoperatively. First, practitioners must maintain strict sterile technique when accessing these lines in order to avoid infection. Second, the lines tend to have smaller diameters and are quite long. Therefore, resistance can be significant, even with larger-bore PICC lines. Consequently, bolus and infusion dosing of drugs can be met with high resistance. These lines are not appropriate for large-volume resuscitation, and care should be taken to secure larger-bore IV access if large fluid shifts or significant blood loss is anticipated.

In selecting the appropriate IV catheter, it is useful to consider the relative effects of catheter length and diameter on solution flow rates. Longer catheters offer more resistance to flow than shorter ones and are therefore less desirable when rapid infusion of a large volume of fluids is necessary (see E-Fig. 51-1 and Figs. 51-1, 51-2). In vitro, catheters that were designed for peripheral

venous access had 18% to 164% greater flow rates when compared with the same-gauge catheters designed for central venous use. Under pressure, as might be employed during emergent volume resuscitation, rates differed up to 17-fold.<sup>42</sup> Although this seems to suggest that short peripheral catheters should be preferred, in vivo data are more complex. In animal models, overall catheter flow rates are less than in vitro rates, and central access presents somewhat less resistance to flow than peripheral access.<sup>43</sup> Finally, when weighing the risks and benefits of central versus peripheral access, it is also interesting to consider that central administration of resuscitation medications may provide little practical advantage over peripheral administration.<sup>44</sup>

Intraosseous devices are now commonly used in the initial resuscitation of critically ill or injured children (see Fig. 48-6).<sup>45,46</sup> Flow rates via these devices depend less on needle diameter than on resistance in the marrow compartment.<sup>47</sup> In the operating room, the intraosseous route has been used for both induction and maintenance of anesthesia.<sup>48-50</sup> However, onset of drug effect is less predictable, and the device is more easily dislodged than an IV catheter. Potential complications include compartment syndrome<sup>51-53</sup> and, very rarely, damage to the growth plate.<sup>46,54</sup> Such devices are probably best considered an emergency or last-resort option.<sup>49</sup>

To prevent accidental volume overload, the amount of IV fluid available to administer to a child at any one time should not exceed the child’s calculated hourly requirement. Particularly in infants, a volumetric chamber should be used to limit the amount of fluid available for infusion. Similarly, a microdrip infusion set limits the rate of fluid administration and permits much greater control. Although a fluid infusion pump provides the most precise mode of regulating the rate of fluid administration (and is therefore very useful in providing supplemental fluids or medications), such devices are impractical on primary access lines because they hinder the ability to administer drugs or fluids rapidly. In addition, the clinician should be mindful that pumps may continue to infuse through dislodged catheters and may give inappropriate reassurance of adequate IV access and fluid administration, providing a false sense of reassurance; administration of a large volume of fluid interstitially will fail to deliver the needed fluid volume (and medications). Moreover, if an identification bracelet of any sort is proximal to the IV insertion site, it may act as a tourniquet, resulting in ischemic digits. Therefore, access to the IV site is important in children, as well as removal of all bracelets that are proximal to ipsilateral IV insertion sites.

In neonates and small infants, when rapid infusion of resuscitation solutions or blood products is anticipated, many practitioners find it helpful to include an in-line stopcock manifold. Additional fluids may be drawn up into syringes and warmed separately; during periods of sudden blood loss, stored syringes may then be inserted into the manifold and a known volume rapidly infused.

Finally, in prolonged surgeries or when volume replacement is great, it is imperative that all IV infusions be adequately warmed. Also, in younger infants and children in whom communication exists between the right and left sides of the circulation (e.g., patency of the foramen ovale), an in-line “bubble” filter is desirable.

### CHOICE AND COMPOSITION OF INTRAVENOUS FLUIDS

In the early 1960s,<sup>55</sup> simultaneous measurements of plasma and extracellular fluid volumes demonstrated that, during surgery, plasma volume is supported at the expense of the extravascular

**TABLE 8-5** Composition of Extracellular Fluid and Common Intravenous Solutions

	mOsm/L	CATIONS (mEq/L)			ANIONS (mEq/L)				
		Na <sup>+</sup>	K <sup>+</sup>	Ca <sup>2+</sup>	Mg <sup>2+</sup>	NH <sub>4</sub> <sup>+</sup>	Cl <sup>-</sup>	HCO <sub>3</sub> <sup>-</sup>	HPO <sub>4</sub> <sup>-</sup>
Extracellular fluid	280-300	142	4	5	3	0.3	103	27	3
Lactated Ringer solution	273	130	4	3			109	28	
0.45% NaCl	154	77					77		
0.9% NaCl (normal saline)	308	154					154		
PLASMA-LYTE A*	294	140	5		3	1.6	98	98	
3% NaCl	1024	513					513		

\*PLASMA-LYTE is a trademark of Baxter International Inc., its subsidiaries or affiliates. (Acetate 27 mEq/L and gluconate 23 mEq/L.)

space. At the same time, it was classically observed that isotonic resuscitation fluids temporarily redistribute from the intravascular spaces to what was originally believed to be a third, nonfunctional space. It is now clear that destruction of the endothelial glycocalyx, as caused by surgical trauma, permits fluid to shift from the intravascular to interstitial space. Therefore, the historical “third space” simply represents reversible expansion of the interstitium. Because of the differences in fluid distribution and renal function in infants compared with older children, it was at first unclear that these findings could be extended to infancy. Thus, fluid restriction remained the standard of care until careful studies specifically demonstrated that fluid and electrolyte requirements are often extremely large in neonates who are undergoing major surgical procedures.<sup>56-58</sup>

Although hypotonic fluids are selected for maintenance hydration throughout the hospital (according to the reasoning outlined previously), isotonic solutions are preferred intraoperatively for several reasons. First, most ongoing volume losses are isotonic, consisting of shed blood and interstitial fluids. Second, large volumes of hypotonic solutions may rapidly diminish serum osmolality, producing very low concentrations of electrolytes (in particular, sodium) and undesirable fluid shifts. Indeed, even large volumes of “isotonic” fluids have been shown to significantly decrease serum osmolality in adult volunteers.<sup>59</sup> Third, as discussed earlier, the plasma volume expansion that is necessary in response to diminished vascular tone under anesthesia is difficult to achieve even with isotonic fluids. Finally, increases in ADH and other elements of intraoperative physiology result in free water retention in excess of sodium if inadequate amounts of the latter are provided.

The compositions of commonly used IV solutions are presented in Table 8-5. Assuming normal plasma osmolality of 275 to 290 mOsm/L, it is noteworthy that 0.9% NaCl (normal saline, NS) is slightly hypertonic to plasma and that LR is isotonic (273 mOsm/L), although slightly hyponatremic (130 mEq/L). For dextrose-containing solutions, added osmolality is rapidly dissipated as sugar is metabolized, resulting in increased volumes of free water. Therefore, administration of 5% dextrose in water is ultimately equivalent to administration of free water.

The controversy regarding the perioperative use of colloid versus crystalloid fluid replacement remains an unresolved subject. It is worth noting that aside from 5% albumin, synthetic colloids are gaining popularity among pediatric practitioners. One reason for this is the development of newer synthetic colloids that have a more favorable side effect profile. Hydroxyethyl starches (HES) are synthetic colloids that are simply modified polysaccharides. Circulating amylases quickly break down natural polysaccharides. HES solutions avoid this problem by substituting hydroxyethyl groups for hydroxyl groups at carbon

positions C-2, C-3, and C-6. This results in a soluble molecule that is resistant to hydrolysis. These compounds are characterized by three attributes: average mean molecular weight (MW), molar substitution (MS), and the C2:C6 ratio, which relates to the relative positions of hydroxyethyl groups on the polysaccharide molecule.

HES solutions with a greater MW-to-MS ratio tend to remain in the intravascular space much longer than those with smaller ratios. However, they also are prone to more significant side effects including hypocoagulability. Newer, low MW/low MS solutions have much less effect on hemostatic mechanisms than older, higher MW/higher MS solutions. The exact mechanism of the effect on coagulation remains unclear, although it is thought that the HES compounds interfere with von Willebrand factor, factor VIII, and platelet function. A greater C2:C6 ratio is responsible for the slower degradation of the starch by amylase with fewer side effects.<sup>60</sup> Newer HES solutions (e.g., HES 130/0.42/6:1) are very safe in children scheduled for surgery who have normal renal function; they maintain hemodynamic stability and produce only mild to moderate changes in acid-base status.<sup>61</sup> Synthetic colloids such as these should be considered in surgical patients who demonstrate the need for aggressive intraoperative fluid resuscitation, such as children with large-volume blood loss or excessive insensible losses. Use of these solutions in cardiac surgery remains controversial given the effects on coagulation factors and platelet function induced by the cardiopulmonary bypass circuit.

The routine intraoperative use of glucose-containing solutions has also been a subject of debate. As a rule, operative stress evokes physiologic responses that increase serum glucose. In practice, therefore, hypoglycemia is seldom a problem in healthy children when glucose is omitted from perioperative IV fluids.<sup>62,63</sup> Indeed, the risk should be particularly small if the period of fasting is limited to less than 10 hours.<sup>63</sup> At the same time, rapid administration of dextrose solutions may certainly produce acute hyperglycemia and hyperosmolality.<sup>62,63</sup> Therefore, glucose-containing solutions should not be used to replace fluid deficits, third space losses, or blood losses. However, some populations, such as debilitated infants,<sup>64</sup> children who are malnourished, neonates and infants < 6 months of age<sup>62,64a,64b</sup> and those undergoing cardiac surgery, have been shown to be at risk for intraoperative hypoglycemia,<sup>65,66</sup> and the use of glucose-containing solutions (1% to 2.5% dextrose)<sup>62,64a,67</sup>, along with intraoperative glucose monitoring, may be beneficial in these children.

## HYPERALIMENTATION

It is now common practice that critically ill children arrive in the operating room with hyperalimentation solutions infusing. Common contents of hyperalimentation solutions are shown in

**TABLE 8-6** Common Contents of Parenteral Nutrition Solutions\*

<b>Carbohydrates</b>
10%, 12.5%, 20%, 25%, 30% Dextrose
Limited to D <sub>10</sub> or D <sub>12.5</sub> if through a peripheral catheter
<b>Protein</b>

<b>Lipids</b>
10%, 20% Lipids
<b>Standard Additives</b>
Sodium: 30 mEq/L
Potassium: 20 mEq/L
Calcium: 15 mEq/L
Magnesium: 10 mEq/L
Phosphorus: 10 mmol/L
Heparin

\*Common contents of parenteral nutrition solutions containing dextrose, protein, lipids, and standard additives such as electrolytes. These values represent standard starting points that may be modified based on individual patient needs.

Table 8-6. In general, children require 0.5 to 3.0 mg/kg/day of protein, 6 to 9 mg/kg/min of glucose, and 0.5 to 3 g/kg/day of fat. Children receiving parenteral nutrition preoperatively should continue to receive those infusions separately, and a corresponding volume should be deducted from isotonic operative fluids. Hyperalimentation typically consists of two infusions: Intralipid (Fresenius Kabi, Uppsala, Sweden) and a concentrated glucose/protein solution. It is prudent to discontinue the Intralipid solution during surgery; but if that is not possible, then every effort should be made to avoid accessing any ports in the line to reduce the risk of contaminating the Intralipid. Conversely, the concentrated glucose/protein solution should be continued at the same rate (because circulating insulin concentrations have acclimated accordingly). Because of hyperglycemic responses to the stress of surgery and reduced metabolism due to anesthesia and hypothermia, some practitioners routinely decrease hyperalimentation infusion rates by one third to one half. If the latter practice is followed, clinicians should consider checking serum glucose concentrations at regular intervals to monitor for hypoglycemia. Under no circumstances should concentrated glucose solutions (such as D<sub>10</sub> or D<sub>20</sub>) be abruptly discontinued, because high levels of circulating insulin may cause a precipitous and profound decrease in the serum glucose concentration.

Concerns regarding the routine use of intraoperative dextrose-containing solutions, in large part from recognition that hyperglycemia may exacerbate neurologic injury after an ischemic or hypoxic event, resulted in most clinicians' avoiding such solutions for routine cases. If dextrose-containing solutions are used, appropriate monitoring is advised to avoid serum glucose extremes. Many practitioners administer glucose-containing solutions as a separate piggyback infusion using an infusion pump or other rate- or volume-limiting device to avoid accidental bolus administration. Alternatively, evidence indicates that isotonic solutions that contain reduced glucose concentrations (e.g., 1% or 2.5% versus 5%) are safe alternative solutions for intraoperative use that minimize both hyponatremia and hyperglycemia.<sup>68</sup>

In the United States, several Food and Drug Administration (FDA)-approved solutions containing 2.5% dextrose are available but none in lower concentrations. In Europe, 1% dextrose electrolyte solutions are now available.<sup>64a,68</sup> Because intraoperative administration of solutions containing 5% dextrose (D<sub>5</sub>LR) frequently causes hyperglycemia, prudent anesthesiologists should selectively administer dextrose-containing solutions to those who are at particular risk for intraoperative hypoglycemia (i.e., neonates, chronic malnourished children, and cachectic children). In these instances, it may be sensible to administer solutions with a reduced dextrose concentration.<sup>60,64a</sup>

### FASTING RECOMMENDATIONS

The goal of fasting is to minimize the volume of gastric contents and thereby lessen the risk of vomiting and aspiration during induction of anesthesia. In children, as opposed to adults, this is of particular concern because in many institutions induction in children is more often accomplished by inhalation than by IV anesthesia and the period of vulnerability to regurgitation is potentially protracted compared with an IV induction.

At issue is the effectiveness of fasting in lowering a child's gastric volume and the benefits of this effect when weighed against the added discomfort and risk of dehydration. Numerous studies of gastric volume and pH have convincingly demonstrated that clear liquids are rapidly emptied from the stomach and the stimulated peristalsis actually serves to decrease gastric volume and acidity. Taking this together with the benefits of improved hydration and mental status, it is clear that prolonged *nil per os* (NPO) status is unwarranted. NPO guidelines currently in use in many institutions are included in Table 4-1.<sup>69</sup> As described earlier, for the vast majority of children, 20 to 40 mL/kg of LR given intraoperatively will provide adequate fluid deficit replacement.

### ASSESSMENT OF INTRAVASCULAR VOLUME

Once the child is anesthetized, many clinical clues to volume status are lost or confounded by operative events. For example, although it is a fairly reliable indicator of volume status in the quietly resting preoperative child, tachycardia may result from any number of factors besides intravascular volume status during surgery. It is the challenge of the anesthesiologist to view the entire clinical picture, consider the possibilities, integrate them into a hypothesis, and then test the hypothesis.

Assessment of intravascular volume begins with knowledge of age-related norms for heart rate and BP (see Tables 2-7 and 2-8). Is the heart rate persistently increased, or does it vary with surgical stimulation? Is the pulse pressure narrow, or, more ominously, is the BP reduced for age? Does it vary with positive-pressure breaths? Are the extremities warm? Is capillary refill brisk? What is the urine output? Are these variables changing? What is the rate of the change? When hypovolemia is suspected, observing the response to a 10- to 20-mL/kg bolus of isotonic crystalloid or colloid may test the hypothesis.

Measurement and continuous monitoring of central venous pressure are often helpful in assessing the status of circulating volume (see Figs. 48-2 to 48-5). In addition to traditional central lines introduced into the superior vena cava or left atrium, animal<sup>70</sup> and limited clinical<sup>71</sup> data suggest that femoral lines that terminate in the abdominal vena cava may also be useful. In infants and children, mean end-expiratory pressure measurements in the right atrial and inferior vena cava differed by less than 1 mm Hg.<sup>71</sup> Assessment of changes in the contour of the

arterial waveform may also be helpful in assessing volume status and the response to volume administration (see Fig. 10-11).

### ONGOING LOSSES AND THIRD-SPACING

During all surgical procedures, fluid loss from the vascular space is primarily the result of three simultaneous physiologic processes. First, whole blood is shed at various rates and must be replaced. Second, capillary leak and surgical trauma result in extravasation of isotonic, protein-containing fluid into interstitial compartments (the so-called third space). Third, anesthetic-induced relaxation of sympathetic tone produces vasodilatation (increased capacitance) and relative hypovolemia (a virtual loss). In very small infants, a fourth source of losses, direct evaporation, must also be carefully considered. These ongoing losses are often difficult to quantitate (or even estimate). Although these losses occur in children of all sizes, the small circulating blood volume of an infant (e.g., for a 5-kg infant,  $80 \text{ mL/kg} \times 5 \text{ kg} = 400 \text{ mL}$ ) leaves little room for error. Faced with uncertainty, the prudent response is constant vigilance and reliance on general principles.

As a rule, 1 mL of shed blood is replaced with 1 mL of colloid (5% albumin or blood) or about 1.5 mL of isotonic crystalloid such as LR.<sup>67,72</sup> Isotonic crystalloid is also used to replenish third space losses. Surgical procedures that involve only mild tissue trauma may entail third space losses of 3 to 4 mL/kg/hr. More extensive surgical procedures involving moderate trauma may require replacement equivalent to 5 to 7 mL/kg/hr to adequately support intravascular volume. In small infants undergoing very large abdominal procedures, the losses may approach 10 mL/kg/hr or more.<sup>56,58</sup> In neonates, fluid requirements for emergent abdominal surgery for necrotizing enterocolitis have been estimated at up to 50 mL/kg/hr.<sup>67</sup> These “losses” result from the vascular compartment and include both evaporation and redistribution of fluid. The latter must be most carefully considered because it is exacerbated by the hemodilution and increased capillary pressures caused by excessive fluid administration.

Although necessary intraoperatively, third space accumulation represents whole-body salt and water overload that will need to be mobilized postoperatively. The price of unchecked fluid administration is generalized anasarca, pulmonary edema, bowel swelling, and laryngotracheal edema. In the healthy child, this relative fluid overload is well tolerated, with most excess fluid excreted over the first 2 postoperative days. In children with impaired pulmonary, cardiac, or renal function, however, such fluid excess may result in clinically important postoperative morbidity.

## Postoperative Fluid Management

### GENERAL APPROACH

Well-planned postoperative fluid management complements the intraoperative plan and accounts for evolving physiology as the child recovers. Replacement of fluid deficits is completed. Ongoing losses are replaced. The child is repeatedly reassessed, and intake is adjusted until normal fluid and electrolyte homeostasis has returned. To aid in decision making, trends in vital signs are identified, all sources of fluid intake and output are quantitated, urine specific gravity is monitored, daily weights are obtained, and serum electrolytes are measured.

In simple outpatient surgeries, discharge is possible after fluid deficits are replaced. In complex cases, replacement fluids may require hourly readjustment that is based on the prior hour's intake and output. Rather than reacting to single pieces of data, such as low urine output, one must discern overall patterns. High urine output and low urine specific gravity may indicate overhydration or diabetes insipidus. Oliguria may suggest hypovolemia when it is accompanied by high urine specific gravity and clinical signs of dehydration or low cardiac output when it is accompanied by signs of poor perfusion. In the well-hydrated child, oliguria may represent renal failure if the urine specific gravity is normal (or dilute) but increased concentrations of ADH if the urine is concentrated. A careful physical examination is necessary; in many cases, certainty in diagnosis requires simultaneous measurement of serum and urine electrolytes.

Frequently, losses via surgical or gastric drains are large in both real and relative terms. For example, a neonate with a nasogastric tube may lose more than 100 mL/kg/day (normally 20 to 40 mL/kg/day) in gastric fluid. Therefore, in determining the volume and composition of replacement fluids, it is sometimes helpful to consider the electrolyte content of various losses (Table 8-7).

### POSTOPERATIVE PHYSIOLOGY AND HYPONATREMIA

Children retain salt and water postoperatively, in part as a result of neuroendocrine activation by stress, continued capillary leak with third space accumulation, non-osmotic stimulation of ADH (fever, stress, opioid administration) and hypovolemia-induced renin secretion. As outlined earlier, intravascular volume depletion is a potent non-osmotic signal for fluid retention and may override osmotic signals under a variety of clinical circumstances.

At the same time, ongoing fluid and electrolyte losses after surgery via chest tubes, nasogastric suction, weeping incisions, and even continued slow bleeding may be substantial. Postopera-

**TABLE 8-7** Composition of Body Fluids

Source	Na <sup>+</sup> (mEq/L)	K <sup>+</sup> (mEq/L)	Cl <sup>-</sup> (mEq/L)	HCO <sub>3</sub> <sup>-</sup> (mEq/L)	pH	Osmolality (mOsm/L)
Gastric	50	10-15	150	0	1	300

\*Varies considerably with fluid intake.

tively, children often depend entirely on IV fluids for replacement of these and other losses.

Therefore, unless isotonic, sodium-containing fluids are provided, postoperative children are universally at risk for developing hyponatremia.<sup>73,74</sup> In a retrospective review of 24,412 surgical admissions to a large children's hospital, the incidence of significant postoperative hyponatremia was 0.34%, with a substantial mortality rate (8.4%) in these previously healthy children.<sup>75</sup> If this measured incidence were extended to the entire population in the United States, 7448 children would present annually with postoperative hyponatremia and 626 would die from an entirely avoidable cause. Mortality rates as great as 40% to 60% have been reported after hyponatremia, although it may only be a surrogate marker for a disease with a poor prognosis rather than the actual cause of the death.<sup>76,77</sup>

In reviewing the etiology of hyponatremia, two factors stand out: extensive extrarenal loss of electrolyte-containing fluid and IV replacement with hypotonic fluids.<sup>75</sup> In addition, delay in recognition often plays a major role in associated morbidity. The solution seems a simple one: (1) administration of hypotonic fluids without a specific indication should be avoided postoperatively, (2) ongoing losses should be replaced in a timely fashion, and (3) serum electrolytes should be measured routinely in children exhibiting potential symptoms of hyponatremia (see later discussion).

### POSTOPERATIVE PULMONARY EDEMA

Children who receive large volumes of fluid intraoperatively are at risk for development of pulmonary edema as operative fluids are mobilized. Usually, fluid mobilization begins to occur on the second postoperative day and continues through day 3 or 4. Although this is less common in children than in the elderly, it occurs occasionally in children with burn injuries<sup>78</sup> or in pediatric patients receiving large amounts of fluid during resuscitation from trauma or sepsis. In one review,<sup>79</sup> 13 patients (11 adults and 2 children) developed postoperative pulmonary edema; all began to exhibit symptoms within 36 hours after surgery and had total net fluid retention in excess of 67 mL/kg postoperatively.

## Pathophysiologic States and Their Management

### FLUID OVERLOAD AND EDEMA

Edema is essentially a "sodium disease," representing sodium and water overload with excessive fluid residing in the extracellular space. Although intracellular volume changes can sometimes be substantial, prolonged cell swelling represents failure of essential volume regulatory functions and is likely a preterminal event. In fluid-overload states, plasma volume is generally increased unless the balance of Starling forces is disturbed, as in nephrotic syndrome or lymphatic obstruction. Edema formation is opposed by (1) low compliance of the interstitial compartment, (2) increased lymphatic flow, (3) osmotic washout of interstitial proteins, and (4) impedance and elasticity of the proteoglycan gel. The differential diagnosis of fluid overload and edema formation is presented in Table 8-8. Principles of therapy for fluid overload states include the following:

- Fluid restriction
- Salt restriction
- Diuresis, dialysis
- Salt-poor albumin for diminished plasma volume

**TABLE 8-8** Differential Diagnosis of Fluid Overload and Edema Formation

Condition	Differential Diagnosis
Imbalance of intake and output	Salt poisoning
	Formula dilution errors
	Intravenous infusion errors
	Drugs given as sodium salts
Steroid excess with normal sodium intake	Congenital adrenal hyperplasia
	Exogenous steroids
Perceived decreases in effective plasma volume	↓ MAP → baroreceptors →
	↑ sympathetic tone, ADH, renin, aldosterone
	Vasodilators
	Congestive heart failure
	Cirrhosis
	Nephrotic syndrome
	Chronic renal failure
Impaired sodium excretion	Acute glomerular disease (↓ GFR with normal tubular function)
	Nonsteroidal antiinflammatory drugs (↓ PGE <sub>2</sub> and RBF)
	SIADH
Water excess	Hypotonic infusion
	Stress (↑ ADH)

ADH, Antidiuretic hormone; GFR, glomerular filtration rate; MAP, mean arterial pressure; PGE<sub>2</sub>, prostaglandin E<sub>2</sub>; RBF, renal blood flow; SIADH, syndrome of inappropriate antidiuretic hormone secretion.

**TABLE 8-9** Clinical Signs and Symptoms for Estimation of Severity of Dehydration in Infants

Clinical Signs	DEGREE OF DEHYDRATION		
	Mild	Moderate	Severe
Weight loss (%)	5	10	15
Behavior	Normal	Irritable	Hyperirritable to lethargic
Thirst	Slight	Moderate	Intense
Mucous membranes	May be normal	Dry	Parched
Tears	Present	Normal to reduced	Absent
Anterior fontanel	Flat	Possibly sunken	Sunken
Skin turgor	Normal	Slightly increased	Increased
Urine output	Normal	Oliguric	Anuric

Modified in part from Herrin J. Fluid and electrolytes. In: Graef J, editor. Manual of pediatric therapeutics. 6th ed. Philadelphia: Lippincott-Raven; 1997. p. 63-75.

### DEHYDRATION STATES

Dehydration states are common in children. The extent of dehydration is best assessed by weight, because clinical signs such as tachycardia, capillary refill, and skin elasticity,<sup>80</sup> although often reliable, may be influenced by factors other than hydration status. A capillary refill time of 1.5 to 3.0 seconds, for example, suggests a fluid deficit of between 50 and 100 mL/kg, yet this sign is extremely dependent on ambient temperature.<sup>81</sup> Similarly, poor skin elasticity reflects significant volume loss, yet elasticity may be well preserved in children with hypernatremic dehydration.<sup>80</sup> Clinical signs associated with varying levels of dehydration are presented in Table 8-9.

As a first approximation, correction of most dehydration states in older children is most readily achieved with administration of a simple bolus of NS, LR, or PLASMA-LYTE 148 (balanced crystalloid solution). In infants or children with unusual, prolonged, or severe dehydration, however, management must be more precise. A five-point questionnaire to assess the severity of dehydration may help develop an appropriate treatment strategy<sup>82</sup>:

1. *Does a volume deficit exist and, if so, how great is it?*

As noted previously, assessment of volume deficit is best made by weight, yet rough estimates of 5% (mild), 10% (moderate), and 15% (severe) may be made in infants based on clinical signs (see Table 8-9).

2. *Does an osmolar disturbance exist? Is it acute or chronic?*

An osmolar imbalance is determined by measuring the serum sodium concentration. The majority of clinically encountered dehydration states (~80%) are isotonic ( $\text{Na}^+ = 130$  to  $150$  mEq/L). These isotonic losses are easily managed by almost any strategy.

Approximately 15% of dehydrated children present with hypertonic dehydration ( $\text{Na}^+ > 150$  mEq/L). These children are at greatest risk and have usually experienced the greatest fluid losses for a given set of clinical signs.<sup>83</sup> If the condition is chronic, they may require extensive, slow rehydration over much longer periods.<sup>84</sup>

Five percent of children present with hypotonic dehydration ( $\text{Na}^+ < 130$  mEq/L). For a given fluid deficit, these individuals are often more symptomatic than others, and their requirement for sodium replacement is greatest. Surprisingly, rapid improvement in clinical condition often results after the first fluid bolus.

In general, chronic dehydration states must be repaired slowly and acute dehydration states (<24 hours) may be corrected more rapidly. This is because cell volume equilibration occurs acutely through gain or loss of electrolytes (which are moved rapidly) and chronically through gain or loss of organic osmolytes (which are moved more slowly).<sup>11</sup> Reequilibration of brain cell volume during correction of hypertonicity can be very slow, mandating patience in correction of chronic fluid deficits. Similarly, rapid correction of hyponatremic disturbances can be hazardous,<sup>75</sup> even when seemingly safe isotonic solutions are employed.<sup>85</sup>

3. *Does an acid-base abnormality exist?*

Quantitation of the child's acid-base status gives useful, although limited, information as to the severity of dehydration. When evaluating acid-base status, it is important to recall that bicarbonate reabsorption and urine acidification are limited in preterm and young infants, leaving even the normal infant in a state of mild metabolic acidosis (pH, 7.3; serum bicarbonate 20 to 21 mEq/L [normal 22 to 26 mEq/L]). Although slow, spontaneous correction of acid-base status is typically observed on rehydration, rapid fluid boluses in poorly perfused children may result in a transient "reperfusion acidosis" as returning circulation washes the products of anaerobic metabolism out of the tissues. In this setting, or when renal insufficiency exists, blood-buffering capacity is such that children with serum bicarbonate concentrations lower than 8 mEq/L or pH lower than 7.2 may benefit from administration of supplemental base (sodium bicarbonate) (Fig. 8-6).<sup>82</sup>

Rapid bedside evaluation of acid-base status utilizes the following general relationships: a pH decrease of 0.1 unit accompanies a base excess (BE) of approximately 6 mEq/L or an increase in carbon dioxide tension ( $\text{PCO}_2$ ) of 10 to

**FIGURE 8-6** Data from children with metabolic acidosis<sup>127</sup> were used to depict the displacement of pH as serum bicarbonate declines. The zone of rapid pH displacement (pH < 7.20) has a slope that is several times greater than the zone of gradual pH displacement (pH ≥ 7.20). As the pH moves through the zone of rapid pH displacement, a further decline of serum bicarbonate, of as little as 1 or 2 mEq/L, produces a highly leveraged further decrease of pH.  $[\text{H}]$ , Hydrogen ion concentration;  $[\text{HCO}_3^-]$ , bicarbonate ion concentration;  $\text{PCO}_2$ , carbon dioxide tension. (From Kallen RJ. The management of diarrheal dehydration in infants using parenteral fluids. *Pediatr Clin North Am* 1990;37:265-86.)

12 mm Hg. The total replacement base required is then determined by the following equation:

$$\text{Dose (mEq)} = 0.3 \times \text{Weight (kg)} \times \text{BE (mEq/L)}$$

Clinically, a smaller sodium bicarbonate dose (1 to 2 mEq/kg) is given initially, the response is verified by blood gas analysis, and the remaining doses are titrated to effect.

4. *Is renal function impaired?*

Initial evaluation includes the timing of the last urine void and recent urine output, measurement of urine specific gravity, and serum levels of blood urea nitrogen and creatinine. If uncertainty persists, measurement of serum and urine electrolytes for comparison and calculation of the  $\text{FE}_{\text{Na}}$  is indicated (see Chapter 26).

$\text{FE}_{\text{Na}}$  values of less than 1% imply prerenal conditions causing renal dysfunction, whereas  $\text{FE}_{\text{Na}}$  values greater than 2% to 3% suggest renal insufficiency. In prematurity, however, values as high as 9% may be seen in otherwise normal infants.

5. *What is the state of potassium balance?*

Potassium homeostasis is critical to life, and serum potassium levels are generally maintained within a very narrow range. Nonetheless, serum potassium concentrations do not reflect whole-body stores and substantial potassium depletion may exist in the presence of modest changes in serum potassium concentration ( $\text{K}^+_{\text{serum}}$ ). Gastrointestinal losses or metabolic

acidosis is usually accompanied by a potassium deficit, whereas other dehydration states are not. Rapid fluid boluses or pH correction, or both, may acutely reduce  $K^+$  serum,<sup>86</sup> and refractory hypokalemia may occur in children deficient in magnesium.<sup>87</sup> In all cases, adequate renal function should be present before administration of potassium, and complete repletion should be accomplished over 48 to 72 hours. Once the nature and severity of dehydration have been determined, the clinician may proceed using any of a variety of correction strategies. In one approach, moderate to severe dehydration deficits may be estimated, as in Table 8-9. Fluid and electrolyte repair may then proceed according to a three-phase approach wherein circulating plasma volume, perfusion, and urine output are restored rapidly using isotonic crystalloid or colloid solution and remaining deficits are corrected over 24 hours as follows<sup>88</sup>:

- Emergency Phase: 20 to 30 mL/kg isotonic crystalloid/colloid bolus
- Repletion Phase 1: 25 to 50 mL/kg over 6 to 8 hours. Anions:  $Cl^-$  75%, acetate 25%
- Repletion Phase 2: remainder of deficit over 24 hours (isotonic) or 48 hours (hypertonic). Include calcium replacement as necessary.

### HYPERNATREMIA AND HYPONATREMIA

As previously detailed, disorders of sodium equilibrium are primarily marked by disturbances of fluid balance and are corrected according to the principles outlined earlier. Serious hypernatremia or hyponatremia is accompanied by neurologic symptoms whose severity is determined by the degree and rate of change of serum sodium concentration ( $Na^+$  serum).

#### Hypernatremia

In contrast to its rareness in adults, acute hypernatremia is common in children. A mortality rate greater than 40% for the acute disorder and 10% for the chronic disorder has been quoted for hypernatremia (serum sodium >160 mEq/L).<sup>76,89</sup> Mortality and permanent neurologic injury are even more common in infants. Depending on degree and duration, neurologic findings include irritability and coma. Seizures may be a presenting symptom, but they are more commonly encountered after the start of therapy. Children with acute conditions are usually symptomatic, whereas those with chronic conditions (acclimated individuals) are typically asymptomatic. General principles for treatment of hypernatremia are as follows:

- In the setting of circulatory collapse, colloid or NS bolus should be administered. Although the assertion is debatable, a colloid bolus provides the theoretical benefit of sustained hemodynamic support with lower fluid load. Saline, in contrast, rapidly reequilibrates, necessitating repeated boluses while adding to the total salt burden.
- Once a stable circulation has been restored, fluid deficit should be assessed as accurately as possible and corrected over 48 to 72 hours. Cautious correction of the serum sodium level is required. The serum sodium concentration and osmolality should be continuously reassessed during fluid administration, aiming for a correction of no more than 1 to 2 mOsm/L/hr. After as little as 4 hours of hypernatremia, idiogenic osmoles (e.g., trimethylamines) appear in the brain to prevent cerebral volume depletion. Rapid administration of free water could induce cerebral edema, seizures, and death. Therefore, free water should be administered slowly. Because of possible

associated hypoglycemia, some solutions should be glucose-containing, and serum glucose levels should be monitored.

- Vigilance for seizures, apnea, and cardiovascular compromise should be maintained, because such complicating factors can be the primary determinants of successful outcome.

#### Hyponatremia

Hyponatremia is also common in infants and children. Increasing prevalence due to erroneous formula dilution has intermittently been reported.<sup>90,91</sup> In the practice of anesthesiology, mild hyponatremia is a common postoperative condition after surgery of any severity<sup>92-94</sup>; in neurosurgical patients, hyponatremia may represent cerebral salt wasting or syndrome of inappropriate antidiuretic hormone secretion (SIADH).<sup>95</sup> In general, symptomatic patients are acutely hyponatremic and asymptomatic individuals are chronically hyponatremic.<sup>96</sup> After surgery, acutely hyponatremic children may present with nonspecific symptoms that are often erroneously attributed to other causes. Early central nervous system symptoms include headache, nausea, weakness, and anorexia. Advancing symptoms include mental status changes, confusion, irritability, progressive obtundation, and seizures. Respiratory arrest (or irregularity) is a common manifestation of advanced hyponatremia.

When planning to correct hyponatremia, the presence of symptoms must be considered a medical emergency, whereas asymptomatic children do not require rapid intervention. Chronic hyponatremia must be corrected slowly and by no more than 0.5 mEq/L/hr to avoid neurologic complications that include central pontine myelinolysis.<sup>97</sup> The best treatment for acute hyponatremia is early recognition and intervention. Because hypoxia exacerbates the neurologic injury, the simple ABCs of resuscitation are attended to first, and the airway is secured in the child who has seizures or respiratory irregularity. Hyponatremic seizures may be quieted by relatively modest (3 to 6 mEq/L) increases of serum sodium.<sup>98</sup> In several series,<sup>91,99,100</sup> such limited, rapid correction of symptomatic hyponatremia with hypertonic saline (514 mEq/L NaCl) was found to be well tolerated. It should be emphasized, however, that complete correction is unnecessary and unwise.<sup>101</sup> Initial therapy is aimed at increasing the serum sodium concentration no more than is necessary to stop seizure activity (usually 3 to 5 mEq/L). Further, the correction takes place over several days. Hypertonic saline may be used for the correction until the serum sodium increases to greater than 120 mEq/L. Remembering that TBW may range from 75% in infancy to 60% or less in older children, total sodium deficit is estimated as follows:

$$\text{Sodium change (mEq/L)} \times \text{fraction TBW (L/kg)} \times \text{weight (kg)} = \text{mEq sodium}$$

$$(\text{Desired } [Na^+]_{\text{serum}} - \text{observed } [Na^+]_{\text{serum}}) \times 0.6 \times \text{weight (kg)} = \text{mEq sodium required}$$

For example, in a 25-kg child, to correct a serum sodium concentration of 110 mEq/L to 125 mEq/L using hypertonic saline (514 mEq/L), infuse

$$(125 \text{ mEq/L} - 110 \text{ mEq/L}) \times 0.6 \times 25 = 225 \text{ mEq total}$$

$$\text{or}$$

$$225 \text{ mEq} / 514 \text{ mEq/L} = 0.44 \text{ L over 48 hours} = 9 \text{ mL/hr}$$

Because such calculations involve estimates, frequent measurement of the serum sodium concentration is necessary during

correction. As with hypernatremia, much of the morbidity and mortality associated with hyponatremia relates to complicating factors such as seizures and hypoxia that may occur during therapy. Therefore, children undergoing therapy should be cared for in a monitored setting. When overzealous correction has occurred, there may be value in acutely relowering  $\text{Na}^+$  serum using hypotonic fluids,<sup>96</sup> although such therapy is not without its own hazards.

General principles for treatment of hyponatremia are as follows:

- Asymptomatic hyponatremia in and of itself need not be rapidly corrected. Associated cardiovascular compromise due to volume depletion may be addressed by colloid bolus or administration of isotonic saline (1 L/m<sup>2</sup>/day). Provision of sodium is accompanied by free water restriction.
- Symptomatic hyponatremia is a medical emergency and may sometimes reflect irreversible neurologic injury. Correction should be rapid, yet limited, as discussed previously. A dose of 2 to 3 mL/kg of 3% saline (514 mEq/L) may be administered over 20 to 30 minutes to halt seizures.
- Subsequent correction is accomplished through calculation of the sodium deficit and provision of sodium so as to slowly correct at a rate not to exceed 0.5 mEq/L/hr or 25 mEq/L (total) in 24 to 48 hours.
- If the attendant fluid load is excessive or if oliguria is present, diuretics may be useful.

## DISORDERS OF POTASSIUM HOMEOSTASIS

### Hyperkalemia

Hyperkalemia is occasionally the presenting finding in conditions such as congenital adrenal hyperplasia. More commonly, it results from acute renal insufficiency, massive tissue injury, acidosis, or iatrogenic mishaps. In the operating room, acute hyperkalemia may follow the use of succinylcholine in children with myopathies, burns, upper and lower motor neuron lesions, chronic sepsis, or disuse atrophy and occasionally during massive, rapid transfusion of red blood cells or whole blood (see Chapters 6 and 10).<sup>102</sup> It may occur with rhabdomyolysis or as a late sign in malignant hyperthermia.

Although neurologic status is the main concern for children with abnormal serum sodium levels, cardiac status (rate and rhythm) determines the care of children with hyperkalemia. In children with hyperkalemia, the appearance of peaked T waves is followed by lengthening of the PR interval and widening of the QRS complex until P waves are lost. Finally, the QRS complex merges with its T wave to produce a sinusoidal pattern (Fig. 8-7). Successful treatment traditionally utilizes the following approach:

- Emergent therapy is first directed toward antagonism of the cardiac effects of potassium by cautious administration of intravenous calcium (calcium chloride [10 to 30 mg/kg] as 0.1 to 0.3 mL/kg of a 10% solution, or calcium gluconate [30 to 100 mg/kg] as 0.3 to 1 mL/kg of a 10% solution) over 3 to 5 minutes to avoid bradycardia. Calcium does not decrease the serum potassium concentration but rather reestablishes the gradient between the resting membrane potential, which is increased in the presence of hyperkalemia, and the threshold potential, which is determined by the calcium concentration. It also increases the refractory period of the action potential, the net effect being the prevention of spontaneous depolarization.
- Serum potassium is then reduced by returning potassium to the intracellular space. This is done by correcting acidosis

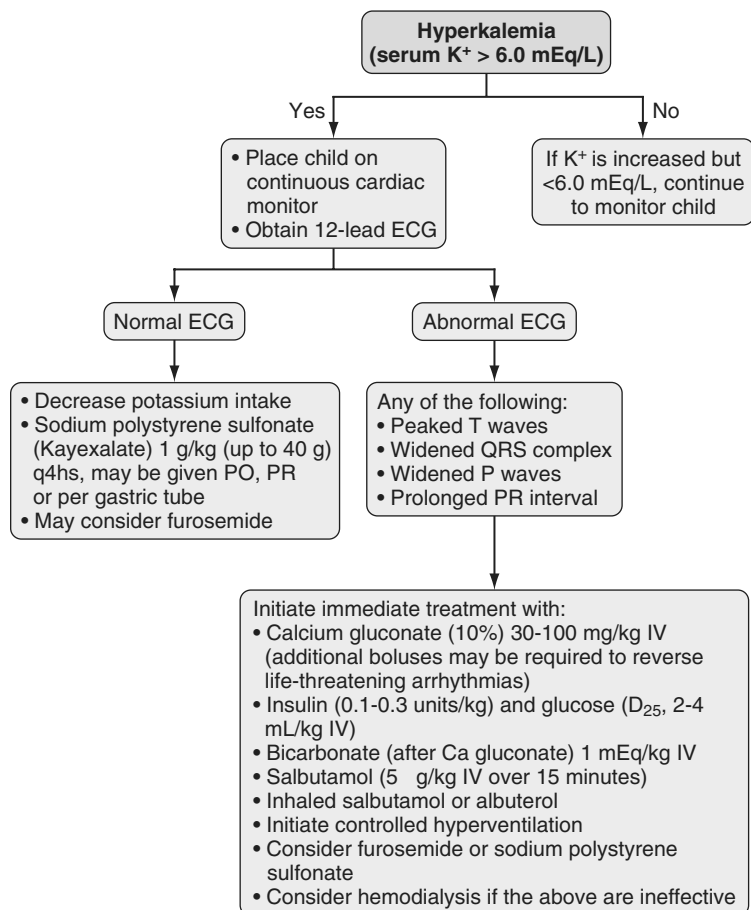

**FIGURE 8-7** Electrocardiographic changes associated with hyperkalemia. (From Williams GS, Klenk EL, Winters RW. Acute renal failure in pediatrics. In: Winters RW, editor. The body fluids in pediatrics: medical, surgical, and neonatal disorders of acid-base status, hydration, and oxygenation. Boston: Little, Brown; 1973. p. 523-57.)

through administration of sodium bicarbonate (1 to 2 mEq/kg), mild to moderate hyperventilation, and administration of a  $\beta$ -agonist.

- To maintain potassium in the intracellular space, glucose and insulin are administered by infusion (0.5 to 1 g/kg glucose with 0.1 U/kg insulin over 30 to 60 minutes).
- After stabilization, attention is directed toward removal of the whole-body potassium burden (sodium polystyrene sulfonate [Kayexalate], furosemide, dialysis) and correction of the underlying cause (Fig. 8-8).

The knowledge that  $\beta$ -adrenergic stimulation modulates the translocation of potassium into the intracellular space<sup>103,104</sup> has prompted the consideration of  $\beta$ -agonists in the treatment of acute hyperkalemia.<sup>105-108</sup> In children, a single infusion of an IV  $\beta$ -agonist such as salbutamol (5  $\mu$ g/kg over 15 minutes) effectively reduces serum potassium concentrations within 30 minutes. Because of the rapidity, efficacy, and safety of salbutamol in children, it has become the first-choice treatment for hyperkalemia.<sup>105</sup> In addition to IV therapy, both salbutamol<sup>109</sup> and albuterol<sup>108</sup> by inhalation effectively reduce the serum potassium concentration. It should be noted that at this time, salbutamol is not available in IV formulations in the United States. The inhalation route has the significant advantages of being readily available in emergency departments and not requiring IV access.

## Treatment Algorithm for Hyperkalemia

**FIGURE 8-8** Algorithm for treatment of hyperkalemia. After stabilization, attention is directed toward removal of the whole-body potassium burden (Kayexalate, dialysis) and correction of the underlying cause. D<sub>25</sub>, 25% dextrose; ECG, electrocardiogram; IV, intravenous; PO, orally; PR, per rectum.

However, the observation that a paradoxical exacerbation of hyperkalemia sometimes occurs on initiation of treatment,<sup>109</sup> together with concerns regarding the possibility of associated arrhythmias,<sup>110</sup> suggests that more experience is required before such therapy can be considered the standard of care. Inhalation of albuterol during such an event in the operating room may speed the reduction in serum potassium while other methods of treatment are instituted.

### Hypokalemia

Hypokalemia is most common in children as a complication of diarrhea or persistent vomiting associated with gastroenteritis. Muscle weakness is the most common sign in hypokalemia and has been correlated with the serum potassium concentration.<sup>111</sup> In the operating room or ICU, hypokalemia may also accompany a wide variety of other conditions, including diabetes, hyperaldosteronism, pyloric stenosis, starvation, renal tubular disease, chronic steroid or diuretic use, and  $\beta$ -agonist therapy. Severe hypokalemia can also be accompanied by electrocardiographic changes, including QT prolongation, diminution of the T wave, and appearance of U waves (see Fig. 8-7).

As noted previously, serum potassium concentrations do not accurately reflect total potassium homeostasis, and low serum concentrations may or may not be associated with significant total body potassium depletion. Indeed, the extracellular fraction of potassium is only a tiny proportion (approximately 3%) of the

entire body store. For these reasons, the precise point at which to begin replacement therapy is controversial, and total replacement requirements are impossible to calculate. In general practice, serum potassium values ( $K^+_{\text{serum}}$ ) between 2.0 and 2.5 mEq/L are corrected before surgery on the assumption that further decreases may predispose the child to muscular weakness, arrhythmias, and hemodynamic instability.

Potassium replacement is best accomplished orally over an extended period while the underlying cause is evaluated and treated. When IV correction is required, concentrations up to 40 mEq/L should be given slowly (*not to exceed 1 mEq/kg/hr*) in a monitored setting. Because such solutions often cause phlebitis, large-bore or central catheters are preferred. In the setting of hypochloremia and hypokalemia, chloride deficits must first be replaced, usually by administration of normal saline.

### SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE SECRETION

Many non-osmotic factors are capable of stimulating ADH release, and these can occasionally override osmotic control priorities. When this occurs, clinicians have historically deemed the increased ADH concentrations “inappropriate” because control of the serum osmolarity is lost (see Chapter 26). As detailed earlier, however, intravascular depletion is the most potent stimulus for vasopressin release, and it is hardly *inappropriate* that defense of circulation takes priority over defense of serum sodium

levels. Pain, surgical stress, critical illness, sepsis, pulmonary disease, central nervous system injury, drugs, and a variety of other factors may all stimulate ADH release above and beyond that necessary to maintain osmolar balance.

SIADH is common in children yet is often overlooked. Minor head trauma, for example, may elicit spikes in ADH levels, although infrequently to the extent that it produces serious hyponatremia and seizures.<sup>112</sup> Urine output after spinal fusion is often reduced because of increased concentrations of ADH, which usually return to normal within 24 hours without therapy.<sup>113</sup> Infants with bronchiolitis and hyperinflated lungs frequently demonstrate markedly increased plasma ADH concentrations and exhibit fluid retention, weight gain, urinary concentration, and plasma hypoosmolality until their illness begins to resolve.<sup>114</sup> Hyponatremia to the point of seizures, however, is only occasionally observed.

The diagnosis of SIADH rests on the identification of impaired urinary dilution in the setting of plasma hypoosmolality. Hyponatremia ( $\text{Na}^+ < 135 \text{ mEq/L}$ ), serum osmolality less than  $280 \text{ mOsm/L}$ , and urine osmolality greater than  $100 \text{ mOsm/L}$  in the absence of volume depletion, cardiac failure, nephropathy, adrenal insufficiency, or cirrhosis are generally considered sufficient for diagnosis. Therapeutic principles are similar to those for hyponatremia and depend on the following:

- Restriction of free water
- Repletion of sodium deficits (if present)
- Administration of diuretics to offset the effects of vasopressin

## DIABETES INSIPIDUS

In the operating room and the ICU, diabetes insipidus is most commonly associated with the care of neurosurgical patients.<sup>115-117</sup> Diabetes insipidus is also caused by neuroendocrine failure in brain death, and management may be necessary if organ donation is requested.<sup>118,119</sup> Diabetes insipidus results from decreased secretion of, or renal insensitivity to, vasopressin (see Chapter 26). Manifestations include massive polyuria, volume contraction, dehydration, and plasma hyperosmolality. Dilute polyuria ( $<250 \text{ mOsm}$ ,  $>2 \text{ mL/kg/hr}$ ) in the presence of hypernatremia ( $\text{Na}^+ > 145 \text{ mEq/L}$ ) with hyperosmolality ( $>300 \text{ mOsm/L}$ ) is the hallmark. In central diabetes insipidus, administration of desmopressin concentrates the urine but water deprivation does not. Postoperative diabetes insipidus may initially be difficult to distinguish from mobilization of operative fluids.

Children with craniopharyngioma or a similarly situated pathologic lesion may not manifest vasopressin deficiency early in the disease but become symptomatic preoperatively after steroid administration or intraoperatively during surgical manipulation. Postoperative diabetes insipidus typically begins on the evening after surgery and may resolve in 3 to 5 days if osmoregulatory structures have not been permanently injured. An often-confusing triphasic response may also occur wherein postoperative diabetes insipidus appears to resolve, fluid status normalizes, or SIADH appears and then vasopressin secretion ceases and diabetes insipidus returns. It is hypothesized that this pattern reflects nonspecific vasopressin release from degenerating neurons in the hypothalamic supraoptic and paraventricular nuclei.

Attempts have been made to develop protocols for perioperative management of diabetes insipidus.<sup>120</sup> Because vasopressin is difficult to titrate to urine output, our practice involves maximal antidiuresis and fluid restriction. In this setting, volume status must be monitored closely, because urine output is no longer a

marker of renal perfusion. Children who need close perioperative monitoring for the development of diabetes insipidus include those with preexisting diabetes insipidus as well as those who are undergoing resection of craniopharyngiomas or pituitary lesions or other procedures that involve resection or manipulation of the pituitary stalk.<sup>121</sup>

## HYPERCHLOREMIC ACIDOSIS

Administration of large amounts of NS can lead to excess serum chloride.<sup>122</sup> The chloride content of NS is  $154 \text{ mEq/L}$ . This excess of chloride ions can lead to a hyperchloremic acidosis, which has been categorized as a strong-ion acidosis.<sup>123,124</sup> This type of acidosis results from an excess of strong anions (e.g., lactate, ketoacids, sulfates) relative to the strong cations. As the strong ion difference increases, acidosis occurs. The magnitude of the acidosis is related to the amount of NS administered as well as the rate of administration. Infusions of  $35 \text{ mL/kg}$  NS over 2 hours in healthy patients undergoing gynecologic surgery resulted in acidosis. Acidosis did not occur with similar infusions of LR.<sup>122</sup>

## HYPOCHLOREMIC METABOLIC ALKALOSIS

Infants with pyloric stenosis and other children with chronic vomiting may develop a hypochloremic metabolic alkalosis. In both of these conditions, chronic vomiting results in large losses of hydrogen and chloride ions and water. This leads to an alkalotic, dehydrated state. In the absence of IV fluid therapy, the renal response is to conserve water by retaining sodium through upregulation of aldosterone, in which hydrogen ions (which are already in short supply because of the vomiting) and potassium ions are excreted in the urine in exchange for sodium. Excretion of the remaining hydrogen ions in exchange for sodium exacerbates the existing alkalosis or prevents resolution of the alkalosis. It also leads to the unusual syndrome of paradoxical aciduria in the presence of a metabolic alkalosis.

The potassium loss leads to hypokalemia. Although hypokalemia between  $3.4$  and  $4.4 \text{ mEq/L}$  may appear trivial because the concentration is small, chronic hypokalemia equilibrates throughout all bodily fluids, including the intracellular fluid volume. The intracellular potassium concentration,  $135$  to  $145 \text{ mEq/L}$ , is 30- to 40-fold greater than the extracellular concentration. Hence, a chronic decrease of  $1 \text{ mEq/L}$  in extracellular potassium, which is only 1% to 2% of the total body potassium, may reflect an enormous deficiency in total body potassium stores, on the order of 100 to 200  $\text{mEq K}^+$  in an adult. However, potassium loss from the extracellular fluid is not linearly related to the total body potassium (due to interference from  $\text{Na}^+/\text{K}^+$  pumps and other electrolyte-stabilizing mechanisms). With an extracellular  $\text{K}^+$  concentration of less than  $3.5 \text{ mEq/L}$ , a small loss in extracellular potassium translates into a huge loss of total body potassium, whereas with an extracellular  $\text{K}^+$  concentration greater than  $4 \text{ mEq/L}$ , extracellular potassium losses exert an attenuated effect on the total body potassium.

In infants and children with chronic hypokalemic, hypochloremic, metabolic alkalosis, correction of the electrolyte abnormalities and hypovolemia is optimally achieved using NS with  $20 \text{ mEq/L K}^+$  infused at a rate of 10 to  $20 \text{ mL/kg/hr}$  through a peripheral IV access until the potassium level is greater than  $3.0 \text{ mEq/L}$ , the chloride concentration is greater than  $95 \text{ mEq/L}$ , and the clinical signs of hypovolemia are resolved. In the case of pyloric stenosis, this may take 24 to 48 hours depending on the severity of the electrolyte and fluid imbalance.

## CEREBRAL SALT WASTING

Cerebral salt wasting (also known as renal salt wasting) is a hyponatremic syndrome of unclear etiology. Most commonly recognized in neurosurgical patients, it is a primary natriuresis probably related to dysregulation of brain or atrial natriuretic peptides. The condition has been increasingly recognized, and an incidence as great as 5% has been reported in children with brain tumors.<sup>125</sup>

Cerebral salt wasting can sometimes be difficult to distinguish from SIADH but, unlike the latter, the former is marked by hyponatremia, natriuresis, and *hypovolemia*. Initial therapy consists of fluid resuscitation with isotonic solutions and ongoing correction of intravascular volume depletion with sodium-containing solutions. Although spontaneous resolution is the norm, persistent cases may require mineralocorticoid therapy.

Platelet Disorders and Bleeding

Idiopathic Thrombocytopenic Purpura

## Coagulation Disorders

Screening

Von Willebrand Disease

Hemophilia

Hypercoagulability

## Cancer and Hematopoietic Stem Cell Transplantation

Cancer

Hematopoietic Stem Cell Transplantation

**HEMATOLOGIC DISORDERS IN CHILDHOOD** may manifest in many ways. They may be the primary cause for a surgical procedure, such as hereditary spherocytosis (HS) in a child undergoing splenectomy, or a factor complicating a surgical procedure, such as sickle cell disease in a child undergoing tonsillectomy. Questions about hematologic problems such as anemia, thrombocytopenia, decreased or increased coagulation, childhood cancer, and hematopoietic stem cell transplantation (HSCT) are often raised in the perioperative setting.

In this chapter, we address the hematologic considerations and diseases that are of significant interest to pediatric anesthesiologists. We highlight considerations important to the hematologist that the anesthesiologist should incorporate in the care of a child.

## The Basics

### LABORATORY VALUES AND DIAGNOSTIC TESTS

What is a normal hematocrit or platelet count for an infant or child who comes to the operating room? Red blood cell (RBC), white blood cell, platelet, and coagulation indices evolve in various ways through late gestation, the neonatal period, infancy, and childhood (Table 9-1).

The term neonate has a relative polycythemia, reticulocytosis, and leukocytosis compared with the child. Neonatal platelet counts are similar to those of adults. Although in vitro function may be impaired for the first postnatal month, most in vivo assays of platelet function indicate normal or accelerated function. Preterm and term neonates have prolongation of the prothrombin time (PT) and activated partial thromboplastin time (aPTT) because of a relative deficiency in vitamin K-dependent factors and contact activation factors, respectively; however, concentrations of factor VIII and von Willebrand factor (vWF) are elevated.<sup>1</sup> The international normalized ratio (INR), a normalized PT, has an average value of 1.0 for all age groups. Fibrinogen concentrations are comparable between the term neonate and adult, although neonatal fibrinogen is qualitatively dysfunctional. The plasma concentrations of many anticoagulant factors

(i.e., tissue factor pathway inhibitor, antithrombin, vitamin K-dependent glycoproteins, and proteins C and S) are decreased in preterm and term neonates. The quantity and quality of plasminogen are decreased in neonates, a condition that increases the risk for thrombosis, especially in a compromised infant.<sup>1,2</sup> Most of these differences between the neonate and older child or adult persist for 3 to 6 months postnatally.

After the immediate neonatal period, preterm and term infants experience physiologic anemia, presumably due to the downregulating effect of increased oxygen supply in extrauterine life on erythropoiesis and to the dilutional effect of a rapidly increasing blood volume. Preterm infants reach their nadir hemoglobin of 7 to 9 g/dL at 3 to 6 postnatal weeks, and term infants reach their nadir hemoglobin concentration of 9 to 11 g/dL at 8 to 12 postnatal weeks. Most hematologic values reach adult

**TABLE 9-1 Hematology Values at Different Ages**

Measurement*	Preterm 28-32 Weeks	Preterm 32-36 Weeks	Term Neonate	1-Year-Old	Child	Adult
Hemoglobin (g/dL)	12.9	13.6	16.8	12	13	15
Hematocrit (%)	40.9	43.6	55	36	38	45
Reticulocyte count (%)	—	—	5	1	1	1.6
White blood cell count (/mm <sup>3</sup> )	5,160	7,710	18,000	10,000	8,000	7,500
Platelet count (/mm <sup>3</sup> )	255,000	260,000	300,000	300,000	300,000	300,000
Prothrombin time (second)	15.4	13	13	11	11	12
International normalized ratio (INR)	—	1	1	1	1	1
Activated partial thromboplastin time (second)	108	53.6	42.9	30	31	28
Fibrinogen (mg/dL)	256	243	283	276	279	278
Bleeding time (minute)	—	3.5	3.5	6	7	5

\*All values expressed as the mean.

analysis is an additional test that is increasingly used for the assessment of platelet abnormalities, and it has the benefit of avoiding some of the difficulties of obtaining a bleeding time in children. Although several studies suggest PFA-100 analysis is equivalent or superior to the bleeding time for detecting bleeding abnormalities, there is no consensus about its role in preoperative screening.<sup>11</sup> With the increasing use of newer agents that modify platelet function (e.g., platelet G protein-coupled receptor P2Y<sub>12</sub> antagonists, glycoprotein GPIIb-IIIa complex antagonists), clinicians must understand that the thromboelastogram, PFA-100, and other methods for assessing platelet function may vary in their ability to monitor the effects of these agents and those of cyclooxygenase inhibitors.<sup>12</sup>

### **GUIDELINES FOR TRANSFUSION**

Critical analyses of the risks and benefits of transfusions in infants and children in the perioperative period have resulted in fewer transfusions. Even for infants and children in intensive care, a restrictive transfusion threshold (i.e., 7 g/dL) reduces transfusions without increasing morbidity compared with a liberal threshold (i.e., 9.5 to 10 g/dL).<sup>13</sup> Data from the United Kingdom's national audit of clinical transfusion, the Serious Hazards of Transfusion (SHOT), indicate that infants and children younger than 18 years of age are at greater risk for adverse transfusion-related reactions (37 and 18 in 100,000, respectively) than are adults (13 in 100,000). Most events were error related, such as administrative, laboratory, clinical judgment, and handling errors.<sup>14</sup>

Guidelines for RBC transfusion for infants and children in the perioperative setting should be consistent with those established by the American Society of Anesthesiologists Task Force on Blood Component Therapy, which propose that transfusion is not indicated for hemoglobin concentrations higher than 10 g/dL but is indicated for concentrations lower than 6 g/dL.<sup>15</sup> When the concentration is between 6 and 10 g/dL, packed red blood cells (PRBCs) should be transfused based on the child's vital signs, adequacy of oxygenation and perfusion, acuity and degree of blood loss, and other physiologic and surgical factors. When the concentration exceeds 10 g/dL, the decision to transfuse PRBCs to a neonate or infant should be based on the increased baseline concentrations of hemoglobin, increased oxygen consumption,

increased affinity of residual fetal hemoglobin for oxygen, absolute blood volume (i.e., 85 mL/kg for a term neonate and 100 mL/kg for a preterm neonate), and other physiologic and surgical factors applicable to all children. The threshold for transfusing a healthy neonate may be 7 g/dL in some clinical settings, but it may be 12 g/dL or higher for a neonate in other settings, such as significant lung disease requiring mechanical ventilation, chronic lung disease, cyanotic congenital heart disease, or heart failure.<sup>16-18</sup> For a preterm infant, the risks of hypovolemia, hypotension, acidosis, and postoperative apnea are magnified in the setting of operative blood loss and anemia. It is impossible to address all of the guidelines in this chapter, but many pediatric hematology and oncology consultants have clearly defined transfusion thresholds for their patient populations that should be reviewed preoperatively.

Guidelines for platelet transfusion have been published by consensus committees from France, the United Kingdom, and the United States; these reports are based on available evidence that has been gathered and critically reviewed (Table 9-2).<sup>15,19-22</sup> Without evidence that platelet function is significantly different in the healthy infant and child, these guidelines should be applicable to these patients. The decision to transfuse platelets must take into account underlying medical conditions, platelet transfusion history, current medications, surgical bleeding, surgical interventions (e.g., cardiopulmonary bypass), and all other factors that may affect platelet function and turnover.<sup>23-27</sup> Sevoflurane and propofol suppress<sup>28</sup> and enhance platelet aggregation in vitro.<sup>29</sup> Despite these effects on platelet aggregation, no change in the bleeding time has been reported, suggesting that the inhibitory effect does not impair hemostasis in vivo.<sup>30</sup>

Guidelines for the transfusion of other blood products, particularly fresh frozen plasma (FFP) and cryoprecipitate, have been established,<sup>15,26,31</sup> and they are discussed later in the context of coagulation disorders. Indications<sup>32</sup> for transfusing FFP are usually limited to the following:

1. Replacement of documented congenital or acquired coagulation factor deficiency when a specific sterilized or combined factor concentrate is unavailable, especially in the setting of anticipated or active bleeding
2. Acquired coagulopathy resulting from massive transfusion
3. Immediate reversal of warfarin's effect

**TABLE 9-2 Triggers for Platelet Transfusion**

Medical Condition or Procedure	Platelet Count (/mm <sup>3</sup> )
Stable hematology-oncology or chronically thrombocytopenic patient	10,000-20,000
Lumbar puncture in stable leukemic child	10,000
Bone marrow aspiration or biopsy	20,000
Gastrointestinal endoscopy in cancer patient	20,000-40,000
Disseminated intravascular coagulation	20,000-50,000
Fiberoptic bronchoscopy in hematopoietic stem cell transplantation patient	20,000-50,000
Neonatal alloimmune thrombocytopenia	30,000
Major surgery	50,000
Dilutional thrombocytopenia with massive transfusion	50,000
Spinal anesthesia	50,000
Cardiopulmonary bypass	50,000-60,000
Liver biopsy	50,000-100,000
Nonbleeding preterm infant	60,000
Obstetric epidural anesthesia	70,000-100,000
Neurosurgery	100,000

Data from references 19, 20, 23, 26, 27, 265.

- Coagulation support in disease processes such as disseminated intravascular coagulation and thrombotic thrombocytopenic purpura
- A source of antithrombin III for children deficient of this inhibitor who require heparin

Cryoprecipitate should be administered only for anticipated or active bleeding in children with congenital fibrinogen deficiencies or von Willebrand disease who are unresponsive to desmopressin acetate (DDAVP) or for patients with acquired hypofibrinogenemia (less than 80 to 100 mg/dL) associated with massive transfusion.

Guidelines have been established by the College of American Pathologists and other transfusion study groups for leukocyte reduction of RBC units,<sup>16</sup> irradiation (x-ray or  $\gamma$ -ray) of cellular blood components,<sup>33</sup> and administration of cytomegalovirus-seronegative RBCs (Tables 9-3 to 9-5).<sup>16</sup> These guidelines are valuable when determining the specific choice of blood components that should be ordered and administered in the perioperative setting. For hematologic patients receiving chronic RBC transfusions, an extended phenotypic crossmatch and leukocyte reduction can decrease the risk of developing alloantibodies and transfusion reactions, especially in children of African descent if the local donor pool is primarily derived from Caucasian populations of Northern European descent.<sup>34</sup> For oncology patients, updated specific requirements for blood products including leukocyte reduction and irradiation are often indicated and should always be reviewed with oncology specialists.

## Hemolytic Anemias

Anemia commonly manifests in the perioperative setting, and primary hemolytic anemias can present unique and challenging problems for the anesthesiologist. Hemolytic syndromes are a

**TABLE 9-3 Indications for Leukocyte-Reduced Red Blood Cell Units**

### Prevention of Alloimmunization

Congenital hemolytic anemias (including sickle cell disease and thalassemia)  
 Hypoproliferative anemias likely to need multiple transfusions  
 Aplastic anemia  
 Myelodysplasia/myeloproliferative syndrome  
 Plasma cell dyscrasias  
 Hematopoietic stem cell transplants  
 Hematopoietic malignancies

### Therapy for Preexisting Conditions

Recurrent, severe febrile hemolytic transfusion reactions  
 Known HLA alloimmunization

### Possible Uses

Alternative to cytomegalovirus-seronegative components (see Table 9-5)  
 Human immunodeficiency virus–infected patients

Modified from Simon TL, Alverson DC, AuBuchon J, et al. Practice parameter for the use of red blood cell transfusions: developed by the Red Blood Cell Administration Practice Guideline Development Task Force of the College of American Pathologists. Arch Pathol Lab Med 1998;122:130-8.

**TABLE 9-4 Indications for Irradiation of Cellular Blood Components**

### Well-Defined Indications

Hematopoietic stem cell transplantation  
 Actual or anticipated congenital cell-mediated immunodeficiency  
 Intrauterine transfusion or after intrauterine transfusion  
 Directed donation from blood relative or HLA-matched donor  
 Hodgkin disease  
 Acute lymphocytic leukemia  
 Immunocompromised organ transplant recipient

### Probable Indications

Malignancy and organ transplantation treated with immunosuppressive therapy  
 Exchange transfusion in neonate  
 Extracorporeal membrane oxygenation in neonate  
 Low-birth-weight neonate (<1200 g)  
 Human immunodeficiency virus–infected patient with opportunistic infection

### Possible Indications

Term neonate (<4 months)  
 Human immunodeficiency virus–infected patient

Modified from Simon TL, Alverson DC, AuBuchon J, et al. Practice parameter for the use of red blood cell transfusions: developed by the Red Blood Cell Administration Practice Guideline Development Task Force of the College of American Pathologists. Arch Pathol Lab Med 1998;122:130-8; Treleaven J, Gennery A, Marsh J, et al. Guidelines on the use of irradiated blood components prepared by the British Committee for Standards in Haematology blood transfusion task force. Br J Haematol 2010;152:35-51.

group of disorders in which erythrocyte lysis often leads to anemia. Although RBCs in these disorders may be characterized by abnormal morphology and shorter life span, these parameters may be normal at baseline. Clinical signs of a hemolytic syndrome include anemia, splenomegaly, and jaundice, signs that

because of the increased risk of overwhelming infection by encapsulated organisms such as *Streptococcus pneumoniae*, *Neisseria meningitidis*, and *Haemophilus influenzae* type B in splenectomized younger children.<sup>39</sup> Preoperative vaccination against these organisms is essential unless surgery is required emergently. Guidelines for the indications and duration of postoperative penicillin prophylaxis vary among institutions.<sup>36</sup>

Splenectomies in children are more frequently performed laparoscopically than by open laparotomy because the former is associated with decreased pain, quicker return of bowel function, shorter hospital stay, and improved cosmetic result. Conversion from laparoscopic to open splenectomy is necessary in fewer than 10% of cases.<sup>40</sup> Partial splenectomies are increasingly performed because they allow retention of some immune function against bacterial infections in younger children while reducing the sequestration of spherocytes. However, residual splenic tissue can increase in size and necessitate total splenectomy at a later time.<sup>41,42</sup> If anemia recurs after splenectomy, it may indicate the presence of accessory splenic tissue that was unrecognized initially. Transient postsplenectomy thrombocytosis marked by dramatic increases in platelet counts may also occur in children,<sup>35</sup> in addition to a general increase in the risk of thromboembolic disease.

Gallstones occur in 21% to 63% of children with HS, but cholecystectomy is usually performed only when children are symptomatic with cholelithiasis. Children who undergo splenectomy and who also have radiographically identified gallstones may undergo concurrent cholecystectomy, whether the stones are symptomatic or not.<sup>43-45</sup>

Table 9-6 summarizes the clinical features and important perioperative considerations for the child with HS undergoing incidental or disease-related surgical procedures.

**TABLE 9-6** Perioperative Concerns for Patients with Hereditary Spherocytosis

<b>Preoperative Considerations</b>
Hemoglobin, reticulocyte count, platelet count
History of transfusions and special blood requirements (e.g., extended phenotypic matching, leukocyte reduction)
History of infections, aplastic crises, and presplenectomy vaccinations
Presplenectomy antibiotic prophylaxis and immunization when indicated
<b>Intraoperative Considerations</b>
Appropriate antibiotic coverage
Attention to physiologic effects of laparoscopy on circulatory and respiratory function
Potential for significant blood loss (unusual in splenectomy and cholecystectomy)
Judicious use of regional anesthesia, intramuscular medications, nasogastric tubes, nasal intubation, and other methods when platelet count is low
Limited use of medications with potential bleeding risk (e.g., ketorolac)
<b>Postoperative Considerations</b>
Sequential hemoglobin determinations and platelet counts
Potential thrombocytosis: management as recommended by hematology consultants
Infection risk

## GLUCOSE-6-PHOSPHATE DEHYDROGENASE DEFICIENCY

G6PD deficiency causes hemolysis in the presence of various oxidative stressors. It is the most common enzyme deficiency in humans, affecting approximately 400 million people worldwide. This enzyme deficiency is inherited in an X-linked, recessive fashion. Although males are most commonly affected, females (heterozygous or homozygous for the gene) may have clinical manifestations of the disease. More than 100 variants have been described, including a relatively mild form that affects about 10% of African American males (i.e., G6PD A-) and a more severe form that affects Italians, Greeks, and other populations in the Mediterranean, African, and Asian regions (i.e., G6PD Mediterranean).<sup>46-48</sup> This deficiency is prevalent in geographic areas where the incidence of malaria is high, presumably because G6PD deficiency may attenuate the severity of malarial infections.

### Pathophysiology

G6PD plays an important role in the hexose monophosphate/pentose phosphate shunt, which is essential for normal energy metabolism in erythrocytes. G6PD generates the reduced form of nicotinamide adenine dinucleotide phosphate (NADPH). NADPH maintains glutathione in the reduced form (GSH), which reduces peroxides and protects cells from oxidative damage in the course of normal biochemical events or in the event of excess free oxygen radical generation. Superoxide ion or hydrogen peroxide, or both, can oxidize hemoglobin, which then precipitates as insoluble membrane inclusions. These inclusions, together with the oxidative damage to cell membranes, lead to cell damage. Erythrocytes are particularly sensitive to oxidative damage because of their lack of synthetic activity. In the presence of oxidants and free radicals (e.g., produced by infection or by ingestion of certain medications and foods), this cascade of events may precipitate hemolysis in the G6PD-deficient child.<sup>46,48</sup>

### Clinical and Laboratory Features

Clinical symptoms of G6PD deficiency may be deceptively variable, and they may occur in the neonatal period or in older age groups as episodic or chronic hemolytic anemia. Presenting signs include anemia and jaundice; in severe cases, these signs can be followed by lumbar and abdominal pain and by renal failure. Acute illness such as diabetic acidosis or ingestion of a variety of substances may precipitate a hemolytic event (Table 9-7). Hemolysis may range from benign and transitory to severe and life-threatening; the latter situation is more likely if the triggering agent is not eliminated or controlled. Laboratory findings include normocytic anemia, increased reticulocyte count and serum bilirubin concentration, and presence of Heinz bodies in the peripheral blood smear.

### Perioperative Considerations

In the perioperative setting, G6PD deficiency does not usually cause problems if the triggering agents are avoided by susceptible children and the precipitating causes are treated or eliminated (Table 9-8). Monitoring for and treatment of possible complications are appropriate; transfusion is rarely required.

Administration of large or excessive doses of medications such as prilocaine, benzocaine, and sodium nitroprusside may trigger hemolysis in G6PD-deficient children in the perioperative setting.<sup>46,48-50</sup> Although these children can reduce methemoglobin that is normally produced by these agents, G6PD-deficient children may not tolerate large amounts of potent oxidizing agents (i.e., superoxide ion and hydrogen peroxide) produced by

<b>Food</b>
Fava (broad) beans

**TABLE 9-8** Perioperative Concerns for Patients with Glucose-6-Phosphate Dehydrogenase Deficiency

<b>Preoperative Considerations</b>
History of hemolysis and precipitating factors
Hemoglobin, reticulocyte count
<b>Intraoperative Considerations</b>
Avoidance of triggering agents
Caution in use of high doses of agents that increase methemoglobin, especially in infants
Hemoglobin and urine output in high-risk settings (e.g., cardiopulmonary bypass)
<b>Postoperative Considerations</b>
Hemoglobin, reticulocyte count, urine output if hemolysis

methemoglobin. Infants may be particularly susceptible to symptomatic methemoglobinemia (because of their low NADPH dehydrogenase activity) and to methemoglobin-induced hemolysis if they are G6PD deficient. Treatment of methemoglobinemia with methylene blue is contraindicated in these infants because the agent itself may precipitate hemolysis.<sup>42</sup> Hemolysis has occurred during cardiopulmonary bypass in G6PD-deficient

children,<sup>50,51</sup> and methemoglobinemia has occurred in a child with partial G6PD deficiency after application of EMLA cream, a eutectic mixture of local anesthetics.<sup>52</sup>

## HEMOGLOBINOPATHIES

### Sickle Cell Disease

First identified by Herrick about 100 years ago, sickle cell disease is a group of inherited hemoglobinopathies with a diverse worldwide prevalence. The disease affects about 1 in 375 African American and 1 in 20,000 Hispanic births.<sup>53</sup> The spectrum of the disease includes sickle cell anemia (HbSS), which accounts for about 70% of the American sickle cell disease population; sickle cell/hemoglobin C disease (HbSC), accounting for about 20%; sickle cell/ $\beta$ -thalassemia (HbS $\beta$ ), accounting for about 10%; and a host of other, uncommon sickle variants whose prevalence is increasing over time.<sup>54</sup> HbS $\beta$  includes HbS $\beta^+$  and HbS $\beta^0$  thalassemias; the distinction depends on whether normal hemoglobin A (HbA) is expressed at all or in only a small concentration. HbS $\beta^0$ , HbSC, and sickle cell/hemoglobin D disease (HbSD) and additional rare forms have the potential to sickle as severely as HbSS. Sickle cell trait (HbAS), in which approximately 40% of hemoglobin is hemoglobin S, occurs in about 8% of African Americans and in a much smaller percentage of Hispanic and other American subpopulations. The sickle gene is found commonly in Africa, Mediterranean areas, southwestern Asia, and other areas where malaria has been historically endemic and for which the gene is protective. Sickle hemoglobinopathies have many implications for perioperative care because they increase perioperative morbidity and mortality.

### Pathophysiology

Hemoglobin A is composed of two  $\alpha$ - and two  $\beta$ -globin chains. Hemoglobin S is caused by a mutant  $\beta$ -globin gene on chromosome 11, which leads to a single amino acid substitution (valine for glutamate at position 6). Replacement of negatively charged and hydrophilic glutamate by noncharged and hydrophobic valine leads to instability of the hemoglobin molecule and decreased solubility of the molecule when deoxygenated. Hemoglobin polymers form, generating long helical strands and inducing a process that leads to hemoglobin precipitation and hemolysis.<sup>55</sup>

Classically, the pathophysiology and clinical complications of sickle cell disease were thought to be related primarily to the accumulation of sickled erythrocytes in the microvasculature in the setting of factors that promote hemoglobin crystallization (i.e., hypoxia, acidosis, and cellular dehydration) and interfere with peripheral perfusion (i.e., dehydration and hypothermia). This accumulation of sickled cells was thought to compromise the microcirculation, producing ischemia and thereby generating a spiral of red cell sickling and end-organ compromise.

The pathophysiologic process in sickle cell disease is much more complex than originally thought.<sup>55-57</sup> Inflammation, vascular endothelial adhesion abnormalities, platelets, and coagulation cascade activation all contribute to vaso-occlusive episodes. The sickle red cell membrane, exposed to the destructive oxidant effects of intracellular iron, develops altered transmembrane ion transport pathways, which lead to altered permeability to sodium, potassium, and calcium, causing dehydration of the cell and irreversible sickling.<sup>58</sup> Membrane abnormalities of phospholipid content also contribute to its deformability, and exposure of phosphatidyl serine facilitates activation of the clotting cascade. These and other factors lead to entrapment of irreversibly sickled

Chronic hemolytic anemia is a hallmark of HbSS disease. It is characterized by a baseline hemoglobin value of 5 to 9 g/dL (often more than 9 g/dL in HbSC disease), reticulocytosis (5% to 10%), and a distinctive red cell morphology observed on a peripheral smear.<sup>57</sup> Chronic hemolysis is associated with increased red cell turnover and a propensity to form biliary stones. It may be complicated by other anemic events, such as acute splenic sequestration, typically occurring in infants and young children after a viral illness; and acute aplastic anemia, typically associated with parvovirus B19 infection. For some children, chronic and acute severe anemia are managed with RBC transfusions, although these children are prone to develop alloantibodies to RBC antigens, and untreated iron overload can lead to life-threatening cirrhosis and cardiac failure. Hydroxyurea is used to prevent vaso-occlusive episodes and end-organ damage. Most children are maintained on chronic folic acid therapy to prevent megaloblastic erythropoiesis that can result from the increased red cell production.

Vaso-occlusive episodes in sickle cell disease occur as a result of episodic microvasculature occlusions at one or more sites. The occlusive process occurs most commonly in the phalanges (i.e., dactylitis or hand-foot syndrome), long bones, ribs, sternum, spine, and the pelvis; it also can occur in the mesenteric microvasculature, producing abdominal pain that may mimic a surgical acute abdomen. Vaso-occlusive episodes are managed with hydration, warming, acute and chronic pain management (including opioids, antiinflammatory agents, and complementary modalities), and in-hospital care. It is essential to foster an ideal environment for pain control (e.g., calm, pleasant distractions, supportive personnel and objects). For children who have frequent or severe crises, oral hydroxyurea therapy has been effective in decreasing the frequency of events through several mechanisms, including inhibiting hemoglobin precipitation by increasing fetal hemoglobin concentrations, reducing the white blood cell count, modifying the inflammatory response, and facilitating NO metabolism.<sup>59,65,66</sup> Inhaled NO may prove to be effective therapy for vaso-occlusive episodes.<sup>67</sup>

ACS is characterized by acute respiratory symptoms concurrent with a new infiltrate observed on the chest radiograph.<sup>68</sup> ACS frequently occurs 2 to 3 days after a vaso-occlusive episode, and although its clinical presentation varies, it often includes fever, tachypnea, cough, and hypoxemia. The process may be self-limited over a period of a few days, or it may progress to respiratory failure (15%) and even death. The inconsistent presentation in part reflects the complex and variable pathogenesis of ACS. An episode may have a single or multiple causes, including infection (i.e., bacteria [often *Chlamydia* or *Mycoplasma*], viruses, and mixed flora), pulmonary fat embolism, pulmonary infarction, and pulmonary hemorrhage.<sup>69</sup> Acute management includes supportive care and oxygen, antibiotics to cover encapsulated and atypical organisms, bronchodilators, pain control,

increased consumption, or altered metabolism, may also play an important role in these processes.<sup>63,68,75</sup>

Infection is a common problem in this disease because of deficits in the immunologic system and the specific effects of splenic atrophy and dysfunction that occur over the first few years of life.<sup>56</sup> As a result of susceptibility to overwhelming infection by *S. pneumoniae* and *H. influenzae* type B, young children receive penicillin prophylaxis until 6 years of age and bacteria-specific immunizations. A host of infectious organisms have been implicated in ACS, and infection with gram-negative organisms (e.g., osteomyelitis caused by *Salmonella*) is common in older children and adults.<sup>69</sup>

Stroke is a devastating complication that occurs in children with sickle cell disease. A history of overt strokes is elicited in 10% or more of these children, and silent strokes occur in another approximately 15%; one fourth of children are at risk for motor or cognitive deficits at the time of presentation for surgery.<sup>76,77</sup> A child's first stroke often appears as early as 2 to 5 years of age.<sup>78,79</sup> Risk factors include a reduced hemoglobin concentration, increased concentration of HbS, increased leukocyte count, and a history of dactylitis. Strokes may be precipitated by pain episodes, ACS, and infection.<sup>80</sup> Children suffering an acute stroke are managed supportively with exchange transfusion to reduce the concentration of HbS to less than 30% and then chronic intermittent transfusions to minimize the risk of recurrence.<sup>81</sup>

The thrust of the current management of stroke is prevention. Based on the findings of the Stroke Prevention Trials (STOP 1 and 2), children are assessed annually by transcranial Doppler, and children with evidence of cerebrovascular compromise and some of those with magnetic resonance imaging abnormalities are managed with chronic transfusion therapy to minimize the risk of a stroke.<sup>82-84</sup>

Renal abnormalities in sickle cell disease develop from repeated sludging episodes, which may cause thrombosis, progressive infarction, and necrosis of the renal medulla. Proteinuria, hematuria, hyposthenuria, renal tubular acidosis, and other clinical abnormalities occur. Acute and chronic renal failure may develop.<sup>85,86</sup> Renal dialysis and transplantation have been successful therapeutic interventions for this population.<sup>87</sup>

The clinical picture of sickle cell disease is altered to various degrees by concomitant qualitative and quantitative changes of hemoglobin. Sickle cell trait (HbAS) usually is benign, although it may be characterized by hematuria and hyposthenuria,<sup>87,88</sup> and sickling may occur with HbAS under extremely altered physiologic circumstances (e.g., cardiopulmonary bypass).<sup>89,90</sup> There is a small but significant risk of pulmonary emboli and sudden

picture, but it may predispose children to a greater incidence of pain episodes.<sup>62</sup>

In addition to the treatment modalities mentioned earlier, many new and experimental modalities show promise in the treatment of sickle cell disease and its complications. They include induction of hemoglobin F by short-chain fatty acids such as butyrate or demethylating agents such as decitabine; membrane-active medications such as the Gardos channel inhibitors, magnesium; and antiadhesion therapies. New therapeutic targets are being identified, such as BCL11A, a zinc finger protein that plays a key role in the silencing of fetal globin genes. Reduction of BCL11A results in an induction of fetal globin.<sup>92</sup> Hematopoietic stem cell transplantation (HSCT) is increasingly used as a curative intervention for sickle cell disease when instituted before development of organ dysfunction, but its application is limited in part by the lack of suitable donors.<sup>56,93</sup> To circumvent this limitation, gene therapy protocols using a child's own stem cells have been approved for use.

### Perioperative Considerations

Perioperative morbidity and mortality are greater in children with sickle cell disease than in the general population. These children often require surgical procedures; the most common are cholecystectomy<sup>94</sup>; ear, nose, and throat procedures<sup>95</sup>; and orthopedic procedures (especially hip procedures for osteonecrosis).<sup>96</sup> Placement of long-term vascular access for transfusions, antibiotics, analgesia, and other therapies is frequently performed. The Cooperative Study of Sickle Cell Disease reported that 7% of all deaths among children with this disease were related to surgery.<sup>54</sup> Early reviews reported perioperative mortality rates as great as 10% and morbidity rates as great as 50% for children with sickle cell disease.<sup>97-100</sup> Studies published in the 1990s indicated that the 30-day mortality rate was about 1%.<sup>101</sup> In a group of more than 600 patients managed according to standard guidelines of care and prospectively studied, the incidence of any complication was about 30%, and the incidences of ACS and pain crisis were 10% and 5%, respectively.<sup>64</sup> Patient factors (e.g., age, history of pulmonary disease, number of prior hospitalizations) and surgical factors (i.e., invasive or superficial) appear to affect the incidence of complications. The impact of newer interventions and technologies (e.g., laparoscopic and robotically assisted cholecystectomy and splenectomy)<sup>102-104</sup> on perioperative morbidity and mortality rates is unclear.

The principles of optimal perioperative care are based on maintaining optimal physiologic parameters throughout the perioperative period, avoiding factors that may precipitate a sickle crisis, optimizing pain management, and close consultation among hematologists, surgeons, and anesthesiologists (Table 9-9).<sup>105</sup> The child with sickle cell disease who is undergoing surgery should be viewed and managed primarily as a hematology patient whose care is being shared with, rather than assumed by, the surgeon and anesthesiologist during the perioperative period. Avoiding unnecessary and potentially dangerous surgical procedures (e.g., exploratory laparotomy to rule out appendicitis in a child who is experiencing an abdominal pain crisis) and minimizing perioperative complications should be the focus of the multidisciplinary care team. Based on a survey of perioperative management of sickle cell disease among anesthesiologists in North America, most anesthesiologists do consult with hematologists in all cases or on a case-by-case basis.<sup>106</sup>

Although there is no evidence to support or refute many of the long-standing guidelines for perioperative care and individual

Anesthetic technique does not have a clear effect on perioperative outcomes for children with sickle cell disease.<sup>114</sup> Inhalational anesthetics do not affect the sickling process, although there is some experimental evidence suggesting that halothane may increase the viscosity of sickled blood.<sup>115</sup> Pharmacokinetics of some agents commonly used with general anesthesia such as atracurium may be altered in this population.<sup>116</sup> Regional anesthesia has been associated with an increased risk of postoperative complications in one retrospective study,<sup>101</sup> but it has not been shown to affect perioperative outcome in others.<sup>94,96</sup> Vasodilatory and analgesic properties of regional anesthesia can be effective in the management of vaso-occlusive episodes and priapism and in providing perioperative anesthetic care.<sup>117,118</sup>

Hyperventilation should be avoided because of its potential to reduce cerebral perfusion in children at an increased risk for stroke.<sup>119</sup> The use of a tourniquet in HbSS and HbAS diseases has been questioned.<sup>120-122</sup> However, tourniquets have been applied intraoperatively for up to 2 hours without complication, and the predominance of evidence supports their safe use as long as they are used carefully and selectively in combination with general guidelines of perioperative care (see Chapter 30).<sup>123-126</sup> Intraoperative blood salvage using cell saver devices has been used safely in sickle cell patients,<sup>127</sup> although there is some evidence that the salvage device itself may produce sickling in the processed blood, even sickle trait blood.<sup>128</sup> Cardiopulmonary bypass seems to be an optimal setting in which to induce sickling, given the cold, hypoxic, acidotic, and stagnant environment created. Although there are reports of bypass surgery conducted in children with HbSS or HbAS with standard bypass procedures without transfusion,<sup>129-132</sup> these children usually are managed with aggressive exchange transfusion before or during bypass.

### Thalassemias

Thalassemia disorders are among the most common genetic disorders worldwide, and they are characterized by a perturbation of the normal 1 : 1 ratio of  $\alpha$  to  $\beta$  polypeptide chains, usually due to reduced synthesis of one polypeptide. The clinical severity of the disease in a child is a function of the degree of alteration of the synthetic ratio, ranging from an asymptomatic carrier state to chronic symptomatic hemolytic anemia to fetal death due to hydrops fetalis.  $\alpha$ -Thalassemias commonly affect children of Southeast Asian descent and occur in those of African and Mediterranean descent.  $\beta$ -Thalassemias affect primarily children of Mediterranean, African, and Southeast Asian descent. Whereas state neonatal assays screening for HbS can often detect many forms of  $\alpha$ -thalassemia, these tests can detect only profound forms of  $\beta$ -thalassemia because of the low levels of adult  $\beta$  chains present in the neonate. The concomitant presence of qualitatively abnormal hemoglobins (e.g., HbS, HbE) affects the clinical course of thalassemia disorders. The primary hemolytic anemia and the therapy used in the treatment of the disease may affect perioperative care.

### Pathophysiology

Anemia in thalassemia is the result of hemolysis and ineffective erythropoiesis; the latter is the result of accelerated cell apoptosis triggered in part by excess deposition of unpaired globin chains in erythroid precursors.<sup>133</sup> Unpaired globin subunits are oxidized and form hemichromes, whose rate of formation determines rate of hemolysis. Precipitation of hemichromes leads to a complex process that includes release of toxic agents and formation of reactive oxygen species; alteration of red cell membranes, causing

cells to become rigid, aggregate, and disintegrate; and activation of the coagulation process. As a result of chronic anemia and ineffective erythropoiesis, bone expansion and extramedullary hematopoiesis may develop in the liver and spleen, and marrow space expansion may occur at sites such as the cranium and paravertebral areas, thereby causing disfiguring bony changes.

### Clinical and Laboratory Features and Treatment

The disease picture in  $\alpha$ -thalassemia reflects complete loss of expression of one to four  $\alpha$ -globin genes. As a four-gene globin deletion, it is characterized by hydrops and in utero or perinatal death unless diagnosed early and supported with in utero transfusions. As a three-gene deletion, or hemoglobin H (HbH) disease, it is relatively benign, characterized by chronic hemolytic anemia, which may be exacerbated by exposure to stress and oxidants.<sup>134,135</sup> The few patients requiring intermittent transfusion therapy usually have a two-gene deletion along with a hemoglobin Constant Spring (HbCS) mutation. A two-gene deletion alone is characterized by mild, clinically insignificant microcytic anemia. A one-gene deletion is characterized by a silent carrier state with no anemia or microcytosis.

The clinical picture in  $\beta$ -thalassemia reflects partial or complete loss of expression of the  $\beta$ -globin genes. The broad spectrum of disease results from the number of genes affected and the degree to which each is affected. When only one  $\beta$ -globin gene is affected (i.e.,  $\beta$ -thalassemia trait), mild microcytic anemia is the primary clinical manifestation. When both  $\beta$ -globin genes are affected, the clinical picture may be mild to moderate (i.e., thalassemia intermedia) or severe (i.e., thalassemia major or Cooley anemia), requiring chronic transfusions. Children with hemoglobin E (HbE)/ $\beta$ -thalassemia have symptoms ranging from very mild to severe, depending on the level of expression of the mutant  $\beta$ -globin gene.

The clinical problems in thalassemia are those associated with chronic anemia: the physiologic response to the need for increased erythropoiesis, transfusions to maintain a hemoglobin concentration greater than 9 g/dL, iron overload from excess transfusions and paradoxical increased iron absorption, and chelation therapy.<sup>134</sup> Clinical problems include transfusion-associated alloimmunization and infection, splenomegaly, bone abnormalities (due to extramedullary hematopoiesis, chelation therapy, and other factors), endocrine dysfunction (including hypogonadism, hypopituitarism, and diabetes mellitus), short stature, pulmonary hypertension, venous thrombosis and thromboembolism, and cardiomyopathy (primarily due to iron overload). Thalassemia patients may be hypercoagulable,<sup>136</sup> a condition that may be exaggerated after splenectomy.<sup>136,137</sup>

Routine therapies used to treat severe diseases and to prevent complications include phenotypic matching and leukocyte reduction of transfused blood, chelation therapy, and hormone and vitamin D therapy. When an appropriate donor is available, HSCT is recommended before severe liver damage occurs because it provides a potential cure for thalassemia. To ameliorate the course of the disease, other therapies are being investigated, including administration of erythropoietin, fetal hemoglobin modifiers (e.g., hydroxyurea, butyrate), and antioxidants. Gene therapy trials are ongoing, and at least one patient has become transfusion independent.<sup>138</sup>

### Perioperative Considerations

Children with moderate or severe thalassemia may require cholecystectomy, splenectomy, and vascular access placement for

affecting children between the ages of 2 and 10 years.<sup>35</sup> Primary

**TABLE 9-11** Perioperative Concerns for Patients with Idiopathic Thrombocytopenia Purpura

<b>Preoperative Considerations</b>
Hemoglobin, platelet count
History of platelet transfusions
History of corticosteroid use
History of infections
Presplenectomy antibiotic prophylaxis and immunizations (when appropriate)
Discussion with a hematologist regarding medical therapy and platelet transfusion for a platelet count $<30,000/\text{mm}^3$
Discontinuation of any platelet-inhibiting medication (e.g., aspirin)
<b>Intraoperative Considerations</b>
Appropriate antibiotic coverage
Stress corticosteroid coverage
Medical therapy and platelet transfusion as above (platelets ideally administered after clamping of the splenic artery during splenectomy)
Judicious use of regional anesthesia, intramuscular medications, nasogastric tubes, nasal intubation, and other methods
Limited use of medications with potential bleeding risk (e.g., ketorolac)
Attention to physiologic effects of laparoscopy on circulatory and respiratory function
<b>Postoperative Considerations</b>
Hemoglobin, platelet count
Infection
Corticosteroid coverage
Pain management

in screening for, diagnosing, and treating a bleeding disorder in the perioperative setting.

### SCREENING

The clinical history of the child and family is the most essential screening tool. The family history should identify family members who have been labeled as bleeders, who have required blood transfusion unexpectedly during surgery, or who returned to surgery for unexpected postoperative bleeding. A history of maternal menorrhagia may also be significant. Suggestive signs and symptoms in a child's medical history are easy bruising, mucosal bleeding, and in older girls, menorrhagia. Although diagnosing easy bruising is subjective, the clinician should suspect bleeding tendencies if skin bruising occurs in nontraumatized sites (e.g., trunk) or is unusually large without evidence of previous trauma. Mucosal bleeding includes epistaxis and gingival bleeding. Occasional nosebleeds can be common in children, but their clinical significance is enhanced by increased frequency, duration, bilaterality, and coexistence with abnormal bleeding from other sites. Gingival bleeding is common after tooth brushing or flossing, but its clinical significance is enhanced by spontaneous occurrence or chronicity, especially in the presence of good dental hygiene.<sup>153</sup>

physical examination result that suggest a bleeding diathesis, especially for children scheduled to undergo procedures associated with large blood loss or that make particular demands on hemostasis, such as tonsillectomy. Laboratory evaluation of all children, regardless of history or type of surgery, may result in false-positive results that lead to costly workups and potentially unnecessary cancellation of operations, both of which can contribute to greater health care inefficiencies and expense. Bleeding due to medications should be distinguished from an actual bleeding disorder.

When a bleeding disorder is strongly suspected, a set of laboratory tests that include a platelet count, PT, INR, aPTT, thrombin time (TT), and fibrinogen concentration should be ordered. The PT test is most sensitive to deficiencies in factors II, V, VII, and X, and it is useful for differentiating a vitamin K deficiency from other causes. The PT is most often used to monitor the anticoagulant effects of warfarin; it is not sensitive to the effects of heparin. The aPTT test is most sensitive to deficiencies in factors VIII, IX, and XI and less sensitive to deficiencies of factor V, factor X, prothrombin, and fibrinogen. The aPTT is also prolonged in deficiencies of the contact or kallikrein/kinin system proteins, factor XII, prekallikrein, and high-molecular-weight kininogen, but these deficiencies are not associated with bleeding. Because aPTT reagents vary in sensitivity for detection of deficiencies of each factor, it is inappropriate to make a general statement about the ability of this test to detect a specific abnormality; abnormal results require discussion with a hematologist or laboratory medicine physician. Although a prolonged aPTT may be caused by a deficiency in one or more factors, it can also result from inhibition by heparin or a plasma inhibitor, such as lupus anticoagulant. Correction of a prolonged aPTT after mixing the child's plasma with normal plasma (1 : 1 mix) suggests a factor deficiency. The TT test, which determines the amount of time it takes for blood to clot, is useful for determining deficiencies or abnormalities in fibrinogen and is very sensitive to heparin contamination. Bleeding time, a thromboelastogram, and platelet function screens (e.g., PFA-100) are probably not appropriate as first-line screening tests.

Children with an upper limit of normal aPTT test result and a strongly suspicious personal or family history for a bleeding disorder may have an abnormality (e.g., von Willebrand disease). These children require further evaluation in consultation with a hematologist. Whether a procedure should be delayed for the consultation depends on several factors, including the patient's history, site and urgency of surgery, potential bleeding risks associated with the planned procedure, and results of previously discussed set of screening tests.

### VON WILLEBRAND DISEASE

von Willebrand disease (vWD) is considered to be one of the most common bleeding disorders, although studies suggest that the prevalence may be as low as 1 case per 10,000 people.<sup>154-157</sup> Initially named *pseudohemophilia* because of an inheritance pattern that is different from that of hemophilia, vWD is the result of an abnormal amount, structure, or function of the vWF.<sup>154</sup>

### Pathophysiology and Classification

The glycoprotein vWF serves two main roles in the coagulation cascade: adhering platelets to damaged subendothelium and carrying factor VIII in plasma. vWF exists as small and large multimers. Large multimers play a more active role in the binding of platelets to subendothelium than do small ones and are therefore

DDAVP when possible or on replacement of factors with factor concentrates.<sup>162</sup> DDAVP is usually effective in type 1 but less so in types 2A and 2M. DDAVP may have little or even undesired effects in some children: it may increase abnormal vWF in types 2A, 2M, and 2N; it can exacerbate thrombocytopenia in type 2B; and its repeated administration may lead to tachyphylaxis. DDAVP usually is not administered to very young children because of the risk of free water retention, hyponatremia, and central nervous system pathology, including seizures. Similarly, intravenous fluids may need to be limited after its administration to any child. Factor concentrates (including factor VIII and vWF [Humate-P or Alphanate]) typically are required for types 2B, 2N, and 3. Cryoprecipitate may be used when vWF-containing concentrates are unavailable, but it is not recommended as first-line therapy because it is not virus free, and vWF in solvent or heat-treated cryoprecipitate may be abnormal.

**TABLE 9-13** Clinical Manifestations of Hemophilia A

Clinical Manifestations	Mild (>10%)*	Moderate (2%-10%)*	Severe (<2%)*
Age at first hemorrhage	3 to 14 years or older	<2 years	<1 years
Signs in neonatal period	None	Postcircumcision bleeding	Postcircumcision bleeding, intracranial hemorrhage
Musculoskeletal bleeding	Unusual except with severe trauma	Joint and muscle bleeding with minor trauma	Spontaneous
Central nervous system bleeding	Rare except with severe trauma	Less prevalent than severe	Prevalence, 3% Mean age, 14 years
Postsurgical bleeding	Hematomas and oozing	Wound hematomas and oozing	Usually frank bleeding
Trauma-related bleeding	Hematomas and deep bleeding with significant trauma	Muscle and joint bleeding with minor trauma	Common with minor trauma
Dental bleeding	Often	Common	Usual
Inhibitors present	Rarely	<3%	Prevalence, 15%-20%

\*Percent factor VIII activity.

## HEMOPHILIA

Hemophilia was first reported in the *Talmud*, in which there are descriptions of 8-day-old boys exsanguinating after ritual circumcision. Widespread public attention was drawn to this disease after members of Queen Victoria's family developed sequelae from hemophilia in the late 19th and early 20th centuries. The discovery of multiple forms of hemophilia was first made in 1944 when blood from two hemophiliacs was mixed and found to clot. In 1952, hematologists explained their earlier finding by noting that a 10-year-old boy, Stephen Christmas, exhibited a type of hemophilia, factor IX deficiency, which differed from the classic form, factor VIII deficiency.

Hemophilia is a group of congenital bleeding disorders caused by deficiency in factor VIII (i.e., hemophilia A, or classic hemophilia), factor IX (i.e., hemophilia B, or Christmas disease), or factor XI (i.e., hemophilia C). During the 10-year period from 1982 through 1991, the incidence of the more common varieties, hemophilia A and B, was 1 case per 5032 live male births in the United States within a six-state surveillance area; the prevalence of hemophilia A was 10.5 cases per 100,000 male births, and that of hemophilia B was 2.9 cases per 100,000 male births.<sup>166</sup>

Because of X-linked recessive inheritance of hemophilia A and B, family history is very important in establishing the diagnosis. Although boys are usually affected, girls may rarely inherit the disorder if their fathers are affected and their mothers are carriers or in instances of extreme lyonization (inactivation of an X chromosome). The daughter of an affected father is an obligate carrier with a 50% chance of passing it on to any of her sons. De novo mutations are relatively common and suspected in male patients lacking a family history.<sup>159</sup> Hemophilia C is a mild form of hemophilia, affecting primarily Ashkenazi Jews. It is distinguished from the other two forms of hemophilia by an autosomal recessive inheritance pattern (linked through chromosome 4), lack of joint bleeding, and infrequent need for treatment. Affected female patients may notice heavy menses, and affected male patients may have frequent nosebleeds and occasionally have excessive bleeding during surgery.

## Pathophysiology

Normal *in vivo* hemostasis initiates at sites of endothelial disruption through interaction of activated factor VII (FVIIa) and tissue factor (TF) to form a complex that activates factor IX and factor

X directly. Activated factor IX in conjunction with factor VIII further activates factor X, which with factor V converts prothrombin to thrombin. Both factor VIII and factor IX are required for sufficient hemostasis, as evidenced by the severe bleeding that occurs if either is completely deficient. Factor XI activates factor IX, but its precise role in the hemostatic pathway is not completely understood.

## Clinical and Laboratory Features and Treatment

The wide range of clinical features is similar for hemophilia A and B (Table 9-13). The severity of bleeding in these children directly relates to the degree of their deficiency.<sup>159</sup> Children with mild or moderate hemophilia may bleed excessively only after a hemostatic challenge such as trauma or surgery, whereas children with severe hemophilia may bleed spontaneously (e.g., hemarthroses).<sup>167</sup> Female carriers on average have 50% of normal factor concentrations and usually are asymptomatic, although they occasionally present with a clinical picture similar to that of mild cases of hemophilia.<sup>159</sup>

Results of a general coagulation screen are typically normal except for the aPTT, which is prolonged in proportion to the concentration of factors in the blood. The diagnosis is confirmed by measuring the specific factor concentrations.<sup>168</sup> If hemophilia is suspected but there is no family history, testing for vWD is prudent, especially for the types that may mimic hemophilia (i.e., types 2N and 3). Because of the variable sensitivity of the aPTT to specific factor deficiencies, the ability of this test to detect carriers varies between laboratories; diagnosis of a carrier state usually requires specific factor assays.

Hemophilias A and B are treated by replacing the deficient factor concentrations. These factor concentrations should be maintained at specified levels to prevent sequelae (Table 9-14). Exposure to plasma products should be minimized. The duration of treatment should be tailored to the severity of disease. DDAVP may be effective in selected mild cases by increasing factor VIII concentrations through the release of endogenous stores. Because tachyphylaxis limits the prolonged use of DDAVP, it is typically recommended only for minor operations.<sup>167</sup> For most cases, especially for those who require increased factor concentrations to be maintained for effective hemostasis, factor concentrates should be used. Although recombinant forms are preferable because they do not carry infectious risk, substitution with plasma-derived

**TABLE 9-14 Treatment Targets for Hemophilia A and B**

Bleeding Site	Target Concentrations for Factor VIII or IX (%)	Duration of Treatment (days)*
Muscle	30-50	1-2
Joint	50-80	1-2
Gastrointestinal tract	40-60	10-14
Oral mucosa	30-50	2-3
Epistaxis	30-50	2-3
Hematuria	30-100	1-2
Retroperitoneal	80-100	7-10
Central nervous system	80-100	14
Trauma or surgery	80-100	14

Modified from Brown DL. Congenital bleeding disorders. *Curr Probl Pediatr Adolesc Health Care* 2005;35:38-62.

\*May be reduced depending on clinical circumstances and severity of disease.

forms may be needed when supplies are limited.<sup>159,167</sup> For the rare patient with hemophilia C who has excessive surgical bleeding, treatment with recombinant factor XI or FFP may be required. It is essential to consult with a hematologist to determine a customized factor treatment plan for every child with hemophilia.

Children who have developed inhibitors to factor concentrates pose a challenge in the perioperative period. Until recently, they were denied surgery unless it was absolutely necessary, at which point they were often managed with increased concentrations of factors or a desensitization regimen. However, a review that included two randomized, controlled trials and data from the Hemophilia Research Society and the Hemophilia and Thrombosis Research Society reported effectiveness of recombinant factor VIIa (rFVIIa) for most of these patients.<sup>169</sup> Among the randomized trials, one study compared two bolus-dosing regimens (35 versus 90 µg/kg), and the other study compared bolus dosing with continuous infusion; the greater dosing regimen was more effective for major operations. Combining data from these studies and the two Research Society databases, the overall effectiveness rate of rFVIIa in controlling bleeding approached 84%, with a low thrombotic rate of less than 1%. Such evidence is providing more options for these difficult-to-manage patients with inhibitors. Alternatively, partially activated prothrombin complex concentrates, such as factor VIII inhibitor bypass activity (FEIBA, Baxter Healthcare Corp., Westlake Village, Calif.), have been effective for patients with inhibitors undergoing surgery.<sup>170</sup>

### Perioperative Concerns

The perioperative concerns in hemophilia focus on prevention and treatment of bleeding, similar to the management of patients with vWD (Table 9-15). Many consider regional anesthesia to be contraindicated for patients with hemophilia, but there are reports of its use without complications as long as factor concentrations are maintained.<sup>171</sup>

### HYPERCOAGULABILITY

A hypercoagulable state is a condition in which the development of thrombus is favored (i.e., thrombophilia). The condition results in an increased risk for abnormal clot formation and venous thromboembolic events (VTEs), which often are the presenting symptoms at the time of diagnosis. Thrombophilia can be acquired or congenital. The incidence of VTE among children

**TABLE 9-15 Perioperative Concerns for Patients with Hemophilia**

<b>Preoperative Considerations</b>
Consultation with hematologist, establishment of correct diagnosis
Determination and testing of treatment plan, including use of desmopressin or factors (concentrates or recombinant)
Consideration of multiple procedures performed together to reduce factor exposure
Discontinuation of any platelet-inhibiting medication (e.g., aspirin)
<b>Intraoperative Considerations</b>
Judicious use of regional anesthesia, intramuscular medications, nasogastric tubes, nasal intubation, and other procedures that may cause bleeding
Limited use of medications with potential bleeding risk (e.g., ketorolac)
Follow coagulation profiles, especially factor levels (factors VIII and IX)
Anticipate and treat bleeding with appropriate blood products
Consider recombinant activated factor VII (rFVIIa) for severe bleeding
<b>Postoperative Considerations</b>
Maintain factor concentrations for specified time period as recommended by the hematologist
Ensure availability of blood products and factors from the blood bank
Anticipate and treat bleeding episodes

is less than it is among adults, even in those with known congenital thrombophilic conditions,<sup>172</sup> although neonates and adolescents are at relatively high risk in the pediatric population.<sup>173</sup> Congenital thrombophilic conditions include factor V Leiden disorder, prothrombin gene mutation, protein C and S deficiencies, and antithrombin III deficiency.<sup>174</sup> Risk factors for acquired thrombophilia include the presence of a central venous catheter, infection, malignancy, surgery, or trauma.<sup>173</sup>

Screening of nonoperative children with suspected hypercoagulability is controversial and not recommended for those who are asymptomatic, even those with a positive family history.<sup>172</sup> Evidenced-based guidelines for children are lacking with regard to screening and prophylactic treatment of those with suspected hypercoagulability. Current evidence suggests pharmacologic prophylaxis in the nonoperative setting is recommended only in children on long-term home total parenteral nutrition (TPN) and those with specific complex cardiac lesions (e.g., Fontan patients).<sup>175</sup> However, children who present for surgery with a strong family history of thromboses may benefit from screening and referral to a hematologist for management and consideration of pharmacologic prophylaxis, such as enoxaparin administered postoperatively. The use of nonpharmacologic prophylaxis, including early mobilization after surgery, adequate hydration, and compression stockings, is left to the discretion of individual providers and to institutional practice based on the child's medical history, family history, and risk factors for VTE.

## Cancer and Hematopoietic Stem Cell Transplantation

### CANCER

Cancer is the second and fourth most common cause of death in children younger than 15 and 20 years of age, respectively.<sup>176,177</sup> The most common malignancies affecting children are different

from those affecting adults, and they include leukemia, brain tumors, lymphomas, and solid tumors such as sarcomas of soft tissue and bone. Embryonal tumors (e.g., neuroblastoma, Wilms tumor, retinoblastoma, medulloblastoma) are unique to early childhood. Survival rates for most pediatric cancers have improved significantly in the past several decades; more than 80% of children diagnosed with a childhood malignancy will become 5-year survivors of their cancers.<sup>178,179</sup> The great improvements in survival for many malignancies of childhood are directly related to advances in diagnostic modalities and the large percentage of children treated on cooperative clinical trial protocols. Treatment follows these protocols and may include chemotherapy, radiation therapy, biologic modifiers, and HSCT.

Children with cancer typically undergo many surgical procedures that require anesthesia. The procedures may occur before the initiation of cancer therapy, during therapy, years into remission, or during terminal stages of the disease. Certain considerations apply to this population, including the direct effects of the tumor, effects of chemotherapy and radiation therapy, impact of the surgical procedure, pain syndromes, and psychologic vulnerabilities of the child and family. Survivors of childhood cancer experience various long-term sequelae after completion of cancer therapy. Although the broad field of pediatric oncology is beyond the scope of this discussion, some commonalities relating to perioperative care are described.

### Clinical and Laboratory Features and Treatment

The direct effects of tumor, even at the time of diagnosis, may contribute to morbidity and mortality. For example, a childhood tumor may manifest with increased intracranial pressure, pleural or pericardial effusion, or compression of abdominal organs. Lymphoma often manifests with symptoms associated with an anterior mediastinal mass, including respiratory distress and cardiorespiratory collapse under anesthesia.<sup>180,181</sup> Most children with Hodgkin disease or non-Hodgkin lymphoma have mediastinal involvement at diagnosis, and almost one half have respiratory symptoms at presentation (see Chapter 13).<sup>182,183</sup>

Myelosuppression, which manifests with various degrees of anemia, thrombocytopenia, and neutropenia, is a common direct effect of cancer in children. Anemia is common at the time of diagnosis of many pediatric cancers, including 50% to 75% of children with newly diagnosed neuroblastoma, rhabdomyosarcoma, Hodgkin disease, Ewing sarcoma, and osteosarcoma<sup>184</sup> and 80% of children with acute lymphoblastic leukemia (ALL).<sup>185</sup> Thrombocytopenia is typically identified during the diagnosis of children with acute leukemia and is common with tumors causing bone marrow infiltration.<sup>186,187</sup> Neutropenia is usual in children with ALL. Hyperleukocytosis is predominant in children with acute myelogenous leukemia (AML), 20% of whom present with a white blood cell count greater than 100,000/mm<sup>3</sup>.<sup>185,188</sup> This high concentration of leukemic blasts, especially when the count is greater than 200,000/mm<sup>3</sup>, may lead to intravascular clumping and the potentially fatal condition of leukostasis.<sup>189</sup> Myelosuppression may be a direct effect of tumor cells and marrow infiltration by tumor cells and may result from radiation therapy and chemotherapy. As a consequence of myelosuppression, children with cancer have a frequent need for transfusion of blood products and are at risk for procedure-acquired and line-related infections and for delayed wound healing after surgical procedures. Frequent hospitalizations and immune compromise predispose them to colonization and infection by nosocomial, community-acquired, antibiotic-resistant organisms

and opportunistic infections. Neutropenia predisposes them to specific infections such as perirectal abscesses and typhlitis.

An uncommon but potentially fatal effect of the tumor itself is tumor lysis syndrome (TLS). TLS is most common with certain hematologic malignancies, especially ALL and Burkitt lymphoma, but it also occurs with other malignancies characterized by a high proliferative rate, large tumor burden, or high sensitivity to cytotoxic therapy. TLS is characterized by rapid and massive destruction of tumor cells and resultant massive release of phosphorus, potassium, nucleic acids, and proteins that is sufficient to cause metabolic derangements and possible renal failure and death.<sup>190,191</sup> TLS can occur spontaneously, especially in children with AML, but it more often manifests in the setting of cytotoxic therapy, radiation therapy, fever, surgery, and anesthesia.<sup>192-197</sup>

Chemotherapy used in pediatric oncology leads to myelosuppression and to a host of important side effects that may be clinically important in the perioperative setting (Table 9-16). These effects of chemotherapy can be synergistic with toxicities of radiation therapy.<sup>198</sup> New chemotherapeutic agents are continuously being introduced, and at academic centers, the use of investigational agents is common. Although it is impossible to provide a comprehensive review of chemotherapeutics, the most common agents that cause toxicities of particular importance to the delivery of anesthesia are briefly mentioned here, and a complete list of toxicities can be found in E-Table 9-1.

Corticosteroids are frequently used and may cause adrenal suppression, hypertension, thromboembolism, and obesity; the latter potentially renders venous access and tracheal intubation difficult. Children who have received corticosteroid therapy have a period of measurable glucocorticoid-induced adrenal suppression of 2 weeks to 8 months after such therapy.<sup>199-205</sup> Because of this variability, administering stress-dose steroids in the first 1 to 2 months after cessation of glucocorticoids is reasonable.<sup>199</sup> However, any child at risk of TLS should not receive corticosteroids without direct discussion with an oncologist.

The anthracycline drugs (e.g., doxorubicin, daunorubicin, idarubicin, and epirubicin) and mitoxantrone cause cardiomyopathy in a dose-dependent fashion, which is aggravated by radiation delivered to the precordial area. About 10% of children who received a cumulative dose of 300 mg/m<sup>2</sup> or more of anthracycline develop clinically significant cardiomyopathy.<sup>206</sup> Later studies demonstrated clinically significant cardiomyopathy after much smaller doses<sup>207,208</sup> and an increased sensitivity in children with trisomy 21 and leukemia.<sup>209</sup> Children receiving anthracyclines should be evaluated with echocardiography at baseline and intermittently during the course of therapy and for a prolonged period after therapy because anthracycline-induced cardiac failure can take years to fully declare itself.<sup>210,211</sup> Physical examination may miss more than 50% of children with heart failure.<sup>212</sup> A recent echocardiogram should be available preoperatively if a child has received anthracycline therapy and any of the following conditions are met: cumulative dose greater than 240 mg/m<sup>2</sup>, any dose received during infancy, or chest irradiation dose greater than 30 Gy with concomitant anthracycline treatment.<sup>213,214</sup> Although uncommon, radionuclide angiography may be chosen for those with poor echocardiographic windows.<sup>210,215</sup>

Several other chemotherapeutic agents are of interest to the anesthesiologist caring for a child with cancer. L-Asparaginase is associated with a 1% to 2% risk of hemorrhage or thrombosis due to deficiencies in fibrinogen, plasminogen, antithrombin III, and vWF,<sup>216-218</sup> as well as hepatic dysfunction and acute hemorrhagic pancreatitis. Bleomycin can produce acute pneumonitis and

**FIGURE 10-5** A study that considered the use of citrated whole blood (blue line) in adults found that bleeding in most cases resulted from dilutional thrombocytopenia. The magenta line represents estimated points of dilutional clotting factor deficiency if solely citrated packed cells are transfused. (Modified from Miller RD. Transfusion therapy and associated problems. ASA Refresher Courses in Anesthesiology 1973;1:107.)

In other scenarios, bleeding is caused by hypothermia, severe metabolic acidosis, poor tissue perfusion, and the release of tissue factors. Body temperature should be maintained by using efficient blood-warming devices, acidosis should be treated, and normovolemia and cardiac output should be restored to prevent a coagulopathy from developing.<sup>166,180-183</sup>

### DILUTIONAL THROMBOCYTOPENIA

Because of the dearth of published data on the effects of massive blood transfusion in children, we must rely on our clinical experience and data extrapolated from adults to anticipate the effects in children. A study of trauma patients during the Vietnam War reported that the onset of clinical bleeding occurred after about 15 units of whole blood had been transfused. The incidence of coagulopathy was unrelated to an abnormal PT or partial thromboplastin time (PTT) but correlated closely with a platelet count of less than 65,000/mm<sup>3</sup>.<sup>51</sup> In a 70-kg adult, the estimated blood volume is approximately 5 L (70 mL/kg × 70 kg = 4900 mL), or approximately 10 units of whole blood. To relate the data in Figure 10-6 to children, assume the 70-kg adult has 5 L of blood, or 10 units of whole blood. If each 10 units of whole blood is one blood volume, some children are expected to develop a coagulopathy after losing about 1.5 blood volumes, but most develop clinical bleeding after losing 2.0 to 2.5 blood volumes. Studies of massive blood loss with *whole blood* replacement appear to support the conclusion that the coagulopathy at these levels of blood loss results from thrombocytopenia rather than a clotting factor deficiency.<sup>51,166-175</sup> Consequently, children should be monitored for thrombocytopenia and possible transfusion of platelets or clotting factor deficiency (see further) after the loss of the first 1.0 to 1.5 blood volumes. After the platelet count has decreased to 50,000/mm<sup>3</sup>, it is likely that approximately one platelet dose (i.e., 6 units for an adult or 10 to 15 mL/kg for a child) will be required for each blood volume replaced. If a coagulopathy develops earlier than expected (i.e., before a 1.0-blood volume loss), a search should be initiated for other causes

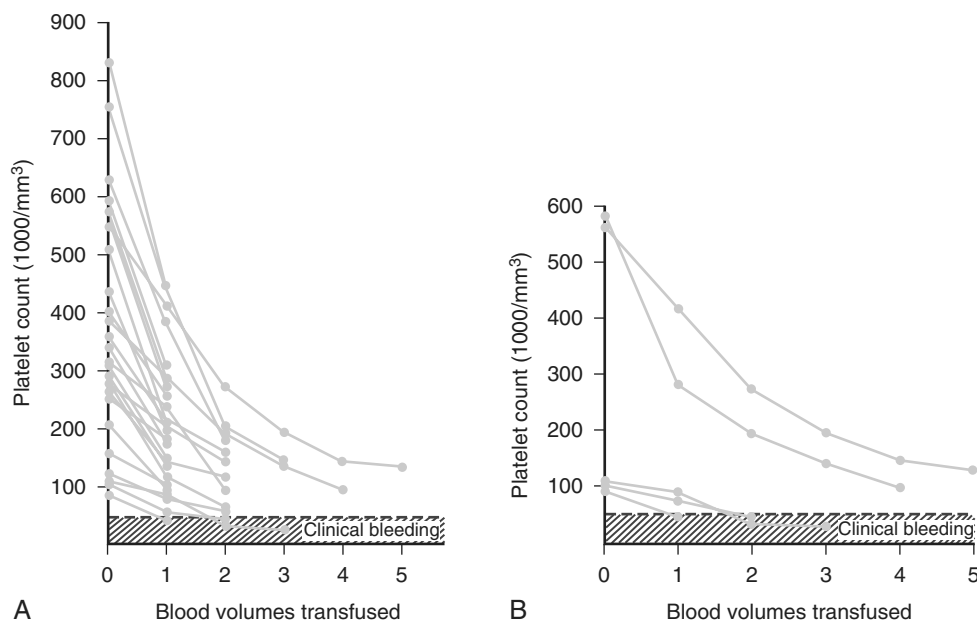

**FIGURE 10-6** Percent of change in platelet count versus blood volumes transfused in adults and children.<sup>51,52</sup> The magenta line represents observed values, whereas the blue line represents calculated values. This difference suggests increased bone marrow production and/or splenic recruitment of platelets during massive transfusion. (From Miller RD, Robbins TO, Tong MJ, Barton SL. Coagulation defects associated with massive blood transfusions. *Ann Surg* 1971;174:794-801; Coté CJ, Liu LM, Szyfelbein SK, Goudsouzian NG, Daniels AL. Changes in serial platelet counts following massive blood transfusions in pediatric patients. *Anesthesiology* 1985;62:197-201.)

of bleeding, such as increased arterial or venous pressure in the surgical field or DIC.

Studies of adult and pediatric patients with acute dilutional thrombocytopenia found that clinical bleeding correlated closely with a platelet count of 65,000/mm<sup>3</sup> or less.<sup>51,166-175</sup> Figure 10-6 compares the calculated reduction in platelet count with the observed decline in platelet count in adults and children. The observed decrement differs from the calculated reduction because platelets are mobilized from the bone marrow, lungs, and lymphatic tissues. The platelet count usually does not decrease to concentrations that cause bleeding until 2.0 to 2.5 blood volumes are lost in children, which is consistent with our observations, or until 20 to 25 units of whole blood are transfused in adults.<sup>52,173,184</sup> Clinical bleeding does not usually occur in children whose platelet counts remain above 50,000/mm<sup>3</sup>, despite blood losses as great as 5.0 blood volumes (Fig. 10-7, A).<sup>52</sup>

The starting platelet count is important for estimating how much blood loss can be tolerated before critical thrombocytopenia occurs. For example, with a starting platelet count of 600,000/mm<sup>3</sup>, dilutional thrombocytopenia is unlikely to occur until 4.0 or more blood volumes are lost, whereas with a starting count of 100,000/mm<sup>3</sup>, dilutional thrombocytopenia may be expected after 1.0 blood volume has been lost (see Fig. 10-7, B). Prophylactic transfusion of platelets typically is not indicated without documented evidence of dilutional thrombocytopenia, visible microvascular bleeding, and ongoing blood loss, although it should be anticipated based on the starting platelet count and the volume of blood lost.<sup>52,56,162,166,185</sup>

Although the primary platelet defect in massive transfusion is thrombocytopenia, some data suggest that platelets may not function normally (i.e., thrombocytopathy) after massive trauma

**FIGURE 10-7** **A**, Serial changes in platelet counts are plotted for 26 pediatric patients who lost one to five blood volumes. Most of the children suffered from severe thermal injuries, and many had relatively high platelet counts at baseline. Clinically evident signs of coagulopathy appeared when the platelet count decreased below 50,000/mm<sup>3</sup>. **B**, Platelet counts of five children abstracted from **A**. The baseline platelet count is invaluable in estimating potential platelet needs in relation to blood volumes transfused. A low initial count suggests the need for early exogenous platelet transfusion, whereas a high initial platelet count indicates that exogenous platelets may not be required until several blood volumes have been lost. The three children who developed a coagulopathy began surgery with a relatively low platelet count, whereas the two children with a very high platelet count did not require platelet transfusion despite the loss of four and five blood volumes. (It should be noted that these children received sufficient FFP so as to maintain the PT and PTT within a normal range.) (Reproduced with permission from Coté CJ, Liu LMP, Szyfelbein SK, Goudsouzian NG, Daniels AL. Changes in serial platelet counts following massive blood transfusions in pediatric patients. *Anesthesiology* 1985;62:197-201.)

or in the presence of hypothermia.<sup>182,186,187</sup> This has not been our experience in the children we studied whose temperature remained within the normal range.<sup>52,167</sup> The only simple test to assess platelet function is the bleeding time. However, this test is also sensitive to thrombocytopenia and its predictive value is of equivocal utility.<sup>162,186,188</sup> The PFA-100 test shows less potential as a rapid screening tool than it once did, because the device uses citrated blood warmed to 37° C and is relatively insensitive to milder defects in platelet-vessel wall interaction, such as that in mild von Willebrand disease. There remains a critical need for a point-of-care device or simple test to assess platelet function. Currently, the platelet count is our best indication for the need for platelet transfusions in situations involving rapid blood loss.<sup>189</sup> Other devices to measure whole blood clotting have been used to guide transfusion therapy, but their efficacy in improving outcomes has not been established.<sup>190</sup>

In several in vitro and animal model systems, recombinant factor VII (rFVIIa) activates factors IX and X on the surface of activated platelets, probably through the binding of rFVIIa to the platelet membrane (from which rFVIIa can also be taken up into storage sites within the platelet) and subsequent recruitment of circulating tissue factor.<sup>191-196</sup> Although this has significantly improved hemostasis for hemophiliacs with inhibitors to factor VIII, there is limited evidence that rFVIIa reduces mortality for off-label use, as in cardiovascular surgery, trauma, and intracerebral hemorrhage. This agent increases the risk of thromboembolism.<sup>197</sup>

Basic clotting studies (e.g., PT, PTT, fibrinogen, platelet count) must be performed before elective surgery when major blood loss can be anticipated to determine the cause of underlying coagulopathies and provide adequate quantities of blood components.

## FACTOR DEFICIENCY

Laboratory assessment of developing deficiencies in clotting factors plays an important part in transfusion decisions in managing massive transfusion. The PT (for the extrinsic system) measures the adequacy of factors VII, X, and V; prothrombin; and fibrinogen,<sup>51</sup> whereas the PTT (for the intrinsic system) measures the adequacy of factors XII, XI, IX, VIII, X, and V; prothrombin; and fibrinogen (see Fig. 10-4). Banked whole blood contains normal plasma concentrations of all of the clotting factors and regulatory proteins, but it has a reduced concentration of factors V and VIII (20% to 50% of normal at the time of outdate). For coagulopathy due to a clotting factor deficiency to develop, factor VIII must be less than 30% of the normal concentration and factor V less than 20% of normal.<sup>167</sup> For these to occur, at least 3.0 blood volumes must be exchanged with *whole blood*. In this scenario, the first coagulation test that is abnormal is the PTT because factor VIII is diluted to less than 30%.<sup>163</sup>

If blood loss is replaced with PRBCs, as is the current practice with blood banking techniques, the amount of plasma that is transfused is minimal because most of it was sequestered in the FFP fraction when it was separated. Massive replacement of blood loss with PRBCs and no other blood products quickly dilutes all of the clotting factors, including fibrinogen (see Fig. 10-4).<sup>\*</sup> Data have confirmed that the PT and PTT are prolonged in children with multiple clotting factor deficiencies (e.g., during massive transfusion) at concentrations of clotting factors that are greater than in children with single clotting factor deficiencies (e.g., congenital coagulopathies).<sup>174,175</sup> This was documented in

<sup>\*</sup>References 3, 162-166, 172, 174, 175, 198-200.

<sup>†</sup>Blood volume loss. NOTE: Not all children in this subset lost a half blood volume or more.

adult patients who were transfused exclusively with PRBCs and crystalloid. The dilution of multiple clotting factors correlated with the volume of blood and crystalloid transfused.<sup>148</sup> Diluting clotting factors to approximately 30% of normal may be expected replacing 1.0 to 1.5 blood volumes with PRBCs and crystalloid exclusively. Because moderate prolongations of the PT and PTT exist without overt signs of clinical bleeding,<sup>174</sup> the indication for FFP should be onset of clinical coagulopathy. However, to avoid falling behind, the anesthesiologist should anticipate that the clotting factors will be diluted and that FFP should be infused after 1.0 blood volume of blood loss has been replaced with a combination of PRBCs and crystalloid. Documented deficiency of fibrinogen (<80 mg/dL) may also be corrected by transfusing FFP, but marked deficiency, particularly in the presence of a consumptive coagulopathy (e.g., DIC, fibrinolysis), may require the addition of cryoprecipitate (0.2 to 0.4 unit/kg).<sup>3,199,201-203</sup> No published studies have examined massive blood replacement in infants and children using exclusively component therapy.

Our experience with 26 children (12 ± 4 years old, weight of 41.9 ± 15.8 kg; 22 Harrington rod procedures, three tumor excisions, and one Whipple procedure) who did not receive FFP or whole blood during surgery that involved blood losses between 0.5 and 1.0 blood volumes showed that none of the children demonstrated clinical signs of coagulopathy. Slight prolongations of the PT or PTT occurred when blood loss was 1.0 blood volume or less (Table 10-10). Two children who lost 1.5 blood volumes, and one who lost 2.0 blood volumes had prolonged PT and PTT values. The only child who had clinical coagulopathy was the one who lost 2.0 blood volumes, and the coagulopathy could have been ascribed to simultaneous dilutional thrombocytopenia.<sup>204,205</sup>

The magnitude of the change in PT or PTT that predicts a clinical coagulopathy is not well defined. However, the consensus panel of the National Institutes of Health and others suggest that greater than 1.5 times normal (or INR >2.0) should be considered pathologic.<sup>56,169,173,206-209</sup> Our studies suggest that the PT and PTT are prolonged to more than 1.5 times normal when the blood loss is 1.5 or more blood volumes and when the blood loss has been replaced with only PRBCs and crystalloid or PRBCs and 5% albumin.<sup>204,205</sup> Our clinical practice is to initiate FFP after loss of more than 1.0 blood volume has been replaced with PRBCs (Table 10-11). At that point, FFP is administered in a

**TABLE 10-11** Minimal Fresh Frozen Plasma Recommendations according to the Type of Blood Product Transfused and the Volume of Blood Lost

Type of Blood Replaced	FFP Indicated	Volume FFP To Be Transfused
Whole blood	After 2.0-3.0 blood volumes lost and each blood volume thereafter	25%-33% of each blood volume lost
PRBCs	After 1.0 blood volume lost and each blood volume thereafter	1 U FFP / 2 U PRBCs

FFP, Fresh frozen plasma; PRBCs, packed red blood cells; U, unit.

ratio of 1 unit for every 2 units of PRBCs transfused. The indications for and timing of FFP depend on which blood product has been transfused, the volume of that transfusion as it relates to the child's blood volume, and whether the blood loss will continue perioperatively. The PT, PTT, fibrinogen concentration, and platelet count should be determined after each blood volume has been replaced and used to guide the need for additional FFP and platelets.

Recombinant factor VIIa (rFVIIa; NOVO Seven) is approved for use in the United States for hemophiliacs with high-titer inhibitors and for congenital factor VII deficiency. Several anecdotal reports describe its efficacy in controlling hemorrhage in a variety of other settings. However, in randomized clinical trials enrolling patients with partial hepatectomy, liver transplantation, prostate surgery, pelvic (orthopedic) surgery, trauma, or upper gastrointestinal tract bleeding, it conferred little or no benefit.<sup>210-215</sup> In a large randomized clinical trial of intracranial hemorrhage, the patients in the largest-dose group showed a small improvement in hematoma expansion, but 10% also experienced thromboembolic complications. In adults receiving rFVIIa, there is a 1.4% to 10% incidence of major thromboembolic complications, including acute myocardial infarction and stroke.<sup>216</sup> There are anecdotal reports of its successful use in children, but they provide little guidance because of the limited data.<sup>1,2,217-219,219a</sup> Until the results of controlled trials demonstrate a clear benefit for its use, rFVIIa should be used with great caution for off-label indications.<sup>210-215,218,220,221</sup>

Several studies<sup>215,222</sup> have compared different transfusion strategies for treating trauma incurred during combat in the Middle East. A consensus conference on massive transfusion concluded that the evidence did not support the up-front use of a 1:1:1 ratio of units of PRBC, FFP, and platelets, but it did support the early use of an antifibrinolytic medication (i.e., tranexamic acid).<sup>222</sup> The consensus conference also recommended an integrated approach to managing massive transfusion that included rapid provision of PRBCs, the use of antifibrinolytics, and a foundation ratio of blood components directed by the results of standard coagulation testing (e.g., PT, PTT, platelet count, fibrinogen) or clot viscoelasticity, or both.<sup>222</sup>

The dilutional coagulopathy associated with massive blood transfusion is reasonably predictable. When using whole blood, dilutional thrombocytopenia usually develops first and may occur as early as after the first blood volume (if the initial platelet count is low) has been replaced. In most cases, clotting factors (particularly factors V and VIII) are not diluted until the blood loss exceeds three blood volumes. On the other hand, when PRBCs are used to replace blood loss, the clotting factors and

platelets may be diluted after as little as 1.0 blood volume is lost. However, the predictable coagulopathy of dilution is only an approximate guide. We should monitor the PT, PTT, fibrinogen, and platelet count during massive transfusions and use this information to guide replacement therapy.

### DISSEMINATED INTRAVASCULAR COAGULATION AND FIBRINOLYSIS

DIC and fibrinolysis are frequently associated with shock, trauma, and other forms of tissue damage, with release of procoagulants (e.g., tissue factor) and fibrinolytics (e.g., tissue plasminogen activator). In the presence of massive blood loss, these processes must be differentiated from dilutional coagulopathy. Differentiation may be difficult, because both are associated with pathologic oozing of blood in the surgical field and each may result in prolongation of the PT and PTT, as well as thrombocytopenia.<sup>223,224</sup> With massive replacement using whole blood or PRBCs and adequate FFP, the fibrinogen level should remain normal; with uncompensated (acute) DIC, it may be decreased. However, replacing the blood loss with PRBCs, albumin, and crystalloid also leads to a reduction in fibrinogen.

The most helpful test for DIC and fibrinolysis is documentation of a significant increase in the level of D-dimer, a small peptide fragment generated during the digestion of fibrin by ongoing thrombolysis (i.e., through plasmin), along with evidence on the peripheral blood smear of schistocytes and helmet cells (i.e., microangiopathic hemolytic anemia).<sup>195,225,226</sup> Abnormal RBCs and RBC fragments are thought to arise from the slicing action of immobilized fibrin strands in the microcirculation, although the precise mechanism remains unknown. A scoring system used for screening for potential DIC has been devised but not evaluated in the operating room setting.<sup>227</sup> If pathologic oozing in the surgical field is observed and 1.0 blood volume or less has been lost in a child who had a normal platelet count and normal PT and PTT values preoperatively, it should be suspected that the child has developed a consumptive coagulopathy.

The most effective treatment for DIC is to eliminate the cause, such as correcting shock, acidosis, or sepsis. Heparin therapy remains controversial even in children with thrombotic manifestations of DIC and is not advisable in children with active bleeding, especially in the operative setting.<sup>224-226,228</sup>

### HYPERKALEMIA

RBCs leak potassium into the extracellular fluid during storage, particularly as the units age. The concentration of adenosine triphosphate (ATP) decreases, and the ATPase-driven  $\text{Na}^+/\text{K}^+$  pump activity decreases. When the blood is outdated, 1 unit of whole blood or PRBCs has approximately 6 mEq of  $\text{K}^+$  in the plasma at a concentration that varies considerably (see Table 10-4) because this 6 mEq of  $\text{K}^+$  is distributed in the plasma and the anticoagulant solution of the stored whole blood and PRBC units. The  $\text{K}^+$  leak is more rapid from RBCs that have been irradiated.<sup>229-231</sup> To avoid the accumulation of large amounts of extracellular  $\text{K}^+$ , irradiated RBCs are stored for a maximum of 28 days (versus 35 or 42 days for whole blood or PRBCs).

Although extracellular  $\text{K}^+$  is present in banked RBCs, clinically important hyperkalemia after routine transfusion has not been reported.<sup>232-238</sup> A study of serum potassium in neonates after exchange transfusion with PRBCs documented a decrease in serum potassium concentrations.<sup>239</sup> A retrospective study of children undergoing massive intraoperative transfusion with PRBCs

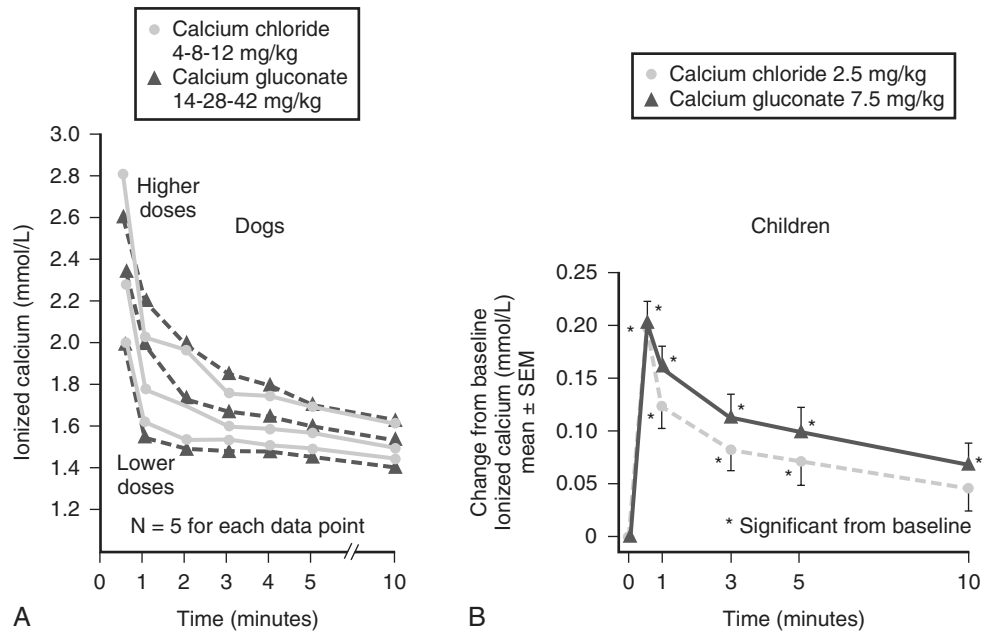

documented transient, but not life-threatening, hyperkalemia.<sup>240</sup> It appears that clinically important hyperkalemia does not usually occur when PRBCs are administered *at normal, slow infusion rates through peripheral IV access*.<sup>241</sup> This may be explained by the combination of the small absolute amount of  $\text{K}^+$  (about 6 mEq per unit); its rapid reabsorption into the potassium-depleted, transfused RBCs; the large volume of distribution; and dilution with crystalloid or albumin during administration. Hyperkalemia in the setting of massive transfusion is usually the consequence of extensive tissue injury or acidemia resulting from inadequate tissue perfusion.

The need to relate the size of the patient to the rate of blood replacement is infrequently a problem in adults, but it is vitally important to consider in an infant or small child. An alert from the Society for Pediatric Anesthesia<sup>242</sup> described 4 deaths among 11 children who developed hyperkalemia during transfusion; 8 were younger than 1 year, and 6 were younger than 6 months old. The Perioperative Cardiac Arrest Registry reported 8 hyperkalemic cardiac arrests related to blood transfusion.<sup>242,243</sup> Hyperkalemia may become a problem when large volumes of whole blood or PRBCs are administered very rapidly in adults (rates  $\geq 120$  mL/min) and in infants and children undergoing rapid blood transfusion, particularly through a central venous catheter.<sup>240,244,245</sup> A rapid transfusion rate of 120 mL/min in a 70-kg adult is equivalent to 1.5 to 2 mL/kg/min of blood, which is relatively easy to infuse in an infant or small child using a pressure bag or a rapid-transfusion device. An adult sustained a cardiac arrest and died after receiving Adsol-preserved PRBCs with a supernatant potassium concentration of 24 to 34 mEq/L at a rate of 6.4 mL/kg/min through a rapid infusion device (see Chapter 51).<sup>246</sup> Similar transfusion rates and greater are possible in infants and children without such devices.<sup>240,247,248</sup>

The principle is to avoid falling behind in replacing the blood loss and to avoid a situation in which a rapid and massive infusion of blood is required. Warming the blood and administering it through a peripheral IV line (rather than a central venous catheter) reduce the severe effects of hyperkalemia on the cardiac conduction system. When the rate of infusion of whole blood or PRBCs exceeds 1.5 to 2.0 mL/kg/min, the electrocardiogram must be closely monitored. If ventricular arrhythmias occur with peaked T waves in the setting of hyperkalemia (see Fig. 8-7), appropriate treatment should be instituted (e.g., calcium chloride or calcium gluconate, hyperventilation, sodium bicarbonate, albuterol, glucose and insulin); Kayexalate is the slowest and least effective in this situation and not recommended as an acute intervention.

Rapid, massive transfusion of whole blood or PRBCs to a neonate, particularly blood that has been stored for several weeks, can cause hyperkalemic cardiac arrest. It is common practice to administer RBC-containing components that are relatively young to avoid hyperkalemia in neonates requiring massive blood transfusion. If relatively young units are not available and time permits, it may be possible to wash the PRBCs to reduce the potassium concentration. However, RBC transfusion to an actively bleeding infant should not be delayed to obtain less than 7-day-old PRBCs or to wash the units. Similarly, blood for intrauterine transfusion, exchange transfusion, or neonates is chosen to be relatively young (usually less than 7 days).

These practices are consistent with the recommendations from the Society for Pediatric Anesthesia Wake Up Safe quality improvement initiative, which directs the physician to anticipate the blood loss and transfuse early and cautions that transfusing

**FIGURE 10-8 A**, Changes in arterial  $iCa^{2+}$  levels in dogs after three equal elemental calcium doses of calcium chloride (4, 8, and 12 mg/kg) or calcium gluconate (14, 28, and 42 mg/kg). The rate of change in the  $iCa^{2+}$  concentration was identical for each form of calcium at each dose. There was no significant difference between the highest and lowest doses after 2 minutes, suggesting that frequent low doses are equally effective and perhaps safer than large boluses of exogenous calcium. **B**, Changes in arterial  $iCa^{2+}$  levels in children who received equal elemental doses of calcium chloride and calcium gluconate. At 30 seconds, both forms of calcium dissociated equally, and these data indicate that hepatic metabolism of the gluconate moiety is not required to liberate ionized calcium from calcium gluconate. (From Coté CJ, Drop LJ, Daniels AL, Hoaglin DC. Calcium chloride versus calcium gluconate: comparison of ionization and cardiovascular effects in children and dogs. *Anesthesiology* 1987;66:465-470.)

the hypovolemic child should be done slowly and through a peripheral IV catheter rather than rapidly through a central venous catheter.<sup>242</sup> If the infant requires irradiated RBC blood components, it is preferable to transfuse them soon after irradiating the blood.

### HYPOCALCEMIA AND CITRATE TOXICITY

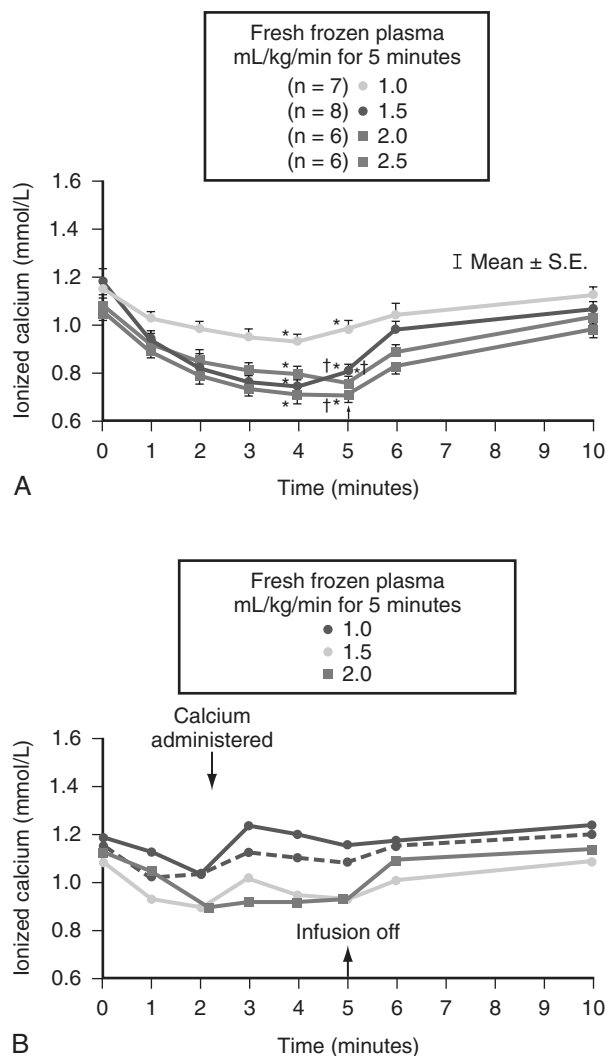

Citrate works as an anticoagulant for stored blood components by chelating ionized calcium ( $iCa^{2+}$ ). As citrate in the blood component is transfused, it is rapidly taken up and metabolized by every nucleated cell in the body, although the primary site of clearance is the liver. During massive transfusion, particularly of whole blood or FFP, the influx of citrate may temporarily overwhelm the capacity to clear it, resulting in its accumulation, which causes the plasma concentration of  $iCa^{2+}$  to decrease.<sup>249-253</sup> The plasma fraction in a unit of PRBCs, which contains the citrate, is a much smaller volume than in a unit of whole blood or FFP. Clinically, it is rare for the  $iCa^{2+}$  level to decrease unless the transfusion rate is very rapid; in adults, this rate must be 1.0 or more units of whole blood or FFP in 3 to 4 minutes.<sup>249</sup> This effect on the  $iCa^{2+}$  concentration has been reported in neonates undergoing exchange transfusion and is more likely to occur in more-premature and lower-weight infants.<sup>253</sup> In adult cardiac surgical patients who received whole blood at 1.5 mL/kg/min, the ventricular function curve did not improve (i.e., cardiac output did not increase although the  $iCa^{2+}$  decreased). When a similar volume of heparinized blood was administered at the same rate, the Frank-Starling response to volume loading was normal (i.e., cardiac output increased, but  $iCa^{2+}$  level did not change).<sup>254</sup> These findings correlate well with earlier studies in that a decrease in  $iCa^{2+}$  concentration of clinical importance (i.e., decreased cardiac

contractility) is expected to occur when the rate of infusion of citrated whole blood exceeds 1.5 to 2.0 mL/kg/min.<sup>249,254</sup>

The change in the  $iCa^{2+}$  level after transfusion of large volumes of PRBCs is less than that observed with whole blood or FFP. Although measurable decreases in the  $iCa^{2+}$  concentration have been observed during rapid transfusion, they have only rarely been associated with cardiac toxicity in adults. The rates of infusion of citrated whole blood that produce hypocalcemia and hyperkalemia are almost identical, whereas the cardiac electrophysiologic effects produced by hypocalcemia and hyperkalemia are opposite. It is important to observe the electrocardiogram for abnormalities, especially widening of the QRS complex, prolonged QT interval, and peaking of the T wave.<sup>167,255</sup>

Treatment for hypocalcemia and hyperkalemia is administration of exogenous calcium. Evidence from normal animals and children with extensive thermal injuries demonstrated that calcium chloride and calcium gluconate dissociate at a similar rate; hepatic metabolism of the gluconate moiety is not necessary (Fig. 10-8).<sup>256</sup> Other studies during the anhepatic phase of liver transplantation also found equal ionization of calcium chloride and calcium gluconate, establishing that hepatic metabolism is not required to release calcium from gluconate.<sup>257</sup> We recommend using calcium chloride or calcium gluconate to treat acute ionized hypocalcemia, with the caveat that calcium gluconate, which contains one third of the ionizable calcium of calcium chloride (by weight), be administered at a threefold greater dose (milligrams per kilogram) than the latter. Frequent, small boluses are as effective as single large boluses and result in smaller fluctuations in plasma  $iCa^{2+}$  values.<sup>256</sup> Ideally, both forms of calcium should be slowly administered through a large peripheral or central vein, because both are sclerosing medications.

**FIGURE 10-9 A**, Changes in arterial  $iCa^{2+}$  levels in children with severe thermal injuries during infusions of fresh frozen plasma at a rate of 1.0 to 2.5 mL/kg/min for 5 minutes through an infusion pump. Notice the dangerous although transient decrease in the  $iCa^{2+}$  concentration, with the nadir occurring between the fourth and fifth minute. Ionized hypocalcemia occurs when the infusion rate equals or exceeds 1 mL/kg/min. **B**, Changes in  $iCa^{2+}$  levels occurred in four thermally injured children who received calcium chloride (arrow) after 2 minutes of fresh frozen plasma infusion. There were no sharp increases or decreases in  $iCa^{2+}$  levels. (From Coté CJ, Drop LJ, Hoaglin DC, Daniels AL, Young ET. Ionized hypocalcemia after fresh frozen plasma administration to thermally injured children: effects of infusion rate, duration, and treatment with calcium chloride. *Anesth Analg* 1988;67:152-60.)

The volume of plasma and therefore the absolute amount of citrate in a unit of FFP are slightly less than the amounts in a unit of whole blood. However, the citrate load can be more rapidly delivered in FFP because it can be infused more rapidly owing to its low viscosity. It is easy to give a large citrate load in a brief period. Caution is urged when FFP or whole blood is rapidly infused, especially if the child already has a low  $iCa^{2+}$  concentration or impaired hepatic function (e.g., neonates and children undergoing liver transplantation). Figure 10-9, A, shows the changes in  $iCa^{2+}$  concentrations that occurred in children who had extensive thermal injuries and who received rapid FFP

infusions at a rate between 1.0 to 2.5 mL/kg/min for 5 minutes. The maximum decrease in  $iCa^{2+}$  levels occurred between the fourth and fifth minute. There was no difference in the nadir in the  $iCa^{2+}$  concentration among the three largest rates of FFP infusion.<sup>258</sup>

If exogenous calcium is administered *during* rapid FFP transfusion, large decreases in the  $iCa^{2+}$  level can be avoided (see Fig. 10-9, B). We transfused FFP at a rate of 2 mL/kg/min for 10 minutes (equivalent to an average adult receiving 1400 mL FFP over 10 minutes) in six children with extensive burn injuries and measured very significant decreases in  $iCa^{2+}$  levels but observed no consistent adverse cardiovascular events. However, because these children had extensive burn injuries, we presumed they were hypermetabolic and therefore able to rapidly metabolize the excess citrate, which limits our ability to extrapolate these data to children without burn injuries (see Chapter 34).<sup>258</sup>

In dogs anesthetized with halothane, we determined that citrate-induced ionized hypocalcemia caused significantly greater cardiovascular depression as the concentration of expired halothane increased.<sup>259</sup> These findings are consistent with the combined myocardial depression caused by ionized hypocalcemia and the myocardial depressant effects of calcium channel blockade caused by the halothane.<sup>260,261</sup> Although halothane seems to exert the greatest calcium channel blocking activity of the inhalational anesthetics, all inhalational anesthetics depress the myocardium through this mechanism and therefore should augment the myocardial dysfunction associated with citrate-induced hypocalcemia, although similar data with sevoflurane and desflurane have not been forthcoming.<sup>262,263</sup>

The adverse cardiac effects of citrate-induced hypocalcemia may be increased if FFP is rapidly administered through a central venous catheter because there is less time to dilute the FFP and metabolize the citrate before it enters the heart and coronary vessels. FFP may be more safely administered through a peripheral IV site. Calcium should be administered *during* rapid transfusion of FFP (>1 mL/kg/min) to attenuate this transient but dangerous citrate toxicity, especially in the presence of potent inhalational anesthetics.<sup>259-263</sup> Our clinical impression is that neonates and small infants are particularly vulnerable to the developing citrate toxicity because it is easier to administer a relatively large volume of FFP over a brief period to them and because citrate may not be eliminated as rapidly (i.e., first-pass effect through the liver) in infants. In addition to thermally injured patients, children undergoing liver transplantation and cardiac surgery are likely to require FFP and may develop hypocalcemia.<sup>264,265</sup> Liver transplantation recipients are particularly susceptible to decreased  $iCa^{2+}$  levels during the anhepatic phase and during the pre-anhepatic phase of surgery because of impaired hepatic metabolism, impaired hepatic blood flow, and the reduced ability to metabolize citrate.<sup>266-270</sup> An IV preparation of calcium should always be available when a major transfusion with FFP is anticipated.

#### ACID-BASE BALANCE

Massive transfusions usually occur in one of two situations: severe trauma with shock or major surgery with massive blood loss. In the first situation, severe metabolic acidosis may occur because of low cardiac output and diminished oxygen delivery. Correction of the acidosis with sodium bicarbonate may be a necessary part of the resuscitation, along with blood volume replacement. In this situation, impaired coagulation may occur because of the acidosis.<sup>164,180,271-273</sup> In the operating room,

intravascular volume is usually maintained, and because most instances of massive blood loss are anticipated, replacement of acute blood loss is more controlled. Even with repeated massive blood loss, metabolic acidosis is not usually a problem provided severe hypovolemia is avoided.<sup>274-276</sup> Sodium bicarbonate therapy must be governed by the child's acid-base status because metabolic acidosis does not usually occur with massive transfusion unless accompanied by severe hypovolemia, low cardiac output, or hypoxemia.

With massive blood transfusion, the child may develop a moderate to severe metabolic alkalosis due to the large volume of transfused citrate and its conversion to bicarbonate, which causes a metabolic alkalosis within hours of a massive transfusion.<sup>250,265,277-279</sup> If exogenous bicarbonate therapy is superimposed on this endogenous metabolic alkalosis, a leftward shift of the oxyhemoglobin dissociation curve may result. It is important to determine the acid-base status *before* administering sodium bicarbonate to avoid overcorrecting the pH and shifting the oxyhemoglobin dissociation curve further.

### HYPOTHERMIA

Hypothermia may be a significant problem associated with major blood loss and its replacement. Hypothermia decreases oxygen consumption and reduces oxygen demand. It may also increase oxygen consumption if the child shivers and decrease tissue delivery of oxygen by a leftward shift of the oxygen-hemoglobin dissociation curve; severe hypothermia (about 32° C) may induce a refractory ventricular tachycardia.<sup>167,280,281</sup> Hypothermia may also profoundly compromise platelet function and impair the coagulation cascade.<sup>164,180-182,271,272,282,283</sup>

Prevention of hypothermia by all available means is considered an essential part of damage-control resuscitation of trauma patients.<sup>284-287</sup> Banked blood products are stored between room temperature and 4° C, depending on the blood component. In the setting of high-volume transfusions, all blood products should be infused through a blood warmer. No other method should be considered (e.g., storing blood in a warming cupboard, immersing in hot water) because RBCs hemolyze readily with prolonged warming or overheating (>42° C). Warming blood and all other IV infusions with a high-capacity blood warmer, using hot air warming blankets and radiant warmers, placing plastic wrap around extremities, inserting a heated humidifier in the anesthesia circuit, covering the child's head, and maintaining a warm to hot operating room contribute to maintaining thermal neutrality. Rapid-transfusion devices markedly improve the rapidity of transfusion and the thermokinetics involved.<sup>288-294</sup> In one case, one author (CJC) and two nurses transfused more than 50,000 mL of blood products and crystalloid in less than 1 hour, and the child's temperature remained at or exceeded 34.5° C.<sup>288</sup>

### MONITORING DURING MASSIVE BLOOD TRANSFUSION

If massive blood loss can be anticipated, adequate monitoring should be instituted *before* surgery begins so that baseline information can be recorded. Large-bore peripheral IV access is preferable (E-Fig. 10-1) because these catheters have reduced resistance and they avoid giving blood products and drugs directly into the heart, as with a CVP line. If a child arrives in the operating room in shock (e.g., trauma patient), the physician must be careful to differentiate hypovolemia from other causes of shock (e.g., tension pneumothorax, cardiac tamponade) (see Chapters 38 and 39). Invasive monitoring inserted during resuscitation helps with the differentiation. Our philosophy is one of aggressive invasive

monitoring to provide maximum data for evaluation and management of a critically hypovolemic child.

1. Routine monitoring includes an electrocardiogram, blood pressure cuff, stethoscope, temperature, pulse oximetry, and expired carbon dioxide monitoring. The use of a pulse oximeter placed on the tongue may be particularly valuable in special circumstances when a child is vasoconstricted, hypothermic, or without peripheral pulses.<sup>295,296</sup> Hypovolemia may occasionally manifest as pulsus paradoxus, identified by the peripheral pulse oximeter.<sup>297</sup>
2. A urinary catheter allows accurate quantitation of urine output and assessment of organ perfusion and intravascular volume status.
3. An arterial catheter enables continuous blood pressure monitoring, arterial blood gas measurements, and determinations of hematocrit, glucose, calcium, potassium, and clotting parameters. The adequacy of the circulating blood volume may be inferred from the shape of the arterial waveform, presence of the dicrotic notch, and absence of exaggerated respiratory variation (Fig. 10-10).
4. A CVP line may provide useful information, and its ease and safety of insertion have been demonstrated for children of all sizes.<sup>298</sup> The use of ultrasound may improve the success and safety of insertion.<sup>299,300</sup> CVP readings may vary depending on the location of the catheter tip and whether there is rapidly running fluid in the same catheter.<sup>301,302</sup> In the latter case, the infusions should be interrupted intermittently to obtain readings. It is our clinical impression that in healthy, anesthetized,

**FIGURE 10-10** Changes in the contour of an arterial tracing with hypovolemia. **A**, The normal tracing shows a sharp upswing of the arterial pulse wave and position of the dicrotic notch. **B**, There is movement of the dicrotic notch and widening of the pulse wave. **C**, The pulse wave widens further. **D**, There is further widening of the pulse wave and loss of the dicrotic notch. An exaggerated ("picket fence") respiratory variation of pulse wave is shown in the *right* tracing compared with the *left*. Factors other than hypovolemia, such as hypothermia, deep anesthesia, vasodilator therapy, or damped tracing (e.g., clot, air bubble), may produce artifactual changes in the shape of the arterial waveform.

**E-FIGURE 10-1** Rapid infusion intravenous catheters are available. A 20-gauge catheter is inserted into a peripheral vein, and a guidewire is advanced. A moderate skin nick is made with the provided scalpel blade, and the dilator (blue catheter) is advanced into the vein. The Rapid Infusion Catheter (white catheter; Rapid Infusion Catheter Exchange Set, Arrow International, Erding Germany) is then advanced into the vein, and the dilator and guidewire are removed. The Rapid Infusion Catheter is sutured in place (side hole on white catheter). In this case, an 8.5-Fr catheter that is only 6.4 cm long is in place, providing a large-bore, low-resistance catheter that is able to adequately function with rapid transfusion devices (see Figs. 51-1 and 51-2). These catheters are available in smaller sizes and from various manufacturers, and the devices are best combined with large-bore extension catheters.

supine children, a very small change in CVP (2 to 3 mm Hg) may represent a change of as much as 10% to 15% of a child's blood volume. In most children, right-sided pressures correlate well with left-sided pressures; the right atrial CVP usually is an accurate indicator of cardiac filling pressures of both ventricles. A CVP line provides access for blood sampling and a reliable site for IV administration of medications, fluid, and blood. A CVP line cannot always be relied on as a volume administration line because resistance is large through the long, narrow lumen; a centrally placed introducer is a reliable volume line.

5. Continuous noninvasive cardiac output devices may in the future provide further clinical guidance.

Monitors and the data they generate are helpful, but anesthesiologists must rely on more than numbers. It serves no purpose to have sophisticated monitoring if the data provided cannot be interpreted and related to clinical events. The final monitor is ultimately the anesthesiologist's attention and judgment.

Thromboelastography provides a standardized means of quantitating the rapidity and quality of clot formation and a means for identifying fibrinolysis.<sup>303,304</sup> This device was first used primarily during massive blood transfusion situations related to liver transplantation and now is used in several areas, particularly cardiac surgery.<sup>303-312</sup> Some studies have found that thromboelastographic screening was not useful in predicting bleeding after cardiac surgery and was associated with a large percentage of false-positive results.<sup>313,314</sup> Use of heparinase helps to improve the accuracy of the results by eliminating the effects of heparin, but this requires two machines to simultaneously sample blood (with and without heparinase) to have results within a useful period.<sup>315</sup> This monitor may also be used to guide the effectiveness of antifibrinolytic therapy.<sup>310,311,316</sup> The exact role of thromboelastography in the routine care of pediatric cardiac surgical patients, liver transplant recipients, and children who have had massive blood loss with ongoing coagulopathy has not been established. Tables 10-10 and 10-11 summarize the expected changes in various blood components when administered on a per kilogram basis and the estimated FFP requirement.

### INFECTIOUS DISEASE CONSIDERATIONS

It is important for anesthesiologists to use basic precautions to minimize their risk when administering blood products and contacting body fluids. Blood and body fluids, even in infants, are capable of transmitting hepatitis B, hepatitis C, and HIV through parenteral exposure (e.g., cuts, needlestick), mucous membrane contact, or exposure to nonintact skin.<sup>4,317-326</sup> Accidental needlesticks were the most common means of exposure in the operating room for anesthesiologists. The introduction of safe IV needles, a needleless IV system, the use of stopcocks, and never recapping used needles has reduced the incidence of this problem.<sup>191-193,327</sup> The incidence of HIV seroconversion after needle puncture is estimated to be 0.2% to 0.5% (~1 in 300), although the conversion rate is much greater after a needlestick injury from individuals with hepatitis.<sup>4,194,317,323-325,328</sup>

Anesthesiologists must practice universal blood and body fluid precautions (e.g., gloves, goggles) and should minimize the use of needles and especially the practice of recapping needles. The management of infants may be less than optimal with the use of three-way stopcocks because of the fluid required to flush the system and the ease of introducing air into the IV line. In these infants, single-use needles without recapping or needleless systems are recommended. If an exposure occurs from a known HIV-positive patient or puncture from a needle of unknown

origin, consult a specialist immediately to determine the need for immediate institution of prophylactic medical therapy as soon as possible.<sup>327,328</sup> Early institution of drug therapy is recommended to reduce the potential for seroconversion (see Tables 49-6 and 49-7).

## Methods to Reduce Exposure to Allogeneic Blood Components

Public awareness of the infectious hazards of transfusion, particularly from HIV and the hepatitis viruses, has generated considerable interest in developing techniques to avoid allogeneic transfusion. These techniques can minimize transfusions and the attendant risks, at least in some settings, assuaging the fears of patients and sparing the blood supply for patients for whom these options were not suitable. Within the medical community, awareness of the hazards of transfusion prompted a more thoughtful approach to transfusion, greater tolerance of asymptomatic anemia, more attention to medical treatment of anemia, and greater focus on surgical hemostasis. The amount of blood transfused for many surgical procedures has decreased steadily during the past 20 years. During the same period, the risks associated with transfusions have decreased. After the HIV and hepatitis C viruses were identified, sensitive tests, some based on amplification technology for viral RNA, were developed to screen the donor population. Transfusions are associated with other deleterious effects, but two of the most significant risks, bacterial infection and mistransfusion, do not differ materially between banked allogeneic and autologous blood. As the risk differential between allogeneic transfusion and its alternatives narrows, a balanced appraisal of the benefits and untoward effects of each is appropriate.

### ERYTHROPOIETIN

Use of recombinant erythropoietin to promote endogenous RBC production can reduce the need for allogeneic RBC transfusions. This therapy has proved useful in many populations, including preterm infants, children on chemotherapy, children with renal failure, children of Jehovah's Witnesses, and children undergoing elective major reconstructive surgery, spinal surgery, liver transplantation, or cardiac surgery. Coordination with the hematology department, blood banking, and the primary patient care team is required to take full advantage of this form of therapy.<sup>329-347</sup> Although usually well tolerated, erythropoietin should be used with careful monitoring in patients with hypertension. Erythropoietin is available in a lyophilized (freeze-dried form for reconstitution) or in a dilute albumin solution. Some members of the Jehovah's Witness faith who refuse albumin should receive the lyophilized formulation, which is albumin free.

### PREOPERATIVE AUTOLOGOUS BLOOD DONATION

Donation and storage of blood before elective surgery have reduced the use of allogeneic RBCs.<sup>230,330,343,348-361</sup> Banked units of PRBCs may be stored for 35 to 42 days in the liquid state,<sup>362,363</sup> permitting the donation of several units and the time required for the patient (usually teenagers) to regenerate the RBC mass before surgery. Children unable to mount an erythropoietic response to phlebotomy may only succeed in making themselves anemic, so administration of iron, vitamin C, and folate is important, as is monitoring for reticulocytosis to ensure the bone marrow is replenishing the donated RBCs. Autologous donation should not be attempted in children with significant cardiac

ischemic disease or those with an active infection because bacteria can seed the collected unit and overgrow during storage. Autologous donation should be discouraged before procedures for which RBC transfusion is unlikely. Donated blood that is not used by the donor must be discarded rather than enter the general blood bank pool.

Patients or family of pediatric patients may wish to obtain blood from family members or friends (i.e., directed donation). Despite the perception that this donor pool may be safer than the pool of volunteer, allogeneic donors, there is no evidence that this is true. Directed donors are considered to be allogeneic donors and are screened and tested in the same manner as any volunteer donor. Because there is a greater risk of transfusion-associated GVHD with cellular components from a donor who is a blood relative, these units are irradiated to eliminate the possibility of this usually fatal complication of transfusion.<sup>364-366</sup>

### INTRAOPERATIVE BLOOD RECOVERY AND REINFUSION: AUTOTRANSFUSION

Recovery of blood from an operative site and reinfusion after some form of processing has been applied to major vascular, cardiac, and multiple trauma situations for many years.<sup>353,358-360,367-377</sup> The common techniques used wash the recovered blood in a centrifuge so the product consists of the child's RBCs suspended in saline at a hematocrit of 50% to 60%.<sup>368,375</sup> Cellular debris, excess citrate or heparin, free hemoglobin, activated clotting factors, and clotted blood are almost completely removed. Autotransfusion avoids the infectious and immunologic risks of allogeneic transfusion and, if reinfusion is carried out in the operating room, minimizes the opportunity for mistransfusion.<sup>367,375,376,378</sup>

Intraoperative blood recovery is not widely used in infants and children.\* The equipment is designed for adults, although some manufacturers have adapted standard devices for pediatric use. We have found blood recovery to be a useful adjunct to minimize allogeneic blood transfusion during scoliosis surgery. This technique may also be used in conjunction with preoperative autologous blood donation, further reducing the need for allogeneic RBC transfusions.<sup>358-360,371,372</sup> The capital investment for the devices and the costs for the disposables and a trained operator are significant. However, these expenses can be offset if three fewer units of allogeneic RBCs are transfused. Development of pediatric-sized equipment should make this technique more widely used and more cost-effective even in smaller children.<sup>383</sup>

#### Indications

The indications for intraoperative blood recovery and reinfusion include any major surgical procedure in which the use of more than 3 units of banked RBCs is likely or in which massive blood loss is occurring; children with rare blood types; and multiple trauma with major bleeding.

#### Contraindications

Major contraindications to blood-recovery devices include contamination of the operative field by bacteria (e.g., bowel trauma, abscess), cancer, and sickle cell disease (e.g., sickling in the device). Recovered blood should not be processed for reinfusion if the surgical field contains topical clotting agents, some topical antibiotics (e.g., Polymyxin, Neomycin), or other foreign materials

(e.g., methylmethacrylate). Surgery for a malignancy is considered to be a relative contraindication because of the (theoretical) concern that malignant cells may be recovered and reinfused; this can be avoided by discarding blood recovered from the operative field while the tumor is being manipulated.<sup>384-386</sup>

### CONTROLLED HYPOTENSION

Controlled hypotension, the intentional reduction of systemic perfusion pressure, has been used to reduce intraoperative blood loss or to provide a relatively bloodless operating field.<sup>329,387-398</sup> Hypotensive anesthesia may be accomplished with several techniques, including continuous infusion of vasodilators,  $\beta$ -adrenergic blockade, deep inhalational anesthesia, and large-dose opioid infusions (e.g., remifentanyl).<sup>388,399-401</sup>

Controlled hypotension is reserved for older children and teenagers undergoing major reconstructive or orthopedic surgery. The choice of technique and the degree of induced hypotension depend on the surgical procedure. For procedures in which a dry surgical field is the end point with little potential for rapid blood loss, a technique that may take some time for recovery is acceptable (e.g., deep inhalational agent with or without  $\beta$ -blockade). If surgery carries the possibility of rapid or massive blood loss, a technique that is rapidly reversed (e.g., nitroprusside, nitroglycerin, remifentanyl) is probably safer. Controlled hypotension with mean arterial pressure (MAP) of 55 to 60 mm Hg is used less in pediatric anesthesia in recent years, although there are insufficient data to categorically state that the risks of controlled hypotension outweigh the purported benefits. Moderate hypotensive techniques with a MAP of 65 to 70 mm Hg are a more common practice and are likely associated with less risk, although no studies have been published in this regard.<sup>347</sup>

#### Physiology

All potent inhalational anesthetics decrease the cerebral metabolic rate for oxygen consumption ( $CMRO_2$ ) and increase cerebral blood flow. Isoflurane appears to offer the greatest advantage because it induces the greatest depression of  $CMRO_2$ , and it has been used as the sole hypotensive agent.<sup>402-408</sup> One of the most important considerations of any hypotensive technique is the effect that it has on cerebral blood flow. Studies of adults demonstrate that little change occurs in cerebral metabolism when the MAP is maintained above 55 mm Hg.<sup>402</sup> There are no comparable data for children. However, experience with children during cardiac bypass suggests that children tolerate cerebral perfusion pressures below this level on an age-related basis. Brain ischemia has been documented when an MAP of 55 mm Hg is combined with hypocarbia; however, no similar pediatric studies have been carried out.<sup>407,408</sup>

Maintenance of normal arterial carbon dioxide tension ( $PaCO_2$ ) is vitally important to ensure adequate cerebral blood flow during induced hypotension. The relationship of cerebral blood flow to  $PaCO_2$  is described in greater detail in Chapter 24. To optimize cerebral blood flow, we typically maintain the MAP at 55 mm Hg or greater and the  $PaCO_2$  at 35 to 45 mm Hg.

Hypotensive anesthesia may be induced by one of several techniques: direct myocardial depression with inhalational anesthetics alone or in combination with  $\beta$ -adrenergic blockade,<sup>404,409,410</sup> direct vasodilators, and other medications (e.g., remifentanyl). Because hypotensive anesthesia with inhalational anesthetics depresses myocardial function and requires time to wash out, a rapid offset is often difficult to achieve. We advocate alternative strategies (e.g., vasodilating agents, remifentanyl) that provide more precise control of blood pressure without

\*References 329, 330, 359, 360, 371, 372, 375-377, 379-382.

depressing the heart. The rapid offset of action of these latter agents may hold a particular advantage in children who incur rapid blood loss because the systolic blood pressure is quickly restored on termination while fluids are infused to reestablish euvoemia. Remifentanyl offers a similar speed of reversal of cardiovascular depression while avoiding the need for high doses of an inhalational agent. Although  $\beta$ -adrenergic blockade decreases the requirements of vasodilators,<sup>411</sup> cardiac arrest can occur with administration to children.<sup>412</sup>

If  $\beta$ -blockade is to be used safely, the clinician must understand the differences in half-lives of anesthetics and the best means for reversing their effects. Esmolol is very short acting, with a half-life in children of approximately 3 minutes.<sup>413</sup> Non-anesthetized children have a greater requirement ( $\mu\text{g}/\text{kg}$ ) than adults.<sup>414</sup> In nonanesthetized children, a loading dose of 500  $\mu\text{g}/\text{kg}/\text{min}$  is followed by a maintenance infusion at a rate of 25 to 200  $\mu\text{g}/\text{kg}/\text{min}$ . Because there is limited published experience esmolol in children under anesthesia, a smaller starting dose (25 to 50  $\mu\text{g}/\text{kg}/\text{min}$ ) and titration of dose every 3 to 5 minutes (increase by 12.5 to 25  $\mu\text{g}/\text{kg}/\text{min}$ ) are indicated. Labetalol<sup>410,415-417</sup> and propranolol<sup>418,419</sup> have been used to help induce hypotensive anesthesia; the half-lives, onset of effect, and time to peak effect of these medications are much greater, and the effects are therefore less controllable and not recommended. Acute  $\beta$ -blocker toxicity can be reversed with high-dose IV glucagon (50  $\mu\text{g}/\text{kg}$  followed by an infusion of 0.3 to 3.0  $\mu\text{g}/\text{kg}/\text{min}$  [extrapolated from adult data])<sup>420-422</sup> and possibly with vasopressin.<sup>423</sup>

### Renal System

Renal blood flow autoregulates between an MAP of 80 and 180 mm Hg. However, general anesthesia with inhalational anesthetics profoundly affects autoregulation. Urinary output is a simple method to monitor the adequacy of intraoperative renal perfusion and function. Reducing the MAP decreases renal blood flow, although the effect on renal function, at least in the case of  $\beta$ -blockers, is insignificant. Renal function returns to normal after the period of controlled hypotension.<sup>415,424-427</sup>

### Pulmonary System

An increase in physiologic dead space and intrapulmonary shunting during induced hypotension has been reported in adults and children.<sup>393,395,428-430</sup> This does not seem to be a clinically important problem in children. Their smaller size compared with adults may reduce the gravitational pooling of blood in the lungs. Nonetheless, it is important to measure the arterial blood gases, expired carbon dioxide, and oxygen saturation to assess for this effect.<sup>393,395</sup> An increasing difference between end-expired carbon dioxide values and measured arterial blood gas values suggest the development of a shunt and increased physiologic dead space. Children with severe scoliosis may have significant arterial-to-alveolar gradients for carbon dioxide even before surgery.

### Hepatic System

Catecholamines,  $\text{PaCO}_2$ , circulating blood volume, and anesthetic agents influence the portal circulation.<sup>431</sup> The liver is oxygenated by the arterial circulation but receives most of its blood flow through the portal circulation, and changes in portal blood flow may have profound effects on total hepatic blood flow. Hepatic oxygenation is maintained during periods of induced hypotension during anesthesia if the  $\text{PaCO}_2$  is within the normal range and an adequate circulating blood volume is maintained.<sup>432</sup>

## Pharmacology

### Sodium Nitroprusside

Sodium nitroprusside has a very rapid onset of action (seconds), brief duration of action (minutes), and minimal side effects when used in the recommended dose range.<sup>433</sup> This agent is extremely potent and is most safely administered by an infusion pump through a separate IV site and with a second pump to provide a continuous, uninterrupted, and stable infusion rate. Its principal mechanism of action is direct vascular smooth muscle relaxation, primarily causing arteriolar dilation and some venodilation.

**DOSAGE.** The initial infusion rate for sodium nitroprusside is 0.5 to 1.0  $\mu\text{g}/\text{kg}/\text{min}$ . The rate can be increased as needed to achieve the desired MAP.<sup>434,435</sup> A satisfactory reduction in systemic perfusion pressure can usually be obtained well below the recommended maximum rate of 10  $\mu\text{g}/\text{kg}/\text{min}$ .

**TOXICITY.** Cyanide toxicity is characterized by an unexplained metabolic acidosis, increased blood lactate concentrations, and an increased mixed venous oxygen content.<sup>435,436</sup> The nitroprusside radical interacts with the sulfhydryl groups of erythrocytes, releasing cyanide. Nitroprusside contains five cyanide molecules; and as the cyanide is released, it is converted to nontoxic thiocyanate by the rhodanese enzyme system in the liver and is then excreted by the kidneys.<sup>436</sup> If the amount of cyanide released overwhelms the capacity of the rhodanese system, cyanide toxicity (i.e., binding to the cytochrome electron transport system) results. This produces a change to anaerobic metabolism, metabolic acidosis, an increase in mixed venous oxygen content, and eventually death.<sup>435,437-441</sup> Several pediatric anesthetic-related deaths have resulted from cyanide toxicity and its treatment.<sup>438-440</sup>

Three responses to sodium nitroprusside infusion may herald impending cyanide toxicity: more than 10  $\mu\text{g}/\text{kg}/\text{min}$  required for a response, tachyphylaxis developing within 30 to 60 minutes, and immediate resistance to the drug.<sup>436</sup> If any of these occur, sodium nitroprusside should be discontinued and the child investigated for possible cyanide toxicity. Treatment of cyanide poisoning is directed at reversal of the binding of cyanide to the cytochrome enzymes. This can be accomplished by producing methemoglobinemia with amyl nitrite. Methemoglobin has a greater affinity for cyanide than it does for the cytochrome system, forcing the reaction in the direction of forming cyanmethemoglobin. The breakdown of cyanmethemoglobin is promoted by administering thiosulfate, which reacts with the cyanide to form nontoxic thiocyanate, which is then excreted by the kidneys. Hydroxocobalamin may prevent toxicity by formation of cyanocobalamin.<sup>442</sup>

This treatment is not without hazard. As Posner states, "Overzealous treatment may merely convert a cytotoxic hypoxia to an anemic hypoxia."<sup>442</sup>

The first step in the treatment of toxicity is the *intermittent* administration of amyl nitrite (by inhalation) until sodium nitrite can be administered intravenously. The second step is sodium nitrite administered as a 3% solution (300 mg/mL, 0.2 mL/kg, not to exceed 10 mL [3 g]). Immediately afterward, sodium thiosulfate in a dose of 175 mg/kg (not to exceed 12.5 g) should be administered. One hundred percent oxygen should be delivered continuously. A cyanide poisoning kit is available (Nithiodote, Hope Pharmaceuticals, Scottsdale, Ariz).

Sodium nitroprusside is a safe medication if doses remain well within the guidelines that have been established by various investigators.<sup>443-445</sup> For children, this is a maximum of 50  $\mu\text{g}/\text{kg}/\text{min}$  for 30 minutes and 8 to 10  $\mu\text{g}/\text{kg}/\text{min}$  for 3 hours, with

frequent blood gas analyses.<sup>435,445</sup> Because of the potential for toxicity and the availability of newer, less toxic vasodilators, this drug has had decreasing popularity for use for controlled hypotension and is now most commonly used for short-term control of blood pressure in special situations.

### *Nitroglycerin*

The main advantages of nitroglycerin are its relatively rapid onset of action (minutes), lack of tachyphylaxis and toxicity, and brief duration of action (minutes). The major disadvantage of nitroglycerin is the limited reduction in blood pressure achievable.

**DOSAGE.** Nitroglycerin is administered by an infusion beginning at a rate of 1 µg/kg/min. The dose is increased until the desired response is obtained. Resistance to the hypotensive effects of nitroglycerin may occur in children. However, in view of the reduced potential for toxicity compared with nitroprusside, nitroglycerin appears to be a reasonable alternative.

**TOXICITY.** Nitroglycerin is relatively free of toxic side effects in the usual doses applied during hypotensive anesthesia.<sup>395,446,447</sup> No toxicities or deaths have been reported with nitroglycerin when it is used for hypotensive anesthesia.<sup>395,446-448</sup> However, several reports have described nitroglycerin-induced methemoglobinemia, and a study of patients undergoing anesthetic procedures using controlled hypotension did not find a relationship between the development of methemoglobin and the dose of nitroglycerin.<sup>449,450</sup> Pulse oximetry may be of value in making the initial diagnosis (i.e., decreased saturation). However, if this occurs, accurate saturation determinations are not possible because of the interference in light absorbance caused by methemoglobin at both ends of the absorbance spectrum used by pulse oximeters.<sup>451,452</sup> The use of other adjuncts (e.g., potent inhalation agents, other vasodilators, β-adrenergic blockade, potent opioid) reduces the total dose of nitroglycerin administered.

### *Remifentanyl*

Remifentanyl-induced hypotension is increasing in popularity because of its relative safety, ease of administration, and titratability, particularly if a patient must be awakened during spinal fusion. Administration should be the same as for any other vasoactive anesthetic agent. It requires dedicated IV access, with the infusion as close to the IV catheter as possible and with a separate pump to avoid fluctuations in the rate of administration. The half-life of this drug is so brief that interruptions while changing IVs or boluses when giving other medications need to be avoided. We have found that the combination of a low-dose inhalational agent, low-dose propofol, and a remifentanyl infusion provides excellent operating conditions. Systemic arterial pressure can be controlled by the rate of opioid infusion without fear of residual opioid effect at the end of the procedure, and this combination does not significantly interfere with sensory and motor potential monitoring. If an intraoperative wake up is needed, a longer-acting opioid such as fentanyl should be administered before awakening.

**DOSAGE.** For most children, the starting dose is 0.1 µg/kg/min, which is then increased or decreased depending on the child's response and the degree of surgical stimulus. The anesthesiologist should expect variable opioid requirements during spinal fusions (doses as great as 2 µg/kg/min and as small as 0.05 µg/kg/min). Analgesic doses of a long-acting opioid such as morphine or hydromorphone should be administered approximately 10 minutes before discontinuation to provide adequate

analgesia on awakening. This technique often allows a smooth but rapid extubation despite a very long surgical procedure.

### **General Concepts of Hypotensive Anesthesia**

Before using controlled hypotension, it is important to understand the rationale for using this technique.<sup>453</sup> If it is used to reduce surgical blood loss, the preparation and monitoring of a child are different from the approach in a procedure in which the main objective for reducing the perfusion pressure is to improve operating conditions (e.g., microsurgical techniques). In the former case, direct assessment of circulating blood pressure and volume with an arterial line and central venous catheter is important, whereas in the latter case, only a direct means of measuring blood pressure (arterial line) is needed.

### *Anesthetic Management*

All inhalational agents, by directly depressing cardiac output, have been used with various degrees of success as a single drug to produce controlled hypotension, but profound cardiovascular depression may be difficult to control and certainly is not readily reversible.<sup>404-406,409,454</sup> We do not advocate hypotensive anesthesia using potent inhalational agents as the sole hypotensive agent because the cardiovascular depression is not rapidly reversed if a problem arises with a relative anesthetic overdose. However, small to moderate concentrations of inhalational anesthetic reduces the amount of vasodilator, β-blocker, or opioid necessary to reduce blood pressure.<sup>455</sup>

The availability of short-acting β-adrenergic blockers offers an alternative method to decrease MAP by directly depressing cardiac output. However, β-adrenergic blockade removes a valuable guide to the depth of anesthesia and volume status. Because the cardiac output in children approximately 2 years old or younger depends on heart rate (see Chapter 16), β-adrenergic blockade is not recommended in this age group. Low-dose, short-acting β-adrenergic blockade may be a reasonable adjunct to hypotensive anesthesia with inhalational anesthetics as a means of reducing the concentration of the anesthetic or as a supplement to reduce the vasodilator requirements.<sup>456</sup> A rapid-acting β-blocker such as esmolol may be the best compromise because its half-life is brief (3 minutes), and it is administered as an infusion. Even with this type of control, serious adverse events have been reported with the use of β-blockers in children.<sup>412</sup>

The safest method to deliver vasodilating agents, ultra-short-acting β-blocking agents, or potent opioids is by using two infusion pumps. The first is used to infuse a continuous and constant flow of fluids through the IV catheter, and the second is used to infuse the hypotensive agent. Use of a separate IV site can minimize an accidental bolus of the hypotensive agent during changes in fluid requirements or during the administration of other medications. The vasodilator, ultra-short-acting β-blocker, or potent opioid should be administered as close to the vein as possible to eliminate dead space and the possibility of accidental bolus administration.

### *Monitoring and Management Principles*

The following baseline parameters are monitored: oxygen saturation and expired carbon dioxide, electrocardiogram, temperature, hematocrit, blood glucose, arterial blood gases, acid-base status, MAP, and CVP. Arterial pressure is measured using the radial artery.

When the desired MAP has been attained, a new baseline CVP should be measured and maintained at this level or a slightly

greater level than the new, reduced CVP value throughout the procedure. To use any hypotensive technique safely, normovolemia is maintained at all times. This means that even small (1 or 2 mm Hg) decreases in the CVP prompt an appropriate fluid response. A small change in cardiac filling pressures in a healthy, supine, anesthetized pediatric patient may represent a significant reduction in circulating blood volume. Even during hypotensive anesthesia, the kidneys should produce 0.5 to 1.0 mL/kg of urine per hour. The failure to detect urine output frequently is caused by obstruction or kinking of the urinary catheter. If the catheter is patent, an IV fluid challenge should be considered. Urine output is one of the best indicators of organ perfusion and renal function during hypotensive anesthesia.

After hypotension has been induced and the surgical field is bloodless, the MAP should be slowly increased in 5- to 10-mm Hg increments until increased bleeding is observed in the surgical field. At that time, the MAP can be again reduced by approximately 5 mm Hg to achieve optimal conditions. With this method, it is sometimes necessary to reduce the MAP only 10% to 20% from baseline to achieve satisfactory hemostasis with hypotensive anesthesia.

**POSITION.** Make the operative field the highest point of the child's body to take advantage of gravitational forces to help reduce blood pressure. When positioning a child, care must also be taken to minimize any possible impedance to venous drainage that may contribute to blood loss. For example, abdominal pressure from a misplaced roll of sheets can markedly increase venous pressure during spinal instrumentation and completely offset any beneficial effects from reduced arterial pressure.<sup>397,453,457,458</sup> If the head is the surgical site, the arterial transducer must be calibrated at head level rather than heart level to ensure adequate cerebral perfusion pressure.<sup>447,459</sup>

**LABORATORY PARAMETERS.** Adequate levels of hemoglobin must be maintained to have sufficient oxygen-carrying capacity. Studies have indicated that at normal blood pressures, a hemoglobin value of 5 g/dL is well tolerated in laboratory animals, but ischemia may occur with a reduced hemoglobin concentration.<sup>460</sup> There is some evidence that the combination of hemodilution and hypotensive anesthesia may fail to deliver adequate oxygenation to some vascular beds (e.g., renal, enteric mucosa).<sup>461,462</sup> Although no similar studies have been conducted in children, for additional safety, we maintain the hemoglobin level at 9 to 10 g/dL during controlled hypotensive anesthesia. This is important for children undergoing spinal instrumentation, in which traction on the spinal cord may alter spinal cord blood flow.

Arterial blood gases must be carefully evaluated on a 30- to 60-minute basis to diagnose changes in oxygenation, ventilation, or perfusion or the development of drug toxicity (e.g., nitroprusside) or adverse anesthesia events.<sup>463-465</sup> A large difference between arterial and expired carbon dioxide values may indicate a pulmonary shunt or air embolization. An increase in mixed venous oxygen content may signal cyanide toxicity. Adequate PaO<sub>2</sub> must be maintained at all times. Continuous examination of the PaO<sub>2</sub> is important during any hypotensive anesthetic technique because cerebral perfusion is directly related to PaCO<sub>2</sub>.<sup>466,467</sup> Normocarbia should be maintained. The combination of hypocarbia and hypotension should be avoided. The metabolic components of acid-base equilibrium must be monitored; development of acidosis reflects inadequate oxygen delivery or toxicity from the hypotensive agent (e.g., sodium nitroprusside).<sup>433</sup>

Although we do not advocate the routine use of  $\beta$ -adrenergic blockade, blood glucose values should be measured serially if

these drugs are part of the chosen hypotensive technique.  $\beta$ -Adrenergic blockade inhibits glycogenolysis and may cause severe, unsuspected hypoglycemia in children.<sup>393,468,469</sup>

### Contraindications

The risks of hypotensive anesthesia are significant.<sup>470</sup> The risk-benefit ratio must always be considered on an individual basis, particularly with neurosurgical patients and those undergoing spinal instrumentation. Any systemic disease compromising the function of a major organ is a relative contraindication to the use of controlled hypotension. Most reported complications are related to the inexperience of the practitioner, inappropriate patient selection, unfamiliarity with the drugs involved, or inattention to details such as blood volume status, pH, PaCO<sub>2</sub>, or blood glucose or not using infusion pumps to carefully titrate medications.\* If a child is healthy and meticulous attention is paid to all the parameters previously detailed, the benefits of improved surgical technique, reduced surgical time, and decreased need for blood transfusion may outweigh the potential risks.

### NORMOVOLEMIC HEMODILUTION

Intentional isovolemic hemodilution is a useful adjunct to an anesthesiologist's strategy for reducing allogeneic blood transfusions.<sup>329,330,353,460,473-480</sup> Two basic methods can be applied:

1. Allow the surgical blood loss to continue until the child's hematocrit value is in the high teens and maintain that hematocrit value until near the end of the procedure. At that time, the hematocrit can be increased to the desired value by transfusing PRBCs. This technique allows surgical bleeding to occur at a reduced hematocrit value, resulting in reduced loss of RBC mass.
2. Blood can be removed from a child at the beginning of the operation while replacing the volume with crystalloid solution (usually) and then returning the blood at the end of the procedure or when significant bleeding occurs.

The latter technique is preferable because it reserves a quantity of the child's own blood, which can be returned at the end of the surgical procedure. For a Jehovah's Witness, this technique often conforms to religious guidelines if direct continuity is maintained with the child's circulation.<sup>460,481-488</sup>

During acute normovolemic hemodilution under anesthesia, the distribution of blood flow improves with the reduced hematocrit. Improved blood rheology is the major compensatory mechanism for maintaining oxygen delivery despite a reduced hematocrit. Oxygen extraction increases in the presence of an inadequate circulating blood volume or when the hematocrit decreases to less than 20%. If the hematocrit decreases to less than 15%, subendocardial myocardial ischemia may develop.<sup>489-492</sup> At this extreme level of anemia, dissolved oxygen begins to assume a more important role in oxygen delivery.<sup>493</sup> In several reports, extreme acute normovolemic hemodilution (hemoglobin as low as 2 g/dL) were well-tolerated,<sup>489,494-497</sup> although we cannot endorse the use of this technique in children because it is impossible to assess the effects of such an extreme hemoglobin concentration on the long-term cognitive ability. Nonetheless, these reports<sup>489,497</sup> indicate that healthy children can tolerate these extreme hematocrit concentrations provided they are anesthetized, normovolemic, slightly hypothermic, and ventilated with 100% oxygen. We limit the absolute minimum hematocrit to

\*References 393, 438, 439, 453, 457, 471, 472.

15%, but we prefer to maintain the hematocrit closer to 20% at all times.

### Technique and Key Concepts

When blood is collected for normovolemic hemodilution, blood flows directly from the arterial line into sterile blood bags that contain the appropriate anticoagulant. Each bag is weighed before any blood is transferred and then continuously during filling by placing it on a scale. The bag is frequently but gently agitated to ensure an even distribution of the anticoagulant. The total volume of blood to be withdrawn should be calculated preoperatively to reduce the hematocrit to the 20% to 25%. Care must be taken to replace the blood removed with 5% albumin milliliter for milliliter or 1.5 to 2 mL of lactated Ringer's solution for each milliliter of blood removed. Sometimes, an even greater volume of replacement fluid is needed.<sup>479</sup> A reasonable estimate of the adequacy of replacement is to obtain a baseline CVP and then maintain the same CVP as blood is withdrawn and replaced. It is preferable to hemodilute before the surgical incision to monitor changes in hemodynamic indices, although it can be performed during the initial phases of surgery. The major concern is to maintain a normal circulating blood volume and provide adequate oxygen-carrying capacity. It is important to make an educated guess about how much blood loss is anticipated during the surgery so that autologous blood can be reinfused in place of homologous blood. Because a small-pore filter (20  $\mu$ m) traps many of the platelets that a large-pore filter ( $\geq 150$   $\mu$ m) allows to pass, the former is best avoided at this juncture. In many hospitals, use of this small pore filter has been discontinued.

### Indications

Hemodilution may be indicated in any procedure in which blood loss is expected to exceed one half of the child's blood volume.

### Contraindications

Hemodilution is contraindicated in children with sickle cell disease, septicemia, cyanotic cardiac disease, or compromised function of any major organ that may be significantly affected by changes in perfusion and oxygenation. We do not recommend combining extreme hemodilution (hematocrit  $<25\%$ ) with controlled hypotension. Children with moderate anemia are not good candidates because not enough units can be removed to make the technique effective.

### Complications

The major complications of hemodilution are related to blood volume status, hemoglobin content (i.e., removing too much blood), and coagulopathy (i.e., dilution of clotting factors). Anesthesiologists must pay meticulous attention to blood volume replacement. As long as normovolemia is maintained and the hematocrit exceeds 15% (preferably about 20%), problems with organ perfusion or oxygenation should not occur. Sepsis becomes a concern if strict sterile techniques are not followed during the collection process.

### Advantages

The benefits of normovolemic hemodilution are that the units of blood collected at the beginning of the procedure pose no risk of infection (unless contaminated by bacteria during the collection process) or mistransfusion (if they are not removed from the operating room) when they are returned to the child at a later time. It yields a net saving in loss of RBC mass because the

surgical losses occur at a hematocrit of 15% to 20% rather than 30% to 45%. The net use of banked RBCs may be reduced if 2 or 3 units can be removed at the beginning of the procedure. This technique can be used only in older children and teenagers, and it is used most frequently in the population undergoing spinal instrumentation.

### The Jehovah's Witness Patient

The children of Jehovah's Witnesses present a particular medical and legal dilemma.<sup>498,499</sup> Transfusion management of anyone with a religious objection to transfusion depends in part on the urgency of the surgical procedure and underlying medical condition of the child. If not emergent, a meeting with the patient (or the parents or guardian if a minor), the patient's spiritual advisor (if the child so chooses), and representatives of the team that will be caring for the child should be held to allow the child to clearly articulate his or her wishes with respect to the refusal of transfusion and its consequences and to discuss possible alternatives, including the use of erythropoietin, iron therapy, acute normovolemic hemodilution, intraoperative cell recovery and reinfusion, and the use of antifibrinolytic medications.<sup>495,496,500-503</sup> Specific inquiries should be made about each child's beliefs regarding the use of albumin, plasma, cryoprecipitate, platelets, and intraoperative cell recovery and reinfusion if the circuit is not continuously connected to the child and, in particular, what the child's response would be if a life-threatening event occurred while he or she was under anesthesia.<sup>481,504</sup> These discussions should be carefully documented in the child's record and informed consent signed beforehand. Not all hospitals or physicians are willing to participate in these cases, in which case arrangements should be made to transfer the child to the care of institutions or physicians who are willing to work within these constraints.

The courts have consistently ruled that the adult patient or emancipated minor has a right to refuse transfusion.<sup>482,505</sup> Physicians have the moral and legal obligations to respect those beliefs if an adult or teenager has made an informed decision and understands that he or she may die or suffer permanent injury without a transfusion if a life-threatening situation occurs. However, in the case of a minor child, the Supreme Courts in the United States and Canada have ruled that the fate of the minor child cannot be determined by the parents' religious convictions. The most important issue is full and open discussion of the effort that will be made to respect the person's religious beliefs and avoid blood transfusions. In the case of minor children about whom a mutual understanding cannot be reached on avoiding blood transfusions, a court order can be obtained to save the child's life. The parents should be informed about this possibility beforehand.<sup>506</sup> The ethics of this issue are discussed in Chapter 5.

### ACKNOWLEDGMENT

The authors wish to thank Richard M. Dsida for his prior contributions to this chapter.

Preoperative Assessment  
Pulmonary Function Tests  
Perioperative Etiology  
and Epidemiology

Upper Respiratory Tract Infection  
Lower Airway Disease  
Cystic Fibrosis  
Sickle Cell Disease  
Summary

**RESPIRATORY PROBLEMS ARE COMMON** in children. The anesthesiologist often encounters pulmonary complications ranging from mild acute respiratory tract infections to chronic lung disease with end-stage respiratory failure during perioperative consultations, intraoperatively, or in the intensive care unit. This chapter discusses the basics of respiratory physiology, how to assess pulmonary function, and the practical anesthetic management of specific pulmonary problems. Airway and thoracic aspects pertinent to ventilation are discussed in Chapters 12 and 13; pulmonary issues specific to neonates, intensive care, and various disease states are addressed in the relevant chapters.

## Respiratory Physiology

The morphologic development of the lung begins at several weeks after conception and continues into the first decade of postnatal life.<sup>1</sup> Intrauterine gas exchange occurs via the placenta, but the respiratory system develops in preparation for extrauterine life, when gas exchange transfers abruptly to the lungs at birth.

Development of the lung, which begins as an outgrowth of the foregut ventral wall, can be divided into several stages (Fig. 11-1). During the embryonic period, the first few postconceptional weeks, lung buds form as a projection of the endodermal tissue into the mesenchyme. The pseudoglandular period extends to the 17th week of life, during which rapid lung growth is accompanied by formation of the bronchi and branching of the airways down to the terminal bronchioli. Further development of bronchioli and vascularization of the airways occurs during the canalicular stage of the second trimester. The saccular stage begins at approximately 24 weeks, when terminal air sacs begin to form. The capillary networks surrounding these air spaces proliferate, allowing sufficient pulmonary gas exchange for extrauterine survival of the premature neonate by 26 to 28 weeks. Formation of alveoli occurs by lengthening of the saccules and

thinning of the saccular walls and has begun by the 36th postconceptional week in most human fetuses. The vast majority of alveolar formation occurs after birth, typically continuing until 8 to 10 years postnatally. The neonatal lung at birth usually contains 10 to 20 million terminal air sacs (many of which are saccules rather than alveoli), one-tenth the number in the mature adult lung. Growth of the lungs after birth occurs primarily as an increase in the number of respiratory bronchioles and alveoli rather than an increase in the size of the alveoli.

The abrupt transition to extrauterine gas exchange at birth involves the rapid expansion of the lungs, increased pulmonary blood flow, and initiation of a regular respiratory rhythm. The development of a respiratory rhythm, detectable initially by intermittent rhythmic fetal thoracic movements, begins well before birth and may be necessary for normal anatomic and physiologic lung development. Interruption of umbilical blood flow at birth initiates continuous rhythmic breathing. Amniotic fluid is expelled from the lungs via the upper airways with the first few breaths, with residual fluid draining through the lymphatic and pulmonary channels in the first days of life. Changes in the partial pressures of oxygen ( $PO_2$ ) and carbon dioxide ( $PCO_2$ ) and in hydrogen ion concentration (pH) cause an acute decrease in pulmonary vascular resistance and a consequent increase in pulmonary blood flow. Increased left atrial and decreased right atrial pressure reverse the pressure gradient across the foramen ovale, causing functional closure of this left-to-right one-way flap valve. Ventilatory rhythm is augmented and maintained in part by the increased arterial oxygen relative to the prior intrauterine levels.

Breathing is controlled by a complex interaction involving input from sensors, integration by a central control system, and output to effector muscles.<sup>2</sup> Afferent signaling is provided by peripheral arterial and central brainstem chemoreceptors, upper airway and intrapulmonary receptors, and chest wall and muscle mechanoreceptors.

**FIGURE 11-1** Timetable for lung development. (Modified with permission from Guttentag S, Ballard PL. Lung development: embryology, growth, maturation, and developmental biology. In: Tausch HW, Ballard RA, Gleason CA, editors. *Avery's diseases of the newborn*. 8th ed. Philadelphia: WB Saunders; 2004, p. 602.)

The peripheral arterial chemoreceptors consist of the carotid and aortic bodies, with the carotid bodies playing the greater role in arterial chemical sensing of both arterial  $O_2$  tension ( $P_{aO_2}$ ) and pH. The central chemoreceptors, responsive to arterial  $CO_2$  tension ( $P_{aCO_2}$ ) and pH, are thought to be located at or near the ventral surface of the medulla.

The nose, pharynx, and larynx have a wide variety of pressure, chemical, temperature, and flow receptors that can cause apnea, coughing, or changes in ventilatory pattern. Pulmonary receptors lie in the airways and lung parenchyma. The airway receptors are subdivided into the slowly adapting receptors, also called pulmonary stretch receptors, and the rapidly adapting receptors. The stretch receptors, found in the airway smooth muscle, are thought to be involved in the balance of inspiration and expiration. These receptors may be the sensors in the Hering-Breuer reflexes, which prevent overdistention or collapse of the lung. The rapidly adapting receptors lie between the airway epithelial cells and are triggered by noxious stimuli such as smoke, dust, and histamine. Parenchymal receptors, also known as juxtacapillary receptors, are located adjacent to the alveolar blood vessels; they respond to hyperinflation of the lungs, to various chemical stimuli in the pulmonary circulation, and possibly to interstitial congestion. Chest wall receptors include mechanoreceptors and joint proprioceptors. Mechanoreceptors in the muscle spindle endings and tendons of respiratory muscles sense changes in length, tension, and movement.

Central integration of respiration is maintained by the brainstem (involuntary) and by cortical (voluntary) centers. Although the precise mechanism of the neural ventilatory rhythmogenesis is unknown, the pre-Bötzinger complex and the retrotrapezoid nucleus/parafacial respiratory group, neural circuits in the ventrolateral medulla, are thought to be the respiratory rhythm

generators.<sup>3</sup> These neuron groups fire in an oscillating pattern, an inherent rhythm that is moderated by inputs from other respiratory centers. Involuntary integration of sensory input occurs in various respiratory nuclei and neural complexes in the pons and medulla that modify the baseline pacemaker firing of the respiratory rhythm generators. The cerebral cortex also affects breathing rhythm and influences or overrides involuntary rhythm generation in response to conscious or subconscious activity, such as emotion, arousal, pain, speech, breath holding, and other activities.<sup>2</sup>

The effectors of ventilation include the neural efferent pathways, the muscles of respiration, the bones and cartilage of the chest wall and airway, and elastic connective tissue. Upper airway patency is maintained by connective tissue and by sustained and cyclic contractions of the pharyngeal dilator muscles. The diaphragm produces the majority of tidal volume during quiet inspiration, with the intercostal, abdominal, and accessory muscles (sternocleidomastoid and neck muscles) providing additional negative pressure. The elastic recoil of the lungs and thorax produces expiration. Inspiration is an active and expiration a passive action in normal lungs during quiet breathing. During vigorous breathing or with airway obstruction, both inspiration and expiration become active processes.

Another effect of age is a change in chest wall compliance. In adults, the end-expiratory volume is equivalent to the functional residual capacity (FRC). In infants, the chest wall is more compliant, so the tendency of the lung to collapse is not adequately counterbalanced by chest wall rigidity. Infants stop expiration at a lung volume greater than FRC, with the inspiratory muscles braking expiration. When this braking mechanism is impaired, as occurs with general anesthesia, the infant has a tendency to develop atelectasis.

## Preoperative Assessment

The preoperative assessment of the respiratory system in a child is based on the history, physical examination, and evaluation of vital signs. Because ventilation is a complex process involving many systems besides the lung, the pulmonary appraisal must also include an assessment of airway, musculoskeletal, and neurologic pathology that might affect gas exchange under anesthesia or in the postoperative period. The potential impacts of esophageal reflux and cardiac, hepatic, renal, or hematologic disease on gas exchange and pulmonary function should be considered. Further investigations, such as laboratory, radiographic, and pulmonary function studies, may be indicated if there is doubt as to the diagnosis or severity of the pulmonary disease.

Because children may be unwilling or unable to give a reliable history, parents or caregivers are often the sole source or an important supplemental source of information during initial evaluation. Risk factors in the history that are associated with an increased risk of perioperative events include a respiratory tract infection within the preceding 2 weeks, wheezing during exercise, more than three wheezing episodes in the past 12 months, nocturnal dry cough, eczema, and a family history of asthma, rhinitis, eczema, or exposure to tobacco smoke.<sup>1,4</sup> Viral upper respiratory tract infections (URIs) are common in children, and the time, frequency, and severity of infection should be established. If wheezing is present, the precipitating causes, frequency, severity, and relieving factors should be determined. Chronic pulmonary diseases often have a variable clinical course, and the details of acute exacerbations of chronic problems should be elicited.

In younger children, the gestational age at birth, the current postmenstrual age, neonatal respiratory difficulties, and prolonged intubation in the neonatal period are particularly important to ascertain. Apneic episodes, subglottic stenosis, and tracheomalacia are possible complications of prematurity and prolonged intubation that may be exacerbated in the perioperative period. Whereas congenital lesions often manifest at birth, symptoms of airway collapse or stenosis may become evident only later in life.

Physical examination begins when you enter the room. Particularly with young children, your best opportunity to observe them before they react to your presence is from across the room, and inspection from a distance can provide useful information. Respiratory rate is a sensitive marker of pulmonary problems, and scrutiny of the rate before a young child becomes agitated and hyperventilates is an important metric. Pulse oximetry is a useful baseline indicator of oxygenation. Nasal flaring, intercostal retractions, and the marked use of accessory respiratory muscles are all signs of respiratory distress. General appearance is also important. Apathy, anxiety, agitation, or persistent adoption of a fixed posture may indicate profound respiratory or airway difficulties, and intense cyanosis can also be detected from a distance. Weight may relate to pulmonary function: Children with chronic severe pulmonary disease are often underweight owing to retarded growth or malnourishment, whereas severe obesity can produce airway obstruction and sleep apnea. Inspection of the chest contour may reveal hyperinflation or thoracic wall deformities.

Closer physical examination adds further information. Atopy and eczema may be associated with hyperreactive airways. Auscultation may reveal wheezes, rales, fine or coarse crepitus, transmitted breath sounds from the upper airway, altered breath

sounds, or cardiac murmurs. Chest percussion can provide an estimate of the position of the diaphragm and serve as a useful marker of hyperinflation. Patience, a gentle approach, and warm hands improve diagnostic yield and patient satisfaction.

## Pulmonary Function Tests

Further pulmonary investigations include chest imaging, measurement of hematocrit, arterial blood gas analysis, pulmonary function tests, and sleep studies. Special investigations are not routinely indicated preoperatively and should be reserved for cases in which the diagnosis is unclear, the progression or treatment of a disease needs to be established, or the severity of impairment is not evident. In most cases, a comprehensive history and careful physical examination are adequate to establish an appropriate anesthetic plan. Before requesting a new investigation, the clinician should have a clear idea of the question the test is expected to answer and how the answer will modify anesthetic management and outcome. Many tests are difficult to perform in children who have short attention spans and who cannot sit still for any length of time. Judgment must be exercised when ordering these tests for young children, and due consideration must be given to the child's age and level of maturity and the influence of the parents.

Pulmonary function tests include dynamic studies, measurement of static lung volumes, and diffusing capacity. Pulmonary function tests enable clinicians to (1) establish mechanical dysfunction in children with respiratory symptoms, (2) quantify the degree of dysfunction, and (3) define the nature of the dysfunction as obstructive, restrictive, or mixed obstructive and restrictive.<sup>5</sup> Table 11-1 presents common indications for pulmonary function testing in children.

**TABLE 11-1 Uses of Pulmonary Function Studies in Children**

- To establish pulmonary mechanical abnormality in children with respiratory symptoms
- To quantify the degree of dysfunction
- To define the nature of pulmonary dysfunction (obstructive, restrictive, or mixed obstructive and restrictive)
- To aid in defining the site of airway obstruction as central or peripheral
- To differentiate fixed from variable and intrathoracic from extrathoracic central airway obstruction
- To follow the course of pulmonary disease processes
- To assess the effect of therapeutic interventions and guide changes in therapy
- To detect increased airway reactivity
- To evaluate the risk of diagnostic and therapeutic procedures
- To monitor for pulmonary side effects of chemotherapy or radiation therapy
- To aid in predicting the prognosis and quantitating pulmonary disability
- To investigate the effect of acute and chronic disease processes on lung growth

In: Chernick V, Boat TF, Wilmott RW, Bush A, editors: *Kendig's disorders of the respiratory tract in children*. 7th ed. Philadelphia: Elsevier Saunders; 2006, p. 168. Reproduced from National Asthma Education and Prevention Program: Full report of the expert panel: guidelines for the diagnosis and management of asthma (EPR-3). Bethesda, Md.: National Heart, Lung, and Blood Institute, National Institutes of Health; 2007.

The dynamic studies, which are the most commonly used tests, include spirometry, flow-volume loops, and measurement of peak expiratory flow. Spirometry measures the volume of air inspired and expired as a function of time and is by far the most frequently performed test of pulmonary function in children. With a forced exhalation after a maximal inhalation, the total volume exhaled is known as the forced vital capacity (FVC), and the fractional volume exhaled in the first second is known as the forced expiratory volume in 1 second (FEV<sub>1</sub>). Figure 11-2 illustrates a normal pulmonary function test (normal flow-volume loop and spirometry parameters).

An obstructive process is characterized by decreased velocity of airflow through the airways (Fig. 11-3), whereas a restrictive defect produces decreased lung volumes (Fig. 11-4). Examination of the ratio of airflow to lung volume assists in differentiating these components of lung disease. Normally, a child should be able to exhale more than 80% of the FVC in the first second. Children with obstructive lung disease have decreased airflow in relation to exhaled volume. If the volume exhaled in the first second divided by the volume of full exhalation (FEV<sub>1</sub>/FVC) is less than 80%, then airway obstruction is present (Table 11-2; see Fig. 11-3).

The FEV<sub>1</sub> needs to be interpreted in the context of the FVC. A small FEV<sub>1</sub> alone is insufficient evidence on which to make a diagnosis of airflow obstruction. Those with restrictive lung disease have both decreased FEV<sub>1</sub> and FVC—decreased flow rate and reduced total exhaled volume. Restrictive lung disease is associated with a loss of lung tissue or a decrease in the lung's ability to expand. A restrictive defect is diagnosed when the FVC is less than 80% of normal with either a normal or an increased FEV<sub>1</sub>/FVC (see Table 11-2 and Fig. 11-4).

Most children with respiratory problems have an obstructive pattern; isolated restrictive diseases are far less common. Asthma

Spirometry Parameter	Units	Predicted Value	Observed	
			Pre	Percent Pred
FVC	Liter	4.86	5.28	109
FEV <sub>1</sub>	Liter	4.19	4.68	112
FEV <sub>1</sub> /FVC	Percent	86	89	103

**FIGURE 11-2** Normal pulmonary function test. The normal flow-volume curve obtained during forced expiration rapidly ascends to the peak expiratory flow (highest point on curve), then descends with decreasing volume, following a reproducible shape that is independent of effort. In this normal flow-volume curve, the forced vital capacity (FVC), forced expiratory volume in 1 second (FEV<sub>1</sub>), and FEV<sub>1</sub>/FVC ratio are all within the normal range for this child's age, height, gender, and race. The shapes of both the inspiratory and expiratory limbs are normal as well. *Pre*, Prebronchodilator; *Pred*, predicted value.

**FIGURE 11-3** This flow-volume curve demonstrates a reversible obstructive defect. The forced expiratory volume in 1 second (FEV<sub>1</sub>) as a percentage of forced vital capacity (FVC), or total volume exhaled, is decreased in patients with airway obstruction. The observed curve shape before bronchodilator use (*blue curve*) is scooped. After administration of a short-acting bronchodilator, the observed curve shape (*brown*) appears normal, and there is an increase in both FEV<sub>1</sub>/FVC and FEV<sub>1</sub>. This child has asthma and demonstrates a marked (40%) increase in FEV<sub>1</sub> after treatment with a short-acting bronchodilator. Reversible airflow obstruction is one of the hallmarks of asthma. *Post*, Postbronchodilator; *Pre*, prebronchodilator; *Pred*, predicted value.

Spirometry Parameter	Units	Predicted Value	Observed		Observed		Percent Change
			Pre	Percent Pred	Post	Percent Pred	
FVC	Liter	1.94	2.15	111	2.14	110	0
FEV <sub>1</sub>	Liter	1.71	1.30	76	1.82	106	40
FEV <sub>1</sub> /FVC	Percent	90	60	67	85	94	42

Spirometry Parameter	Units	Actual	Predicted	Percent Pred
FVC	Liter	2.59	3.34	77
FEV <sub>1</sub>	Liter	2.14	3.00	71
FEV <sub>1</sub> /FVC	Percent	83	92	90

**FIGURE 11-4** Flow-volume curve demonstrating a restrictive defect. The flow-volume curves in children with restrictive defects are near-normal in configuration but smaller in all dimensions. The ratio of forced expiratory volume in 1 second (FEV<sub>1</sub>) to forced vital capacity (FVC) is normal, but both FEV<sub>1</sub> and FVC are reduced. The curve shape appears normal. This child has interstitial lung disease. *Pred*, Predicted value.

**TABLE 11-2** Characteristics of Obstructive and Restrictive Patterns of Lung Disease

Measurement	DISEASE CATEGORY	
	Obstructive	Restrictive
FVC	Normal/decreased	Decreased
FEV <sub>1</sub>	Decreased	Decreased
FEV <sub>1</sub> /FVC	Decreased	Normal

FEV<sub>1</sub>, Forced expiratory volume in 1 second; FVC, forced vital capacity.

is the most common obstructive pulmonary disease in children. Rare causes of obstruction include airway lesions, congenital subglottic webs, and vocal cord dysfunction. Restrictive lung disease can arise from limitations to chest wall movement such as chest wall deformities, scoliosis, or pleural effusions or from space-occupying intrathoracic pathology such as large bullae or congenital cysts. Alveolar filling defects (e.g., lobar pneumonia) also reduce lung volume and can be considered as restrictive processes. Although the diseases arise from specific isolated genetic disorders, children with cystic fibrosis (CF) and sickle cell disease (SCD) can have highly variable pulmonary pathologic processes with both obstructive and restrictive components of lung disease. Bronchopulmonary dysplasia may also result in both obstructive and restrictive pathology.

Pulmonary function tests can also be used to differentiate fixed from variable airway obstruction and to localize the obstruction as above or below the thoracic inlet (Figs. 11-5 through 11-7, E-Fig. 11-1). This information can be gleaned from distinctive changes

in the configuration of the flow-volume loop, a graphic representation of inspiratory and expiratory flow volumes plotted against time. A fixed central airway obstruction, such as a tumor or stenosis, may obstruct both inspiration and expiration, flattening the flow-volume curve on both inspiration and expiration (See Video 12-1). The child with tracheal stenosis, for example, has flattening of both inhalation and exhalation curves (see Fig. 11-6). A variable obstruction tends to affect only one part of the ventilatory cycle. On inhalation, the chest expands and draws the airways open. On exhalation, as the chest collapses, the intrathoracic airways collapse. Variable extrathoracic lesions tend to obstruct on inhalation more than exhalation, whereas variable intrathoracic lesions tend to obstruct more on exhalation. This produces the characteristic flow-volume patterns.

In addition to diagnostic uses, spirometry is used to assess the indication for, and efficacy of, treatment. For example, the obstruction in patients with asthma is usually reversible, either gradually over time without intervention or much more rapidly after treatment with a short-acting bronchodilator. An improvement in FEV<sub>1</sub> of 12% and 200 mL is considered a positive response. In addition to confirming the diagnosis of asthma, the degree of airflow obstruction, as indicated by the FEV<sub>1</sub>, is one measure of asthma control. A low FEV<sub>1</sub> or an acute decrease from baseline may indicate a child whose asthma is not under good control and therefore who potentially is at greater risk for a perioperative exacerbation (see Fig. 11-3).

Because it measures the amount of air entering or leaving the lung rather than the amount of air in the lung, spirometry cannot provide data about absolute lung volumes. Information about FRC and lung volumes calculated from FRC, such as total lung capacity and residual volume, must be obtained by different means, such as gas dilution or body plethysmography. Gas dilution is based on measuring the dilution of nitrogen or helium in a circuit in closed connection to the lungs, whereas body plethysmography calculates lung gas volumes based on changes in thoracic pressures.

## Perioperative Etiology and Epidemiology

Respiratory problems account for most of the perioperative morbidity in children,<sup>6,7</sup> and cause almost one third of perioperative pediatric cardiac arrests.<sup>8</sup> Adverse events include laryngospasm, airway obstruction, bronchospasm, hemoglobin oxygen desaturation, prolonged coughing, atelectasis, pneumonia, and respiratory failure.<sup>4,9,10</sup> The incidence of perioperative adverse respiratory events in one study of 755 children was 34%,<sup>9</sup> whereas in another observational study of 9297 children it was 15%.<sup>4</sup> The triggers of these problems included airway manipulation, alteration of airway reflexes by anesthetic drugs, surgical insult, and depression of breathing caused by anesthetic and analgesic medications. Various diseases common among children can further affect the frequency of respiratory complications in pediatric anesthesia.

Studies have consistently reported greater respiratory morbidity among younger compared with older children.<sup>4,6,7,11-13</sup> In particular, neonates are sensitive to respiratory problems for many reasons. Although the FRC approaches adult capacity (in liters per kilogram) within days after birth, a persistently large closing capacity increases the likelihood of alveolar collapse and intrapulmonary shunt. Residual patency of the ductus arteriosus can contribute to shunting. The greater metabolic rate of the infant increases oxygen requirements and decreases the time to arterial

FVC	Liter	1.41	1.19	84
$FEV_1$	Liter	1.22	0.83	68
$FEV_1/FVC$	Percent	91	70	77

**FIGURE 11-6** Pulmonary function test showing an extrathoracic airway obstruction; both the inspiratory and expiratory limbs of the flow-volume curve are flattened. This child has subglottic stenosis that developed at the site of her tracheotomy 2 years after the tracheostomy was removed.  $FEV_1$ , Forced expiratory volume in 1 second; FVC, forced vital capacity; *Pred*, predicted value.

desaturation after an interruption to ventilation and gas exchange. The work of breathing is greater due to high-resistance, small-caliber airways, increased chest wall compliance, and reduced lung parenchymal compliance.

### UPPER RESPIRATORY TRACT INFECTION

Upper respiratory tract infections (URIs) are a common problem among young children. Children are typically infected several times a year, possibly even more frequently if they are in day care. Viruses cause the majority of URIs, with rhinoviruses constituting approximately one third to one half of etiologic species.<sup>14,14a</sup> Other common respiratory viruses in childhood include adenoviruses and coronaviruses.

Although most URIs are short-lived, self-limited infections and are by definition limited to the upper airway, they may increase airway sensitivity to noxious stimuli or secretions for several weeks after the infection has cleared. The mechanisms probably involve a combination of mucosal invasion, chemical mediators, and altered neurogenic reflexes.<sup>14</sup> URIs may also impair pulmonary function by decreasing FVC,  $FEV_1$ , peak expiratory flow, and diffusion capacity.<sup>15,16</sup>

Compared with uninfected children, children with a recent or current URI have an increased incidence of perioperative laryngospasm, bronchospasm, arterial hemoglobin desaturation, severe coughing, and breath holding (Table 11-3).<sup>4,12,13,17-20</sup> However, most complications can usually be predicted and successfully managed without long-term sequelae by suitably experienced and prepared clinicians.<sup>14,18,20-23</sup> An approach to the child with a URI is to detect the pathologic process and associated

comorbidity, establish the acuteness and severity of the URI, and then decide whether to modify the anesthetic technique or postpone surgery (Table 11-4, Fig. 11-8).

The basis for diagnosing a URI is a careful history and physical examination, with further investigations in limited situations. Because they are usually familiar with their child's state of health, the parents or caregivers can provide helpful insight into the presence and severity of a URI. The child should be evaluated for fever (defined as a temperature greater than 100.4° F [38° C]), change in demeanor or behavior, dyspnea, productive cough, purulent sputum production, nasal congestion, rales, rhonchi, and wheezing. A chest radiograph may be considered if the pulmonary examination is questionable, but because the radiographic changes lag behind clinical symptoms, it is typically of limited value. Although laboratory tests may confirm the

diagnosis of a viral or bacterial URI, they are not cost-effective or practical in a busy surgical setting.

For children with symptoms of an uncomplicated URI who are afebrile with clear secretions and who are otherwise healthy, anesthesia may proceed as planned, because the problems encountered are typically transient and easily managed.<sup>4,14,18,20-23</sup> Elective surgery is usually postponed for children with more severe symptoms that include at least one of the following: mucopurulent secretions; lower respiratory tract signs (e.g., wheezing) that do not clear with a deep cough; a pyrexia greater than 100.4° F (38° C); or a change in sensorium (e.g., not behaving or playing normally, has not been eating properly).<sup>14,23</sup>

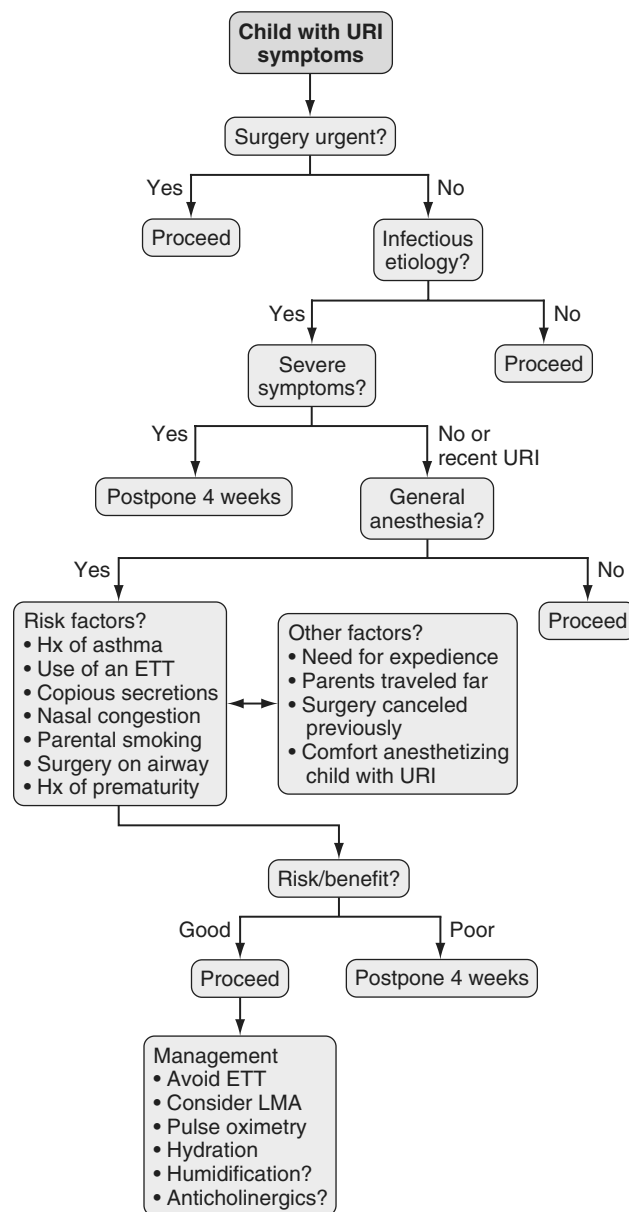

The decision to proceed with surgery becomes much more difficult when the signs of the URI are between the extremes of mild and severe. For these intermediate URIs, other

considerations play a greater role in assessment of the risk/benefit ratio. These include the presence of comorbidities such as asthma, cardiac disease, or obstructive sleep apnea; a history of prematurity; the frequency of URIs; prior cancellations; the type, complexity, duration, and urgency of the surgery; the age of the child; and the socioeconomic implications for the family. The comfort level and experience of the anesthesiologist may also be an underestimated but important factor in the decision to proceed with or postpone surgery, because less experienced anesthesiologists have a greater incidence of complications.<sup>4</sup> The need to admit a child postoperatively because of anesthetic complications or an exacerbation of the URI may expose other children to a contagious illness.

**FIGURE 11-8** Suggested algorithm for assessment and management of the child with an upper respiratory tract infection (URI). ETT, Endotracheal tube; Hx, history; LMA, laryngeal mask airway. (Modified from Tait AR, Malviya S. Anesthesia for the child with an upper respiratory tract infection: still a dilemma? *Anesth Analg* 2005;100:59-65.)

If the decision is to proceed with general anesthesia, management is directed toward avoiding stimulation of the potentially sensitized airway. Use of an endotracheal tube (ETT) should be avoided, if possible, because it increases the risk of complications, especially in younger children.<sup>4,18</sup> Although airway management with a facemask is associated with the smallest frequency of airway complications,<sup>4</sup> it may be inappropriate for certain cases. The laryngeal mask airway (LMA) is associated with fewer episodes of respiratory events than an ETT, but its use may similarly be contraindicated by the type of surgical procedure and the need to protect the airway from pulmonary aspiration of gastric contents. Whichever airway technique is chosen, it is essential that the depth of anesthesia be adequate to obtund airway reflexes during

placement of an airway device. The optimal depth of anesthesia at which to remove an airway device is less clearly defined. Several studies in children with and without URI did not detect a difference in emergence complications between awake and deep extubation,<sup>4,13,18,24</sup> whereas others found a greater incidence of arterial oxygen desaturation or coughing after removal of the ETT or LMA in awake children.<sup>25,26</sup>

The optimal time when an anesthetic can be given after a URI without increasing the risk of adverse respiratory events remains contentious, but most clinicians wait 2 to 4 weeks after the resolution of the URI before proceeding.<sup>4,13,27</sup> This reflects a balance among three critical factors: the time interval to diminish both upper and lower airway hyperreactivity; the perioperative respiratory risk, which includes a recurrence of the URI; and the need to perform the procedure.

Anesthetic techniques may affect complication rates. An observational study of 9297 children reported significantly less laryngospasm after maintenance of anesthesia with propofol than with sevoflurane.<sup>4</sup> This finding might be attributed to a differential effect of propofol versus sevoflurane on airway reflexes.<sup>28</sup> The effect of spraying the cords with lidocaine on the incidence of laryngospasm and bronchospasm is unclear.<sup>4</sup> However, a randomized, controlled trial showed that topical lidocaine gel lubricant applied to the LMA in children with URIs significantly reduced the frequency of adverse airway events.<sup>29</sup> Prophylactic treatment with glycopyrrolate, ipratropium, or albuterol is not effective in preventing URI-related adverse events.<sup>30,31</sup> However, an observational study reported that prophylactic salbutamol was effective in reducing perioperative airway sequelae in children with URIs.<sup>32</sup> Nasal vasoconstrictors (such as phenylephrine or oxymetazoline nose drops) have been recommended for reducing oropharyngeal secretions in children with URIs, but their efficacy remains anecdotal.<sup>23</sup>

## LOWER AIRWAY DISEASE

Acute lower respiratory tract infections in infants and children may result in rapid deterioration necessitating aggressive intervention, including tracheal intubation and ICU admission. Many children are treated with antibiotics on the presumption that the infection is bacterial. However, many may be affected by viruses. In infants and children up to 18 months of age, respiratory syncytial virus is a very serious and common viral infection that infects the lower respiratory tract.<sup>32a</sup> Other viruses include parainfluenza virus, adenovirus, and human metapneumovirus.<sup>32b</sup> Acute inflammation of the small airways may result in bronchiolitis with edema of the small airways leading to desaturation, hypercapnia, and acute respiratory failure. In many instances, bronchiolitis results in several days of tracheal intubation until the acute infection has resolved.

Croup or laryngotracheobronchitis, defined as acute inflammation of the airway (below the vocal cords), has been attributed primarily to parainfluenza virus as well as to adenovirus.

Asthma is one of the most common chronic diseases of childhood, affecting by estimate more than 6 million children in the United States.<sup>33,34</sup> A history of wheezing is associated with an increased risk of perioperative bronchospasm.<sup>4</sup> Rare perioperative complications associated with asthma include anaphylaxis, adrenal crisis, and ventilatory barotrauma such as pneumothorax or pneumomediastinum.<sup>35</sup> An anesthetic approach to children with asthma should include a basic understanding of the disease, an assessment of the child's current state of health, modification

of anesthetic technique as appropriate, and recognition and treatment of complications if they occur.

It is difficult to define asthma with precision, because the exact pathophysiology remains unclear. The word *asthma* derives from the Greek *aazein*, which means "to breathe with open mouth or to pant."<sup>36</sup> A working definition of asthma is a common chronic disorder of the airways that is complex and characterized by variable and recurring symptoms, airway obstruction, inflammation, and hyperresponsiveness of the airways.<sup>33</sup>

Clinical expressions of asthma include wheezing, chest tightness or discomfort, persistent dry cough, and dyspnea on exertion. Severe respiratory distress can occur during acute exacerbations and may be characterized by chest wall retraction, use of accessory muscles, prolonged expiration, pneumothorax, and progression to respiratory failure and death. In some children, the development of chronic inflammation may be associated with permanent airway changes, referred to as *airway remodeling*, that are not prevented by or fully responsive to current available treatments. There is a strong association between asthma and atopy, or immunoglobulin E (IgE)-mediated hypersensitivity.<sup>33</sup>

The diagnosis of asthma can be challenging because cough, wheezing, and bronchospasm may arise from many disease processes. Asthma itself is unlikely to be a single disease entity, and the disease process is markedly modified by various genetic and environmental factors.<sup>33,36</sup> Many young children wheeze, and there is no definitive confirmatory blood, histologic, or radiographic diagnostic test. Given the difficulty with diagnosis, the label "preschool wheezers" may be a more appropriate description for young children with reversible airway obstruction than a diagnosis of "asthma."<sup>36</sup>

The Tucson birth cohort study was the largest longitudinal study in the United States to attempt to differentiate wheezing or asthma phenotypes in children who did not subsequently develop asthma.<sup>37-39</sup> This study examined 826 children at ages 3 years and 6 years from a cohort of 1246 neonates. By the age of 6 years, 48.5% of the children had experienced at least one documented episode of wheezing and were categorized into three groups. "Transient wheezers" were children who wheezed only in response to viral infections, typically during the first 3 years of life. "Non-atopic wheezers" were children who wheezed beyond the first few years of life, often in response to viral infections, but who were less likely to persistently wheeze in later childhood. "Atopy-associated wheezers" were children who had a reversible wheeze together with a tendency toward IgE-mediated hypersensitivity; they had the greatest risk of persistent symptoms into late childhood and adulthood.<sup>37</sup>

The development of asthma is a complex process that probably involves the interaction of two crucial elements: host factors (specifically genetic modifiers of inflammation) and environmental exposures (e.g., viral infections, environmental allergens, pollution) that occur during a crucial time in the development of the immune system.<sup>33</sup> Therefore, the population of young children who wheeze includes a spectrum of disorders rather than one specific pathologic process.

Asthma must be differentiated from other distinct causes that produce similar symptoms (Table 11-5). Tracheomalacia or bronchomalacia may produce wheezing, but this tends to be present from birth (which is unusual for asthma), and the wheezing is commonly of a single pitch heard loudest in the central airways, whereas asthma typically produces polyphonic sounds from the lung periphery. Breathing difficulties due to chronic aspiration are often related to feeding times.

**TABLE 11-5** Causes of Wheezing in Children

<b>Acute</b>	
Bronchiolitis	Pneumothorax
Asthma	Endobronchial intubation
Foreign body	Herniated ETT cuff
Inhalation injury	Aspiration
	Anaphylaxis
<b>Recurrent or Persistent</b>	
Bronchiolitis	Mediastinal mass
Asthma	Tracheomalacia/bronchomalacia
Foreign body	Vascular ring
Bronchopulmonary dysplasia	
Cardiac failure	Tracheal web/stenosis
Cystic fibrosis	Bronchial stenosis
Recurrent aspiration	Roundworm infestation
Sickle cell disease	

ETT, Endotracheal tube.

Unremitting wheeze or stridor is often caused by a fixed obstruction or foreign body.

Chronic cough is the most common manifestation of asthma in children. Many children who cough may never be heard to wheeze but still have asthma. A cough with or without wheeze may be caused by a viral infection, whereas a persistent, productive cough may suggest suppurative lung disease such as CF.<sup>35</sup> A positive response of the cough to asthma medications suggests the diagnosis of asthma.

The exact incidence of perioperative complications in the pediatric asthma population is difficult to ascertain because of variations in the definition of asthma, the definition and detection of complications, the presence of coexisting diseases, overlap with adult populations, and changing anesthetic management techniques.

A retrospective review of 706 adult and pediatric patients with a rigorous definition of asthma found an incidence of documented bronchospasm of 1.7% and no instances of pneumonia, pneumothorax, or death.<sup>40</sup> Of 211 children younger than 12 years of age, none developed bronchospasm at the time of surgery. A retrospective review of more than 136,000 computer-based anesthesia records found a 0.8% incidence of bronchospasm in patients with asthma.<sup>41</sup> By contrast, older studies from the 1960s reported that 7% to 8% of asthmatic patients wheezed.<sup>42,43</sup> A blinded, prospective study of 59 asthmatic patients detected transient wheezing after tracheal intubation in 25% of cases; however, most events were brief and self-limited.<sup>44</sup> An observational study of 9297 children reported an overall incidence of 2% for bronchospasm; in the subgroup of 2256 children with a history of respiratory problems, the incidence was 6%.<sup>4,35</sup> An editorial review of the subject of asthma and anesthesia concluded that, although the true incidence of major complications is small, severe adverse outcomes do result from bronchospasm, and children with asthma are at heightened risk for severe morbidity.<sup>45</sup>

Both the severity and the control of asthma must be established preoperatively. These two aspects of the current disease state should be clearly differentiated.<sup>46</sup> For example, asthma may be severe yet well controlled, whereas even mild asthma may be

poorly controlled. Both situations may present a heightened potential for perioperative complications, because even the child with intermittent but poorly controlled asthma can have a severe exacerbation.

Severity and control may be assessed by the frequency of symptoms, limitation of effort tolerance, night awakenings, medication use, emergency department attendance, hospitalizations, and need for ventilatory support. An approach to assessment of severity and control in children aged 5 to 11 years is outlined in E-Tables 11-1 through 11-3. A history of a nocturnal dry cough, more than three wheezing episodes in the past 12 months, or a history of past or present eczema is associated with an increased risk of bronchospasm.<sup>4</sup>

Maintenance treatment of asthma is based on a stepwise approach, so that the type of therapy is often an indication of severity. Short-acting inhaled  $\beta$ -agonists are first-line therapy, with inhaled corticosteroids for those patients with persistent symptoms poorly managed by bronchodilators as the preferred second step. Alternative treatments at this step include a leukotriene receptor antagonist, a mast cell stabilizer such as cromolyn sodium or nedocromil, and a methylxanthine bronchodilator such as theophylline. The third step in therapy involves increasing the dose of inhaled corticosteroid or adding an alternative treatment to a smaller dose of corticosteroid; a long-acting  $\beta$ -agonist, a leukotriene receptor antagonist, or theophylline may be considered. Step 4 involves a medium dose of corticosteroid together with a long-acting  $\beta$ -agonist. The final steps of therapy involve a high dose of inhaled corticosteroid or commencing an oral corticosteroid (E-Fig. 11-2).

Most children with asthma have disease that is intermittent or persistent but mild and will be treated with inhaled short-acting  $\beta$ -agonists on an as-needed basis, alone or in combination with low-dose inhaled corticosteroids or an adjunctive therapy. Poor control may relate to poor compliance with medication, inadequate inhaler technique, or incorrect diagnosis. Severe asthma is diagnosed when symptom control is poor despite high doses of corticosteroids (steps 5 or 6 in E-Fig. 11-2). A small group of children have “brittle asthma” that is difficult to control despite optimal therapy and may lead to life-threatening respiratory compromise. A history of severe attacks or admission to intensive care is particularly ominous.

Special investigations are not routinely indicated but may be useful in specific circumstances. A chest radiograph is not usually helpful to assess the severity of asthma but can help diagnose a superimposed infection, pneumothorax, or pneumomediastinum during an acute exacerbation. Pulmonary function tests are important in monitoring long-term responses to therapy but are of little use in the immediate, routine preoperative workup of cases at a stable clinical baseline. Measurements of nitric oxide and various inflammatory markers are primarily of use as research tools at present, but their role in asthma management is evolving.<sup>47</sup>

Although an assessment of disease severity is essential, an important caveat is that many asthma deaths in the community setting occur not in those with severe disease but in those with what was thought to be mild or moderate disease. Asthma is often undertreated,<sup>46</sup> so the sensitivity of medication prescription as a marker of disease activity must be viewed with some caution. Some studies have found a poor correlation between assessment of disease severity and the occurrence of perioperative bronchospasm. However, disease *activity*, as noted by recent asthma symptoms, use of medications for symptom treatment, and recent

**E-TABLE 11-1** Classification of Asthma Severity in Children 5 to 11 Years of Age Who Are Not Currently Taking Long-Term Control Medication

Components of Severity*	Intermittent Asthma	PERSISTENT ASTHMA		
		Mild	Moderate	Severe
Impairment				
Symptoms	≤2 days/week	>2 days/week but not daily	Daily	Throughout the day
Nighttime awakenings	≤2 times/month	3-4 times/month	>1 time/week but not nightly	Often 7 times/week
Short-acting β <sub>2</sub> -agonist use for symptom control (not prevention of EIB)	≤2 days/week	>2 days/week but not daily	Daily	Several times per day
Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
Lung function	Normal FEV <sub>1</sub> between exacerbations FEV <sub>1</sub> ≥80% predicted FEV <sub>1</sub> /FVC >85%	FEV <sub>1</sub> /FVC >80% FEV <sub>1</sub> ≥80% predicted	FEV <sub>1</sub> = 60%-80% predicted FEV <sub>1</sub> /FVC = 70%-80%	FEV <sub>1</sub> <60% predicted FEV <sub>1</sub> /FVC <75%
Risk				
Exacerbations <sup>†</sup> requiring oral systemic corticosteroids	0-2/year	≥2 in 1 year		
	Consider severity and interval since last exacerbation. Frequency and severity may fluctuate over time for patients in any severity category.			
	Relative annual risk of exacerbations may be related to FEV <sub>1</sub> .			

Reproduced from National Asthma Education and Prevention Program: Full report of the expert panel: guidelines for the diagnosis and management of asthma (EPR-3). Bethesda, Md.: National Heart, Lung, and Blood Institute, National Institutes of Health; 2007.

EIB, Exercise-induced bronchospasm; FEV<sub>1</sub>, forced expiratory volume in 1 second; FVC, forced vital capacity.

\*Level of severity is determined by both impairment and risk. Assess impairment domain by patient or caregiver recall of the previous 2 to 4 weeks and results of spirometry. Assign severity to the most severe category in which any feature occurs.

<sup>†</sup>Exacerbation is defined as an acute episode of signs and symptoms requiring oral systemic corticosteroids. More than two exacerbations per year indicates persistent asthma. There are no data indicating correspondence of frequency of exacerbations with severity category within the classification of persistent asthma. In general, more frequent exacerbations and more intense exacerbations (e.g., requiring urgent, unscheduled care hospitalization or admission to an intensive care unit) indicate greater underlying disease severity.

**E-TABLE 11-2** Classification of Severity after Asthma Becomes Well Controlled, by Lowest Level of Treatment Required to Maintain Control

	Intermittent Asthma	PERSISTENT ASTHMA		
		Mild	Moderate	Severe
Lowest level of treatment required to maintain control*	Step 1	Step 2	Step 3 or 4	Step 5 or 6

Reproduced from National Asthma Education and Prevention Program: Full report of the expert panel: guidelines for the diagnosis and management of asthma (EPR-3). Bethesda, Md.: National Heart, Lung, and Blood Institute, National Institutes of Health; 2007.

\*See E-Fig. 11-2 for treatment steps.

**E-TABLE 11-3** Assessment of Asthma Control in Children 5 to 11 Years of Age

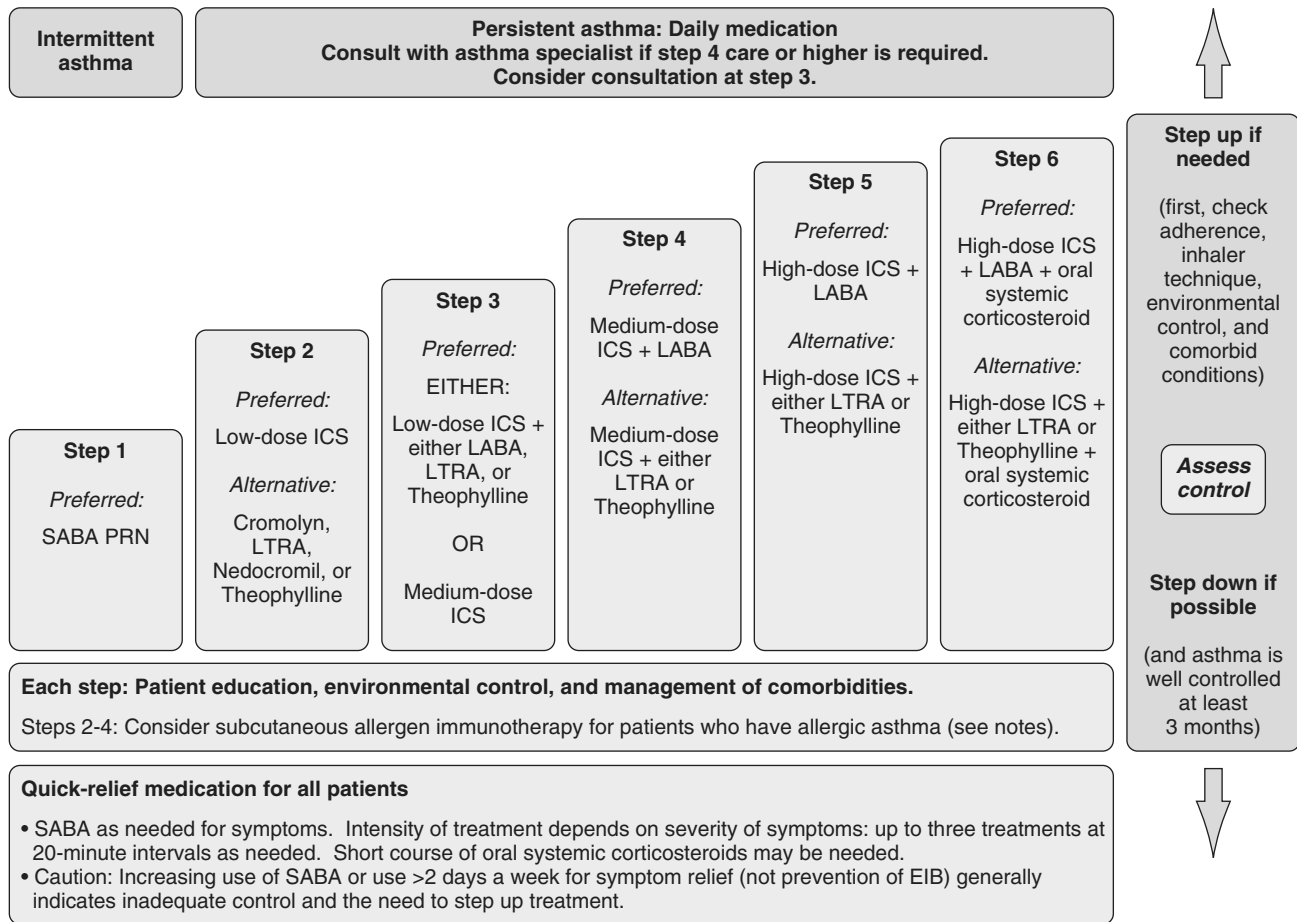

Components of Control*	Well Controlled	Not Well Controlled	Very Poorly Controlled
<b>Impairment</b>			
Symptoms	≤2 days/week but not more than once on each day	>2 days/week or multiple times on <2 days/week	Throughout the day
Nighttime awakenings	≤1 time/month	>2 times/month	>2 times/week
Interference with normal activity	None	Some limitation	Extremely limited
Short-acting $\beta_2$ -agonist use for symptom control (not prevention of EIB)	≤2 days/week	>2 days/week	Several times per day
Lung function			
FEV <sub>1</sub> or peak flow	>80% predicted/personal best	60%-80% predicted/personal best	<60% predicted/personal best
FEV <sub>1</sub> /FVC	>80% predicted	75-80% predicted	<75% predicted
<b>Risk</b>			
Exacerbations <sup>†</sup>	0-1/year	2-3/year	>3/year
Reduction in lung growth	Evaluation requires long-term follow-up.		
Treatment-related adverse effects	Medication side effects can vary in intensity from none to very troublesome and worrisome. The level of intensity does not correlate to specific levels of control but should be considered in the overall assessment of risk.		

Reproduced from National Asthma Education and Prevention Program: Full report of the expert panel: guidelines for the diagnosis and management of asthma (EPR-3). Bethesda, Md.: National Heart, Lung, and Blood Institute, National Institutes of Health; 2007.

EIB, Exercise-induced bronchospasm; FEV<sub>1</sub>, forced expiratory volume in 1 second; FVC, forced vital capacity.

\*The *level of control* is based on the most severe impairment or risk category. Assess impairment domain by patient or caregiver recall of previous 2-4 weeks and by spirometry or peak flow measures. Symptom assessment for longer periods should reflect a global assessment, such as inquiring whether the patient's asthma is better or worse since the last visit.

<sup>†</sup>Exacerbation is defined as an acute episode of signs and symptoms requiring oral systemic corticosteroids.

Key: **Alphabetical order is used when more than one treatment option is listed within either preferred or alternative therapy.**  
ICS, Inhaled corticosteroid; LABA, inhaled long-acting beta<sub>2</sub>-agonist; LTRA, leukotriene receptor antagonist; SABA, inhaled short-acting beta<sub>2</sub>-agonist

#### Notes:

- The stepwise approach is meant to assist, not replace, the clinical decisionmaking required to meet individual patient needs.
- If alternative treatment is used and response is inadequate, discontinue it and use the preferred treatment before stepping up.
- Theophylline is a less desirable alternative due to the need to monitor serum concentration levels.
- Step 1 and 2 medications are based on Evidence A. Step 3 ICS + adjunctive therapy and ICS are based on Evidence B for efficacy of each treatment and extrapolation from comparator trials in older children and adults—comparator trials are not available for this age group; steps 4-6 are based on expert opinion and extrapolation from studies in older children and adults.
- Immunotherapy for steps 2-4 is based on Evidence B for house-dust mites, animal danders, and pollens; evidence is weak or lacking for molds and cockroaches. Evidence is strongest for immunotherapy with single allergens. The role of allergy in asthma is greater in children than in adults. Clinicians who administer immunotherapy should be prepared and equipped to identify and treat anaphylaxis that may occur.

**E-FIGURE 11-2** Stepwise approach for managing asthma in children 5 to 11 years of age. (Reproduced from National Asthma Education and Prevention Program: Full report of the expert panel: guidelines for the diagnosis and management of asthma [EPR-3]. Bethesda, Md.: National Heart, Lung, and Blood Institute, National Institutes of Health; 2007.)

**FIGURE 11-9** **A**, Tracing of expired carbon dioxide (PECO<sub>2</sub>) in a child with acute bronchospasm. Notice the slowly rising PECO<sub>2</sub> value. **B**, Tracing from the same patient after administration of inhaled albuterol. Note that the PECO<sub>2</sub> waveform now has a flat plateau, indicating relief of the bronchospasm and efficient elimination of CO<sub>2</sub> from all areas of the lungs.

therapy in a medical facility for asthma, is significantly associated with perioperative bronchospasm.<sup>40</sup>

Children should continue their regular medications before anesthesia. Midazolam has been reported to be a safe premedication for asthmatics.<sup>48</sup> Corticosteroids may help prevent postintubation bronchospasm in adults,<sup>49</sup> although controlled clinical data to substantiate this practice in children are lacking.<sup>35</sup> Inhaled  $\beta$ -agonists before or shortly after induction of anesthesia attenuate the increases in airway resistance associated with tracheal intubation.<sup>50,51</sup> Ketamine is the traditional choice of intravenous induction agent in children with severe asthma, although its superiority over other agents has not been substantiated in clinical trials.<sup>52,53</sup> Propofol is typically preferred over thiopentone because it causes less bronchoconstriction.<sup>44,54</sup> Desflurane is associated with an increased risk of bronchospasm compared with sevoflurane or isoflurane, and because it can increase airway resistance in children, should be avoided in asthmatics.<sup>4</sup>

Tracheal stimulation is a potent stimulus for bronchospasm.<sup>4</sup> In children with URI, in whom the airways may be acutely hyperactive, the avoidance of tracheal intubation is associated with a reduced incidence of pulmonary complications.<sup>4,17</sup> There are inadequate clinical outcome data on the perioperative management of asthma to make definitive recommendations about airway management. Nevertheless, avoidance of tracheal and vocal cord stimulation by use of a facemask or an LMA instead of an ETT whenever possible seems a sensible approach. If tracheal intubation is mandatory, a deep plane of anesthesia is preferred to blunt airway hyperreactivity. Similarly, unless contraindicated by other factors, deep extubation is preferred for the same reason. Surgical stimulation is another trigger of bronchospasm, and anesthetic depth and analgesia should be adequate to prevent this response.

Intraoperative bronchospasm is characterized variously by polyphonic expiratory wheeze, prolonged expiration, active expiration with increased respiratory effort, increased airway pressures, a slow upslope on the end-tidal CO<sub>2</sub> monitor, increased end-tidal CO<sub>2</sub>, and hypoxemia (Fig. 11-9). Other causes of wheezing must be excluded, such as partial obstruction of the ETT (secretions or herniation of the cuff causing obstruction), main-stem intubation (deep endobronchial intubation), aspiration, pneumothorax, or pulmonary edema. Mechanical obstruction of the circuit or ETT must also be excluded.

First-line treatment for bronchospasm involves removing the triggering stimulus if possible, deepening anesthesia, increasing the fraction of inspired oxygen (FIO<sub>2</sub>) if appropriate, decreasing the positive end-expiratory pressure (PEEP), and increasing the expiratory time to minimize alveolar air trapping. In severe status

**FIGURE 11-10** Adaptor that allows administration of albuterol through an endotracheal tube (ETT) and timing of that dose with inspirations so as to provide maximum delivery; notice that the nebulized albuterol is directed down the ETT (arrow). Use of a long intravenous catheter that extends to the tip of the ETT is an alternative method to further improve drug delivery.

asthmaticus, ventilation strategy focuses primarily on achieving adequate oxygenation, rather than attempting to normalize PaCO<sub>2</sub> at the potential cost of inducing pulmonary barotrauma. All children who experience anything more than minor bronchospasm should also receive corticosteroids, if they have not already done so.

Inhaled  $\beta$ -agonists can be delivered by nebulizer or by a metered-dose inhaler down the airway device with specially designed adaptors (Fig. 11-10). Alternatively, a 60-mL syringe can be used to deliver doses of the nebulizer into the breathing circuit (E-Fig. 11-3). However, the efficiency of delivery through an inhaler that is actuated at the elbow of the breathing circuit is poor, especially in small-diameter ETTs.<sup>55</sup> To improve the delivery efficiency of the aerosol in pediatric-size ETTs, the inhaler may be actuated 10 to 20 times at the elbow or once or twice into a narrow-gauge catheter that is passed to the end of the ETT.<sup>55,56</sup>

If intravenous salbutamol is available, the intravenous route is preferred over tracheal administration. In this case, 10  $\mu$ g/kg IV salbutamol may be repeated, followed by an infusion of 5 to 10  $\mu$ g/kg/min for the first hour until there is an improvement in the bronchospasm. Thereafter, salbutamol should be infused at 1 to 2  $\mu$ g/kg/min until the bronchospasm resolves.

**E-FIGURE 11-3 A and B,** A 60-mL syringe may be attached to a port in the circuit to administer aerosolized drugs such as albuterol.

TABLE 11-6 Formal Evaluation of Asthma Exacerbation Severity

	Mild	Moderate	Severe	Subset: Respiratory Arrest Imminent
<b>Symptoms</b>				
Breathlessness	While walking Can lie down	While at rest (infant—softer, shorter cry, difficulty feeding) Prefers sitting	While at rest (infant—stops feeding) Sits upright	
Talks in	Sentences	Phrases	Words	
Alertness	May be agitated	Usually agitated	Usually agitated	Drowsy or confused
<b>Signs</b>				
Respiratory rate*	Increased	Increased	Increased	
Use of accessory muscles; suprasternal retractions	Usually not	Commonly	Usually	Paradoxical thoracoabdominal movement
Wheeze	Moderate, often only end expiratory	Loud; throughout exhalation	Usually loud; throughout inhalation and exhalation	Absence of wheeze
Pulse/minute <sup>†</sup>	Slightly increased	Increased	Tachycardia	Bradycardia
Pulsus paradoxus	Absent <10 mm Hg	May be present 10-25 mm Hg	Often present >25 mm Hg (adult) 20-40 mm Hg (child)	Absence suggests respiratory muscle fatigue
<b>Functional Assessment<sup>‡</sup></b>				
PEF (% of predicted or of personal best)	≥70%	Approx. 40%-69% or response lasts <2 hours	<40%	<25% (PEF testing may not be needed in very severe attacks)
PaO <sub>2</sub> (while breathing room air)	Normal (test not usually necessary)	≥60 mm Hg (test not usually necessary)	<60 mm Hg: possible cyanosis	
PCO <sub>2</sub>	<42 mm Hg (test not usually necessary)	<42 mm Hg (test not usually necessary)	>42 mm Hg: possible respiratory failure (see text)	
SaO <sub>2</sub> % (while breathing room air) at sea level	>95% (test not usually necessary)	90%-95% (test not usually necessary)	<90%	

Modified from National Asthma Education and Prevention Program: Full report of the expert panel: guidelines for the diagnosis and management of asthma (EPR-3). Bethesda, Md.: National Heart, Lung, and Blood Institute, National Institutes of Health, 2007.

PaO<sub>2</sub>, Arterial oxygen tension; PCO<sub>2</sub>, partial pressure of carbon dioxide; PEF, peak expiratory flow; SaO<sub>2</sub>, oxygen saturation.

\*Guide to rates of breathing in awake children: at age <2 months, normal rate is <60 breaths/minute; at 2-12 months, <50/minute; at 1-5 years, <40/minute; at 6-8 years, <30/minute.

<sup>†</sup>Guide to normal pulse rates in children: at age 2-12 months, normal rate is <160 beats/minute; at 1-2 years, <120/minute; at 2-8 years, <110/minute.

<sup>‡</sup>PaO<sub>2</sub> or PCO<sub>2</sub> or both may be tested. Hypercapnia (hypoventilation) develops more readily in young children than in adults and adolescents.

The anesthesiologist may be involved in the management of status asthmaticus when consulted to assist a child in the emergency department or on the wards. A drowsy, silent child with a quiet chest on auscultation is in imminent danger of respiratory arrest and requires emergent intubation by an experienced practitioner. Signs and symptoms to assess the severity of an asthma exacerbation are outlined in Table 11-6, and an algorithm for management issued by the American National Heart, Lung and Blood Institute is presented in E-Figure 11-4.

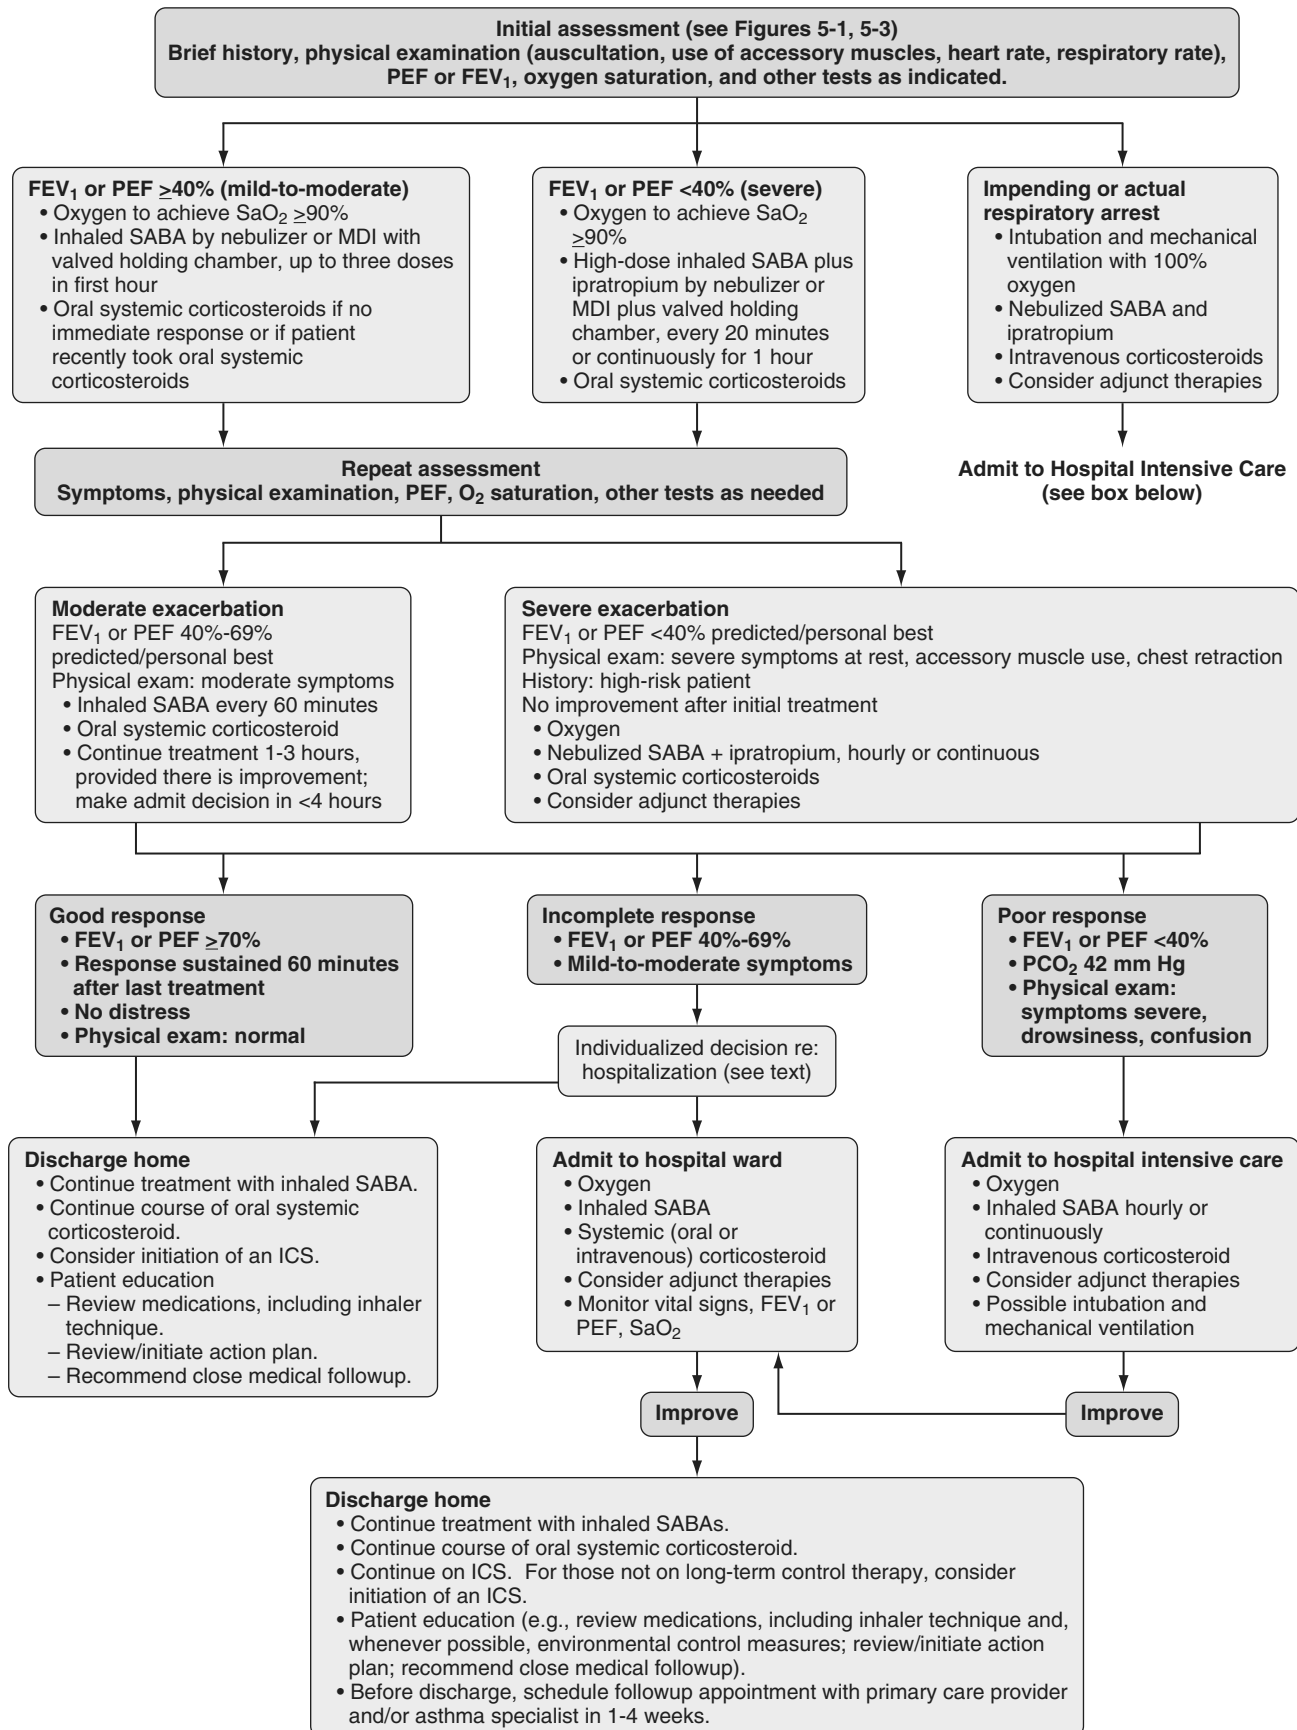

Oxygen is recommended for most children to maintain the oxygen saturation at greater than 90%. Repetitive or continuous administration of short-acting  $\beta$ -agonists is first-line therapy for all children and is the most effective way of reversing airflow obstruction. The addition of ipratropium to a  $\beta$ -agonist may produce additional bronchodilation and may have a modest effect to improve outcome. Systemic corticosteroids should be given to those who do not respond completely and promptly to  $\beta$ -agonists. For severe exacerbations unresponsive to the treatment listed earlier, intravenous magnesium may decrease the

likelihood of intubation, although the evidence is limited. Current recommended drug doses are listed in E-Table 11-4.

There is much debate about the role of methylxanthines such as aminophylline in the management of acute exacerbations of asthma. In some countries, aminophylline is considered a first-line treatment in asthma, whereas in others it is considered second-line or used less frequently. The difference in practice may be attributed to its equivocal clinical efficacy in the treatment of acute exacerbations of asthma and to complications from toxicity (including vomiting).<sup>57-60</sup>

Antibiotics are not recommended except for comorbid conditions. Aggressive hydration is not recommended in adults or older children, although it may be indicated in younger children who become dehydrated as a result of decreased oral intake and increased respiratory rate. In general, chest physical therapy and mucolytics are not recommended.

Children with severe atopy-associated asthma are possibly at greater risk of developing anaphylaxis in response to neuromuscular blocking drugs, antibiotics, and latex.<sup>35</sup> Bronchospasm

**E-FIGURE 11-4** Management of asthma exacerbations in emergency department and hospital-based care. FEV<sub>1</sub>, Forced expiratory volume in 1 second; ICS, inhaled corticosteroid; MDI, metered dose inhaler; PCO<sub>2</sub>, partial pressure carbon dioxide; PEF, peak expiratory flow; SABA, short-acting beta<sub>2</sub>-agonist; SaO<sub>2</sub>, oxygen saturation. Bethesda, Md.: National Heart, Lung, and Blood Institute, National Institutes of Health; 2007.)

**E-TABLE 11-4 Doses of Drugs for Asthma Exacerbations in Emergency Settings or Hospital**

Medication	Adult Dose	Child Dose*	Comments
<b>Inhaled Short-Acting <math>\beta_2</math>-Agonists</b>			
<i>Albuterol</i>			
Nebulizer solution (0.63 mg/3 mL, 1.25 mg/3 mL, 2.5 mg/3 mL, 5.0 mg/mL)	2.5-5 mg every 20 minutes for 3 doses, then 2.5-10 mg every 1-4 hours as needed, or 10-15 mg/hour continuously	0.15 mg/kg (minimum dose 2.5 mg) every 20 minutes for 3 doses, then 0.15-0.3 mg/kg up to 10 mg every 1-4 hours as needed, or 0.5 mg/kg/hour by continuous nebulization	Only selective $\beta_2$ -agonists are recommended. For optimal delivery, dilute aerosols to a minimum of 3 mL at a gas flow of 6-8 L/minute. Use large-volume nebulizers for continuous administration. May mix with ipratropium nebulizer solution.
MDI (90 $\mu$ g/puff)	4-8 puffs every 20 minutes up to 4 hours, then every 1-4 hours as needed	4-8 puffs every 20 minutes for 3 doses, then every 1-4 hours inhalation maneuver as needed. Use valved holding chamber. Add mask in children <4 years.	In mild-to-moderate exacerbations, MDI plus valved holding chamber is as effective as nebulized therapy with appropriate administration technique and coaching by trained personnel.
<i>Bitolterol</i>			
Nebulizer solution (2 mg/mL)	See albuterol dose.	See albuterol dose; thought to be half as potent per milligram as albuterol	Has not been studied in severe asthma exacerbations. Do not mix with other drugs.
MDI (370 $\mu$ g/puff)	See albuterol MDI dose.	See albuterol MDI dose.	Has not been studied in severe asthma exacerbations.
<i>Levalbuterol (R-albuterol)</i>			
Nebulizer solution (0.63 mg/3 mL, 1.25 mg/3 mL)	1.25-2.5 mg every 20 minutes for 3 doses, then 1.25-5 mg every 1-4 hours as needed	0.075 mg/kg (minimum dose 1.25 mg) every 20 minutes for 3 doses, then 0.075-0.15 mg/kg up to 5 mg every 1-4 hours as needed	Levalbuterol administered in one-half the dose of albuterol provides comparable efficacy and safety. Has not been evaluated by continuous nebulization.
MDI (45 $\mu$ g/puff)	See albuterol MDI dose.	See albuterol MDI dose.	—
<i>Pirbuterol</i>			
MDI (200 $\mu$ g/puff)	See albuterol MDI dose.	See albuterol MDI dose; thought to be half as potent per milligram as albuterol	Has not been studied in severe asthma exacerbations.
<b>Systemic (Injected) <math>\beta_2</math>-Agonists</b>			
Epinephrine 1:1000 (1 mg/mL)	0.3-0.5 mg every 20 minutes for 3 doses SC	0.01 mg/kg up to 0.3-0.5 mg every 20 minutes for 3 doses SC	No proven advantage of systemic therapy over aerosol.
Terbutaline (1 mg/mL)	0.25 mg every 20 minutes for 3 doses SC	0.01 mg/kg every 20 minutes for 3 doses, then every 2-6 hours as needed SC	No proven advantage of systemic therapy over aerosol.
<b>Anticholinergics</b>			
<i>Ipratropium bromide</i>			
Nebulizer solution (0.25 mg/mL)	0.5 mg every 20 minutes for 3 doses, then as needed	0.25-5 mg every 20 minutes for 3 doses, then as needed	May mix in same nebulizer with albuterol. Should not be used as first-line therapy; should be added to SABA therapy for severe exacerbations. The addition of ipratropium has not been shown to provide further benefit once the patient is hospitalized.
MDI (18 $\mu$ g/puff)	8 puffs every 20 minutes as needed up to 3 hours	4-8 puffs every 20 minutes as needed up to 3 hours	Should use with valved holding chamber and face mask for children <4 years. Studies have examined ipratropium bromide MDI for up to 3 hours
<i>Ipratropium with albuterol</i>			
Nebulizer solution (each 3-mL vial contains 0.5 mg ipratropium bromide and 2.5 mg albuterol)	3 mL every 20 minutes for 3 doses, then as needed	1.5 mL every 20 minutes for 3 doses, then as needed	May be used for up to 3 hours in the initial management of severe exacerbations. The addition of ipratropium to albuterol has not been shown to provide further benefit once the patient is hospitalized.

**E-TABLE 11-4** Doses of Drugs for Asthma Exacerbations in Emergency Settings or Hospital—cont'd

Medication	Adult Dose	Child Dose*	Comments
MDI (each puff contains 18 µg ipratropium bromide and 90 µg albuterol)	8 puffs every 20 minutes as needed up to 3 hours	4-8 puffs every 20 minutes as needed up to 3 hours	Should use with valved holding chamber and facemask for children <4 years.
<b>Systemic Corticosteroids</b>			
Prednisone	40-80 mg/day in 1 or 2 divided doses until PEF reaches 70% of predicted or personal best	1 mg/kg in 2 divided doses (maximum = 60 mg/day) until PEF is 70% of predicted or personal best	For outpatient "burst," use 40-60 mg in single or 2 divided doses for 5-10 days in adults (children: 1-2 mg/kg/day, maximum 60 mg/day, for 3-10 days).

*Notes:*

- There is no known advantage for higher doses of corticosteroids in severe asthma exacerbations, nor is there any advantage for intravenous administration over oral therapy, provided gastrointestinal transit time or absorption is not impaired.
- The course of systemic corticosteroids for an asthma exacerbation requiring an emergency department visit or hospitalization may last from 3 to 10 days. For corticosteroid courses of less than 1 week, there is no need to taper the dose. For slightly longer courses (e.g., up to 10 days), there probably is no need to taper, especially if patients are concurrently taking inhaled corticosteroids.
- Inhaled corticosteroids can be started at any point in the treatment of an asthma exacerbation.

ED, Emergency department; MDI, metered-dose inhaler; PEF, peak expiratory flow; SABA, short-acting β-agonists; SC, subcutaneous.

\*Children <12 years of age.

caused by anaphylaxis is differentiated from that due to asthma; it produces additional systemic signs such as angioedema, flushing, urticaria, and cardiovascular collapse.

Adrenal crisis during major surgical stress is a potential complication associated with severe asthma due to iatrogenic suppression of the hypothalamic-pituitary-adrenal axis.<sup>35</sup> Adrenal suppression should be considered in any child who is taking significant doses of corticosteroids for a prolonged period. Short courses of prednisolone used to treat acute flares of asthma may affect function for up to 10 days, but prolonged dysfunction is unlikely. Large doses, prolonged therapy for more than a few weeks, and evening dosing may suppress adrenal function for up to 1 year. Prophylactic corticosteroid administration may be indicated for those receiving prolonged systemic corticosteroids, when their corticosteroid regimen is interrupted by the surgical schedule, or for those who have received high-dose inhaled corticosteroids in the recent past (see Chapter 25).

### CYSTIC FIBROSIS

CF is an autosomal recessive disorder that is caused by one of more than 1200 mutations in the gene coding for the CF transmembrane conductance regulator (located on chromosome 7), a protein that contributes to the regulation of chloride and other ion fluxes at various epithelial surfaces.<sup>61,62</sup> The incidence of CF is approximately 1 of every 2000 births in Caucasian, making it the most common fatal inherited disease in this population.

The disruption of electrolyte transport in the epithelial cells of the sweat ducts, airways, pancreatic ducts, intestine, biliary tree, and vas deferens causes increased sweat chloride concentrations, viscous mucus production, lung disease, intestinal obstruction, pancreatic insufficiency, biliary cirrhosis, and congenital absence of the vas deferens. The clinical outcome is widely variable, even among children with identical mutations at the CF locus. Absence of the gene influences expression of several other gene products, including proteins important to the inflammatory response, ion maturational processing, transport, and cell signaling. These other proteins are potential modifiers of the phenotype and may help explain the substantial differences in clinical severity.

Lung disease is the main cause of morbidity and mortality in CF, and consequently it is the focus of anesthetic concern. The pathophysiology involves mucus plugging, chronic infection, inflammation, and epithelial injury.<sup>63-65</sup> Mucus clearance defends the lung against inhaled bacteria. The mucociliary transport system requires two fully functioning layers to be effective. The base layer of ciliary epithelia bathed in a watery liquid (sol) is overlaid by a more viscous gel (mucus) that is responsible for transporting particles along the tips of the cilia. Normally, mucus is transported at about 10 mm/min, expelling foreign particles and pathogens from the lungs. The efficacy of clearance depends on adequate hydration of the mucus.<sup>66</sup> Lack of regulation of sodium absorption and chloride secretion decreases liquid on the airway luminal surfaces, slows mucus clearance, and promotes the formation of adherent plugs in the airway.<sup>67</sup> Increased secretions, viscous mucus, and impaired ciliary clearance contribute to airway impaction, providing a nidus for infection.

At birth, the lung structure is almost normal.<sup>61</sup> However, chronic and recurrent bacterial infections occur early in life, assisted by the pooling of secretions and impaired neutrophil bacterial killing on airway surfaces.<sup>63,68</sup> Repeated and persistent infections stimulate a chronic neutrophilic inflammatory response,

ultimately destroying the airway walls. Early pathogens include *Staphylococcus aureus* and *Haemophilus influenzae*. *Pseudomonas aeruginosa* typically invade later in life, acquire a mucoid phenotype, and form a biofilm in the lung, an event that is associated with accelerated decline in pulmonary function. The invasion of the lung by antibiotic-resistant pathogens such as certain strains of *Burkholderia cepacia* is often devastating, markedly increasing the death rate from lung disease.

Various insults such as bacteria, viruses, and airborne irritants can cause acute exacerbations of respiratory symptoms of cough and sputum production. This is often accompanied by systemic manifestations such as weight loss, anorexia, and fatigue. These changes from baseline are termed *pulmonary exacerbations*.<sup>69</sup>

Recurrent exacerbations are associated with progressive airway obstruction, bronchiectasis, emphysema, ventilation/perfusion mismatching, and hypoxemia. Growth of blood vessels with advancing bronchiectasis predisposes to hemoptysis. Bronchial hyperreactivity and increased airway resistance are common, whereas bullae formation can lead to pneumothorax.

Pulmonary function abnormalities are commonly obstructive in nature and include increased FRC, decreased FEV<sub>1</sub>, decreased peak expiratory flow rate, and decreased vital capacity (see Fig. 11-5). Compensatory hyperventilation typically produces a reduced PaCO<sub>2</sub>, although hypercapnia may supersede in end-stage pulmonary pathology. End-stage cor pulmonale may lead to cardiomegaly, fluid retention, and hepatomegaly.

Malnutrition is a common problem in CF that follows from pancreatic insufficiency, failure of enzyme secretion, impaired gastrointestinal motility, abnormal enterohepatic circulation of bile, increased caloric demand due to severe lung disease, and anorexia of chronic disease.<sup>61</sup> Low weight and body mass index are closely associated with, and can predict, poor lung function.

CF-related diabetes arises from progressive pancreatic disease and scarring that compromises the pancreatic islets. More than 12% of CF teenagers older than 13 years of age have insulin-dependent diabetes, and the incidence increases with age. Evidence is accumulating that diabetes contributes to the lung disease and worse outcome.<sup>63-65</sup> In addition, classic diabetic complications occur in older CF patients. Hepatic dysfunction decreases plasma cholinesterase and clotting factors II, VII, IX, and X, whereas malabsorption of vitamin K may also contribute to coagulation issues.<sup>70</sup>

When CF was first distinguished from celiac syndrome in 1938, life expectancy was approximately 6 months. Since then, substantial advances in sustained multidisciplinary supportive care have increased the median survival time to 35 years (E-Fig. 11-5).<sup>61,71</sup> Currently almost half of the CF population are adults.<sup>70</sup> The pillars of treatment include nutritional repletion, relief of airway obstruction, and antibiotic therapy for lung infection. Suppression of inflammation has been a more recent focus of therapy. Organ transplantation, and in particular lung transplantation, has been used in an attempt to improve quality of life and prolong survival, but a clear benefit remains to be demonstrated.<sup>71</sup>

The multisystem nature of the disease and changing demographics mean that children present for a wide variety of surgical procedures. The most common indications for anesthesia in children are nasal polypectomy and ear, nose, and throat surgery, as a result of the frequency of upper airway pathologic processes such as chronic sinusitis and nasal polyps (Table 11-7).<sup>72,73</sup> The investigation or correction of gastrointestinal disorders is the

**E-FIGURE 11-5** Median survival age for patients with cystic fibrosis at various times since the first description of the disease. Data before 1970 are gleaned from the then-current literature. Data since 1985 are from the Cystic Fibrosis Foundation Data Registry and represent projections of median survival age for a child born in that year with cystic fibrosis. (Reproduced from Davis PB. Cystic fibrosis since 1938. *Am J Respir Crit Care Med* 2006;173:475-82.)

**TABLE 11-7** Most Frequent Indications for Anesthesia in Cystic Fibrosis

Neonates	Children/Teenagers	Adults
Meconium ileus	Nasal polypectomy	Esophageal varices
Meconium peritonitis	Intravenous access	Recurrent pneumothorax

		Lung (liver) transplantation

Modified from Della Rocca G. Anaesthesia in patients with cystic fibrosis. *Curr Opin Anaesthesiol* 2002;15:95-101.

next most common procedural category that requires anesthesia in the CF population. Other indications for anesthesia include bronchoscopy and pulmonary lavage, gastrointestinal endoscopy, sclerosing injection of varices due to portal hypertension, insertion of venous access devices, and incidental surgical problems.<sup>73-75</sup>

Because of the increasing longevity of this population, the pediatric anesthesiologist may also be involved in the care of adults.<sup>70</sup> Surgical procedures in adults typically include treatment of recurrent pneumothorax, cholecystectomy, and lung or cardiac transplantation. Consultation may also be requested for obstetric cases as increasing numbers of patients survive to adulthood.

Pulmonary disease is the predominant concern when planning anesthesia for these patients. Historically, morbidity and mortality from pulmonary complications were significant, but more recently, the mortality rate has decreased. In 1964, a retrospective study reported a perioperative mortality rate of 27%,<sup>76</sup> but by 1972, this incidence had decreased to 4%.<sup>72</sup> More recent studies confirmed a substantial morbidity rate with a low mortality rate. An observational study of 333 anesthetics for bronchoalveolar lavage reported minor complications (transient worsening of cough or low-grade postoperative fever or both) in 52% of patients; more serious problems, including prolonged intraoperative oxygen desaturation or high fever, occurred in 12% of children.<sup>77,78</sup> A report of 45 bronchoscopies under anesthesia noted a rate of minor intraoperative complications (coughing, desaturation) of 13.3%.<sup>79</sup> A study of 199 anesthetics in 53 patients for ear/nose/throat surgery reported a 5% incidence of minor pulmonary problems and no deaths.<sup>80</sup> A report of 126 anesthetics found no mortality and a CF-specific complication rate of 9% (predominantly pulmonary complications).<sup>73</sup> A 1984 study of 18 patients undergoing anesthesia for pleural surgery concluded that, although the risks for this procedure were great, the anesthetic hazards of CF could be minimized with careful management.<sup>81</sup> In 11 patients undergoing anesthesia for injection of esophageal varices, there were no serious anesthetic complications, but significant deteriorations in pulmonary function tests were detected 48 hours after general anesthesia.<sup>82</sup> It was unclear if these changes persisted past the immediate postoperative period. A larger study found no difference between pulmonary function tests measured 3 months before and 3 months after surgery.<sup>73</sup> Although pulmonary morbidity is a significant problem, mortality is infrequent with modern anesthetic management techniques.

An assessment of the severity, current state, and progression of pulmonary disease should guide anesthetic planning. Fitness is a positive predictor of survival,<sup>61</sup> and exercise tolerance is a useful marker of pulmonary function. The quality and quantity

of secretions, recent and chronic infections, use and effectiveness of bronchodilators, and number of hospitalizations are also important points to elucidate in the history. Examination of the cardiopulmonary systems should aim to detect compromise of cardiac, pulmonary, and hepatic function. Special investigations are not routinely indicated but may quantify organ dysfunction in end stages of the disease. Arterial blood gas analysis, chest radiography, pulmonary function tests, electrocardiography, echocardiography, and liver function tests may assist the planning of anesthetic technique in selected children.<sup>75</sup>

Children are often emotionally vulnerable, not simply because of the usual preoperative anxieties but because of the psychological consequences of progression of an ultimately fatal disease. A preoperative visit should aim to allay distress; oral benzodiazepines have been successfully used as anxiolytics.<sup>73,80</sup> Prophylactic use of osmotic laxatives may be indicated if opioid-induced ileus is anticipated.<sup>75</sup>

Because dehydration of secretions is a central pulmonary issue in CF, general anesthesia poses specific problems. During spontaneous ventilation under normal conditions, inspired gases are warmed to body temperature and saturated with water vapor, reaching this state at the isothermic saturation point just distal to the carina.<sup>83,84</sup> This ensures that the lower airways are kept moist and warm. The alveolar environment in optimal circumstances has a saturated water vapor pressure of 47.1 mm Hg and an absolute humidity of 43.4 g/m<sup>3</sup> at 98.6° F (37° C).

The inspiration of cold, desiccated anesthetic gases and vapors can impair the warming and humidification of the airways. The use of any airway device (oropharyngeal airway, laryngeal mask, or ETT) bypasses the nasal and oropharyngeal passages and delivers cold, dry gas farther down the airway.<sup>85</sup> This shifts the isothermic saturation point distally, forcing bronchi that normally function in optimal conditions to take part in heat and gas exchange.<sup>84</sup> These parts of the airway are less adapted to moisture exchange and tend to dehydrate more rapidly, thereby impairing the mucociliary escalator and predisposing to impaction of secretions.<sup>86,87</sup> Direct impairment of mucociliary motion by anesthetic medications, as well as blunting of the cough response and ventilatory drive, can further contribute to the problem.

It is therefore particularly important to minimize mucus desiccation in the perioperative period. Inhalation of hypertonic saline (7% sodium chloride) accelerates mucus clearance, increases lung function, and improves quality of life<sup>88-90</sup>; this is now typically part of the routine maintenance management of CF. Nebulized saline treatments should continue up to the start of anesthesia and recommence after the procedure. Inhaled gases should be humidified, or an artificial "nose" should be inserted into the circuit to conserve airway moisture and minimize inspissation of secretions.

Although removal of pulmonary secretions is considered important in principle, a small prospective trial of intraoperative bronchial wash-out and physical therapy reported an acute increase in airway resistance with no significant long-term benefit in measures of lung function.<sup>91</sup>

At the conclusion of surgery, complete reversal of neuromuscular blockade should be confirmed. Whenever possible, the trachea should be extubated and the child encouraged to breathe spontaneously. A 30- to 40-degree head-up position assists movement of the diaphragm and ventilation. Postoperatively, physiotherapy, airway humidification, close attention to analgesia, and early mobilization should enhance clearance of secretions and minimize atelectasis. The use of regional or local anesthesia, as

well as nonopioid analgesics, is useful to avoid respiratory depression. Ambulatory surgery is optimal, if feasible, because it minimizes disruption to the patient's schedule and decreases exposure to nosocomial infection.

### SICKLE CELL DISEASE

SCD is an inherited hemoglobinopathy that results from a point mutation on chromosome 11. The mutant gene codes for the production of hemoglobin S, a mutant variant of the normal hemoglobin A. This leads to widespread and progressive vascular damage.<sup>92,93</sup> Clinical features of the disease include acute episodes of pain, acute and chronic pulmonary disease, hemorrhagic and occlusive stroke, renal insufficiency, and splenic infarction, with mean life expectancy shortened to just over 3 decades.<sup>94</sup> Perioperative problems and management are covered in more detail in Chapter 9, and the discussion here is limited to a brief review of the pulmonary pathology of SCD.

Acute chest syndrome (ACS) is an acute lung injury caused by SCD. Diagnostic criteria include a new pulmonary infiltrate involving at least one lung segment on the radiograph (excluding atelectasis) combined with one or more symptoms or signs of chest pain, pyrexia greater than 101.3° F (38.5° C), tachypnea, wheezing, or cough.<sup>95-97</sup> Precipitants include infection, fat embolism after bone marrow infarction, pulmonary infarction, and surgical procedures.<sup>97-99</sup> Potential risk factors for the development and severity of perioperative ACS include a history of lung disease, recent clustering of acute pulmonary complications, pregnancy, increased age, and the invasiveness of the surgical procedure.<sup>92</sup> A study of 60 laparoscopic surgeries noted that ACS was associated with younger-age patients, reduced body temperature, and greater blood loss.<sup>100</sup>

Minor procedures such as inguinal hernia repair or distal extremity surgery have a reduced risk of pulmonary complications (<5%), whereas intraabdominal or major joint surgery has an ACS rate of 10% to 15%.<sup>99,101,102</sup> Although the overall perioperative mortality from SCD is quite small, <1%,<sup>99</sup> ACS can lead to prolonged postoperative hospitalization, respiratory failure, and death. One study of 604 patients noted that ACS typically developed about 3 days postoperatively and persisted for approximately 8 days; 2 patients died in approximately 60 episodes.<sup>98</sup>

SCD also causes chronic lung damage, known as sickle cell lung disease (SCLD).<sup>103</sup> Because lung function has not yet been assessed longitudinally in a cohort from early childhood to adulthood, the precise pathology of and relationship between the obstructive and restrictive patterns of lung disease is unclear.<sup>104</sup> Children appear to have a predominantly obstructive pattern,<sup>105</sup> whereas adults have more restrictive pulmonary findings.<sup>103,106,107</sup> The later stages of lung damage involve decreased vital and total lung capacities, impaired gas diffusion, pulmonary fibrosis, pulmonary artery hypertension, right-sided cardiomyopathy, and progressive hypoxemia.<sup>103,107</sup> The development of pulmonary artery hypertension, which can precede clinically apparent lung damage, is a particularly ominous sign of disease progression and is associated with a heightened risk of sudden death.<sup>106</sup> Recurrent ACS is an independent risk factor for the development of end-stage SCLD, but subtle evidence of parenchymal and vascular damage commonly precedes clustered episodes of ACS.<sup>103</sup>

Assessment of lung function should include a history of the occurrence, frequency, severity, and known precipitants of ACS and a search for progression of chronic lung damage. A recent chest radiograph can serve as a baseline for comparison if postoperative radiographs are needed and can also delineate lung

pathology. Early features of lung damage include decreased distal pulmonary vascularity and diffuse interstitial fibrosis, whereas later stages are characterized by pulmonary fibrosis, pulmonary hypertension, and right ventricular hypertrophy.<sup>103,108</sup> Pulmonary function testing can reveal the need for bronchodilators and the presence of obstructive or restrictive lung disease.

The efficacy of preoperative or intraoperative management techniques beyond basic standards of care has not been clearly demonstrated; well-delivered anesthetic and postoperative care may be the best guarantor of a good outcome.<sup>92,93</sup> Because the effect of perioperative red blood cell transfusion (versus no transfusion) in preventing ACS or other SCD complications has not been tested by an adequately controlled study, the efficacy of prophylactic erythrocyte transfusion is controversial. One guideline suggested that children in low-risk situations should not be transfused prophylactically, but children in high-risk situations may be transfused.<sup>92</sup> A survey of North American pediatric anesthesiologists found that most tend not to transfuse children assessed as being at low risk undergoing minor procedures, whereas a greater number do transfuse those at greater risk (i.e., sicker children undergoing more invasive procedures).<sup>109</sup>

If transfusion is undertaken, exchange transfusion aiming to decrease the concentration of hemoglobin S to 30% is no more efficacious than correction of anemia to a hematocrit of 30% in preventing SCD exacerbations but results in more transfusion-related complications.<sup>98</sup> Consequently, if a decision is made to transfuse in the hope of preventing ACS, the target should be a hematocrit of 30% rather than a specific dilution of hemoglobin S.

The one high-risk group that merits mention are children who have experienced or are at risk for a stroke. Risk factors for strokes include low hemoglobin, hypertension, and male gender as well as three single nucleotide polymorphisms.<sup>110,111</sup> Transcranial Doppler ultrasound and magnetic resonance imaging of the brain have been used serially to detect pathologic changes in blood flow or subclinical strokes, respectively, and in these children transfusion has been effective in reducing subsequent strokes.<sup>112,113</sup> Silent cerebral strokes have been detected in up to 30% of asymptomatic children with SCD.<sup>110</sup> To reduce the risk of stroke, these children are transfused at regular intervals, based on the results of the serial investigations. However, this approach raises concern about iron overload and other complications associated with repeated blood transfusions. A recent study to limit the number of transfusions in those at risk for a stroke had to be stopped prematurely because two strokes occurred despite serial transcranial Doppler monitoring.<sup>114</sup> Chronic hydroxyurea therapy has also been shown to be effective in reducing the risk of stroke.<sup>115</sup>

Children with SCD frequently develop postoperative atelectasis. It is unclear whether this relates to an underlying sickle lung disease, difficulty with analgesia, other causes, or a combination of factors. Pain management can be difficult in these children. Large doses of opioids can depress ventilation and cause atelectasis.<sup>116</sup> ACS tends to involve the lower segments of the lung,<sup>97</sup> suggesting an association between atelectasis and ACS. Incentive spirometry can prevent the development of atelectasis and pulmonary infiltrates associated with ACS.<sup>117</sup> Regional analgesia, supplemental nonopioid analgesics, prophylactic incentive spirometry, early mobilization, and good pulmonary toilet may decrease the incidence of atelectasis and ACS.

Treatment of ACS is focused on supporting gas exchange. Supplemental oxygen, noninvasive ventilatory support such as

continuous positive airway pressure, or intubation and mechanical ventilation are indicated by the degree of dysfunction. Bronchodilators, incentive spirometry, and chest physiotherapy may be useful in preventing progression of the disease. In the presence of a significant ventilation/perfusion mismatch, correction of anemia can improve arterial oxygenation. Erythrocyte transfusion increases oxygen-carrying capacity, decreases fractional peripheral tissue extraction, and increases returning venous oxygen levels. Because the mean arterial oxygen content in the presence of a shunt is significantly affected by the oxygenation of blood returning from nonventilated parts of the lung, increasing venous oxygen levels can improve arterial oxygen content. Although transfusion has not been clearly shown to improve outcome, both exchange and simple transfusion can improve oxygenation.<sup>97</sup>

## Summary

Pulmonary complications are a major cause of perioperative morbidity in the pediatric population. Although preexisting pulmonary pathologic processes in children can present significant challenges to anesthetic delivery, a thorough assessment of the problem combined with meticulous anesthetic management allows most children to undergo surgical interventions without long-term adverse sequelae. Consultation with a pediatric pulmonologist is indicated when appropriate for specific problems as outlined in this chapter; a team approach may markedly improve operative and postoperative outcomes.

 **THE DIFFERENCES BETWEEN A** child's airway and an adult's dictate differences in anesthetic management techniques. Knowledge of normal developmental anatomy and physiologic function is required to understand and manage both the normal and the pathologic airways of infants and children (Video 12-1). Techniques and principles to assist in this management are reviewed in this chapter.

## Developmental Anatomy of the Airway

The classic works by Negus, Eckenhoff, and Fink and Demarest form the foundation of our knowledge about the structure and function of the pediatric and adult airway.<sup>1-3</sup> They suggested that there are five major anatomic differences between the neonatal and the adult airway, which are outlined in this section, although more recent studies suggest that not all of these long-held beliefs are supported by science.<sup>2-4</sup> In addition, the relatively large head of an infant negates the need to place anything under the head to achieve a proper "sniffing position." Older children have airway features that represent a transition between the infant and the adult anatomy.

### TONGUE

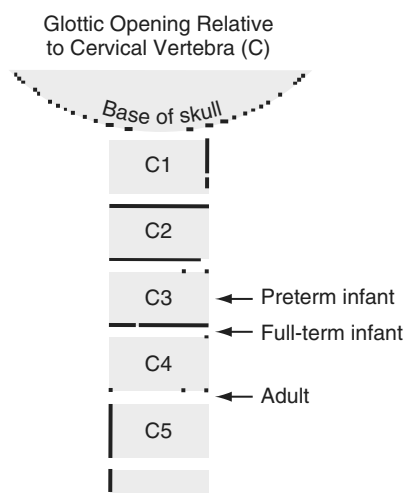

In the past, it was thought that an infant's tongue is relatively large in proportion to the rest of the oral cavity and therefore can more easily obstruct the airway, especially in a neonate. However, magnetic resonance imaging (MRI) studies have now demonstrated that there is proportional growth of the tongue and other soft tissues in relation to the bony structures of the oral cavity in children 1 to 11 years of age.<sup>5</sup> Furthermore, the contribution of the tongue to upper airway obstruction with sedation

or induction of anesthesia is relatively minor; much of the obstruction is more likely due to nasopharyngeal and epiglottic collapse, although in a patient of any age the tongue may also contribute to obstruction.<sup>6,7</sup>

### POSITION OF THE LARYNX

An infant's larynx is higher (more cephalad) in the neck, classically described at the level of C3-4, than an adult's larynx, which is at the level of C4-5 (Fig. 12-1). MRI and computed tomography (CT) have confirmed the higher (more cephalad) position of the larynx in children and demonstrated that the hyoid bone is at the C2-3 level in infants and children up to 2 years of age.<sup>8</sup> Consequently, the distances between the tongue, hyoid bone, epiglottis, and roof of the mouth are smaller in infants than they are in an older child or adult.

The proximity of the tongue to the more superior larynx also makes visualization of laryngeal structures more difficult, because it produces a more acute angle between the plane of the tongue and the plane of the glottic opening. It is for this reason that a straight laryngoscope blade, which lifts the tongue from the field of view during laryngoscopy, facilitates visualization of an infant's larynx. This anatomic relationship is further complicated in certain conditions such as the Treacher Collins anomaly and other syndromes associated with mandibular and midfacial hypoplasia that make direct visualization of the glottis difficult and sometimes impossible with standard laryngoscopy (Fig. 12-2). The reason for this difficulty is that with mandibular and midfacial hypoplasia, the base of the tongue is positioned more caudally (known as glossoptosis) and in closer proximity to the laryngeal inlet than normal; the result is an even greater acute angle between the plane of the tongue and the plane of the

**FIGURE 12-1** In a preterm infant, the larynx is located at the middle of the third cervical vertebra (C3); in a full-term infant, it is at the C3-4 interspace; and in an adult, it is at the C4-5 interspace. (Adapted from Negus VE. The comparative anatomy and physiology of the larynx. Oxford: Butterworth-Heinemann, 1949.)

**FIGURE 12-2** Three-dimensional reconstruction of a child with the Treacher Collins anomaly demonstrates the retrognathic and more posterior position of the mandible, the midfacial hypoplasia, and the closer proximity and exaggerated angle between the base of the tongue and the laryngeal inlet (almost 90 degrees), which makes direct visualization of the larynx difficult.

laryngeal inlet (often 90 degrees) (Fig. 12-3). In this situation, conventional rigid laryngoscopy provides excellent visualization of the esophageal inlet rather than the laryngeal inlet, necessitating the use of special equipment or special techniques to intubate the trachea.

## EPIGLOTTIS

An adult's epiglottis is flat and broad, and its axis is parallel to that of the trachea (Fig. 12-4), whereas the infant's epiglottis is narrower, omega shaped, and angled away from the axis of the trachea (Fig. 12-5). It is therefore more difficult to lift the infant's epiglottis with the tip of a laryngoscope blade.

## VOCAL FOLDS

In contrast to the adult, in whom the axis of the vocal folds is perpendicular to that of the trachea, the vocal folds (cords) of an infant are angled such that the anterior insertion is lower (caudad) compared with the posterior insertion (compare Fig. 12-4, A, with Fig. 12-5, A). This anatomic feature alters the angle at which the tracheal tube approaches the laryngeal inlet and occasionally leads to difficulty with tracheal intubation, especially with the nasal approach. In the latter case, the tip of the endotracheal tube (ETT) may be held up at the anterior commissure of the vocal folds.

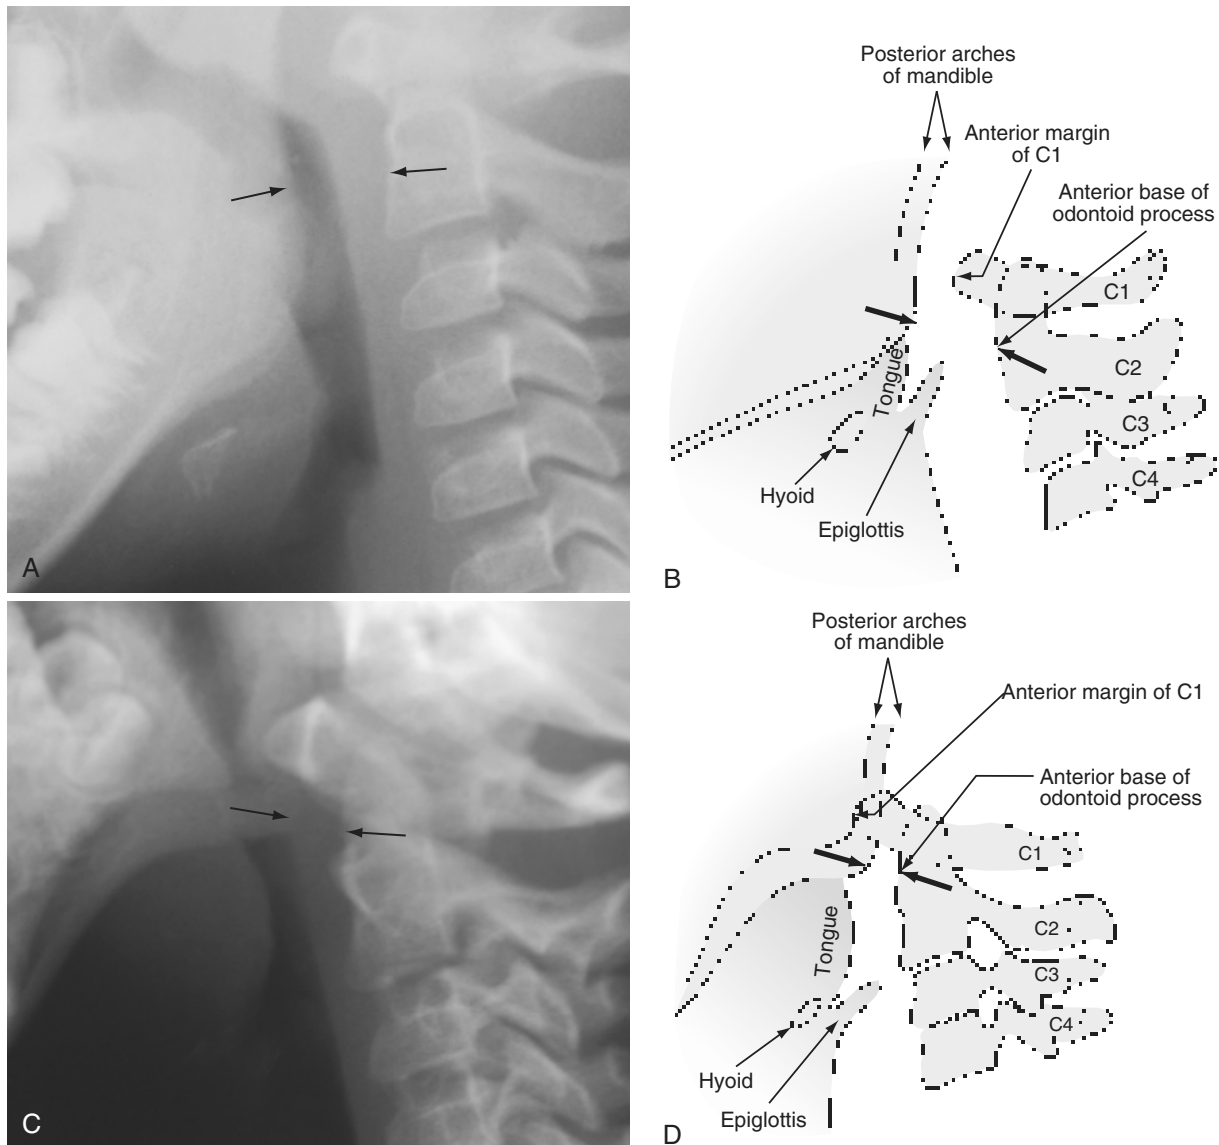

## SUBGLOTTIS

Classic teaching holds that the narrowest part of an infant's larynx is the cricoid cartilage; in an adult, it is the rima glottidis. This teaching was supported by an MRI and CT study in young children (<2 years of age) who were sedated with oral medications and breathing spontaneously.<sup>8</sup> In contrast, a more recent study in children 2 months to 13 years of age undergoing MRI with propofol sedation and spontaneous respirations reported that the narrowest portions of the pediatric larynx were the glottic opening and the immediate sub-vocal cord level and that this finding did not change relative to the dimensions of the cricoid ring throughout childhood.<sup>9</sup> Nonetheless, when a relatively large-diameter tube is inserted into the glottic aperture, the tube passes through the cords but may meet resistance immediately below the cords (e.g., in the subglottic or cricoid ring region). Although these studies demonstrate *in vivo* physiologic relationships, the cricoid cartilage is *functionally* the narrowest portion of the upper airway.

Growth of the subglottic airway occurs rapidly during the first 2 years of life; thereafter, growth of the airway is linear.<sup>10</sup> At 10 to 12 years of age, the cricoid and thyroid cartilages reach adult proportions, thus eliminating both the angulation of the vocal cords and the narrow subglottic area.

In the adult, the rima glottidis is considered the narrowest part of the airway, and an ETT that traverses the glottis passes into the trachea without resistance. However, in about 70% of adult cadavers, the narrowest portion of the airway was also in the subglottic region.<sup>11</sup> The range in diameter for adult females was 10 to 16 mm, and for adult males it was 13 to 19 mm. The likely reason that ETTs pass easily through the glottic opening into the trachea of an adult is that, overall, the narrowest portion of the airway is still larger than the most commonly used ETT sizes. The apparent subglottic narrowing in adults is generally not evident unless there is the need to pass a larger-diameter ETT such as a double-lumen tube. In contrast, in a child, it is common for an ETT to pass easily through the vocal folds (glottic opening) but not through the subglottic region (Fig. 12-6; see Video 12-1). The larynx in both adults and children should be considered funnel shaped, although this configuration is exaggerated and is of greater import in infants and young children.

The cricoid is the only complete ring of cartilage in the laryngotracheobronchial tree and is therefore nondistensible. Because the mucosa that lines the upper airway is loose-fitting

**FIGURE 12-3** The larynx in children with mandibular hypoplasia is located more posteriorly than in children with normal anatomy. **A**, Lateral radiograph of the upper airway including the base of the skull and cervical spine of a normal 7-year-old child; the arrows denote the posterior border of the ramus of the mandible and the anterior border of the second cervical vertebra. **B**, Diagrammatic representation of the normal anatomy in **A**. **C**, The same radiographic projection in a 6-year-old child with Treacher Collins syndrome; the arrows again denote the posterior border of the ramus of the mandible and the anterior margin of the second cervical vertebra. **D**, Diagrammatic representation of the anatomy in **C**. Notice the significantly smaller space between the ramus of the mandible and the second cervical vertebra, compared with the normal anatomy; the anterior margin of the first cervical vertebra overlaps the posterior margin of the mandible. This extreme posterior location of the tongue and larynx makes direct visualization of the laryngeal inlet almost impossible in many children with this anomaly because of the acute angulation between the base of the tongue and the laryngeal inlet. (Radiographs courtesy Donna J. Seibert, MD, John A. Kirkpatrick, Jr., MD, and Robert H. Cleveland, MD.)

pseudostratified columnar epithelium, pressure on the mucosa may cause reactive edema that could encroach on the diameter of the lumen. A tight-fitting ETT that compresses the tracheal mucosa at this level may cause inflammation and edema when it is removed, reducing the luminal diameter and increasing the airway resistance at the time of extubation (e.g., postextubation croup). Because the subglottic region in the infant is smaller than in the adult, the same degree of airway edema results in greater resistance in the infant. For example, assuming that the diameter of the cricoid ring in the infant is 4 mm and the diameter of

the adult cricoid ring or trachea is 8 mm, 1 mm of edema circumferentially within the airway (i.e., reduction of the diameter of the airway by 2 mm) would decrease the cross-sectional area of the airway in the infant by approximately 75% (to 2 mm), whereas the adult cross-sectional area would decrease by only about 44% (to 6 mm). Physiologically, because the resistance to airflow in the upper airway is turbulent during crying or deep breathing, this reduction in diameter of the upper airway would increase the resistance to flow by the radius to the fifth power, or 32-fold, in the infant, compared with 5-fold in the adult. (Fig. 12-7).<sup>2</sup>

**FIGURE 12-4** Lateral neck xerogram (A) and schematic diagram (B) of the larynx in an adult. Notice the relatively thin, broad epiglottis, the axis of which is parallel to the trachea. The hyoid bone “hugs” the epiglottis; there is no subglottic narrowing. Also note how the vocal cords are perpendicular to the axis of the trachea.

**FIGURE 12-5** Lateral neck xerogram (A) and schematic diagram (B) of an infant's larynx. Notice the angled epiglottis and the narrow cricoid cartilage. Also note that the vocal cords are angled with a higher attachment anteriorly than posteriorly compared with the perpendicular position of the vocal cords in adults.

## The Larynx

Understanding the anatomy and function of the larynx is critical to knowledgeable, safe, and successful airway management.

### ANATOMY

#### Structure

The larynx is composed of one bone (hyoid) and eleven cartilages (the single thyroid, cricoid, and epiglottic cartilages and the paired arytenoid, corniculate, cuneiform, and triticea cartilages). These cartilages are suspended by ligaments from the base of the

**FIGURE 12-6** Configuration of the larynx of an adult (A) and an infant (B). Notice that both larynxes are somewhat funnel shaped, but this shape is exaggerated in the infant and toddler. The adult laryngeal structures are of such size that most endotracheal tubes pass easily into the trachea. In infants and toddlers, it is common for the endotracheal tube (ETT) to pass easily through the vocal cords but to become snug at the level of the nondistensible cricoid cartilage. Concern for causing edema at this point resulted in the classic teaching that uncuffed ETTs should be used in young children (see text for more details). A, Anterior; P, posterior.

skull. The body of the cricoid cartilage articulates posteriorly with the inferior cornu of the thyroid cartilage. The paired triangular arytenoid cartilages rest on top of, and articulate with, the superoposterior aspect of the cricoid cartilage. The arytenoid cartilages are protected by the thyroid cartilage (Fig. 12-8). The triticeal cartilages are rounded nodules of cartilage, approximately the size of a pea in adults, located in the margins of the lateral thyrohyoid ligament.

Tissue folds and muscles cover these cartilages. In contrast to adults, but comparable to most mammals, the cartilaginous glottis accounts for 60% to 75% of the length of the vocal folds in children younger than 2 years of age.<sup>10</sup> Contraction of the intrinsic laryngeal muscles alters the position and configuration of these tissue folds, thus influencing laryngeal function during respiration, forced voluntary glottic closure (Valsalva maneuver), reflex laryngospasm, swallowing, and phonation (Fig. 12-9).

The laryngeal tissue folds consist of the following:

- Paired aryepiglottic folds extending from the epiglottis posteriorly to the superior surface of the arytenoids (the paired cuneiform and corniculate cartilages lie within for support and reinforcement)
- Paired vestibular folds (false vocal cords) extending from the thyroid cartilage posteriorly to the superior surface of the arytenoids
- Paired vocal folds (true vocal cords) extending from the posterior surface of the thyroid plate to the anterior projection or vocal process of the arytenoids
- A single interarytenoid fold (composed of the interarytenoid muscle covered by tissue) bridging the arytenoid cartilages
- A single thyrohyoid fold extending from the hyoid bone to the thyroid cartilage

### Histology

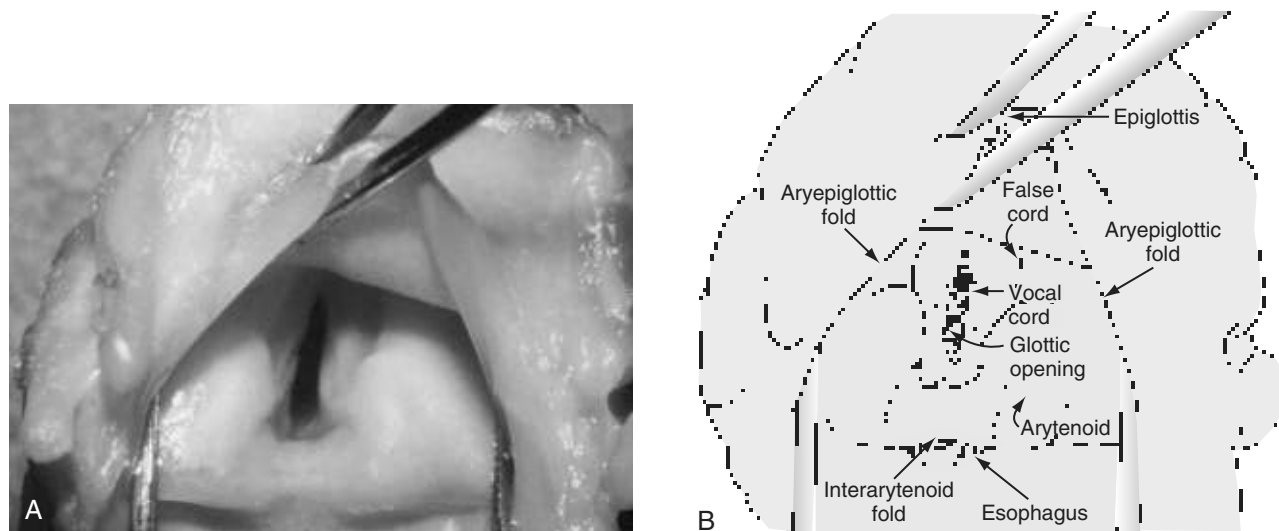

The highly vascular mucosa of the mouth is continuous with that of the larynx and trachea. This mucosa consists of squamous, stratified, and pseudostratified ciliated epithelium. The vocal cords are covered with stratified epithelium. The mucosa and submucosa are rich in lymphatic vessels and seromucus-secreting

**FIGURE 12-7** Relative effects of airway edema in an infant and an adult. The normal airways of an infant and an adult are presented on the left. Edematous airways display 1 mm of circumferential edema, reducing the diameter of the lumen by 2 mm. Notice that resistance to airflow is inversely proportional to the radius of the lumen to the fourth power for laminar flow (beyond the fifth bronchial division) and to the radius of the lumen to the fifth power for turbulent flow (from the mouth to the fourth bronchial division). The net result in an infant with a 4-mm diameter airway is a 75% reduction in cross-sectional area and a 16-fold increase in resistance to laminar airflow, compared with a 44% reduction in cross-sectional area and a 3-fold increased resistance in an adult with a similar 2-mm reduction in airway diameter. With turbulent airflow (upper airway), the resistance increases 32-fold in the infant but only 5-fold in the adult.

**FIGURE 12-8** Laryngeal cartilages. The natural positions of the laryngeal cartilages are presented on the left, with the individual cartilages separated on the right. (Reprinted by permission from Fink BR, Demarest RJ. *Laryngeal biomechanics*. Cambridge, Mass.: Harvard University Press, © 1978 by the President and Fellows of Harvard College.)

**FIGURE 12-9** Photograph (A) and schematic diagram (B) of the larynx of a premature infant.

glands, which lubricate the laryngeal folds. The submucosa consists of loose fibrous stroma; therefore, the mucosa is loosely adherent to the underlying structures in most areas. However, the submucosa is scant on the laryngeal surface of the epiglottis and the vocal cords, so the mucosa is tightly adherent in these areas.<sup>12,13</sup> Most inflammatory processes of the airway above the level of the vocal cords are limited by the barrier formed by the firm adherence of the mucosa to the vocal cords.<sup>13</sup> For example, the inflammation of epiglottitis is usually limited to the supraglottic structures, and the loosely adherent mucosa explains the ease with which localized swelling occurs (see Figs. 31-15 and 31-16). In a similar manner, an inflammatory process of the subglottic region (laryngotracheobronchitis) results in significant subglottic edema in the loosely adherent mucosa of the airway below the vocal cords, but it does not usually spread above the level of the vocal cords (see Fig. 31-14, C).<sup>12</sup>

### Sensory and Motor Innervation

Two branches of the vagus nerve, the recurrent laryngeal and the superior laryngeal nerves, supply both sensory and motor innervation to the larynx. The superior laryngeal nerve has two branches: the internal branch, which provides sensory innervation to the supraglottic region, and the external branch, which supplies motor innervation to the cricothyroid muscle. The recurrent laryngeal nerve provides sensory innervation to the subglottic larynx and motor innervation to all other laryngeal muscles.<sup>13,14</sup> Local anesthetic agents injected to block the superior laryngeal nerve result in anesthesia of the supraglottic region down to the inferior margin of the epiglottis and motor blockade of the cricothyroid muscle, which causes relaxation of the vocal cords. Translaryngeal injection of local anesthetic through the cricothyroid membrane or a specific recurrent laryngeal nerve block is required for infraglottic and tracheal anesthesia.<sup>15-17</sup>

## Blood Supply

Laryngeal branches of the superior and inferior thyroid arteries provide the blood supply to the larynx. The recurrent laryngeal nerve and artery lie in close proximity to each other, which accounts for the occasional vocal cord paresis after attempts to control bleeding during thyroidectomy.<sup>18</sup>

## FUNCTION

### Inspiration

During inspiration, the larynx is pulled downward (caudad) by the negative intrathoracic pressure generated by the descent of the diaphragm and contraction of the intercostal muscles. Longitudinal stretching of the larynx results, thus increasing the distance between the aryepiglottic and vestibular folds as well as the distance between the vestibular and vocal folds. When the intrinsic muscles within the larynx contract, the arytenoids move laterally and posteriorly (rocking backward and rotating laterally), thereby increasing the interarytenoid distance and separating as well as stretching the paired aryepiglottic, vestibular, and vocal folds. Overall, inspiration enlarges the laryngeal inlet, both longitudinally (like opening a telescope) and laterally, allowing the passage of greater quantities of air through the airway per unit time.

### Expiration

At the end of expiration, the larynx reverts to its resting position, with longitudinal shortening of the distance between the aryepiglottic, vestibular, and vocal folds (like closing of a telescope). The arytenoids return simultaneously to their resting position by rotating medially and rocking forward, thus decreasing the interarytenoid distance and reducing the tension on the paired aryepiglottic, vestibular, and vocal folds and causing them to thicken.

### Forced Glottic Closure and Laryngospasm

Glottic closure during forced expiration (forced glottic closure or Valsalva maneuver) is voluntary laryngeal closure and is physiologically similar to involuntary laryngeal closure (laryngospasm). Forced glottic closure occurs at several levels. Contraction of the intrinsic laryngeal muscles results in (1) marked reduction in the interarytenoid distance; (2) anterior rocking and medial movement of the arytenoids, causing apposition of the paired vocal, vestibular, and aryepiglottic folds; (3) longitudinal shortening of the larynx that obliterates the space between the aryepiglottic, vestibular, and vocal folds (like complete closing of a telescope). Contraction of an extrinsic laryngeal muscle, the thyrohyoid, pulls the hyoid bone downward (caudad) and the thyroid cartilage upward (cephalad), leading to further closure.<sup>1,3,4,19-22</sup>

Closure of the larynx during laryngospasm is similar to, but not identical to that described for voluntary forced glottic closure. There are two important differences. First, laryngospasm is accompanied by an inspiratory effort, which longitudinally separates the vocal from the vestibular folds. Second, in contrast to forced glottic closure, neither the thyroarytenoid muscle (an intrinsic muscle of the larynx) nor the thyrohyoid muscle contracts; thus, apposition of the aryepiglottic folds and median thyrohyoid folds is minimal. These two differences allow the upper portion of the larynx to be left partially open during mild laryngospasm, resulting in the hallmark high-pitched inspiratory stridor (see Video 12-1).<sup>1,19</sup> Anterior and upward displacement of the mandible (jaw thrust) longitudinally separates the base of the

tongue, the epiglottis, and the aryepiglottic folds from the vocal folds, helping to relieve laryngospasm.<sup>20</sup>

### Swallowing

Glottic closure during swallowing is also similar to that which occurs during forced closure of the glottis. Protection of the glottic opening is achieved primarily by apposition of the laryngeal folds and secondarily by upward (cephalad) movement of the larynx. The upward movement of the larynx brings the thyroid cartilage closer to the hyoid bone, resulting in folding of the epiglottis over the glottic opening.<sup>1,19,21,22</sup> With loss of consciousness or deep sedation, the normal protective mechanism of the larynx may be lost or obtunded, thus predisposing to pulmonary aspiration of pharyngeal contents.

### Phonation

Phonation is accomplished by alteration of the angle between the thyroid and cricoid cartilages (the cricothyroid angle) and by medial movement of the arytenoids during expiration.<sup>1,14,23</sup> These movements result in fine alterations in vocal fold tension during movement of air, causing vibration of the vocal folds. Lesions or malfunctions of the vocal folds (e.g., inflammation, papilloma, paresis) therefore affect phonation. Phonation is the only laryngeal function that alters the cricothyroid angle.<sup>1</sup> Therefore, despite significant airway obstruction during inspiration, it may still be possible to phonate.

## Physiology of the Respiratory System

### OBLIGATE NASAL BREATHING

Infants are considered to be obligate nasal breathers.<sup>24,25</sup> Obstruction of their anterior or posterior nares (nasal congestion, stenosis, choanal atresia) can cause asphyxia.<sup>26-28</sup> Immaturity of coordination between respiratory efforts and oropharyngeal motor and sensory input accounts in part for obligate nasal breathing.<sup>29</sup> Furthermore, because the larynx is higher (more cephalad) in the neck of an infant and oropharyngeal structures are closer together, the tongue rests against the roof of the mouth during quiet respiration, resulting in oral airway obstruction.<sup>25</sup> Multiple sites of pharyngeal airway obstruction may also contribute to airway obstruction when the infant attempts to breathe against a partially obstructed upper airway or with relaxation of upper airway muscle tone after sedation or induction of anesthesia.<sup>30-34</sup>

As the infant matures, the ability to coordinate respiratory and oral function increases. The larynx enlarges and moves down lower (more caudad) in the neck as the cervical spine lengthens and the infant begins to breathe adequately through the mouth. This maturation occurs by age 3 to 5 months. Studies have shown that the ability to breathe through the mouth when the nares are obstructed is age dependent: 8% of preterm infants of 31 to 32 weeks postconceptional age were able to breathe through the mouth in response to nasal occlusion, compared with 28% of more mature preterm infants of 35 to 36 weeks postconceptional age<sup>35</sup>; approximately 40% of full-term infants can switch from nasal to oral breathing.<sup>36</sup> However, more recent data contradict these earlier data. Slow and fast nasal occlusion applied to 17 healthy preterm infants (gestational age, 32 ± 1 weeks; postnatal age, 12 ± 2 days) led to a switch from nasal to oral breathing. The authors attributed the difference in findings to the more extended observation period in their study (>15 seconds).<sup>37</sup> The presence of a nasogastric tube may also significantly affect the

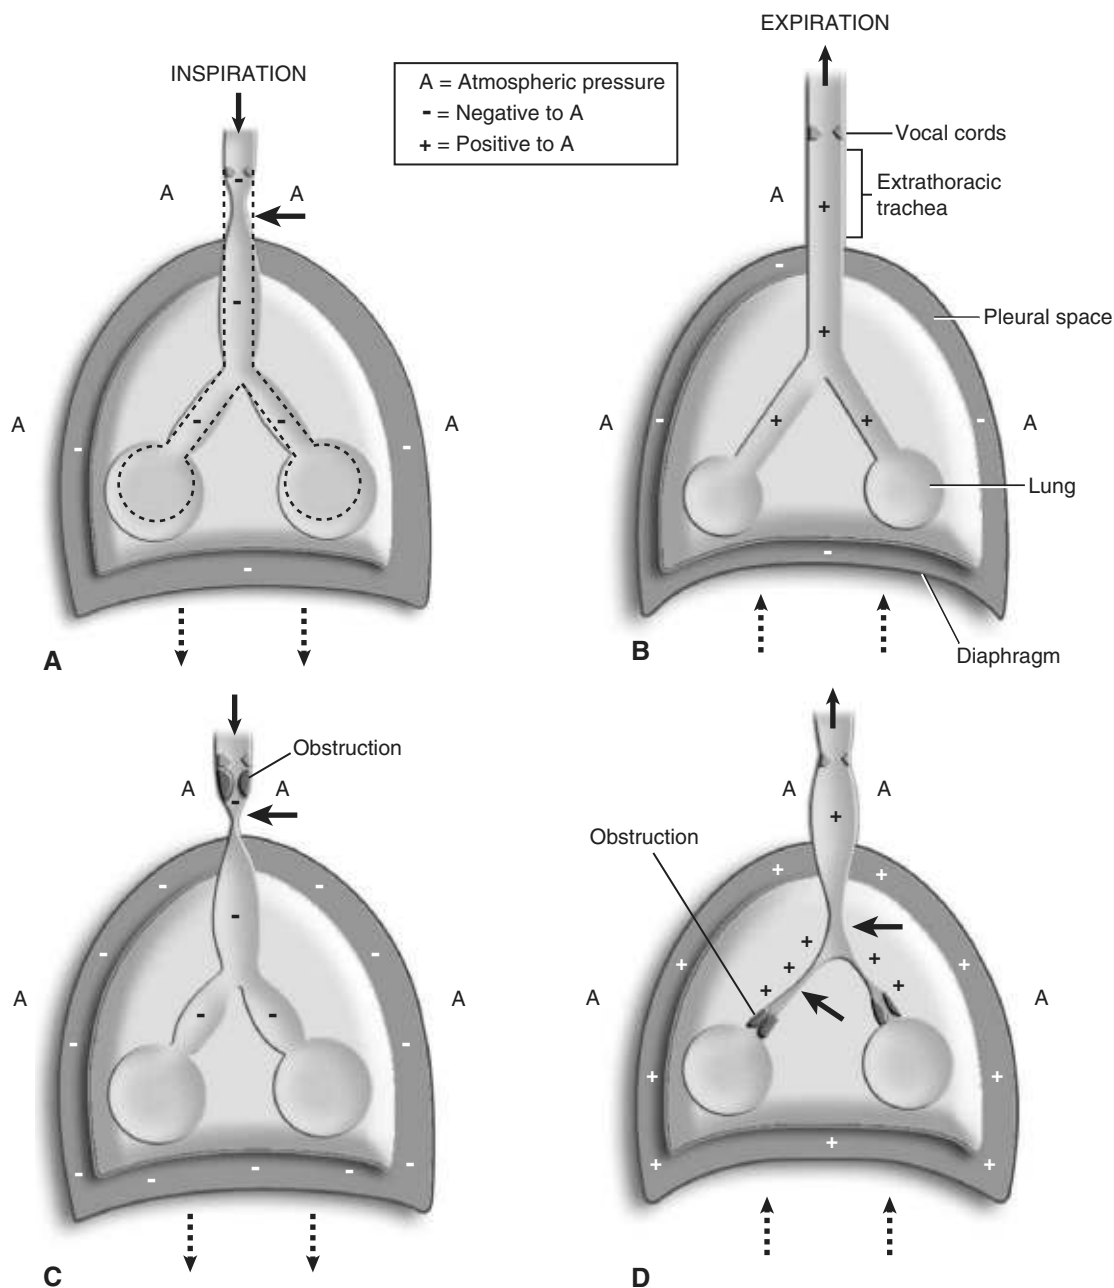

infant's breathing if the "unobstructed" nasal passage has an existing underlying obstruction.

### TRACHEAL AND BRONCHIAL FUNCTION

Tracheal and bronchial diameters are a function of elasticity and of distending or compressive forces (Fig. 12-10). The larynx,

trachea, and bronchi in the infant are quite compliant compared with those in the adult and therefore are more subject to distention and compression forces.<sup>24,38,39</sup> The intrathoracic trachea is subject to stresses that are different from those in the extrathoracic portion.<sup>38</sup> During expiration, intrathoracic pressure remains slightly negative, thus maintaining patency of the intrathoracic

**FIGURE 12-10** **A**, With descent of the diaphragm and contraction of the intercostal muscles, a greater negative intrathoracic pressure relative to intraluminal and atmospheric pressure is developed. The net result is longitudinal stretching of the larynx and trachea, dilatation of the intrathoracic trachea and bronchi, movement of air into the lungs, and some dynamic collapse of the extrathoracic trachea (arrow). The dynamic collapse is due to the highly compliant trachea and the negative intraluminal pressure in relation to atmospheric pressure. **B**, The normal sequence of events at end-expiration is a slight negative intrapleural pressure stenting the airways open. In infants, the highly compliant chest does not provide the support required; therefore, airway closure occurs with each breath. Intraluminal pressures are slightly positive in relation to atmospheric pressure, with the result that air is forced out of the lungs. **C**, Obstructed extrathoracic airway. Notice the severe dynamic collapse of the extrathoracic trachea below the level of obstruction. This collapse is greatest at the thoracic inlet, where the largest pressure gradient exists between negative intratracheal pressure and atmospheric pressure (arrow). (Extrathoracic upper airway obstruction is characterized by inspiratory stridor.) **D**, Obstructed intrathoracic trachea or airways. Notice that breathing against an obstructed lower airway (e.g., bronchiolitis, asthma) results in greater positive intrathoracic pressures, with dynamic collapse of the intrathoracic airways (prolonged expiration or wheezing [arrows]).

trachea and bronchi (see Fig. 12-10, *B*). During inspiration, a greater negative intrathoracic pressure dilates and stretches the *intrathoracic* trachea and bronchi.<sup>40</sup> The *extrathoracic* trachea at the thoracic inlet is slightly narrowed by dynamic compression that results from the differential between intratracheal pressure and atmospheric pressure. However, the cartilages of the trachea, along with the muscles and soft tissues of the neck, maintain patency of the airway (see Fig. 12-10, *A*).

Obstruction of the extrathoracic upper airway that can occur with epiglottitis, laryngotracheobronchitis, or an extrathoracic foreign body alters normal airway dynamics. Inspiration against an obstruction results in more negative intrathoracic pressure, further dilating the intrathoracic airways. Clinically, the net effect is a dynamic collapse of the extrathoracic trachea below the level of the obstruction. This collapse is maximal at the thoracic inlet, where the greatest pressure gradient exists between negative intratracheal and atmospheric pressures. As a result, inspiratory stridor is prominent (see Fig. 12-10, *C*, and Video 12-1).<sup>38-45</sup> With intrathoracic tracheal obstruction (e.g., foreign body, vascular ring) (see Video 12-1), stridor may occur during both inspiration and expiration.<sup>46-49</sup> In lower airway obstruction (e.g., asthma, bronchiolitis), significant intrathoracic tracheal and bronchial collapse may occur as a result of the prolonged expiratory phase and greatly increased positive extraluminal pressure (see Fig. 12-10, *D*).<sup>50</sup> In addition, because the airways in children are very compliant, they may be more susceptible to closure during bronchial smooth muscle contraction (e.g., with reactive airway disease). Preterm and term infants may experience airway closure even during quiet respirations.

Avoiding dynamic airway collapse is particularly important. The very compliant trachea and bronchi of an infant or child are prone to collapse, particularly at the extremes of transmural pressures that may occur when a child is crying vigorously. The susceptibility of a child to these dynamic forces on the airway is inversely related to age, with preterm infants being most susceptible and adults being least susceptible.<sup>51</sup> For this reason, it is essential that children with airway obstruction remain calm. Skill and understanding are required on the parts of the parents, nursing staff, and physicians. *Sedatives and opioids should be used with caution before insertion of an ETT, because they may depress or ablate the life-sustaining voluntary efforts to breathe, resulting in significant morbidity or mortality.*

## WORK OF BREATHING

*Work of breathing* (WOB) may be defined as the product of pressure and volume. It may be analyzed by plotting transpulmonary pressure against tidal volume. The WOB per kilogram body weight is similar in infants and adults. However, the oxygen consumption of a full-term neonate (4 to 6 mL/kg/min) is twice that of an adult (2 to 3 mL/kg/min).<sup>52</sup> This greater oxygen consumption (and greater carbon dioxide production) in infants accounts in part for their increased respiratory frequency compared with older children. In preterm infants, the oxygen consumption related to breathing is three times that in adults.<sup>53</sup>

The location of airway resistance within the tracheobronchial tree differs between infants and adults. The nasal passages account for 25% of the total resistance to airflow in a neonate, compared with 60% in an adult.<sup>25,54</sup> In infants, most resistance to airflow occurs in the bronchi and small airways. This results from the relatively smaller diameter of the airways and the greater compliance of the supporting structures of the trachea and bronchi.<sup>24,55,56</sup>

In particular, the chest wall of a neonate is very compliant; the ribs provide less support to maintain negative intrathoracic pressure. This lack of negative intrathoracic pressure combined with the increased compliance of the bronchi can lead to functional airway closure with every breath.<sup>57-59</sup> In infants and children, therefore, small-airway resistance accounts for most of the WOB, whereas in adults, the nasal passages provide the major proportion of flow resistance.<sup>25,57,58,60-65</sup>

In the presence of increased airway resistance or decreased lung compliance, an increased transpulmonary pressure is required to produce a given tidal volume, and therefore the WOB is increased. Any change in the airway that increases the WOB may lead to respiratory failure. Recall that the WOB (resistance to air flow) is inversely proportional to the fourth power of the radius of the lumen during laminar flow (beyond the fifth bronchial division) and proportional to the fifth power of the radius during turbulent flow (upper airway to the fifth bronchial division). Because the diameter of the airways in infants is smaller than in adults, pathologic narrowing of the airways in infants exerts a greater adverse effect on the WOB. Increase in the WOB may also occur with a long ETT of small diameter, an obstructed ETT, or a narrowed airway. All of these situations increase oxygen consumption, which in turn increases oxygen demand.<sup>66</sup> The increased oxygen demand is initially addressed by an increase in respiratory rate, but the increased WOB may not be sustainable. The end result may be exhaustion, which leads to respiratory failure (CO<sub>2</sub> retention and hypoxemia).

The difference in histology of the diaphragm and intercostal muscles of preterm and full-term infants compared with older children also contributes to increased susceptibility of infants to respiratory fatigue or failure. Type I muscle fibers permit prolonged repetitive movement; for example, long-distance runners through repeated exercise increase the proportion of type I muscle fibers in their legs. The percentage of type I muscle fibers in the diaphragm and intercostal muscles changes with age (preterm infants < full-term infants < 2-year-old children) (Fig. 12-11). Any condition that increases the WOB in neonates and infants may fatigue the respiratory muscles and precipitate respiratory failure more readily than in an adult.<sup>67-69</sup>

**FIGURE 12-11** Muscle fiber composition of the diaphragm and intercostal muscles related to age. Note that a preterm infant's diaphragm and intercostal muscles have fewer type I fibers compared with term newborns and older children. The data suggest a possible mechanism for early fatigue in preterm and term infants when the work of breathing is increased. (Data from Keens TG, Bryan AC, Levison H, Iannuzzo CD. Developmental pattern of muscle fiber types in human ventilatory muscles. *J Appl Physiol* 1978;44:909-13.)

## AIRWAY OBSTRUCTION DURING ANESTHESIA

Airway obstruction during anesthesia or loss of consciousness appears to be most frequently related to loss of muscle tone in the pharyngeal and laryngeal structures rather than apposition of the tongue to the posterior pharyngeal wall.<sup>30,31,70,71</sup> The progressive loss of tone with deepening anesthesia results in progressive airway obstruction primarily at the level of the soft palate and the epiglottis.<sup>30,31,34,70,72,73</sup> In children, the pharyngeal airway space decreases in a dose-dependent manner with increasing concentrations of both sevoflurane and propofol anesthesia.<sup>74-76</sup> This reduction in pharyngeal space has been observed mainly in the anteroposterior dimension. As the depth of propofol anesthesia in children increases, upper airway narrowing occurs throughout the entire upper airway but is most pronounced in the hypopharynx at the level of the epiglottis. Extension of the head at the atlantooccipital joint with anterior displacement of the cervical spine (sniffing position) improves hypopharyngeal airway patency but does not necessarily change the position of the tongue. This observation supports the concept that upper airway obstruction is not primarily caused by changes in tongue position but rather by collapse of the pharyngeal structures.<sup>32-34</sup>

Pharyngeal airway obstruction also occurs during obstructive sleep apnea in infants and adults.<sup>29,77</sup> The sniffing position increases the cross-sectional area and decreases the closing pressure of both the retropalatal and the retroglossal space in anesthetized adults with obstructive sleep apnea.<sup>78</sup> The application of continuous positive airway pressure (CPAP) is a common method to overcome such airway obstruction (see Figs. 31-6 and 31-7). During propofol anesthesia in children, CPAP works primarily by increasing the transverse dimension of the airway.<sup>75</sup> This occurs despite the fact that anesthesia obstructs the airway mostly by narrowing the anteroposterior dimension. Chin lift and jaw thrust also improve airway patency in anesthetized children with adenotonsillar hypertrophy.<sup>79-81</sup> Lateral positioning (also known as the “recovery position”) dramatically enhances the effects of these airway maneuvers<sup>80,81</sup>; lateral positioning alone improves airway dimensions.<sup>6</sup> Compared with chin lift and CPAP, the jaw thrust maneuver is known to be the most effective means to improve airway patency and ventilation in children undergoing adenoidectomy.<sup>79</sup> (See Video 4-3, *A* and *B*.)

## Evaluation of the Airway

A history and physical examination with specific reference to the airway should be performed in all children who require sedation or anesthesia. In particular, a history of a congenital syndrome or physical findings of a congenital anomaly (e.g., microtia, which has been associated with difficult laryngoscopy<sup>82</sup>) should alert the practitioner to the possibility of difficulties with airway management. In special situations, radiologic and laboratory studies are required to further evaluate and clarify a disorder revealed by the history and physical examination. Although many methods exist for evaluating and predicting the difficult airway (DA) in adults,<sup>83-87</sup> no published studies have assessed the use of any of these techniques in children.<sup>88,89</sup> Routine evaluation of the airway in all children, followed by correlation with any airway problems occurring during anesthetic management, helps the practitioner to develop experience. This experience then may be used to identify in the future children who might have airway difficulties during or after anesthesia.

## CLINICAL EVALUATION

The *medical history* (both present and past) should investigate the following signs and symptoms; a positive history should alert the practitioner to the potential problems that are noted in parentheses.

- Presence of an upper respiratory tract infection (predisposition to coughing, laryngospasm, bronchospasm, and desaturation during anesthesia or to postintubation subglottic edema or postoperative desaturation)<sup>90-94</sup>
- Snoring or noisy breathing (adenoidal hypertrophy, upper airway obstruction, obstructive sleep apnea, pulmonary hypertension)
- Presence and nature of cough (“croupy” cough may indicate subglottic stenosis or previous tracheoesophageal fistula repair; productive cough may indicate bronchitis or pneumonia; chronicity affects the differential diagnosis [e.g., the sudden onset of a persistent cough may indicate foreign-body aspiration])
- Past episodes of croup (postintubation croup, subglottic stenosis)
- Inspiratory stridor, usually high pitched (subglottic narrowing [see Video 12-1], laryngomalacia [see Video 12-1], macroglossia, laryngeal web [Video 12-2], extrathoracic foreign body or extrathoracic tracheal compression)
- Hoarse voice (laryngitis, vocal cord palsy, papillomatosis [see Video 12-1], granuloma [see Video 12-1])
- Asthma and bronchodilator therapy (bronchospasm)
- Repeated pneumonias (incompetent larynx with aspiration, gastroesophageal reflux, cystic fibrosis, bronchiectasis, residual tracheoesophageal fistula, pulmonary sequestration, immune suppression, congenital heart disease)
- History of foreign-body aspiration (increased airway reactivity, airway obstruction, impaired neurologic function)
- History of aspiration (laryngeal edema [Video 12-3], laryngeal cleft)
- Previous anesthetic problems, particularly related to the airway (difficult intubation, difficulty with mask ventilation, failed or problematic extubation)
- Atopy, allergy (increased airway reactivity)
- History of smoking by primary caregivers (increased airway resistance, increased propensity to desaturation)<sup>95</sup>
- History of a congenital syndrome (many are associated with DA management)

The *physical examination* should include the following observations:

- Facial expression
- Presence or absence of nasal flaring
- Presence or absence of mouth breathing
- Color of mucous membranes
- Presence or absence of retractions (suprasternal, intercostal, subcostal [see Video 12-1])
- Respiratory rate
- Presence or absence of voice change
- Mouth opening (Fig. 12-12, *A*)
- Size of mouth
- Size of tongue and its relationship to other pharyngeal structures (Mallampati Score)
- Loose or missing teeth (see Fig. 12-12, *B*)
- Size and configuration of palate
- Size and configuration of mandible
- Location of larynx in relation to the mandible (see Fig. 12-12, *C*)

**FIGURE 12-12** **A**, How far can a child open his or her mouth? Are there any abnormalities of the mouth, tongue, palate, mandible? **B**, Are any teeth loose or missing? **C**, Is the mandible of normal configuration? How much space is there between the genu of the mandible and the thyroid cartilage? This space is an indication of the extent of the superior and posterior displacement of the larynx; there should normally be at least one finger breadth in a newborn and three finger breadths in an adolescent.

- Presence of stridor and, if present:
  - Is stridor predominantly inspiratory, suggesting an upper airway (extrathoracic) lesion (epiglottitis, croup, extrathoracic foreign body)?
  - Is stridor both inspiratory and expiratory, suggesting an intrathoracic lesion (aspirated foreign body, vascular ring, or large esophageal foreign body)? (see Video 12-1)
  - Is the expiratory phase prolonged or stridor predominantly expiratory, suggesting lower airway disease?
- Baseline oxygen saturation in room air
- Microtia: Bilateral but not unilateral microtia is associated with difficulty in visualizing the laryngeal inlet (grade 3 or 4 in the Cormack-Lehane classification, see Fig. 12-22).<sup>82</sup> Five (42%) of 12 children with bilateral microtia were found to have a difficult laryngeal view, compared with 2 (2.5%) of 81 children with unilateral microtia and 0 of 93 children without microtia.<sup>82</sup> Microtia may represent a mild form of hemifacial microsomia and its associated mandibular hypoplasia. The advantage of understanding this association is that ear deformity is often a more easily recognized clinical finding than mandibular hypoplasia.
- Global appearance: Are there congenital anomalies that may fit a recognizable syndrome? *The finding of one anomaly mandates a search for others.* If a congenital syndrome is diagnosed, specific anesthetic implications must be considered (see E-Appendix 12-1, which is available online).

## DIAGNOSTIC TESTING

Routine evaluation of the airway usually requires only a careful history and physical examination. In the presence of airway pathology, however, laboratory and radiologic evaluation can be extremely valuable. Radiographs of the upper airway (anteroposterior and lateral films and fluoroscopy) may provide evidence about the site and cause of airway obstruction. When necessary, MRI and CT provide more detailed information.<sup>96-112</sup> *Radiologic airway examination in a child with a compromised airway may be undertaken only if there is no immediate threat to the child's safety and only in the presence of skilled and appropriately equipped personnel able to manage the airway.* Securing the airway through tracheal intubation must not be postponed in order to obtain a radiologic diagnosis when the child has severely compromised air exchange. Blood gas analysis is occasionally of value in assessing the degree of physiologic compromise, especially with chronic airway obstruction and compensated respiratory acidosis. Performing an

arterial (or venous) puncture for blood gas analysis, although providing helpful information, is often upsetting to the child and may risk aggravation of the underlying airway obstruction through dynamic airway collapse. Candidates for blood gas analysis must be carefully selected and the procedure skillfully performed.

Endoscopic evaluation (flexible fiberoptic endoscopy) of the airway before tracheal intubation can be useful in infants and in cooperative older children if a glottic pathologic process is suspected or if difficulty is anticipated when visualizing the glottis.

## Airway Management: The Normal Airway

### MASK VENTILATION

Face masks are available in many sizes and shapes. We commonly use the disposable, clear plastic masks with an inflatable cushioned rim. The inflatable rim molds to the contour of the face to provide an atraumatic seal. The use of clear plastic in the cone of the mask allows visualization of humidity (indicating air exchange), secretions, vomitus, or cyanotic lip color. The appropriately sized mask should rest on the bridge of the nose (avoiding the eyes) and extend to the mandible. Although mask anesthesia appears to be easy, it is, in fact, one of the most difficult skills to master. The most common error during mask ventilation is to tightly compress the submental triangle with fingers placed below the mandibular ridge, thereby partially occluding the airway. Minimal pressure is required, and the fingers should rest on the mandible. Another common problem arises when the mouth is completely closed while the face mask is being applied. The upper airway may become completely obstructed, with ventilation becoming impossible both spontaneously and by manual control. In such a circumstance, the fingers should be removed from the mandible and face and a single digit applied to each coronoid process while lifting toward the hairline. This maneuver sublaxes the temporomandibular joint, thereby opening the mouth and pulling the tongue and other soft tissues off the posterior pharyngeal wall. A hand should be on the reservoir bag at all times to monitor the effectiveness of ventilation and to provide CPAP if needed to maintain a patent airway. An alternative method is to partially close the adjustable pressure-limiting valve to inflate the reservoir bag and provide CPAP. Insertion of an oral airway may also facilitate gas exchange.

Admonitions against extreme positions of the infant's head during bag-and-mask ventilation are intended to minimize the

**FIGURE 12-13** Correct airway selection. An artificial airway of proper size should relieve airway obstruction caused by the tongue without damaging laryngeal structures. The appropriate size can be estimated by holding the airway against the child's face: the tip of the airway should end just cephalad to the angle of the mandible (**A**). Use of the correct size should result in proper alignment with the glottic opening (**B**). If too large an oral airway is inserted, the tip will line up posterior to the angle of the mandible (**C**) and obstruct the glottic opening by pushing the epiglottis down (**D**, arrow). If too small an oral airway is inserted, the tip will line up well above the angle of the mandible (**E**) and exacerbate airway obstruction by kinking the tongue (**F**, arrows).

risk of stretching and thus narrowing and obstructing the very compliant infant trachea. However, a study of 18 healthy, full-term infants younger than 4 months of age showed that the tracheal dimensions did not change when the head position changed.<sup>113</sup> Therefore, stretching of the trachea may not result in narrowing of the tracheal lumen in otherwise healthy infants (Video 12-4). However, this study did not examine the effects of these head positions on the supraglottic airway or in the preterm infant. It is possible that these maneuvers (head extension) could result in supraglottic airway obstruction in some children.

### OROPHARYNGEAL AIRWAYS

An infant's tongue may obstruct the airway during induction of anesthesia or loss of consciousness. An oropharyngeal airway of appropriate size (or a supraglottic airway [SGA] such as the laryngeal mask airway [LMA; LMA North America, San Diego]) may be inserted to relieve the obstruction. By holding the oral airway as shown in Figure 12-13, one can estimate the appropriate size for the child; airways one size larger and one size smaller should be readily available as well. A tongue depressor may be inserted over the tongue to facilitate insertion of the oral airway by preventing downfolding of the tongue, which could impair

venous and lymphatic drainage, causing tongue swelling and airway obstruction. If the airway device is too long, it may push the epiglottis into the glottic aperture, creating an additional site of airway obstruction or causing traumatic epiglottitis, or the tip may impinge on the uvula, causing uvular swelling and airway obstruction (see Fig. 12-13, C, D).<sup>114,115</sup> If the airway device is too short, it may rest against the base of the tongue, forcing it posteriorly against the roof of the mouth and further aggravating airway obstruction (Fig. 12-13, E, F). Oral airways should not be considered panaceas for upper airway obstruction. Care must be taken to avoid trauma to the lips and tongue, which may be caught between the teeth and the flange of the airway. An oral airway is also used to protect an ETT from compression by the child's teeth, and it serves to separate the mandible and maxilla to facilitate oropharyngeal suctioning.

### NASOPHARYNGEAL AIRWAYS

Nasopharyngeal airways are occasionally used in children to relieve upper airway obstruction; the distance from the naris to the angle of the mandible approximates the proper length. Commercial airways are available in sizes 12F to 36F (Rüsch Inc., Duluth, Ga.). Some have an adjustable flange that enables manipulation of the airway to the appropriate length. Alternatively, for infants and small children, a shortened ETT may be used, although this is not as soft and pliable as a commercially available nasopharyngeal airway and may be more likely to cause trauma on insertion. The nasopharyngeal airway may be better tolerated in the lightly anesthetized child than an oropharyngeal airway. Nasopharyngeal airways are usually avoided to prevent trauma to, and bleeding from, hypertrophied adenoids, and they are more commonly used to relieve residual airway obstruction on emergence from anesthesia.

### TRACHEAL INTUBATION

#### Technique

As previously discussed, because of differences in anatomy, there are differences in techniques for intubating the trachea of infants and children compared with adults.<sup>1-4,20-22,101,116,117</sup> Because of the smaller dimensions of the pediatric airway, there is increased risk of obstruction with trauma to the airway structures. A technique to be avoided is that in which the blade is advanced into the esophagus with laryngeal visualization achieved during withdrawal of the blade. *This maneuver may result in laryngeal trauma when the tip of the blade scrapes the arytenoids and aryepiglottic folds.*

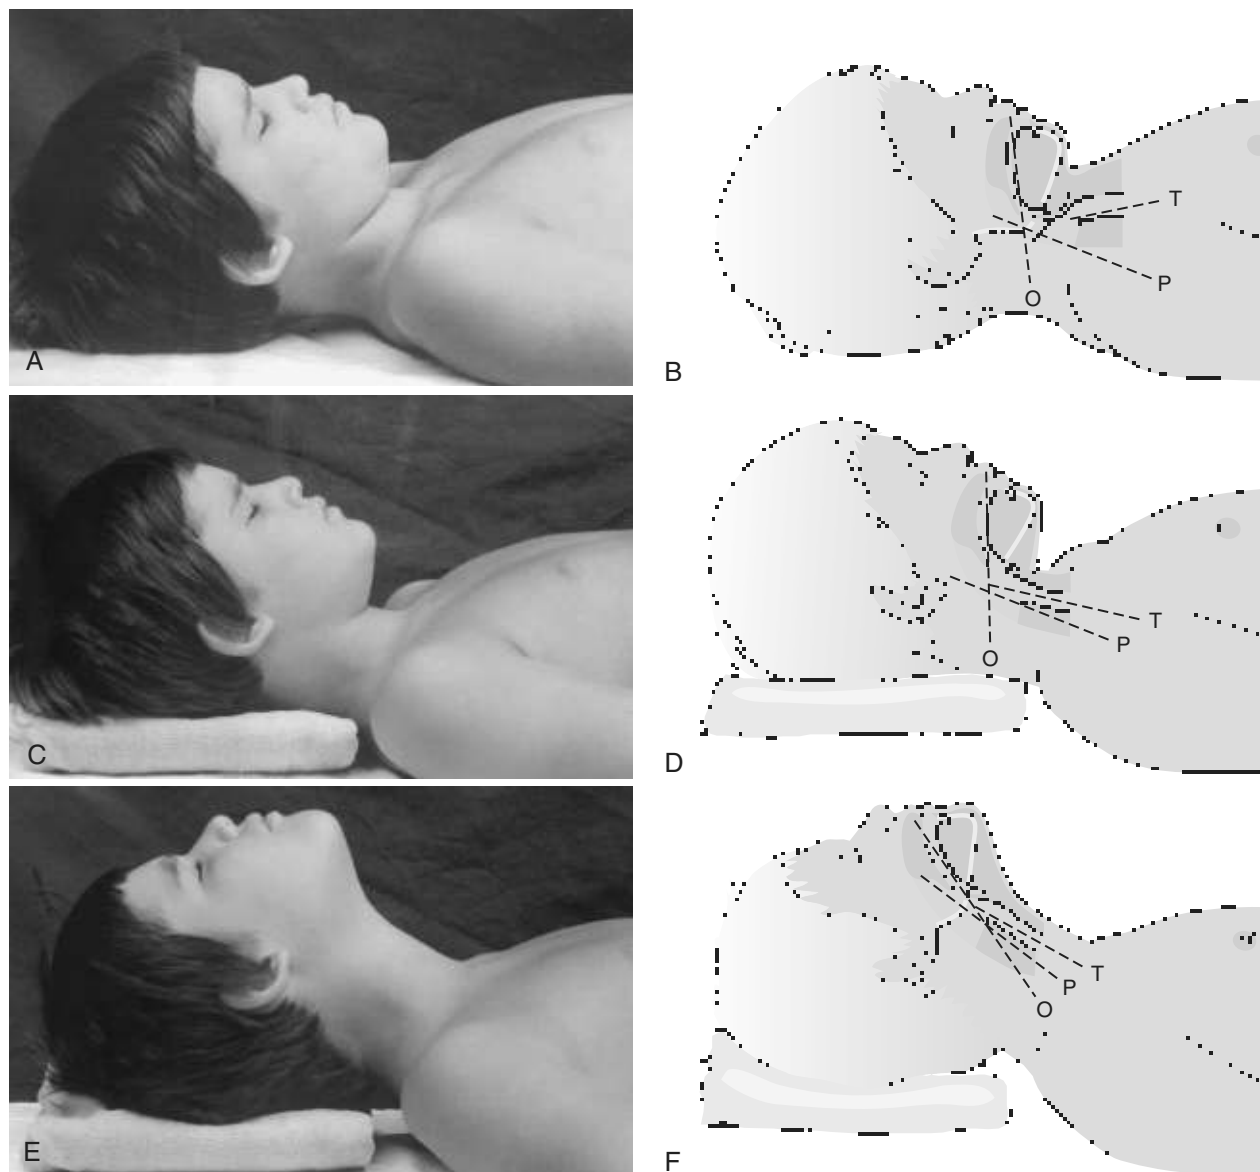

There are several approaches to exposing the glottis in infants with a Miller blade. One approach consists of advancing the laryngoscope blade under constant vision along the surface of the tongue, placing the tip of the blade directly in the vallecula, and then using this location to pivot or rotate the blade to the right to sweep the tongue to the left and adequately lift the tongue to expose the glottic opening. This technique avoids trauma to the arytenoid cartilages. Lifting the base of the tongue lifts the epiglottis, exposing the glottic opening. If this technique is unsuccessful, the epiglottis may be lifted directly with the tip of the blade (see Video 12-1). Another approach is to insert the Miller blade into the mouth at the right commissure over the lateral bicuspid/incisors (paraglossal approach). The blade is advanced down the right gutter of the mouth, aiming the blade tip toward the midline while sweeping the tongue to the left. Once the blade is under the epiglottis, the epiglottis is lifted with the tip, exposing the glottic aperture. By approaching the mouth

over the bicuspid/incisors, dental damage is obviated. This is a particularly effective approach for the infant or child with micrognathia. Whichever approach is used, care must be taken to avoid using the laryngoscope blade as a fulcrum through which pressure is applied to the teeth or alveolar ridge. If there is a substantive risk that pressure will be applied to the teeth, a plastic tooth guard may be applied to cover the teeth at risk (the central incisors of the maxilla).

Optimal positioning for laryngoscopy changes with age. The trachea of older children ( $\geq 6$  years) and adults is most easily exposed when a folded blanket or pillow is placed beneath the occiput of the head (5 to 10 cm elevation), displacing the cervical spine anteriorly.<sup>118</sup> Extension of the head at the atlantooccipital joint produces the classic "sniffing" position.<sup>101,119,120</sup> These movements align three axes: those of the mouth or oral (O), pharynx (P), and trachea (T). Once aligned, these three axes permit direct visualization of laryngeal structures. They also result in improved hypopharyngeal patency.<sup>32,34,70,78,119,120</sup> Figure 12-14 demonstrates maneuvers for positioning the head during airway management. In infants and younger children, it is usually unnecessary to elevate the head because the occiput is large in proportion to the trunk, resulting in adequate anterior displacement of the cervical spine; head extension at the atlantooccipital joint alone aligns the airway axes. If the occiput is displaced excessively, exposure of the glottis may actually be hindered. In neonates, it is helpful for an assistant to hold the patient's shoulders flat on the operating room table with the head slightly extended. Some practitioners have adopted the practice of placing a rolled towel under the shoulders of neonates to facilitate tracheal intubation. This technique may be disadvantageous if the laryngoscopist stands but may be advantageous if he or she is seated.

The validity of the three-axis theory (alignment of the O, P, and T) to describe the optimal intubating position in adults has been challenged.<sup>121-124</sup> Some authors question the notion that elevation of the occiput improves conditions for visualization of the laryngeal inlet based on evidence from both MRI and clinical investigations.<sup>121,123</sup> However, one MRI study in children with an LMA in place found that slight head extension improved the alignment of the glottic and pharyngeal axes but worsened the alignment of the pharyngeal and laryngeal axes.<sup>125</sup> In a study of adults, neck extension alone was adequate for visualization of the larynx in most patients, but for obese patients and those with limited neck extension, an optimal intubating position was not determined.<sup>121</sup> Others favor the sniffing position but with varying support for the three-axis theory.<sup>126-132</sup> Even if the tracheas of only a few patients are intubated more easily when placed in the sniffing position compared with simple head extension, the current routine application of the sniffing position appears to be the best clinical practice.

Laryngoscopy can be performed while the child is awake, anesthetized and breathing spontaneously, or anesthetized and paralyzed. Most tracheal intubations in children who are awake are performed in neonates, an approach that is not usually feasible or humane in older awake and uncooperative children. Awake intubation in the neonate is generally well tolerated if it is performed smoothly and rapidly; however, an international consensus group and others have cautioned against this practice unless intravenous (IV) access is not available or there is a life-threatening situation.<sup>133-136</sup> Data suggest that preterm and term infants are better managed with sedation and paralysis to minimize adverse hemodynamic responses.<sup>137-141</sup>

**FIGURE 12-14** Correct positioning for ventilation and tracheal intubation. When a patient is lying flat on the bed or operating table (**A**), the oral (**O**), pharyngeal (**P**), and tracheal (**T**) axes pass through three divergent planes (**B**). A folded sheet or towel placed under the occiput of the head (**C**) aligns the P and T axes (**D**). Extension of the atlantooccipital joint (**E**) results in alignment of all three axes (**F**).

### Selection of Laryngoscope Blade

A straight blade is generally more suitable for use in infants and young children than a curved blade because it better elevates the base of the tongue to expose the glottic opening. Curved blades are satisfactory in older children. The blade size chosen depends on the age and body mass of the child and the preference of the anesthesiologist. Table 12-1 presents the ranges commonly used.

### Endotracheal Tubes

Since 1967, all materials used in the manufacture of ETTs have been subjected to rabbit muscle implantation testing in accordance with the standards promulgated by the Z79 Committee.<sup>141a</sup> If the material causes an inflammatory response in the rabbits, it cannot be used in the manufacture of ETTs. This has resulted in the elimination of organometallic constituents, which were used in the manufacture of red rubber ETTs.

**TABLE 12-1** Laryngoscope Blades Used in Infants and Children

Age	BLADE SIZE		
	Miller	Wis-Hipple	Macintosh
Preterm	0	—	—
Neonate	0	—	—
Neonate-2 years	1	—	—
2-6 years	—	1.5	1 or 2
6-10 years	2	—	2
>10 years	2 or 3	—	3

Selection of the proper size of an ETT depends on the individual child.<sup>142</sup> The only size requirement for a manufacturer is a standardized inner diameter (ID). The external (outer) diameter (OD) varies among manufacturers, depending on the material from which the ETT is constructed. This diversity in OD

**TABLE 12-2** Endotracheal Tubes (ETTs) Used in Infants and Children

Age	Size (mm ID) Uncuffed	Size (mm ID) Cuffed
Preterm		
1000 g	2.5	
1000-2500 g	3.0	
Neonate-6 months	3.0-3.5	3.0-3.5*
6 month-1 year	3.5-4.0	3.0-4.0
1-2 years	4.0-5.0	3.5-4.5
>2 years	(age in years + 16)/4	(age in years/4) + 3

ID, Inner diameter.  
 \*In some neonates, a cuffed ETT may not have a leak below 30 cm H<sub>2</sub>O, and therefore an uncuffed ETT may be more appropriate.

mandates checking for proper ETT size and leakage around the tube. An appropriately sized uncuffed ETT may be approximated according to the child's age and weight (Table 12-2).<sup>143</sup>

ETTs one-half mm ID greater or less than the anticipated size should be available because of variability in the size of the airway. Use of the diameter of the terminal phalanx of either the second or fifth digit is unreliable.<sup>144</sup> Children with Down syndrome often require an ETT with a diameter smaller than anticipated.<sup>145</sup> After tracheal intubation and stable cardiorespiratory indices are obtained, a sustained inflation to 20 to 25 cm H<sub>2</sub>O (short-term intubation perhaps as high as 35 cm H<sub>2</sub>O) should be applied to detect an audible or auscultatory air leak over the glottis. If no leak is detected, the ETT should be exchanged for one with an ID 0.5 mm smaller. An air leak at this pressure is recommended because it is believed to approximate the capillary pressure of the adult tracheal mucosa. If lateral wall pressure exceeds this amount, ischemic damage to the subglottic mucosa may occur.<sup>146</sup> Be aware, however, that if the trachea has been intubated without muscle relaxants, laryngospasm around the ETT may prevent any gas leak and mimic a tight-fitting ETT.<sup>147</sup> If such a situation is suspected, the anesthetic depth should be increased, and an air leak may become evident. Changes in head position may also increase or decrease the leak.<sup>147</sup> These maneuvers are important for making the occasional diagnosis of unrecognized subglottic stenosis (see Fig. 36-3, and Videos 12-1 and 12-5).

Traditional teaching has advocated the use of uncuffed ETTs for children younger than 8 years, because an uncuffed ETT with an air leak exerts minimal pressure on the internal surface of the cricoid cartilage and thus poses potentially less risk for postextubation edema (croup).<sup>143,146,148</sup> An uncuffed ETT also allows insertion of a tube with a larger ID, resulting in less airway resistance, although this holds relevance only for a spontaneously breathing child.<sup>149</sup> However, more recent clinical data and clinical practice have challenged these assumptions<sup>150-158</sup>; a number of studies demonstrated no differences in the incidence of postextubation complications after cuffed and uncuffed tubes.<sup>150,155</sup> Cited advantages of cuffed ETTs include decreased numbers of laryngoscopies and intubations to determine the appropriate size for the ETT, reduced subglottic pressure, reduced operating room pollution and costs of anesthetic agents, decreased risk of aspiration, accurate control of carbon dioxide tension (PCO<sub>2</sub>), better ability to accurately measure the sophisticated physiologic respiratory functions of modern ventilators, absolute ability to deliver increased airway pressures in children with restrictive lung disease,

**FIGURE 12-15** The MICROCUFF endotracheal tube (MICROCUFF, PET, I-MPEDC; MICROCUFF GmbH, Weinheim, Germany) (*right*) is designed with an ultrathin polyurethane (10  $\mu$ m) high-volume/low-pressure cuff that has a more distal position along the shaft of the tube to better accommodate pediatric anatomy. In contrast to more traditional pediatric cuffed endotracheal tubes (*left*), the elimination of a Murphy eye allows a more distal position of the upper cuff border. The location of the cuff on the shaft of the tube helps to ensure cuff placement below the subglottis—perhaps with the advantage of less risk for endobronchial intubation or intralaryngeal cuff position. An anatomically based depth mark on the surface of the tube helps to guide correct placement.

the ability to control cuff pressure, and no increased risk of postextubation stridor.<sup>150-156,159-161</sup>

A drawback of cuffed tubes is the greater variability in functional OD compared with uncuffed tubes because of differences in cuff shape, size, and inflation characteristics.<sup>162</sup> In general, if a cuffed ETT is inserted, an ETT with a smaller ID should be selected to compensate for the ETT cuff. One study found a 99% rate of appropriate cuffed tube size selection for full-term infants through children 8 years of age using the following formula<sup>155</sup>:

$$\text{ID (mm)} = (\text{age}/4) + 3$$

To overcome the shortcomings of the many pediatric cuffed tubes, the MICROCUFF ETT (MICROCUFF, PET, I-MPEDC; MICROCUFF GmbH, Weinheim, Germany, distributed by Kimberly-Clark USA) was designed with a high volume/low pressure cuff that is more distally placed along the shaft of the ETT to better accommodate the anatomy of the airway in infants and children (Fig. 12-15).<sup>163</sup> The ultrathin polyurethane cuff (10  $\mu$ m) allows tracheal sealing at low pressures and provides a uniform and complete surface contact with minimal formation of cuff folds.<sup>157,159,163-166</sup> At 20 cm H<sub>2</sub>O inflation pressure, the cuffs have a cross-sectional cuff area of approximately 150% of the maximal internal tracheal cross-sectional area. Uninflated, the cuff adds only a minimal amount to the OD of the ETT. Shortened cuffs and the elimination of a Murphy eye allow a more distal position of the cuff, thereby theoretically reducing the risk of pressure being applied to the cricoid ring and adjacent mucosa.<sup>167</sup> The location of the cuff on the shaft of the tube helps to ensure cuff placement below the subglottis, perhaps with the

advantage of less risk for endobronchial intubation or intralaryngeal cuff position. An anatomically based depth mark on the surface of the tube helps to guide correct placement.

An investigation of this specially designed ETT for children used the following guidelines to select cuffed ETT sizes<sup>159</sup>:

- For children  $\geq 2$  years, ID (mm) = (age/4) + 3.5
- For children 1 to 2 years of age, ID 3.5 mm
- For neonates  $\geq 3$  kg and infants  $\leq 1$  year, ID 3.0 mm

Use of these formulas resulted in the need to reintubate to change tube size in 1.6% of children (6/500).<sup>159</sup> The incidence of postintubation croup was 0.4% (2/500 children). In a randomized, multicenter study in 2246 young children (mean age, 1.9 years), investigators reported a similar findings for cuffed (MICROCUFF) and uncuffed tubes: postextubation stridor, 4.4% and 4.7%, respectively, and ETT exchange, 2.1% and 30.8%.<sup>161</sup> However, in a cost/benefit analysis of the MICROCUFF tube (three to six times that of standard ETTs), the reduction in anesthetic cost offset the cost of the MICROCUFF ETT.<sup>160</sup>

As a rule, if a cuffed ETT is chosen, the cuff should be inflated to the minimal pressure that seals the air leak; with the MICROCUFF ETT, this appears to be approximately 10.6 cm H<sub>2</sub>O.<sup>159,161,168,169</sup> This air leak must be reevaluated during the anesthetic procedure if nitrous oxide is used, because the gas may diffuse into the cuff, producing excessive tracheal mucosal pressure.<sup>168-170</sup> In fact, the MICROCUFF ultrathin polyurethane ETT cuff has greater permeability for nitrous oxide than conventional polyvinyl chloride cuffs and therefore may increase the cuff pressure more rapidly than other cuffed tubes. However, with the cuff of the MICROCUFF ETT sealing the air leak at approximately 10 cm H<sub>2</sub>O in children, the time interval to reach 25 cm H<sub>2</sub>O cuff pressure was greater than with a conventional cuffed ETT.<sup>171</sup> Routinely checking cuff pressure or filling the cuff with nitrous oxide is recommended.<sup>172</sup> A pressure relief valve that can be connected to the pilot balloon of a cuffed ETT to limit cuff pressures to 20 cm H<sub>2</sub>O when nitrous oxide is used has been described.<sup>173</sup>

### Endotracheal Tube Insertion Distance

The length of the trachea (vocal cords to carina) in neonates and children up to 1 year of age varies from 5 to 9 cm.<sup>40</sup> In most infants 3 months to 1 year of age, if the 10-cm mark of the ETT is placed at the alveolar ridge, the tip of the tube rests above the carina. In preterm and full-term infants, the distance is less. In children 2 years old, 12 cm is usually appropriate. An easy way to remember these lengths is 10 for a newborn, 11 for a 1-year old, and 12 for a 2-year old. After 2 years of age, the correct length of insertion (in centimeters) for oral intubation may be approximated by formulas based on age or weight (Table 12-3)<sup>174-177</sup>:

$$\begin{aligned} &[\text{Age (yr)}/2] + 12 \\ &[\text{Weight (kg)}/5] + 12 \\ &\text{ID of ETT} \quad 3 \end{aligned}$$

Some practitioners suggest using anatomic markers to choose the appropriate depth for the tube in the trachea in neonates.<sup>178,179</sup> An advantage of anatomic measurements is that the infant's weight may not be available immediately after birth or in sick neonates who present to the emergency department with urgent respiratory or cardiac compromise. One study that used chest radiographs to evaluate final ETT position determined that the length of the foot was as accurate as weight-based formulas to determine the depth of insertion for a nasotracheal tube (44% versus 56% rate of optimal placement, and 83% versus 72%

**TABLE 12-3** Distance for Insertion of an Oral Endotracheal Tube by Patient Age

Age	Approximate Distance of Insertion (cm) Even with Alveolar Ridge
Preterm <1000 g	6-7
Preterm 1000-2000 g	7-9
Term newborn	9-10
1 year	11-12
2 years	12-13
6 years	15-16
10 years	17-18
16 years	18-20
20 years	20-22

satisfactory placement).<sup>179</sup> Alternatively, the nasal-tragus length (the distance from the base of the nasal septum to the tip of the tragus) or the sternal length (the distance from the suprasternal notch to the tip of the xiphoid process) predicted the depth of insertion of the ETT. Either distance plus 1 cm accurately estimated oral ETT tube insertion distance; either distance plus 2 cm accurately estimated nasotracheal tube insertion distance.<sup>178</sup> Both measurements compared favorably with weight-based formulas when tube position was verified by chest radiography.

After the ETT has been inserted and the first strip of adhesive tape has been applied to secure it, one must observe for symmetry of chest expansion and auscultate for equality of breath sounds in the axillae and apices (not on the anterior chest wall). The anterior chest wall in the child is not used to verify tracheal intubation because breath sounds may reverberate across the precordium in small children, precluding the diagnosis of an endobronchial intubation. A CO<sub>2</sub> monitor confirms intratracheal positioning but does not confirm that the tip of the ETT is not in an endobronchial position. A capnogram that diminishes during the first few breaths suggests an esophageal intubation. Unexpectedly increased airway pressures, persistent desaturation, and asymmetrical chest wall movement all suggest an endobronchial intubation. Visible humidity on the walls of the ETT during expiration also confirms tracheal placement, but the humidity may not be visible in younger infants. It is also important to auscultate over the stomach and to observe for desaturation or cyanosis. Once satisfactory position is achieved, a second strip of tape ensures secure fixation (Fig. 12-16).

We have observed a number of children whose ETT moved into a main stem bronchus after initial correct position during repositioning for the surgical procedure; this manifested as a slight but persistent decrease in oxygen saturation (e.g., from 100% to a range of 93% to 95%). Several studies have demonstrated that simple flexion or extension of the neck can move the ETT sufficiently to cause an endobronchial intubation or dislodgement of the tube from the trachea, respectively.<sup>180-182</sup> *When a small but persistent change in oxygen saturation is noted, rather than increase the inspired oxygen concentration (FIO<sub>2</sub>), one must first investigate the cause and reassess the position of the ETT.*<sup>183</sup>

### Complications of Tracheal Intubation

#### Postintubation Croup

Perioperative postintubation croup (also referred to as postextubation croup) occurs in 0.1% to 1% of children.<sup>156,159,184,185</sup> Factors associated with increased risk of croup include an ETT with an

**FIGURE 12-16** Securing the endotracheal tube (ETT). After insertion of the oral ETT and examination for proper position, the area between the nose and upper lip and both cheeks is coated with tincture of benzoin. **A**, After the benzoin is dry, tape that has been split up the middle is applied to the cheek, and the ETT is placed at the division of the split tape. **B**, One half is wrapped circumferentially around the tube, and the other half is applied to the space above the upper lip. **C**, A second piece of tape is applied in similar fashion from the opposite direction. A nasal ETT may also be secured with this technique.

OD that is too large for the child's airway (no leak at >25 cm H<sub>2</sub>O pressure or resistance at the time of insertion), changes in position during the procedure, a position other than supine, repeated attempts at intubation, traumatic intubation, patient age between 1 and 4 years, duration of surgery greater than 1 hour, coughing on the ETT, and previous history of croup.<sup>171,172</sup> Concurrent upper respiratory infection has been variously reported as a risk factor and as unrelated.<sup>90,185</sup>

Treatment of postintubation croup consists of nebulized epinephrine and dexamethasone. The rationale for this treatment is based primarily on experience with the treatment of infectious croup.<sup>186-195</sup> Caution should be exercised when translating treatments from one type of croup to another, because the two types of croup are not identical processes, and efficacy of the interventions for the treatment of postintubation croup has not been proved in controlled trials. Studies that examined the effect of dexamethasone given before extubation in children with prolonged intubation are conflicting.<sup>196-199</sup> Methylprednisolone given intramuscularly for the same indication has been reported to reduce postintubation stridor.<sup>200</sup>

### *Laryngotracheal (Subglottic) Stenosis*

Ninety percent of acquired subglottic stenoses are the result of tracheal intubation, particularly prolonged intubation (see Videos 12-1 and 12-2).<sup>201-205</sup> The incidence of subglottic stenosis after prolonged intubation in preterm neonates is reduced because the cricoid cartilage is relatively immature. At this age, the cartilage structure is hypercellular and the matrix has a large fluid content, making the structures more resilient and less susceptible to ischemic injury.<sup>206</sup>

The pathogenesis of acquired subglottic stenosis is ischemic injury secondary to lateral wall pressure from the ETT. Ischemia results in edema, necrosis, and ulcerations of the mucosa. Secondary infection results in exposure of the cartilage. Within

48 hours, granulation tissue begins to form within these ulcerations. Ultimately, scar tissue forms, resulting in narrowing of the airway (Fig. 12-17).<sup>207-209</sup> Specimens obtained from partial cricotracheal resection in children were found to have severe and sclerotic scarring with squamous metaplasia of the epithelium, loss of glands and elastic mantle fibers (tunica elastica), and dilation of the remaining glands with formation of cysts.<sup>210</sup> Also, the cricoid cartilage was affected on the internal and external side, with irreversible loss of perichondrium on the inside and resorption by macrophages of cartilage on both sides.<sup>194</sup>

Factors that predispose to subglottic stenosis include use of an ETT that is too large, laryngeal trauma (e.g., traumatic intubation, chemical or thermal inhalation, external trauma, surgical trauma, gastric reflux),<sup>211-213</sup> prolonged intubation (particularly greater than 25 days), repeated intubation, sepsis and infection, chronic illness, and chronic inflammatory disease.<sup>204,214,215</sup>

### **LARYNGEAL MASK AIRWAY**

The LMA has become a standard alternative for airway management during general anesthesia.<sup>216-221</sup> A variety of types have been introduced into practice since the development of the original LMA, which is now called the LMA Classic (Fig. 12-18). These include the disposable LMA Unique, the ProSeal LMA (PLMA, described later), the Flexible LMA, the LMA Supreme (discussed later), and the intubating LMA Fastrach. The Fastrach is available in sizes 3, 4, and 5 and has been described for use in children who weigh more than 40 kg.<sup>222</sup> The LMA Classic is made of medical-grade silicone and consists of a large-bore tubular structure (barrel) that has a 15-mm adapter at its proximal end and an elliptical, mask-like device that fits over the laryngeal inlet at its distal end. All masks are inflated by means of a valved pilot tube and balloon. The LMA Classic and the PLMA can be sterilized for reuse up to 40 times. The LMA Classic is available in eight sizes. Guidelines for selecting the appropriate mask for

**FIGURE 12-18** Three types of laryngeal mask airway (LMA) are available in pediatric sizes: the reusable LMA Classic, the disposable LMA Unique, and the ProSeal LMA (PLMA). Displayed are pediatric size 2 LMAs of each type. **A**, The transparent material of the disposable LMA Unique (*center*) is medical-grade polyvinylchloride (PVC), whereas the reusable PLMA (*left*) and LMA Classic (*right*) are made of medical-grade silicone. Notice the differences in structure. The drainage tube outlet of the PLMA can be seen at the most distal tip of the cuff. The PLMA uses the drain tube to elevate the epiglottis away from the larynx, whereas the Classic and Unique have aperture bars. In contrast to the Classic and Unique LMAs, the PLMA cuff is softer, has a special shape, and has a deeper mask bowl. These features of the PLMA allow for improved sealing for positive-pressure ventilation. **B**, In profile, the distinct shape of the PLMA (*left*) can be appreciated. The dual-tube structure (drainage and airway lumens) creates a larger tube profile that incorporates a bite block and improves stability.

**TABLE 12-4** Size Selection and Recommended Cuff Volumes for the Laryngeal Mask Airway (LMA)

Mask Size	Patient's Weight	Maximum Cuff Volume (mL)	Largest Endotracheal Tube (ID, mm), LMA Classic	Largest Endotracheal Tube (ID, mm), LMA Unique*	Largest Endotracheal Tube (ID, mm), ProSeal LMA*
1	Neonate/infants up to 5 kg	4	3.5	3.5	N/A
1.5	Infants 5-10 kg	7	4.0	4.0	4.0, some manufacturers 3.5
2	Infants/children 10-20 kg	10	4.5	4.5	4.0
2.5	Children 20-30 kg	14	5.0	5	4.5
3	Children/small adults 30-50 kg	20	6.0, cuffed	5.0, cuffed	5.0
4	Adolescents/adults 50-70 kg	30	6.0, cuffed	5.5, cuffed	5.0, cuffed
5	Large adolescents/adults 70-100 kg	40	7.0, cuffed	6.0, cuffed	6.0, cuffed
6	Anyone >100 kg	50	7.0 cuffed	N/A	N/A

ID, Inner diameter; LMA, laryngeal mask airway; N/A, not applicable.

\*These sizes differ from the manufacturers' recommendations but have been found by the authors to be the better alternatives to ensure easy passage of the endotracheal tube through the LMA. In some cases the tubes listed are smaller; in some cases a cuffed alternative is given as an option rather than an uncuffed tube.

cuff but the profile of the mask has been altered to improve sealing. The PLMA is reported to be easy to insert, to allow greater airway pressures with positive-pressure ventilation, and to provide better protection against gastric insufflation.<sup>233,234</sup> A number of studies support the efficacy of the PLMA for use in children for both spontaneous and controlled ventilation.<sup>234-238</sup> In children, the PLMA is reported to be similar to the LMA Classic in ease of insertion, confirmation of proper position by fiberoptic visualization, and frequency of mucosal trauma. The advantage is that oropharyngeal leak pressure is greater and gastric insufflation is less common with the PLMA.<sup>234,236,238</sup> In children, the ability to provide pressure support ventilation with the PLMA during anesthesia also improves gas exchange and reduces WOB compared with the application of CPAP.<sup>239,240</sup> The greater sealing pressure may also protect against aspiration, as was reported in a 5-year-old child after inguinal hernia repair.<sup>241</sup>

Pediatric gastroscopy is reported to be quicker and to involve fewer airway complications when performed around the PLMA compared with nasal cannulas and with a conventional approach utilizing an anesthetic technique in which children breathed a sevoflurane-air-oxygen mixture spontaneously with 1-mg/kg IV boluses of propofol.<sup>242</sup>

Flexible diagnostic and therapeutic bronchoscopy, radiation therapy, radiologic procedures, ear/nose/throat surgeries, and ophthalmologic procedures are the most commonly described pediatric indications for the LMA.<sup>221,223,243-246</sup> An advantage of the LMA for securing the airway in ophthalmologic surgery is that it is associated with no increase in intraocular pressure, in contrast to endotracheal intubation.<sup>247</sup> The advantage of the LMA for diagnostic and therapeutic flexible bronchoscopy is that it provides a conduit for oxygenation and ventilation while allowing a larger bronchoscope to be used than can be passed through

an age-appropriate ETT.<sup>244,245,248,249</sup> It also allows visualization and evaluation of the laryngeal structures. Some LMAs may provide better bronchoscopic conditions than others due to their material or preconfigured shape.<sup>250</sup> For children requiring frequent anesthetics over a short period, as in radiation therapy, the LMA provides a secure airway without the trauma of repeated intubation.<sup>221</sup> The LMA has also been advocated for use in place of intubation in children who are at increased risk for bronchial airway reactivity (e.g., upper respiratory tract infection, history of reactive airway disease).<sup>251-254</sup> However, caution is required in children with an upper respiratory tract infection because the risk of laryngospasm remains substantive.

 The LMA has also become an important tool in the management of the DA, particularly in neonates (see later discussion) (Video 12-6). However, it should be noted that the LMA is an SGA device and, as such, does not reliably protect against pulmonary aspiration of gastric contents.<sup>228-230</sup> Because of their gastric access lumens, the PLMA and the LMA Supreme may be better alternatives in this setting, but formal study in children has not been done.<sup>255</sup>

The recommended insertion technique for the LMA is the same for children as for adults (see Video 12-6). The correct technique mimics deglutition or swallowing of food.<sup>256</sup> The cuff is completely deflated, and the posterior surface of the mask is well lubricated. These actions mimic lubrication of a food bolus with saliva and formation of a soft, flattened, wedge-shaped bolus. The child is placed in the age-appropriate intubating position. Induction may proceed by inhalation of halothane or sevoflurane or by IV propofol (3 to 5 mg/kg).<sup>223,257</sup> The nondominant hand is used to extend the head and flex the neck (sniffing position). This head position mimics the elevation of the larynx, neck flexion, and head extension that occurs with swallowing. The LMA is inserted with the mask aperture facing anteriorly (toward the tongue). The index finger of the insertion hand should be placed in the cleft between the mask and the barrel. With the index finger, the LMA is pushed upward and backward, toward the top of the child's head. This flattens the mask against the palate. Continued backward pressure (toward the top of the child's head) guides the LMA along the palate and down into the upper esophageal sphincter. It is essential that pressure be applied to force the LMA against the roof of the mouth. The mask is advanced along the palate until some resistance is felt. These actions mimic the propulsion of a food bolus into the hypopharynx caused by tongue pressure, first upward and backward, then downward in an arc. When resistance is felt, air is injected into the mask cuff (see Table 12-4 for size recommendations and maximum recommended inflation volumes).

Inflation of the cuff causes the end of the airway to move out of the mouth about 1 cm and forms a loose seal around the esophageal inlet, thereby directing gas flow into the trachea. *If no outward movement is observed with inflation of the mask, the LMA may not be properly positioned.* Proper position can be ascertained further by auscultation of breath sounds, movement of the anesthesia bag, measure of expired CO<sub>2</sub>, the ability to provide gentle assisted ventilation, and, if necessary, by direct visualization with rigid or fiberoptic laryngoscopy. If the lungs cannot be gently ventilated (peak airway pressure <20 cm H<sub>2</sub>O) or no breath sounds are heard, the LMA must be immediately removed because it has not been properly positioned, or the child's airway might be obstructed. After proper placement is confirmed, the LMA may be secured with tape and a soft bite block (e.g., a rolled gauze) inserted.

Several reports claim that when the traditional insertion technique is used in children, the LMA frequently hangs up in

the posterior pharynx, making proper positioning difficult.<sup>258,259</sup> Therefore, other insertion techniques have been described. The rotational or reverse technique for children has been advocated to be simpler and more successful than the traditional placement technique.<sup>260</sup> The LMA is placed in the mouth with the cuff facing the hard palate (the opposite of the traditional technique). It is then advanced and rotated into position simultaneously (Video 12-7).<sup>258,259,261</sup> A partial mask inflation technique has also been advocated as more successful than the traditional (mask deflated) technique.<sup>261-264</sup> The LMA is left partially inflated to smooth the edges of the mask and then is inserted in the usual manner,<sup>262,263</sup> or in a lateral manner and then rotated and advanced,<sup>264</sup> or with a complete 180-degree rotation.<sup>261</sup> For placement of the PLMA, the rotational technique was found to have no advantage over the standard technique in children.<sup>265</sup> A jaw thrust maneuver and the use of a rigid laryngoscope have also been advocated to assist in placement of the LMA Classic.<sup>266</sup>

Regardless of insertion method, the most common cause of failure is use of a wrong size LMA. An LMA that is too large will not pass beyond the posterior pharynx. An LMA that is too small will pass easily but may not seal against the laryngeal inlet. Another common mistake when using the traditional insertion method is to try to press the LMA *down* into the pharynx. Pressure should be directed *back*, toward the pharyngeal wall, so that the airway will follow the natural curve of the pharynx and seat correctly in the esophageal sphincter without kinking. Attempting to place the LMA when the child is inadequately anesthetized may make advancement impossible or result in laryngospasm.

LMA use can result in injuries to upper airway structures<sup>267-269</sup> and in damage to the recurrent laryngeal<sup>270</sup> or the hypoglossal nerves.<sup>271</sup> The incidence of sore throat may be equal to or greater than that seen with tracheal intubation.<sup>272-274</sup> LMA use in infants requires special caution. A review of the use of the size 1 LMA in 50 infants found that the LMA sometimes migrated over time, even after apparent correct initial placement; delayed airway obstruction occurred in 12 infants after apparent successful placement.<sup>275</sup> Vigilance is required to prevent loss of the airway.

LMA placement has been used successfully for neonatal resuscitation<sup>276-278</sup>; it may be an easier skill to acquire than bag-and-mask ventilation.<sup>279,280</sup> Given the recent recognition<sup>280a</sup> that chest compressions are the most important factor in successful outcomes after cardiac arrest and the need to avoid interrupting compressions during cardiopulmonary resuscitation, the LMA may assume a greater role in airway management in cardiac arrest in the neonate. The LMA has also been used to deliver surfactant to neonates with respiratory distress syndrome,<sup>281</sup> for longer-term intensive care management of neonates with DAs,<sup>282-284</sup> and for intrahospital transport of neonates with DAs.<sup>285</sup>

The LMA Fastrach was specifically designed to allow the blind passage of an ETT in an emergent situation in which direct laryngoscopy is not possible or in patients with cervical spine immobilization.<sup>178,286-288</sup> This is a rigid device with a fixed angulation designed primarily for adults (available in sizes 3, 4, and 5). It requires special, flexible ETTs with an ID of 6.0 to 8.0 mm.

The timing for removal of the LMA in children is controversial. Experts have advocated both "awake" and "deep" removal.<sup>289-294</sup> Awake removal ensures return of protective reflexes but with the attendant problems of airway reactivity. Deep removal avoids excessive airway reactivity and potential laryngospasm but may increase the risk of aspiration or airway obstruction (or both) as the child emerges from anesthesia later in the recovery room. One author suggested leaving the cuff inflated until the child

**FIGURE 12-19** The LMA Supreme offers the advantages of a built-in suction port and a built-in bite block. This design may be particularly useful for tonsillectomy, because the ventilating tube is molded in a caudad direction and the bite block offers protection against distortion by a mouth gag or the child's biting on it during emergence.

begins swallowing or is able to open the mouth on command as a means for reducing the potential for laryngospasm. The proposed mechanism is that secretions are swept away from the larynx, reducing the stimulus for laryngospasm.<sup>294</sup> Lubrication of the cuff with 2% lidocaine jelly or the addition of an intravenously administered opioid to the anesthetic may reduce coughing and laryngeal stimulation on emergence.<sup>262</sup>

The LMA Supreme is a single-use, curved laryngeal mask with an elliptical airway tube and an integrated drain tube that extends to the tip of the mask bowl. The proximal end of the airway tube consists of a bite block, which should lie between the teeth when the mask is properly positioned. A fixation tab allows the mask to be secured to the face. The deflated mask is held at the fixation tab and is inserted along the palate into the pharynx in a fashion similar to that used for the LMA Classic. Once in place, the cuff is inflated and the mask position is confirmed to be appropriate with the use of simple confirmatory tests (Fig. 12-19). An appropriately positioned mask forms a leak-free seal with the glottis, and the mask tip is embedded in the upper esophageal sphincter. A simple test to confirm the position of the mask is the suprasternal notch test, wherein a small amount of water-soluble lubricant is applied to the drain tube of the airway. Application of slight pressure in the suprasternal notch should result in a slight up-and-down movement of the applied lubricant on the drain tube. This confirms that the drain tube is contiguous with and adequately sealed in the upper esophageal sphincter. The ability to easily place a gastric tube through the drain tube further confirms correct positioning of the airway. Suction should not be applied to the gastric tube until it has been advanced into the stomach; this prevents collapse of the drain tube and potential injury to the upper esophageal sphincter. The LMA Supreme is now available in all pediatric sizes. A study comparing the LMA Supreme with the PLMA and the Classic LMAs in a neonatal manikin model demonstrated higher inflation pressures and shorter insertion times with the LMA Supreme.<sup>295</sup> Although the LMA Supreme has been found to be effective in adult populations,<sup>296-299</sup> there are currently no human evaluations of the pediatric sizes.

#### OTHER SUPRAGLOTTIC AIRWAY DEVICES

Many other manufacturers have created their own versions of a SGA device similar to the LMA Classic. Some of these devices

**TABLE 12-5** Size Selection and Recommended Cuff Volumes for the Laryngeal Tube

Tube Size	Body Size	Recommended Cuff Volume (mL)	Connector Color
0 Newborn	<5 kg	10	Clear
1 Infants	5-12 kg	20	White
2 Children	12-25 kg	35	Green
3 Adults: small	<155 cm	60	Yellow
4 Adults: medium	155-180 cm	80	Red
5 Adults: large	>180 cm	90	Purple

have design features that make them better conduits for tracheal intubation than the LMA Classic. Some have larger-diameter airway tubes that allow passage of larger (and cuffed) ETTs, lack glottic aperture bars (which can impede ETT advancement during an intubation attempt), and shorter airway tubes. Some devices also offer advantages in terms of cost.<sup>300-302</sup> Those SGAs that have a different design and different mechanism for maintaining the airway are discussed next.

#### The Laryngeal Tube

The Laryngeal Tube (LT; VBM Medizintechnik GmbH, Sulz, Germany) is designed to secure a patent airway during either spontaneous breathing or controlled ventilation. This device is available with a single lumen for ventilation only or with a double-lumen tube that also allows suction of gastric contents. This system seals the esophagus at the distal end with a small cuff attached at the tip (distal cuff), and a larger balloon cuff at the middle part of the tube (proximal cuff) stabilizes the device and blocks the oropharynx and nasopharynx. The two openings that lie between the cuffs are positioned so that the more distal opening faces the glottis. The cuffs are inflated through a single pilot tube and balloon, through which cuff pressure can be monitored. There are three black lines on the tube, near a standard 15-mm connector, that indicate adequate depth of insertion when aligned with the teeth. The nondisposable device is made of silicone (latex free) and is reusable up to 50 times after sterilization in an autoclave. There are four variations: (1) standard single-lumen, reusable (LT); (2) single-lumen, disposable (LT-D); (3) double-lumen with drain tube, reusable (LT-suction II, or LTS II); and (4) double-lumen with drain tube, disposable (LTS-D) (E-Fig. 12-1).<sup>303</sup> It is available in six sizes, suitable for neonates up to large adults (Table 12-5).

The LT should be inserted while the child's head and neck are placed in the sniffing or neutral position. The tip of a well-lubricated LT is placed against the hard palate behind the upper incisors. The device is then slid down the center of the mouth until resistance is felt or the device is almost fully inserted. After connection to the anesthesia circuit, proper placement is confirmed by assessing ease of ventilation. Some adjustment (usually slight withdrawal) may be required to provide optimal ease of ventilation. Care should be taken not to push the tongue backward into the posterior pharynx. Ease of insertion of the standard LT is reported to be comparable to that of the LMA Classic, although the LT may require more readjustments of its position to obtain a clear airway.<sup>304,305</sup> The incidence of complications with the two devices appears to be similar.<sup>304</sup> The LT may provide a better seal than the Classic LMA.<sup>306</sup> Compared with the PLMA, the LT may be less effective and more difficult to insert.<sup>307-309</sup>

**E-FIGURE 12-1** The Laryngeal Tube (LT) (VBM Medizintechnik GmbH, Sulz, Germany) is a single-lumen tube closed at the distal end with a small cuff attached at the tip (distal cuff) and a larger balloon cuff at the middle part of the tube (proximal cuff). The proximal cuff provides a seal in the upper pharynx, and the distal cuff seals the esophageal inlet. Two openings lie between the two cuffs, and the device is positioned so that the more distal opening faces the glottis. The cuffs are inflated through a single pilot tube and balloon, through which cuff pressure can be monitored. There are three black lines on the tube, near a standard 15-mm connector, that indicate adequate depth of insertion when aligned with the teeth. The LT is available in four types (standard LT, disposable LT, LT-suction II, and disposable LT-suction II) and in six sizes, including those that are designed for children. Specially marked and color-coded syringes are supplied to ensure proper cuff inflation. Two different sizes of the Laryngeal Tube are shown.

Although the LT-suction device may have similar success to the PLMA,<sup>310</sup> there are scant data in children.<sup>311-316</sup> An initial report of its use in children ages 2 to 12 years found a successful placement rate of 96% (77/80 children). Complications occurred in two children; one had laryngospasm that resolved with deepening of the anesthetic, and the other complained of mild difficulty with swallowing postoperatively.<sup>312</sup> A study comparing the LT with the LMA found it to be less effective for either spontaneous or assisted ventilation and for fiberoptic evaluation of the airway in children younger than 10 years of age.<sup>311</sup> A study of 70 children using sizes 0 to 3 reported failure to place the LT in 12% of children. Failures were caused by inability to ventilate, hypoxemia, gastric insufflation, cough, and laryngospasm or stridor, particularly for children weighing less than 10 kg; therefore, the LT was not recommended for children of this size.<sup>313</sup> Although the manufacturer states that a flexible fiberoptic bronchoscope (FOB) may be passed through the device, the openings are of insufficient size to permit passage of an ETT.

### The Cobra Perilaryngeal Airway

The Cobra Perilaryngeal Airway (CobraPLA; Engineered Medical Systems, Indianapolis, Ind.) is a disposable SGA that is marketed for the same indications as the LMA Classic but creates a seal more cephalad in the hypopharynx using a cylindrical inflatable cuff. The distal end of the device sits over the larynx, but the distal end is not inflatable (E-Fig. 12-2).<sup>301,317,318</sup> An initial report comparing the CobraPLA with the LMA Classic found that insertion time, airway adequacy, and number of repositioning attempts were similar. Peak airway sealing pressure was significantly greater with the CobraPLA; the authors concluded that the CobraPLA has better airway sealing capabilities than the LMA Classic.<sup>319</sup> A more recent group of investigators studying the CobraPLA in adults raised concerns about both the design and the safety of this device, particularly during controlled ventilation. After studying 29 patients, investigations were suspended and later stopped after two cases of significant pulmonary aspiration occurred in patients while using the CobraPLA.<sup>320</sup> The device is available in eight sizes and can be used in infants as small as 2.5 kg (Table 12-6).<sup>317</sup> The distal grill has a long center slit that is specifically designed to allow passage of a fiberoptic bronchoscope (FOB) and ETT (the size 0.5 neonate CobraPLA allows easy passage of a 3.5 uncuffed ETT). In a pediatric study, the orientation of the larynx as viewed through the CobraPLA using video was obtained in 45 infants and children. An acceptable view of the airway was obtained in all subjects, but the laryngeal view was almost obstructed or completely obstructed by the folding of the epiglottis over the glottic opening in 77% of children weighing less than 10 kg. (A similar problem was encountered in approximately 80% of children managed with the LMA Classic as well.<sup>321</sup>) The investigators suggested extra vigilance to prevent airway obstruction in small children. Also, because the grill bars of the CobraPLA were closely apposed to the epiglottis and supraglottic structures in almost all subjects, it was suggested that removal of the device in a deeper plane of anesthesia may minimize laryngeal stimulation. Further study of this device in children, particularly infants, is needed to define its role compared with the LMA.<sup>322-324</sup>

### The i-gel

The i-gel SGA (Intersurgical, Liverpool, N.Y.) consists of a dual-channeled, noninflatable laryngeal mask made from a gel-like thermoplastic elastomer (Fig. 12-20). It has a built-in bite block and is available in sizes 1, 1.5, 2, 3, 4, and 5 (Table 12-7). One

**TABLE 12-6** Suggested CobraPLA Size, Weight, Cuff Volume, and Endotracheal Tube Sizes

Size	Patient Weight (kg)	Cuff Volume (mL)	Inner Diameter (ID, mm)	Maximal Size of Endotracheal Tube (mm ID)
0.5	>2.5	<8	5.0	3.0
1	>5	<10	6.0	4.5
1.5	>10	<25	6.0	4.5
2	>15	<40	10.5	6.5
3	>35	<65	10.5	6.5
4	>70	<70	12.5	8.0
5	>100	<85	12.5	8.0
6	>130	<85	12.5	8.0

**TABLE 12-7** Suggested i-gel Supraglottic Device Size, Inner Diameter, Endotracheal Tube Size, and Nasogastric Tube Size

Size	Patient Weight (kg)	ID (mm)	Maximal Size of Endotracheal Tube (mm ID)*	Maximal Size of Nasogastric Tube (French)
1	2-5	5.6	3	
1.5	5-12	6.8	4	10
2	10-25	8.8	5	12
2.5	25-35	10.2	5	12
3	30-60	11.2	6	12
4	50-90	12.3	7	12
5	>90	12.5	8	14

channel functions as the airway tube while the second channel exits at the tip of the device and provides gastric access when seated properly. The lubricated posterior surface of the i-gel is inserted along the palate into the posterior pharynx. An observational study in 50 children reported easy insertion in all patients with a mean leak pressure of 25 cm H<sub>2</sub>O; gastric access was successfully obtained in all children.<sup>325</sup> A study that compared the i-gel to the Ambu AuraOnce laryngeal mask (Ambu, Glen Burnie, Md.) showed higher leak pressures and longer insertion times with the i-gel. The authors noted a tendency for the i-gel to slide out and recommended taping to prevent dislodgment intraoperatively.<sup>326</sup>

### Summary

A variety of SGAs are currently available. Some are imitators of the LMA Classic but available at a reduced cost, whereas others are completely new designs. There are many new devices with various designs to assist in the management of normal and DAs in children, but there are insufficient data to clearly state that one device or one manufacturer is superior to another.

## Airway Management: The Abnormal Airway

### CLASSIFYING THE ABNORMAL PEDIATRIC AIRWAY

It is important to recognize circumstances that may cause airway obstruction or difficult laryngoscopy. Conditions that predispose

**E-FIGURE 12-2** The CobraPLA (perilaryngeal airway) (Engineered Medical Systems, Indianapolis) is a disposable supraglottic device that is marketed for the same indications as the laryngeal mask airway but creates a seal higher in the hypopharynx using a cylindrical inflatable cuff. Three different sizes are shown (A). The distal end of the device sits over the larynx but is not inflatable. A long midline slit in the distal end of the device allows passage of a fiberoptic scope and endotracheal tube (B).

**FIGURE 12-20** The i-gel supraglottic device (A) consists of a malleable non-latex-containing, noninflatable cuff that is designed to seal over the laryngeal inlet after insertion. The stem of the i-gel contains a “buccal cavity stabilizer” which is designed to resist accidental rotation after insertion and is made from a hard polymer that resists biting. The i-gel also contains a gastric suction channel next to the 15-mm connector (B), with which practitioners may evacuate gastric contents when the device is in the correct inserted position. C, The distal position of the suction port.

to airway problems may be grouped according to anatomic location and may result from congenital, inflammatory, traumatic, metabolic, or neoplastic disorders. Tables 12-8 and 12-9 list the more common pediatric airway problems according to anatomic location. E-Appendix 12-1 lists the more common pediatric syndromes and associated anesthetic considerations; more complete information may be obtained elsewhere.<sup>327-330</sup>

### MANAGEMENT PRINCIPLES

For any laryngoscopy, but especially for a DA, the proper array of equipment must always be available. We advocate the creation of a DA cart stocked with equipment useful in the management of the DA for children of all sizes and ages. Suggestions for contents are listed in Table 12-10. The approach to a DA, as described earlier, must include a careful history and physical examination and, when indicated, radiologic evaluation. In the past, lateral neck xerograms have been useful in delineating anatomic aberrations; however, ultrasound, MRI, and CT imaging have replaced this modality.<sup>97-99,101-112,120,331-336</sup> In addition to the airway pathology, the pathophysiology of the congenital syndrome or associated disease process must be fully evaluated.

The safest approach to managing a DA is to formulate a plan that includes several contingencies for failure or loss of the airway and to have skilled help available, especially a surgeon who is experienced in performing pediatric bronchoscopy and tracheostomy. To maximize success and safety, a skilled assistant should help to position the child, facilitate airway management, and observe the monitors and the child's vital signs. To direct an assistant, there should be clear communication about the airway management plan and specific details about maneuvers needed

to facilitate the process. Familiarity with DA algorithms and DA management reviews can help the practitioner formulate a reasonable plan and ensure that no viable management options are missed.<sup>337-343</sup>

Certain principles apply to the care of any child in whom difficulty with airway management is anticipated. In most circumstances, an awake or mildly sedated approach would be the primary management strategy for the anticipated DA if airway concerns were considered in isolation. However, often the practitioner who is caring for a child is restricted from choosing an awake approach because of difficulty obtaining the child's cooperation. Assisted spontaneous ventilation during general anesthesia is the preferred technique when abnormal airway anatomy is present and difficulty with patient cooperation is anticipated; it provides adequate oxygenation while the airway is evaluated for the appropriate approach to tracheal intubation. Therefore, the first choice for management of a potential DA, whether the child is sedated or under general anesthesia, is to *maintain spontaneous ventilation*.<sup>338,343</sup> There are two reasons for maintaining spontaneous gas exchange. First, neuromuscular blockade may result in total airway obstruction due to loss of tone of the tongue, pharyngeal and laryngeal muscles, and suspensory ligaments. This obstruction may not be easily alleviated with manual ventilation of the lungs. Neuromuscular blockade should not be used if airway obstruction or the potential for airway obstruction exists.<sup>34</sup> Second, if a child is paralyzed, the loss of spontaneous breath sounds eliminates a valuable guide to locating the glottis. For example, in children with craniofacial anomalies or cervical burn contractures, one may be able to visualize only the tip of the epiglottis with standard rigid laryngoscopy. In such cases, if specialized airway management equipment is unavailable, shaping

**E-FIGURE 12-3, cont'd** **F**, The ETT was then removed, leaving the airway exchange catheter in place (**G**). **H**, The child was then administered oxygen by facemask and observed for satisfactory ventilation and oxygenation, after which the airway exchange catheter was removed.

**E-FIGURE 12-4** **A**, A device that may be substituted for a jet ventilation system that allows delivery of oxygen at low flows is the Enk Oxygen Flow Modulation set (Cook Critical Care, Bloomington, Ind.). Occlusion of the side holes with the thumb and first finger allows diversion of flow into a transtracheal or translaryngeal cannula, and removal of the occlusion allows flow to exit the side of the device. **B**, A low-cost alternative is to simply cut a side hole in the oxygen delivery tubing and use it in the same way as the Enk system.

pursued (e.g., a surgical airway). There are now many other SGA devices reported to be useful in the management of the child with a DA, but comparative studies in pediatrics are lacking.<sup>255,378</sup>

### Percutaneous Needle Cricothyroidotomy

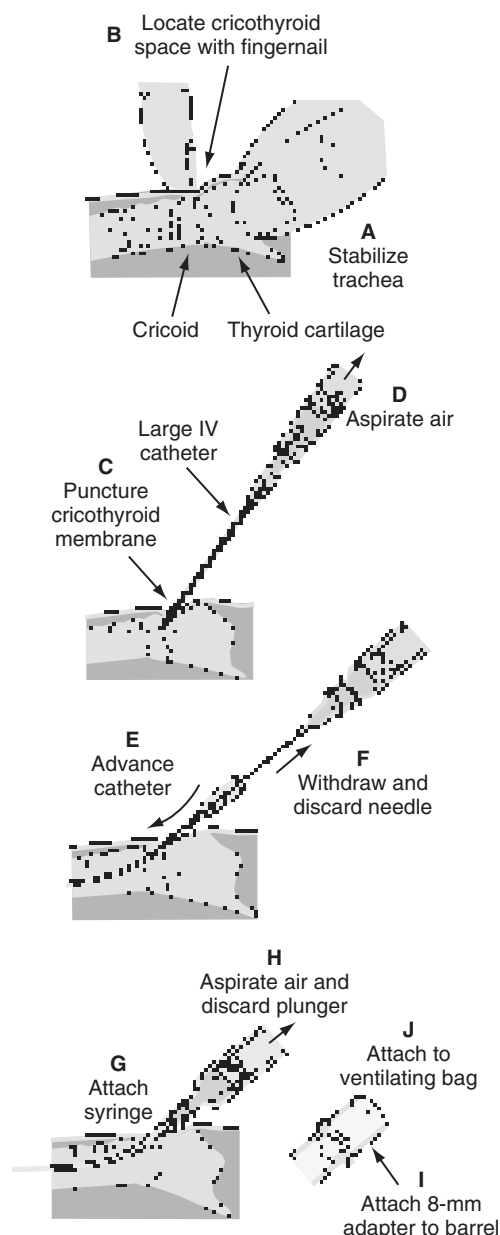

In 1992, the American Heart Association changed its recommendations for emergency airway management to a percutaneous needle cricothyroidotomy over a surgical cricothyroidotomy because it was believed that the former entails less risk of injury to vital structures such as the carotid arteries or jugular veins, particularly in the hands of nonsurgical trained practitioners. In addition, most practitioners can more rapidly perform the percutaneous procedure. However, the cricothyroid membrane has a relatively small width in infants and children. Attempts at cricothyroidotomy may readily damage cricoid and thyroid cartilages, resulting in laryngeal stenosis and permanent damage to the speech mechanism. Therefore, this procedure should be reserved for use only under emergency circumstances.<sup>379,380</sup>

Because percutaneous needle cricothyroidotomy is rarely used, it is recommended that experience be gained with patient simulators or in animal models, because success in the hands of the inexperienced is not assured.<sup>381,382</sup> A schema of this procedure is presented in Figure 12-25. A commercial product called the Jet-Ventilation-Catheter (VBM) is available in three sizes: 16, 14, and 13 gauge. It consists of a slightly curved puncture needle within a Teflon, kink-resistant cannula nearly identical to an IV catheter (Fig. 12-26, A). This cannula has two lateral eyes at its distal end and a combined Luer-Lok and 15-mm adapter at its proximal end (see Fig. 12-26, B). It also has a fixation flange and foam neck tape to secure the airway.

*Percutaneous needle cricothyroidotomy provides only a means for oxygen insufflation and does not reliably provide adequate ventilation.* In the spontaneously breathing patient, simple delivery of intratracheal oxygen (1 to 2 L/min) may be sufficient in the short term, because hypercarbia is generally well tolerated by healthy children.<sup>379,383,384</sup> A number of children with arterial CO<sub>2</sub> values well above 150 mm Hg have survived neurologically intact when adequate oxygenation was maintained.<sup>384</sup> Therefore, simple oxygenation without attempts at ventilation may be all that is required to sustain life (Fig. 12-27). For the child without respiratory effort, there is a need to provide ventilation in addition to oxygenation. An Ambu bag with the pop-off disabled can provide limited ventilation through a percutaneous catheter, but these devices will be ineffective at standard pop-off pressures.<sup>379,385</sup> Extremely high ventilating pressures are required, but midtracheal pressures are significantly lower (10 to 16 cm H<sub>2</sub>O).<sup>379</sup> A percutaneous cricothyroidotomy catheter can also be used with a jet ventilation system. Jet ventilation via a catheter passed through a narrow glottic opening has been described.<sup>386-389</sup>

If upper airway obstruction is present (e.g., after multiple unsuccessful attempts at rigid laryngoscopy), there will be a limited pathway for the egress of air and oxygen, and barotrauma may result from insufflation of oxygen or attempts at ventilation. Very serious morbidity and mortality may result from massive subcutaneous emphysema or tension pneumothorax.<sup>390,391</sup> Therefore, jet ventilation must be used with extreme caution in infants and children.<sup>392</sup>

Another IV catheter-type emergency airway device is the Emergency Transtracheal Airway Catheter (Cook Critical Care), which consists of a 6-F reinforced catheter that is advanced over a 15-gauge needle similar to the devices described earlier

**FIGURE 12-25** Percutaneous cricothyroidotomy. Extend the head in the midline with a rolled towel or folded sheet beneath the shoulders. **A**, Standing to the left of the child, stabilize the trachea with the right hand. **B**, The cricothyroid membrane is located with the index fingertip of the left hand between the thyroid and cricoid cartilages. This space is so narrow (1 mm) in an infant that only a fingernail can discern it. The trachea is then stabilized between the middle finger and thumb of the left hand while the fingernail of the index finger marks the cricothyroid membrane. **C**, A large intravenous (IV) catheter (12 to 14 gauge) is then inserted through the cricothyroid membrane, and air is aspirated (**D**). The catheter is advanced into the trachea through the membrane, and the needle is discarded; an intraluminal position is reconfirmed by attaching a 3-mL syringe (**E**) and aspirating for air (**F**). A 3-mm adapter from a pediatric endotracheal tube can be attached to any intravenous catheter (**G**). Ventilation is accomplished by attaching to a breathing circuit with a standard 22-mm connector (**H**). An alternative would be to leave the barrel of the 3-mL syringe attached to the intravenous catheter, insert an 8-mm endotracheal tube adapter to the syringe barrel (**I**), and then attach to a ventilating system with a standard 22-mm adapter (**J**). (From Coté CJ, Eavey RD, Todres ID, Jones DE. Cricothyroid membrane puncture: oxygenation and ventilation in a dog model using an intravenous catheter. *Crit Care Med* 1988;16:615-619, © by Williams & Wilkins.)

**FIGURE 12-26** **A**, The Jet-Ventilation-Catheter (VBM Medizintechnik GmbH, Sulz, Germany) is available in three sizes: From left to right: 13 gauge (adult), 14 gauge (child), and 16 gauge (infant). It consists of a slightly curved puncture needle within a Teflon, kink-resistant cannula. The procedure for insertion is similar to that described in Figure 12-25. **B**, This cannula has two lateral eyes at its distal end and a combined Luer-Lok and 15-mm adapter (surrounding the Luer-Lok) at its proximal end, allowing either jet or standard ventilation. It also has a fixation flange and foam neck tape to secure the airway.

(E-Fig. 12-5). One study simulated use of the Enk Oxygen Flow Modulation set with a variety of IV cannulae and the Emergency Transtracheal Airway Catheter. The investigators concluded that the device worked best when all holes on the Enk device were occluded simultaneously and that minimum flow should never be less than 1 L/min. They also suggested that initial fresh gas flow be set to 1 L/min and then adjusted up or down to effect.<sup>393</sup> Successful ventilation with uncuffed devices may depend on the patency of the upper airway (i.e., the greater the patency, the less the effectiveness of ventilation in the nonbreathing patient).<sup>394</sup> None of these devices has been examined in controlled trials to confirm efficacy, in part because these events are so rare. Therefore, we recommend training on simulators so that each practitioner can determine what device is best in his or her hands.

A number of percutaneous emergency airway devices are available that use a short but large-diameter needle or a needle, guidewire, and dilator to aid insertion of a percutaneous airway.<sup>381,395-397</sup> The Quicktrach (Rüsch) is a device that consists of a tapered 2- or 4-mm catheter with a fixation flange for securing with cloth tape. A removable plastic stopper is designed to limit the depth of needle insertion. This device requires several steps: puncture of the skin, aspiration for air, removal of the stopper, removal of the needle/syringe, and attachment to standard 22-mm connector. A flexible connector is also provided

(E-Fig. 12-6). A rabbit model to simulate infant cricothyroidotomy found success in all attempts but 2 of 10 attempts resulted

**A**

**B**

**FIGURE 12-27** **A**, Changes in arterial blood gases and pH are plotted over time for six dogs with spontaneous ventilation; baseline values in room air are plotted at time -3; values after 2 to 3 minutes of hypoxemia as a result of airway obstruction are plotted at time 0. Marked, sustained increases in arterial oxygen tension ( $P_{aO_2}$ ) follow cricothyroid membrane puncture with delivery of only 1.0 L/min oxygen. **B**, Changes in arterial blood gases and pH are plotted over time for five dogs that were not making spontaneous ventilatory efforts. Both oxygenation and ventilation were achieved with a self-inflating bag introduced through the cricothyroid membrane.  $P_{aCO_2}$ , Carbon dioxide tension; SEM, standard error of the mean; Sig., significant difference. (From Coté CJ, Eavey RD, Todres ID, Jones DE. Cricothyroid membrane puncture: oxygenation and ventilation in a dog model using an intravenous catheter. Crit Care Med 1988;16:615-619, © by Williams & Wilkins.)

**E-FIGURE 12-5** *Top*, A transtracheal kink-resistant catheter is available in a 6-F external diameter (Emergency Transtracheal Airway Catheter; Cook Critical Care, Bloomington, Ind.). The system is similar to a simple intravenous catheter device inserted percutaneously with a syringe (*bottom*). Aspiration of air confirms tracheal position, and the catheter is advanced as described in Figure 12-25. The catheter can be attached to either a jet ventilation system (*top*) or the system described in Figure 12-25.

**E-FIGURE 12-6** QuickTrach Emergency Cricothyroidotomy Device (Rüsch Inc., Duluth, Ga.) is available in three sizes (**A** and **B**, *bottom to top*): 1-mm neonatal, 2-mm toddler, and 4-mm older child. This device is similar to the devices presented in Figure 12-25, but the diameter of the introducing needle is larger and the final size catheter also has a larger diameter. A white plastic stopper (**C**) is designed to prevent excessive depth of insertion and is removed after successful entry into the trachea. The fixed curve of the large needle requires a change in angle from 90 degrees with the skin at insertion to 60 degrees with the skin after entry into the trachea. The built-in flange and strap allow rapid fixation. The size of these devices would seem to limit their utility to larger children and adults, and it would appear that some training on a simulator would be advised.

in fracture of the cricoid cartilage and 1 resulted in damage to the mucosa of the posterior tracheal wall.<sup>398</sup> Conversely, this device has been shown to allow more rapid establishment of an airway than other devices that use a Seldinger technique.<sup>399,400</sup> A larger, cuffed adult model is now available (E-Fig. 12-7).

Other devices that use the Seldinger technique (i.e., needle, guidewire, scalpel incision of the skin, and passage of a dilator and tracheostomy tube) are the Arndt and Melker devices (Cook Critical Care).<sup>401</sup> These devices provide a 3.0-mm ID airway that is sufficient for ventilation as well as oxygenation (E-Fig. 12-8). However, the time required to insert such devices may be longer than for simpler devices and may be inappropriate for immediate rapid establishment of an airway.<sup>381,399,400</sup> In contrast, a porcine cadaver study found greater comfort with this technique compared with a scalpel technique.<sup>402</sup> These devices are useful for elective percutaneous tracheostomy.<sup>403</sup>

Another device, Petrach (Engineered Medical Systems, Indianapolis, Ind.), uses a split needle on a syringe to puncture the cricothyroid membrane (E-Fig. 12-9). A skin incision is made, and an introducer with tracheostomy tube (3.0-mm ID) is directed into the trachea, splitting the needle, which is removed. The introducer is then removed, and the airway is secured with tracheostomy tape. There are no case reports in the literature to determine the ease or difficulty of insertion in children, but the multiple steps required suggest that it may be a device for elective tracheostomy rather than emergent establishment of a surgical airway.

Another percutaneous tracheostomy device is the Bivona Pedia-Trake kit (Smiths Medical, St. Paul) (E-Fig. 12-10). A skin incision is made with a scalpel, and a large needle is introduced with a skin dilator, which in theory opens the incision sufficiently to allow passage of an obturator and a 3.0-, 4.0-, or 5.0-mm ID tracheostomy tube (with or without cuff). This device appears sufficiently complicated so as to not be useful in a CICV emergency; it might be better suited when there is an urgent need to establish surgical access to the airway.

Other devices with limited pediatric use<sup>395</sup> are kits designed to place a full-sized tracheostomy tube, such as the Nu-Trake (International Medical Devices, Northridge, Calif.) and Abelson (Gilbert Surgical Instruments, Bellmawr, N.J.) devices. They may potentially cause tracheal or laryngeal injury in small patients because of the relatively large size of the needle; again, little experience in children has been published.<sup>396,397,404</sup>

### Laryngeal Mask Airway versus Percutaneous Needle Cricothyroidotomy and Transtracheal Jet Ventilation

The LMA Classic has proved to be an extremely useful device in airway emergencies. In contrast to percutaneous needle cricothyroidotomy, it is an effective device for ventilation as well as a conduit for intubation. The LMA is easily inserted and requires a relatively low level of skill, as demonstrated in numerous studies comparing this technique with other airway management skills (e.g., mask ventilation, endotracheal intubation). More importantly, in contrast to transtracheal jet ventilation, the complication rate with the LMA Classic is exceedingly low.<sup>405</sup> However, this is an SGA device. If glottic or subglottic obstruction to ventilation is present, it will be ineffective, and a surgical airway with or without transtracheal jet ventilation is still the emergency technique of choice. Since the introduction of the LMA, clinical experience suggests that if glottic or subglottic pathology is not suspected, LMA placement to establish ventilation may be appropriately attempted first.<sup>340</sup>

### Surgical Airway

Establishing a surgical airway emergently requires great technical skill. It is difficult to perform quickly, and other methods to provide oxygenation should be pursued first. In nonemergent airway management for children, a tracheostomy is preferred to a cricothyroidotomy because of fewer long-term complications and better results with later decannulation of the airway.<sup>381,406</sup>

### Anterior Commissure Scope and Rigid Ventilating Bronchoscope

Two pieces of equipment used by otolaryngologists that can assist in visualizing the larynx and providing a method of ventilation are the anterior commissure scope and the rigid ventilating bronchoscope. The anterior commissure scope is a rigid, tubular, straight-blade laryngoscope with a light at the tip. The technique to place the anterior commissure scope and the advantages for visualization are similar to those described later for the straight blade used with the retromolar approach.<sup>407</sup>

## SPECIAL TECHNIQUES FOR INTUBATION

### Rigid Laryngoscopy

The rigid laryngoscope is the most familiar and most universally available piece of airway equipment; therefore, it is critical for the practitioner to become facile in its use and to know a variety of techniques. Some suggestions are reviewed here. It is reasonable to take a second look with the rigid laryngoscope after an unexpected failed intubation; however, a good rule is to always change something about the approach that may improve visualization. In the past, awake rigid intubation was the traditional approach to the problematic neonatal airway, but this approach should be used only in an extreme emergency or when IV access is not available.<sup>133-136</sup> Some anatomic features are completely unfavorable for success with the rigid laryngoscope, regardless of technique. Repeated unsuccessful attempts should be avoided, because this can lead to airway trauma and edema. Because infants and children already have smaller airway structures, they are uniquely susceptible to a rapid progression from “cannot intubate, can ventilate” to the CICV scenario.

Whether the child has a normal or an abnormal airway, it is essential to ensure correct positioning and to use age-appropriate equipment. The following maneuvers have been found to be helpful in achieving successful intubation of the child with a DA.

### Optimal External Laryngeal Manipulation

Pressure can be applied externally to the larynx during the intubation to maximize visualization of the larynx.<sup>408</sup> Optimal external laryngeal manipulation (OELM) is particularly helpful for children with immobile or shortened necks and for infants. Either an assistant or the laryngoscopist can perform OELM. When the laryngoscopist performs the maneuver, the assistant either can pass the ETT into the glottis while the laryngoscopist maintains OELM or OELM can be assumed by the assistant to allow the laryngoscopist to pass the ETT.<sup>408</sup> OELM may also be used in conjunction with other, more advanced airway devices such as the GlideScope (discussed later).<sup>409-411</sup>

### Intubation Guides

Intubation guides include plastic-coated, flexible metal stylets and the gum elastic bougie. These can be used for blind placement of the ETT under the epiglottis. A flexible stylet is placed inside the ETT and preformed to shape the ETT tip to one that will optimize intubation success (see Fig. 12-21). A hockey-stick

**E-FIGURE 12-7** **A** and **B**, QuickTrach Emergency Cricothyrotomy Device for older patients. The device is shown assembled (**A**) and disassembled (**B**). The principles of insertion are similar to those described in Figure 12-25, but this device provides a much larger airway with a cuff, allowing better seal. It would appear that this device would only be appropriate for teenagers due to the size of the insertion needle.

**E-FIGURE 12-8** The Arndt Emergency Cricothyrotomy Set (Cook Critical Care, Bloomington, Ind.) provides a 3.0-mm ID airway that is sufficient for ventilation as well as oxygenation. Percutaneous dilation cricothyroidotomy uses a five-step staged technique, similar to the Seldinger technique used for placement of central venous catheters, to place a secure airway. 1) A percutaneous needle cricothyroidotomy is performed, and negative pressure measured via a syringe and side port confirms aspiration of air. 2) A guidewire is then passed through the needle. The needle is removed, leaving the wire within the trachea. 3) A scalpel is used to puncture the skin. 4) A dilator and cricothyroidotomy tube together are threaded over the guidewire into the trachea. The dilator and guidewire are removed, leaving the cricothyroidotomy tube (airway) in place. A connection for jet ventilation is also provided. There is limited experience with this device in children, particularly infants. Other similar devices are available (see text for details).

**E-FIGURE 12-9** **A**, The Pertrach system (Pulmonary, Indianapolis,) uses a split needle on a syringe to make a puncture through the cricothyroid membrane. **B**, An introducer/dilator is passed through the needle into the trachea. **C**, A skin incision is made and the introducer, together with a 3.0-mm ID airway, is advanced into the trachea while the needle is split and removed. The introducer is then removed, and the airway is secured with tracheostomy tape.

**E-FIGURE 12-10** **A**, The Bivona Pedia-Trache percutaneous tracheostomy device (Smiths Medical, St. Paul) uses a multiple-step technique that may not be appropriate for an emergent situation. A large-bore needle on a syringe is used to puncture the cricothyroid membrane, and surrounding the needle is a sharp, tapered dilation system. **B**, After successful entry into the trachea, the syringe and needle are withdrawn, and the opening is dilated. A size 3-, 4-, or 5-mm ID tracheostomy tube is then inserted and secured with tracheostomy tape.

**FIGURE 12-28** A through C, The retromolar, paraglossal, or lateral approach to rigid laryngoscopy utilizing a straight blade. Notice that the child's head is turned to the left and that the laryngoscope blade is inserted over the molars toward the glottic opening (see text for details).

configuration is frequently useful, particularly if only the epiglottis or the most posterior portion of the glottis can be visualized. The gum elastic bougie has a preformed, angled tip. It is placed alone and then the ETT is threaded over it and into the trachea (E-Fig. 12-11). When the bougie is successfully placed in the trachea, one can detect the subtle “bumpy” feel of the bougie making contact with the anterior tracheal rings. This device may also be used to facilitate intubation through an LMA or as an adjunct to other airway devices.<sup>412-415</sup>

#### *Oxyscope*

The Oxyscope (Heine Optotechnik, Herrsching, Germany) is a Miller 1 laryngoscope blade with an insufflation channel along its length so that it may be attached to an oxygen source. An Oxyscope provides increased  $\text{FiO}_2$  and is particularly useful for intubation in spontaneously breathing neonates with high oxygen consumption in whom desaturation may rapidly develop (E-Fig. 12-12).<sup>416-418</sup>

#### *Dental Mirror*

The authors of one report used a short-handled dental mirror (no. 3, Storz Instrument Company, Manchester, England) to assist in the indirect visualization of the larynx of a 10-week-old infant. Laryngoscopy was impossible with a Miller no. 1 blade. The infant was returned to spontaneous ventilation, a Macintosh no. 1 blade was used to expose the pharynx, and the mirror was used to visualize the larynx. A styleted ETT was then passed into the glottis under indirect vision.<sup>419</sup>

#### *Retromolar, Paraglossal, or Lateral Approach using a Straight Blade*

Use of a straight blade in a retromolar approach may allow glottic visualization when the classic rigid intubation technique fails, particularly if the difficulty is secondary to a large tongue or small mandible (Fig. 12-28).<sup>407,410,413,420-424</sup> With the child's head turned slightly to the left, a no. 1 Miller blade is introduced into the extreme right side of the mouth. It is advanced in the space between the tongue and the lateral pharyngeal wall; the tongue is swept completely to the left and is essentially bypassed. It is very helpful to have an assistant pull back the right corner of the mouth with a small retractor (e.g., Senn retractor) to increase the space for ETT placement. The blade is advanced while staying to the right, overlying the bicuspid and lateral incisors until the epiglottis or the glottis is visualized. When the epiglottis comes in view, it is lifted with the blade tip to expose the glottic opening. It is extremely unlikely that pressure from the laryngoscope blade on the bicuspid and lateral incisors could loosen these teeth, because they have double roots or longer roots than the central incisors.

At this point in the laryngoscopy, it may be possible to move the proximal end of the blade toward the midline of the mouth to increase room for ETT placement and manipulation, although care must be taken to avoid applying pressure on the central incisors of the maxilla, lest they become loosened. If the glottis is not visualized, the head can be rotated farther to the left and the blade can be kept lateral to improve visualization. The ETT should be styleted and formed into a 90-degree bend configuration to assist in placement (see Fig. 12-21), particularly if the view

**E-FIGURE 12-11** A gum elastic bougie may be used as a guide to pass the endotracheal tube into the laryngeal inlet. A hockey-stick configuration is frequently useful, particularly when only the epiglottis or the most posterior portion of the glottis can be visualized. The gum elastic bougie has a preformed angled tip. When the bougie is successfully placed in the trachea, one can detect the subtle “bumpy” feel of the bougie making contact with the anterior tracheal rings. This device may also be used to facilitate intubation through a laryngeal mask airway or as an adjunct to other airway devices.

**E-FIGURE 12-12 A**, The Oxyscope (Heine Optotechnik, Herrsching, Germany), a modified laryngoscope, delivers 2 L/min of oxygen and, if connected to the anesthesia circuit, anesthetic agent at the tip of the blade during laryngoscopy. **B**, Increased levels of arterial oxygen tension ( $PO_2$ ) were achieved during laryngoscopy of spontaneously breathing infants. (From Todres ID, Crone RK. Experience with a modified laryngoscope in sick infants. *Crit Care Med* 1981;9:544-5, © Williams & Wilkins.)

of the glottis is only partial. A shorter-length blade (usually a Miller no. 1, even in older children) than that used in the traditional midline approach is chosen because the distance to the glottis with this method is greatly shortened.

Several mechanisms are responsible for the improved view of the glottis with the retromolar approach to laryngoscopy. First, there is a reduced need for soft tissue displacement and compression because the lateral placement of the blade bypasses the tongue. This approach to an improved view of the glottic opening is particularly useful for children with micrognathia.<sup>410,413,421,423,424</sup> In such children, the space available to displace the tongue is reduced compared with the traditional midline approach to rigid laryngoscopy. Second, there is an improved line of visualization because the incisors and maxillary structures are bypassed by lateral blade placement and by shifting of the head to the left. Third, the use of a straight blade avoids the possible intrusion of a curved blade into the line of site.<sup>407,420-422</sup> Finally, both the angle and the distance from the insertion of the straight blade at the right commissure of the mouth are reduced, facilitating an easier view of the glottic opening, particularly during a difficult intubation, compared with inserting the blade in the midline.

### Fiberoptic Laryngoscopy

An advantage of using the FOB for intubation of the child with a DA is that it does not require extensive head or neck manipulation and is therefore useful in children who have cervical inflexibility (Klippel-Feil syndrome) or cervical instability (Down syndrome, achondroplastic dwarfism, trauma) (Video 12-9 and 12-11). The technique is also versatile because the flexible instrument conforms to a variety of abnormal airways; it is well tolerated by the sedated, spontaneously breathing child.<sup>344</sup>

Its disadvantage is that the fiberoptic bundle is small, permitting only a limited field of vision. For this reason, the presence of blood or copious secretions may render the FOB ineffective. In addition, use of the FOB requires extensive experience and practice in normal airways first. Our experience suggests that each size of available FOB should be used in at least 20 normal airways before use is attempted in an abnormal airway.<sup>425</sup> Practice with all available sizes of FOBs is important because the manual skills required for each size differ somewhat. Also, FOBs are fragile and expensive. Great care must be taken when using and storing FOBs to prevent breakage of the fiberoptic bundles and the adjustable tip mechanism. They must also be sterilized between uses to maintain the patency of the working channel and clear, bright vision through the fiberoptic bundles and to avoid transmission of infection.

### Equipment

FOBs with directable tips are available in various sizes; the smallest, 2.2 mm in diameter (Olympus LFP; Olympus, Tokyo), can fit through a 2.5-mm ID ETT with or without the 15-mm adapter removed. However, unlike most of the larger FOBs, this scope has no working channel for suctioning or administration of oxygen or topical anesthesia. Newer FOBs with the light source incorporated into the body of the scope are now available. These increase the portability of the instrument, making its use both outside and inside the operating room more simple and convenient.

### Ancillary Equipment

Endoscopy masks can be used to provide oxygen to the spontaneously breathing child and to ventilate the paralyzed child during fiberoptic laryngoscopy. The Frei endoscopy mask (E-Fig. 12-13)

and the Patil-Syracuse endoscopy mask are commercially available.<sup>426,427</sup> Patil-Syracuse masks are available in a child size but are too large for most children younger than age 4 years.<sup>88</sup> The Frei mask can mask a child as small as 10 cm in length and 10 cm in width.

**E-FIGURE 12-13** The Frei endoscopy mask is used for oxygenation and ventilation of a patient. A fiberoptic laryngoscope with a softened endotracheal tube of appropriate size presoaked in warm sterile water (not shown) is passed through a membrane opening in the mask. This allows one to maintain a constant depth of anesthesia and continuous oxygenation while visualizing the airway with the fiberscope.

**FIGURE 12-29** Suction can be applied to the tip of the tongue to facilitate pulling it forward to improve glottic visualization. This technique is particularly useful when the tongue is slippery due to secretions or if the mouth opening is small and prevents direct grasping of the tongue with a dry gauze.

in children are less than in adults, the most common initial error when using this technique is to advance the FOB too deeply and into the esophagus. To avoid this pitfall, the FOB should be advanced only toward identifiable airway structures.

Once the FOB is introduced into the airway, a common problem is resistance to passage of the ETT. To minimize this occurrence, the ETT should be loaded onto the scope with the bevel facing down (Murphy eye up) for oral intubation and bevel facing up for nasal intubation.<sup>431,432</sup> This can be remembered by the mnemonic *UNDO*: bevel **U**p for Nasal intubation, **D**own for **O**ral intubation (see Video 12-10).<sup>433</sup> If persistent resistance is encountered while attempting to pass the ETT past the glottic opening, the ETT should be rotated 90 to 180 degrees to place the bevel in a more favorable orientation for passage through the vocal cords. The depth of anesthesia or sedation as well as oxygen saturation (pulse oximetry) must be carefully monitored throughout the procedure. Arrhythmias may be avoided by providing an adequate depth of analgesia/anesthesia and ensuring a patent airway.

Fiberoptic laryngoscopy techniques should be perfected on manikins and on children with normal anatomy before such techniques are attempted on children with pathologic airway anatomy.<sup>434-440</sup> In a study that compared the time to intubation and complications in 40 infants with the Miller no. 1 laryngoscope or the Olympus LFP FOB, the time to intubation was slightly greater with the FOB (22.8 versus 13.6 seconds), whereas the complication rate was similar.<sup>441</sup> The authors concluded that routine use of the FOB for intubation in normal infants is a safe and reasonable method to gain and maintain skills with this technique.<sup>441</sup> For children, video-assisted fiberoptic intubation appears to offer advantages over fiberoptic intubation using a traditional eyepiece. These include faster mastering of this skill and an overall improved success rate when compared with the traditional method.<sup>425,442</sup>

### Staged Techniques

Staged methods of fiberoptic intubation can be used in infants and small children when the available FOBs are too large to pass through the appropriately sized ETT.<sup>443</sup> One method requires an

FOB with a working channel and a cardiac vascular catheter with guidewire. The guidewire is passed through the working channel of the FOB to within 1 inch of its tip. The FOB is then introduced into the mouth and positioned above the vocal cords. The guidewire is advanced under direct observation through the glottis into the trachea. The FOB is removed, leaving the guidewire in place. The lungs are ventilated by mask while an assistant passes the cardiac catheter over the guidewire (to stiffen the guidewire and facilitate passage of the ETT). The ETT is threaded over the catheter/guidewire combination, which is then removed, leaving the ETT in place.<sup>443-445</sup> Some authors have found that threading of the cardiac catheter over the guidewire is unnecessary. A modification of this technique when the FOB has no working channel has also been described.<sup>446</sup> The authors used an 8-F red rubber catheter attached by waterproof tape to the insertion cord of the FOB proximal to the flexible tip. The larynx was visualized with the FOB, and a guidewire was threaded through the rubber catheter into the trachea. With the guidewire in position, the FOB (with the red rubber catheter) was withdrawn, and an ETT was passed over the guidewire into the trachea.

Another alternative for intubation when the FOB is too large to pass through the appropriately sized ETT is intubation under fiberoptic observation.<sup>447-449</sup> The FOB is introduced through one naris to visually aid the placement of the ETT that is passed through the other naris and manipulated into the glottis. Alternatively, if the observed ETT is not easily passed into the glottis, a small catheter may be more easily manipulated into the glottis and used as a stylet to pass the ETT into the trachea. Spontaneous ventilation is preserved, and oxygen can be administered via the ETT during the intubation. This technique was used successfully in two neonates, one with congenital fusion of the jaws and a second with Dandy-Walker syndrome associated with Klippel-Feil syndrome, micrognathia, hypoplasia of the soft palate, and anteversion of the uvula.<sup>447,448</sup> More recently, an adult video-FOB was used to intubate the trachea of a toddler with temporomandibular joint ankylosis.<sup>450</sup>

If the available FOB is both too large and lacks a working channel, another staged fiberoptic intubation technique can be used. The FOB is loaded with an ETT that is larger than the larynx of the infant. The larynx is visualized with the FOB, and the ETT is advanced and positioned just above the vocal cords. The FOB is then removed, and an ETT changer or catheter is advanced into the trachea through the larger ETT. The larger ETT is then removed, and the appropriately sized ETT for the child is threaded over the tube changer or catheter into the trachea. This technique was used successfully in a 6-month-old infant whose operation had previously been canceled because of failure to intubate.<sup>451</sup>

### Lighted Stylet

A lighted stylet (light wand) is a useful adjunct for managing the pediatric DA (E-Fig. 12-14).<sup>452-456</sup> A number of these devices are available: Trachlight (Laerdol Medical Corporation, Wappingers Falls, N.Y.), Surch-Lite Lighted Intubation Stylet (Aaron Medical Industries, St. Petersburg, Fla.), Light Wand (Vital Signs, Totowa, N.J.), and Trachlite (Rüsch, Tuttlingen, Germany). These devices essentially comprise a malleable stylet with a high-intensity light at the tip; the stylet is shaped into a curve similar to that anticipated for successful passage into the laryngeal inlet (45 to 90 degrees). To begin, an ETT is passed over a well-lubricated lighted stylet. The tip of the stylet should remain within the tip of the ETT to minimize the potential for airway trauma. The room

**E-FIGURE 12-14** Lighted stylets are available from a number of manufacturers. **A**, Trachlight (Laerdol Medical Corporation, Wappingers Falls, N.Y.). **B**, Surch-Lite Lighted Intubation Stylet (Aaron Medical Industries, St. Petersburg, Fla.). Also available are the Light Wand (Vital Signs, Totowa, N.J.) and the Trachlite (Rüsch, Tuttlingen, Germany). These devices provide a blind method for placing larger-sized endotracheal tubes. **C**, A bright light on the surface of the neck at the level of the larynx indicates the correct location for passage into the trachea. If no light is visible, this usually indicates passage into the esophagus.

lights should be dimmed at this time to ensure that the stylet is visible when the wand is in the mouth. The lighted stylet is then introduced into the mouth while the proximal end of the stylet is flat against the cheek. As the stylet is inserted into the mouth, the proximal end of the handle is rotated counterclockwise until it is upright. The stylet continues to pass through the oropharynx, following the curvature of the tongue. If the tip of the lighted stylet is not in the proper position (e.g., in the esophagus), a diffuse light or no light will be observed on the surface of the neck. Proper position is usually ensured when a sharp, well-defined, bright circle or cone of light is observed transilluminating the neck directly in the midline at the level of the cricothyroid membrane (see E-Fig. 12-14). Once proper position is ensured, the ETT is gently advanced and the stylet is removed.<sup>455,457</sup>

This technique is useful in those children in whom there is no intrinsic laryngeal or airway pathology but in whom visualization is anticipated to be difficult. The light wand may also be of value in children with a fracture of the cervical spine, because tracheal intubation can be accomplished with minimal movement of the neck.<sup>458</sup> The hemodynamic response to intubation with this technique is similar to that observed with rigid laryngoscopy.<sup>454</sup> The limitations of this technique are that it is a blind technique, the diameter of the device limits its use to larger-sized ETTs, and it may require multiple attempts; however, the success rate markedly increases with experience.<sup>455,457</sup> The most common cause of difficulty in passing the ETT is that the tube hangs up on the epiglottis. When this occurs, the lighted stylet may be withdrawn and its position slightly adjusted more posterior to allow passage behind and beyond the epiglottis. Alternatively, the ETT can be rotated along the long axis of the stylet so that the bevel is facing up. Our advice for using this technique is similar to that for bronchoscopy: it should be used in children with normal anatomy to gain the necessary experience required for managing children with abnormal airway anatomy. This adjunct has also been combined with an LMA to guide the stylet into the trachea.<sup>459</sup>

### Bullard Laryngoscope

The Bullard laryngoscope is used for direct visualization of the laryngeal inlet in children with airway pathology (E-Fig. 12-15). It is available in three sizes: adult, pediatric, and pediatric long. This instrument combines fiberoptic bundles and mirrors. It is positioned within the larynx like a laryngoscope blade, and the direction of force used to displace the tongue is similar to that used with a standard laryngoscope, although this is not intuitively obvious from its configuration. It is designed to provide visualization around a 90-degree bend at the tip (i.e., around the base of the tongue). This configuration may be helpful for direct visualization of the larynx in children with mandibular hypoplasia syndromes (e.g., Robin sequence, Treacher Collins syndrome,<sup>460</sup> Goldenhar syndrome, cervical fracture restricting motion), when the acute angulation of the base of the tongue to the glottic opening is exaggerated, and in children with congenital trismus (Hecht syndrome).<sup>461</sup> The technique used in children is different from that used in adults. Once the laryngeal inlet is visualized, a styleted ETT, with a bent configuration similar to the curve of the Bullard laryngoscope (see Fig. 12-21, B), is inserted just to the side of the Bullard laryngoscope blade and advanced under direct vision into the trachea. Success with this instrument is directly proportional to the experience of the anesthesiologist, because the perspective seen through this laryngoscope, the method of

visualization, and the indirect method of ETT placement are so different from standard laryngoscopy.<sup>462,463</sup>

Despite the availability of pediatric Bullard laryngoscopes,<sup>464</sup> adult scopes have also been successfully used in children.<sup>465,466</sup> Although tracheal intubation in children 1 to 5 years of age with a Bullard laryngoscope takes more time than with a Wis-Hipple 1.5 blade, the adult Bullard laryngoscope complements the Wis-Hipple 1.5 blade. Occasionally, the Bullard laryngoscope provides a superior laryngeal view and thus allows successful intubation when a failure with the Wis-Hipple blade occurs. When multiple passes of the tube off the adult Bullard laryngoscope were required, this is usually because of contact with the right aryepiglottic fold or anterior vocal cord. The latter appears to be more problematic when the adult laryngoscope is used in children.<sup>465,466</sup>

Additional limitations of the Bullard laryngoscope are that the ETT can partially obstruct the view of the larynx during insertion and that it can be used only for oral intubation.<sup>464</sup> An advantage is that there appears to be minimal motion of the cervical spine in patients with cervical spine disarticulations.<sup>467-469</sup>

### Retrograde Wire-Guided Intubation

The technique of retrograde wire-guided intubation utilizes trans-tracheal passage of an IV catheter through the cricothyroid membrane into the larynx and retrograde passage of a guidewire from a Seldinger vascular cannulation set to create a guide for intubation.<sup>470-477</sup> A commercial kit is available for use with ETTs that are 5 mm ID or larger (Cook Critical Care). This technique is rarely used in children because of the greater compressibility of the trachea and the increased risk of posterior tracheal wall perforation by the catheter in children compared with adults.

### Video and Indirect Intubating Devices

Advances in technology have led to the reduction in size of video cameras and optical lenses. The integration of these devices into various laryngoscopes and stylets has produced several enhanced tools for securing the airway in children.<sup>478</sup> Several of these new scopes improve visualization during laryngoscopy<sup>412,479-485</sup> and perform better than traditional laryngoscopy in children with difficult direct laryngoscopy.<sup>486-492</sup> However, they are often associated with prolonged time to intubation compared with direct laryngoscopy, and their utility is limited in the presence of blood and secretions. These new devices can be categorized as (1) video laryngoscopes, which incorporate a video camera into the tip of the device; (2) optical laryngoscopes, which use a series of mirrors, prisms, or both to transmit the image from the tip of the device; and (3) optical stylets, which incorporate video or optical systems into a rigid or malleable stylet.

### Video Laryngoscopes

**GLIDESCOPE.** The GlideScope (Verathon, Bothell, Wash.) (E-Fig. 12-16) consists of a hypercurved blade that incorporates a high-resolution camera with a built-in antifog system. It is available in six sizes (0, 1, 2, 2.5, 3, 4) that accommodate all sizes of patients, including as small as approximately 1 kg. Before clinical use, the GlideScope is switched on to allow the antifog system to warm up. A styleted ETT is necessary for successful intubation, and the stylet's curvature should mimic that of the selected GlideScope blade. The manufacturer markets a GlideScope-specific rigid stylet, but a standard malleable stylet has been shown to be equally effective.<sup>493</sup> Unlike traditional direct laryngoscopy, sweeping the tongue to the left of the blade is unnecessary because

**E-FIGURE 12-15** The Bullard laryngoscope is available in three sizes: adult, pediatric, and pediatric long. The device shown at the top is the adult version, which has an attached endotracheal tube guide; the pediatric versions do not have this guide. This instrument combines fiberoptic techniques and mirrors; the fiberoptic bundles are contained within an instrument that functions and is positioned within the larynx like a laryngoscope blade. It is designed to provide visualization around a 90-degree bend at the tip (*arrow*) (i.e., around the base of the tongue). This configuration may be helpful for direct visualization of the larynx in children with mandibular hypoplasia syndromes (e.g., Pierre Robin syndrome, Treacher Collins syndrome, Goldenhar syndrome, cervical fracture restricting motion) when the acute angulation of the base of the tongue to the glottic opening is exaggerated. Once the laryngeal inlet is visualized, a styleted endotracheal tube with a bent configuration similar to the curve of the Bullard laryngoscope (see Fig. 12-21, *B* and *C*) is inserted just to the side of the Bullard laryngoscope blade and advanced under direct vision into the trachea.

**E-FIGURE 12-16** **A**, The GlideScope (Verathon, Bothell, Wash.) consists of an inner reusable video baton and an outer disposable plastic blade that is available in 6 sizes. The lubricated, styleted endotracheal tube (ETT) is formed into the same shape as the GlideScope blade before insertion. **B**, The laryngoscopist advances the GlideScope into the midline or left side of the pharynx to expose the glottic opening and then inserts the ETT alongside the scope while watching the video screen. **C**, The ETT is advanced into the glottic opening under direct vision.

of the distally located camera. The GlideScope blade is ideally placed in the midline or slightly to the left in the pharynx (Video 12-12). This position maximizes the space available for introduction of the ETT. The blade tip is placed in the vallecula, and slight elevation of the blade exposes the glottis. The epiglottis may be elevated if placement of the blade tip in the vallecula does not result in optimal visualization. A poor view may occur if the blade size is inappropriate or if the blade is inserted too deeply in the pharynx. OELM may also be used to facilitate laryngeal visualization.<sup>479,494</sup>

Once the best view is obtained, the styleted ETT is inserted under direct vision alongside the GlideScope blade until it just passes the palatoglossal arches and is in full view on the GlideScope monitor. The technique of sequentially visualizing the ETT directly and then on the monitor and creating space by inserting the GlideScope slightly to the left in the pharynx helps minimize the risk of injury to the soft tissues of the airway during advancement of the ETT.<sup>495-499</sup> When the ETT is visible on the monitor, the tip is directed into the glottic inlet. The stylet should be pulled back once the ETT tip is inserted through the cords, because this facilitates the advancement of the ETT down the trachea. Difficult ETT insertion despite a good view of the glottic opening is an occasional problem encountered with the GlideScope and other video and optical laryngoscopes. This is because of the indirect approach to intubation and the need for good hand-eye coordination. These skills can be acquired by frequent use of the device in children with normal airways.<sup>500,501</sup> The GlideScope Cobalt was successfully used for intubation in a cohort of 121 infants. The average intubation time was 30 seconds, and 95% of the intubations were successful on the first two attempts.<sup>502</sup> It has also been used to facilitate intubation in children with craniofacial abnormalities.<sup>409,503-505</sup>

**STORZ VIDEO LARYNGOSCOPE.** The Storz Video Laryngoscope (Karl Storz GbmH, Tuttlingen, Germany) integrates a camera into Miller- and Macintosh-type blades. This design allows the operator to perform laryngoscopy in the traditional fashion as the Miller-type blade with the video view available if necessary. The video view has been shown to provide a single Comack-Lehane grade improvement over the direct line-of-sight view because of the angulation of the video camera at the tip.<sup>506</sup> It has no antifog mechanism, so use of an antifog solution is needed for unimpaired visualization. Intubation with the Miller video blade can be performed without a stylet, although a styleted ETT with a slight bend at the tip facilitates intubation (E-Fig. 12-17). The Storz Video Laryngoscope is inserted in a similar fashion to the GlideScope. The tip of the blade can be placed in the vallecula; however, because of the magnified lens of the camera, the epiglottis often obstructs the camera view. If this occurs, the blade tip is best utilized to lift the epiglottis to expose the glottis. Once optimal visualization is obtained, the ETT is placed directly along the shaft of the video blade, which guarantees immediate visualization of the ETT in the magnified field of view of the camera and avoids injury to airway soft tissues.

When the Storz Video Laryngoscope was compared with the GlideScope in a pediatric manikin model with normal and DA configurations, the times to intubation and the visual analogue scale scores for field of view and ease of use of the two devices were similar.<sup>507</sup> In another infant manikin study, the Storz Video Laryngoscope was associated with better views, more successful intubations, and similar intubation times as the standard Miller laryngoscope.<sup>506</sup> The Storz Video Laryngoscope has been successfully used to intubate infants and newborns with difficult and

normal airways.<sup>506,508</sup> As with all video laryngoscopes, good hand-eye coordination is necessary for successful intubation. In addition, the operator has to develop the skills necessary to manipulate the ETT indirectly and on a magnified scale. This magnification effect makes subtle movements of the ETT appear large on the video monitor and adds an additional challenge to intubation with these devices. Practice on children with normal airway anatomy is recommended before use on children with abnormal airways.<sup>478</sup>

**MULTIVIEW SCOPE.** The MultiView Scope (Medical Products International, Tokyo) is a recently introduced video laryngoscope system that integrates a camera into Miller- and Macintosh-style blades (E-Fig. 12-18). The handle of the device has a mounted video screen that displays the image from the blade tip. The image from the screen can be transmitted to an external monitor wirelessly, using a manufacturer-supplied attachment (AirView). Aside from being magnified, the direct line-of-sight view is identical to the camera view, making this an ideal tool for teaching direct laryngoscopy. The MultiView Scope also comes with a malleable stylet attachment that provides the ability to insufflate oxygen through the mounted ETT.

### Optical Laryngoscopes

**AIRTRAQ.** The Airtraq (Prodol Meditec S.A., Vizcaya, Spain) is a single-use, curved plastic laryngoscope that utilizes lenses and prisms to transmit the image from its distal tip to an eyepiece. It may reduce the incidence of esophageal intubation and may offer greater success rates, particularly in the hands of the inexperienced laryngoscopist.<sup>509</sup> It has a molded channel into which the ETT is inserted (Fig. 12-30), thereby eliminating the need to manipulate the ETT independently during intubation as is required with the GlideScope, Truview, and Storz Video Laryngoscope. The manufacturer offers a wireless monitor for use with the device. The device should be turned on 30 seconds before use to allow the built-in antifog system to warm up. A disadvantage is that a minimum mouth opening of 16 mm is required for insertion of the Airtraq.

The selected ETT and guide channel of the Airtraq are lubricated, and the cuff of the ETT is fully deflated to avoid cuff damage during advancement of the tube in the channel.<sup>510,511</sup> The appropriately sized ETT is loaded into the guide channel of the device, and the child's head is placed in a neutral position. The Airtraq is inserted in the midline in the pharynx and is advanced along the tongue base into the vallecula (Video 12-13). The epiglottis may be elevated to optimize the view, if necessary. Once in position, the Airtraq is gently lifted to obtain optimal glottic exposure, the glottis is centered in the viewfinder by rotating the entire device slightly clockwise or counterclockwise as necessary, and the ETT is advanced after the optimal centered view is obtained. On occasion, the ETT is directed below the glottic opening; if this occurs, the Airtraq should be withdrawn slightly and the advancement attempted again. The guide channel deflects the ETT slightly leftward (an effect that is more pronounced in infants and neonates); this tendency may be countered by rotating the device slightly clockwise as needed.<sup>512,513</sup> Once the trachea is intubated, the Airtraq is separated from the ETT by holding the tube at the mouth and moving it laterally from the guide channel. The Airtraq is then rotated gently out of the oropharynx.

A suboptimal view with the Airtraq is often a result of inserting the device past the glottis. If this happens, the device should be withdrawn slowly until the larynx comes into view. As with

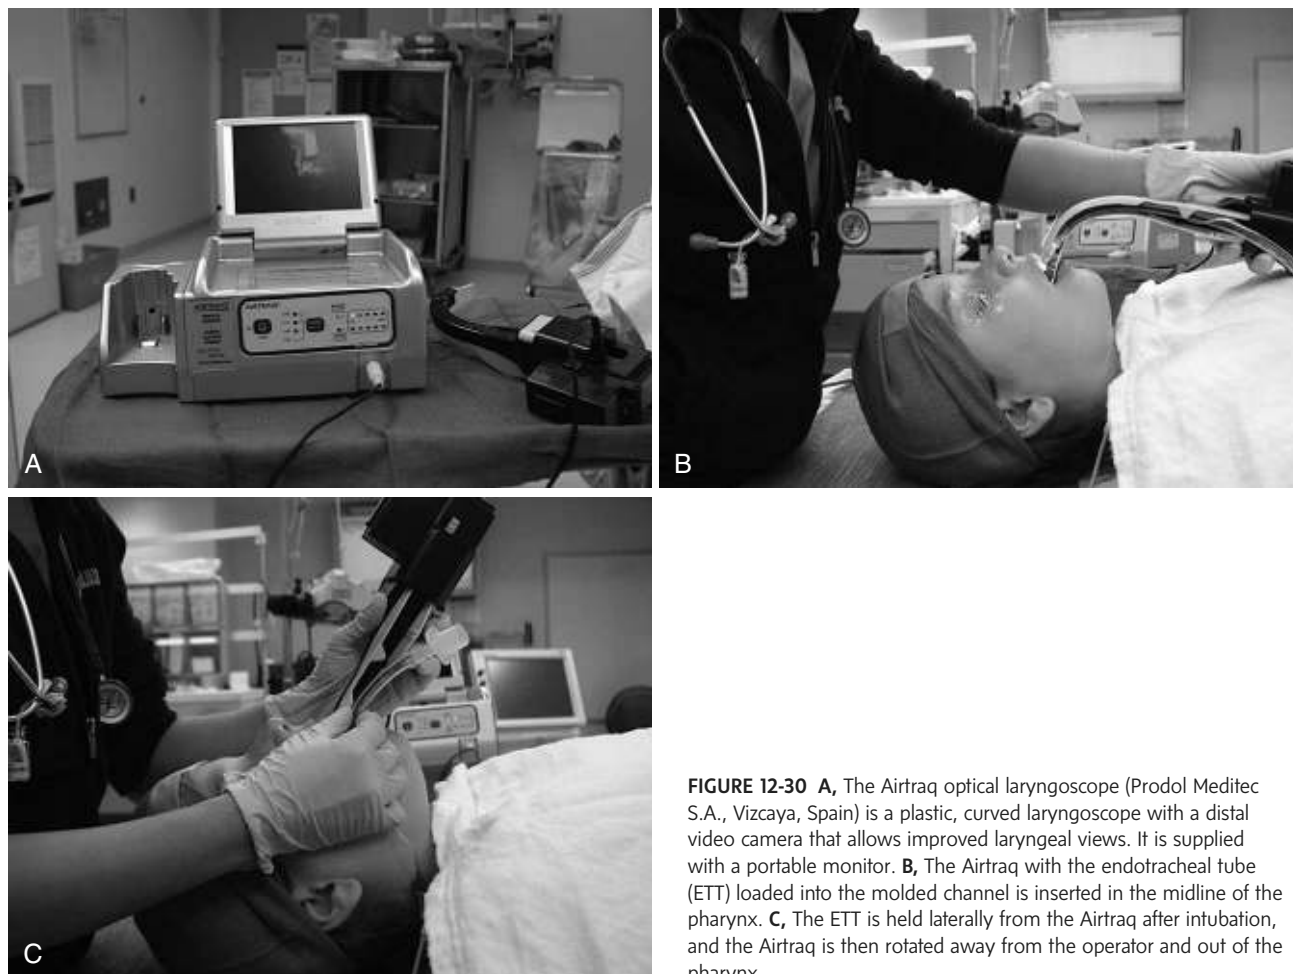

B

C

**E-FIGURE 12-17** The Storz Video Laryngoscope system (Karl Storz GmbH, Tuttlingen, Germany) integrates a camera into Miller- and Macintosh-type blades. **A**, The blade is inserted in the usual fashion. **B**, The epiglottis often obstructs the camera view. **C**, The glottis is exposed by standard means of lifting or angling the blade. **D**, The styleted endotracheal tube is inserted in the usual fashion down the right side of the oropharynx along the shaft of the video blade. **E**, The laryngoscopist directs the endotracheal tube through the glottic opening while watching the video screen.

**FIGURE 12-30** **A**, The Airtraq optical laryngoscope (Prodol Meditec S.A., Vizcaya, Spain) is a plastic, curved laryngoscope with a distal video camera that allows improved laryngeal views. It is supplied with a portable monitor. **B**, The Airtraq with the endotracheal tube (ETT) loaded into the molded channel is inserted in the midline of the pharynx. **C**, The ETT is held laterally from the Airtraq after intubation, and the Airtraq is then rotated away from the operator and out of the pharynx.

other optical and video-enhanced laryngoscopes, the Airtraq has been associated with airway soft tissue injury. A tonsillar injury in a 4-year-old child was attributed to the width of the guide channel of the device.<sup>514</sup> Care should be taken when using the device in small children, given its size relative to the pharyngeal space. An Airtraq devoid of the guide channel is available for nasal intubations; the intubation may be facilitated with the use of Magill forceps or a gum elastic bougie.<sup>515</sup> The Airtraq has been successfully used for intubation in children with normal and difficult airways; however, despite its having a guide channel, some reports have noted difficulty with directing the ETT in neonates and infants.<sup>412,480-482,516-518</sup> The Airtraq is easily learned and used.<sup>519,520</sup> As with many optical and video devices, there remains a learning curve to using the device,<sup>521</sup> particularly the manipulation of the tracheal tube into the glottis in small patients.<sup>478</sup>

**TRUVIEW.** The Truview EVO2 Infant (Truphatek International Ltd., Netanya, Israel) is an optical laryngoscope with an angulated, stainless steel blade that transmits a magnified image from the tip of the device to an eyepiece using lenses (E-Fig. 12-19). A camera is available for connection to the eyepiece to allow the image to be viewed on a monitor. A side port is integrated into the blade to allow oxygen insufflation to clear the lens during intubation; however, caution should be exercised when insufflating oxygen in neonates and infants because of the risk of pneumothorax and gastric rupture.<sup>522-524</sup> Because of the indirect

view afforded by the device, a stylet is necessary for successful intubation; a preformed stylet is available from the manufacturer. As with the GlideScope, the ETT should be shaped in a curve similar to the Truview blade. The blade is placed centrally along the tongue in the pharynx to the vallecula, and slight elevation should expose the vocal cords. The ETT is then passed alongside the device, taking care to look in the mouth during initial insertion to make sure the airway soft tissues are not injured. The Truview EVO2 has been compared to laryngoscopy with a Miller blade in children, with results showing improved views of the larynx but longer intubation times.<sup>484</sup> If the head is in the neutral position as for cervical spine instability, application of OELM will improve the view.<sup>525</sup> A study in adults found an improved laryngeal view compared with standard laryngoscopy without the need to align the tracheal, pharyngeal, and oral axes.<sup>526</sup> Once again, there is a learning curve with this device, and practice should shorten intubation times and minimize injury to soft tissues.<sup>478</sup>

#### Optical Stylets

Use of optical stylets, unlike FOB intubation, allows the operator to visualize the ETT as it enters the glottis. This is because the stylet is located just within the distal tip of the ETT, providing the operator with a view of the leading edge of the ETT. This view allows immediate recognition of impediments to ETT advancement such as the right arytenoid and enables negotiation

**E-FIGURE 12-19** **A**, The Truview EVO2 Infant (Truphatek International Ltd., Netanya, Israel) is an optical laryngoscope with an angulated, stainless steel blade that transmits a magnified image from the tip of the device to an eyepiece using lenses. The device contains an integrated side port for oxygen insufflation. **B**, The device is inserted in a similar manner as for routine direct laryngoscopy. **C**, The endotracheal tube is inserted into the trachea with the use of the proximal eyepiece.

of the stylet around these obstacles. The Shikani and the Bonfils are two optical stylets available for pediatric use. Secretions, fogging, and airway soft tissue can impede intubation with optical stylets because of their small lenses and limited depth of view. Impairment of visualization by airway soft tissue can be addressed by combining these devices with direct laryngoscopy. The direct laryngoscope allows the creation of space for visualization with the optical stylet but may require two operators for successful intubation. Optical stylets may be easier to learn and maneuver than FOBs, although some have questioned the utility of these devices in the pediatric population, particularly in the presence of copious secretions.<sup>527,528</sup>

**SHIKANI OPTICAL STYLET.** The Shikani Optical Stylet (SOS; Clarus Medical, Minneapolis) is a malleable, J-shaped fiberoptic stylet that transmits the image from its distal tip to an eyepiece (E-Fig. 12-20). It has an adjustable tube stop to secure the tube and a port for oxygen insufflation, which should be used with caution in small children.<sup>524,529</sup> The nondominant hand is used to perform a jaw thrust, elevating the epiglottis from the posterior pharyngeal wall, and the stylet is then inserted in the midline in the pharynx (Video 12-14). The tongue base, uvula, and epiglottis are visualized in succession, and the tip is placed just above or just into the glottic inlet. The ETT is then advanced while the SOS is held steady. The SOS is a useful adjunct in the management of the pediatric DA.<sup>530,531</sup>

**STORZ BONFILS OPTICAL STYLET.** The Bonfils Optical Stylet (Karl Storz) is a rigid fiberoptic stylet with a fixed 40-degree curvature (E-Fig. 12-21). It delivers a higher-quality image than the SOS but is not malleable. Although the manufacturer recommends a retromolar approach to intubation, a midline approach similar to that of the SOS has been found to be successful in children.<sup>532</sup> The Bonfils is available in pediatric and infant sizes and can be coupled to a portable monitor (available from the manufacturer). The use of an antisialagogue and suctioning greatly improves visualization when intubating with optical stylets. When the Bonfils was compared with direct laryngoscopy in a cohort of children with normal airways, the Bonfils was associated with better views but had a greater incidence of intubation failure.<sup>527,528,533</sup>

**SHIKANI VERSUS STORZ BONFILS OPTICAL STYLETS.** Both of these devices consist of a metal stylet containing a fiberoptic illumination fiber and a fiberoptic vision fiber that are connected to an eyepiece or a video monitor. The light source may be external or battery powered and attached to the housing at the base of the eyepiece; the latter version allows easy transport in an emergency outside the traditional operating room location (see E-Figs. 12-20 and 12-21).<sup>534,535</sup> These devices are described for use either with or without rigid laryngoscopy. There are slight differences between them. Both provide an adapter to hold the ETT that allows delivery of oxygen through the tip of the ETT, but the SOS requires removal of the 15-mm adapter, whereas the Storz Bonfils device uses the 15-mm adapter to hold the tube in place. The pediatric SOS is slightly malleable and can accommodate a 3.0-mm ID ETT; a 2.5-mm ID ETT fits but is tight. The Storz device is not at all malleable but readily accommodates a 2.5-mm ID ETT.<sup>530,534,536,537</sup> One further difference is that the quality of light (on battery mode) seems a bit brighter with the Storz device.

### Laryngeal Mask Airway as a Conduit for Intubation

Numerous case reports affirm the usefulness of the LMA as a conduit for intubation. Several methods for placing the ETT through the LMA have been described: blind, FOB assisted,

stylet or bougie assisted, and retrograde assisted.<sup>359,538-544</sup> Because of the high occurrence in children of the epiglottis overlying the laryngeal inlet,<sup>321</sup> even with apparently correct placement as judged by ability to ventilate, a visual technique for ETT placement (i.e., FOB assisted) may be the best method. However, because the LMA and conventional ETTs have similar lengths, all intubation methods are complicated by the inability to stabilize the ETT position as the laryngeal mask is withdrawn; that is, LMA removal over the ETT may cause simultaneous withdrawal of the ETT.<sup>545-548</sup> Proposed solutions are leaving the LMA in place,<sup>548-550</sup> splitting the LMA,<sup>286</sup> cutting and shortening the LMA,<sup>547,551,552</sup> and using longer ETTs,<sup>553</sup> but each technique has disadvantages. Leaving the LMA in place makes securing the ETT difficult and precarious. Modifying the LMA may adversely affect its function, and removing a split LMA can easily dislodge the ETT. Longer ETTs may not be readily available. When an FOB is used to place the ETT, the LMA may be withdrawn first over the scope. The ETT is then grasped, passed through the LMA, and threaded over the FOB into the trachea.<sup>541,554,555</sup> An alternative is to telescope two identical ETTs end to end or to use two that differ in size by 0.5-mm ID, either larger or smaller (E-Fig. 12-22 and Video 12-15).<sup>556-558</sup> These ETTs are then threaded onto the FOB. The upper tube is used to maintain the lower tube in position as the LMA is withdrawn.<sup>375,559</sup> The upper ETT is then removed, the 15-mm adapter is replaced on the lower tube, and the correct position is confirmed by exhaled CO<sub>2</sub> and auscultation. The apnea time from insertion of the fiberscope into the LMA until the ETT has been advanced into the trachea can be minimized by using continuous ventilation through a swivel adapter attached to the LMA or ETT.<sup>545,560,561</sup>

It has been suggested that smaller-sized, cuffed ETTs should be used for easier passage and then the cuff can be inflated to eliminate leaks. However, the pilot balloon of a cuffed ETT does not pass through the internal lumen of pediatric LMA sizes of 1.0 to 2.5 (Video 12-16). In larger LMAs, the ETT pilot balloon connection may be too short, so that the pilot balloon can become stuck within the LMA during withdrawal.<sup>562</sup> The largest ETT that will pass through each size of LMA is listed in Table 12-4. For the pediatric-sized LMA Unique and PLMA, even smaller ETTs must be used. The LMA Fastrach is available only in sizes 3, 4, and 5.

### The air-Q

The air-Q Masked Laryngeal Airway (Mercury Medical, Clearwater, Fla.) is an oval shaped laryngeal mask with a shortened, wide, hypercurved airway tube (Fig. 12-31). The air-Q intubating laryngeal mask is available in smaller sizes for younger children and offers some advantages over traditional laryngeal masks when used as an intubation conduit in children. It has a wider airway tube that accommodates cuffed ETTs, and its length is shorter, facilitating removal of the mask after tracheal intubation. The air-Q performs well as a conduit for tracheal intubation and has been successfully used in children with DAs.<sup>563-567</sup> The air-Q is supplied with a red tag attached to the pilot balloon of the mask. This tag equalizes the pressure in the mask to atmospheric pressure, and the mask should be inserted with the tag attached. The manufacturer recommends light lubrication of the back of the mask and the tip of its inner surface.

The air-Q is held in the operator's dominant hand by its airway tube and is inserted into the pharynx at an angle (Video 12-17). The mask is advanced along the tongue base until slight resistance is encountered; a jaw thrust is then performed with the

**E-FIGURE 12-20** Optical stylets. *Top*, Shikani Optical Stylet (Clarus Medical, Minneapolis) is a malleable optical stylet capable of use with 3.0-mm ID endotracheal tubes (ETTs). The somewhat malleable tip allows the anesthesiologist to configure the shape as needed for each patient. This device provides another alternative for managing the difficult airway at a much lower cost than fiberoptic equipment. *Bottom*, Storz Bonfils Optical Stylet (Karl Storz GmbH, Tuttlingen, Germany) is a rigid device with a preformed 40-degree bend. This device allows passage of a 2.5-mm ID ETT. Both devices provide an adapter that allows administration of oxygen or oxygen and anesthetic gases at the tip of the ETT during airway manipulations (see text for details).

**E-FIGURE 12-21** In this series of photographs, the Storz Bonfils Optical Stylet is used to accomplish tracheal intubation in a patient with extensive head and neck scar contractures. **A**, The endotracheal tube (ETT) is loaded into the Bonfils and introduced into the patient's mouth. **B**, The glottic inlet is identified, and the Bonfils is held directly in the opening **C** and **D**, The ETT is advanced off the Bonfils into the trachea. **E**, The Bonfils is then carefully removed while the ETT is held in place.

**E-FIGURE 12-22** The laryngeal mask airway (LMA) can be used as a conduit for fiberoptic intubation, allowing better control of the airway while locating the glottis. The LMA also helps to maintain the fiberoptic bronchoscope (FOB) in the midline. Two endotracheal tubes (ETTs) are wedged together end to end (**A**) after removal of the 15-mm adapter from the distal ETT (usually the proximal ETT is one-half size smaller than the distal tube). An assistant holds the LMA in place, and the FOB is introduced into the LMA (**B**). When the tip of the FOB is located within the trachea, the double-length ETT is passed into the trachea (**C**). The proximal ETT is used to hold the distal ETT in place while the LMA is threaded off the ETTs. The original 15-mm adapter is replaced, and the ETT is taped in place. With the appropriate size FOB, this technique may be used with ETT sizes of 3.5 mm ID or greater.

**FIGURE 12-31** **A**, The air-Q Intubating Laryngeal Airway (Mercury Medical, Clearwater, Fla.) offers some advantages over traditional laryngeal masks when used as an intubation conduit in children. It has a wider airway tube that accommodates cuffed endotracheal tubes (ETTs), and its length is shorter, which facilitates removal of the mask after tracheal intubation. Before the intubation attempt, one should check that the ETT and its cuff will easily pass through the laryngeal airway size to be used. The 15-mm adapter of the air-Q is removed, the trachea is intubated with a bronchoscope, and the ETT is advanced into the trachea. **B**, When correct tracheal position is assured, a special stylet (coudé-tip Tracheal Tube Introducer, available in three sizes for pediatric-sized ETTs) is inserted into the lumen of the ETT, the cuff of the air-Q is deflated, and with slight advancing pressure the ETT is held in place while the air-Q is gently withdrawn.

nondominant hand, and the mask inserted slightly farther until it becomes seated in the airway. When the air-Q is used as a conduit for intubation, the ETT and its cuff should be checked before the intubation attempt to be sure they will easily pass through the size to be used. The external surface of the ETT should be liberally lubricated. The 15-mm adapter of the air-Q is removed, the trachea is intubated with a bronchoscope, and the ETT is advanced into the trachea. When correct tracheal position is assured, a special stabilizer (available in three sizes for pediatric-sized ETTs) is inserted into the lumen of the ETT. The cuff of the air-Q is deflated, and with slight advancing pressure the ETT is held in place while the air-Q is gently withdrawn (Video 12-17). Proper ETT position is then reconfirmed, and the ETT is taped in place.

The air-Q was compared with the LMA Unique in a cohort of 50 children aged 6 to 36 months. The air-Q had higher airway leak pressure and superior fiberoptic grade of view than the LMA Unique.<sup>568</sup> In another study that evaluated the air-Q as a conduit for tracheal intubation in infants, the mean oropharyngeal leak pressure was  $18.5 \pm 1.8$  cm H<sub>2</sub>O, and the mean insertion time

was  $13.3 \pm 3.9$  seconds; tracheal intubation was successful in 19 of 20 infants.<sup>569</sup> The successful use of the air-Q as a conduit for tracheal intubation has also been reported in infants with difficult direct laryngoscopy.<sup>567,570</sup>

### Combined Techniques

#### *Retrograde Wire and the Flexible Fiberoptic Bronchoscope*

A case series reported the use of a combined retrograde wire and FOB technique in 20 children aged 1 day to 17 years.<sup>571</sup> Equipment required includes: a ventilating endoscopic mask, equipment for retrograde wire intubation, an FOB with a working channel, and grabbing forceps. The technique begins similarly to retrograde wire-guided intubation. A venous cannula is passed through the cricothyroid membrane in a cephalad manner. The needle is removed, and lidocaine is injected to provide topical anesthesia. Aspiration is done first; detection of air confirms correct placement of the cannula within the lumen of the trachea. A guidewire of suitable length is passed through the cannula and advanced cephalad into the pharynx until it can be retrieved with the forceps from the mouth. The wire is then passed into the working channel of an FOB in a retrograde manner starting at the tip of the FOB (some FOBs may require removal of tip components to allow the wire to pass). An appropriately sized ETT should already be threaded onto the FOB. The FOB is then advanced along the wire while the laryngoscopist looks for familiar anatomic structures. After placement of the FOB tip below the vocal cords is confirmed, the wire is removed in the caudad direction from the IV cannula. The FOB is further advanced to the midtrachea, and the ETT is threaded into place.

Tips for success with this technique are to preserve spontaneous ventilation and to remove the guidewire in the caudad direction, because this tends to pull the FOB farther into the airway rather than out of the airway, which might occur if it is removed in the opposite direction. This technique may improve success over retrograde techniques alone, because the FOB allows direct visualization and is a stiffer guide for the ETT than the wire alone. It also may improve success over the FOB alone, because the glottis is more readily identified even in the presence of blood or secretions.

#### *Rigid Laryngoscopy and the Flexible Fiberoptic Bronchoscope*

The rigid laryngoscopy blade may be used to facilitate exposure so that an FOB can be used to visualize the larynx.<sup>572</sup>

#### *Flexible Fiberoptic Bronchoscope Used in a Retrograde Manner*

An FOB was used in a retrograde manner in a 4-year-old child with Nager syndrome who presented for tracheocutaneous fistula closure after decannulation of a tracheostomy. After failed attempts at rigid and direct fiberoptic ETT placement, a FOB was placed in a retrograde fashion, using direct vision, through the fistula, past the vocal cords, into the nasopharynx, and out the naris. It was then used as a stylet for ETT placement.<sup>573</sup> The clinical scenario was unusual, but the technique was successful for this child.

### ACKNOWLEDGMENTS

We wish to thank Melissa Wheeler for her prior contributions to this chapter and I. David Todres posthumously.

Many manufacturers have graciously provided us samples of airway devices so that we could illustrate examples of commonly available equipment. There is insufficient room to illustrate all available devices. Lack of illustration of a device should not be

construed as lack of efficacy, nor should illustration of a device be interpreted as endorsement. Practitioners are encouraged to use all equipment available and to make their own educated decision about what devices provide the greatest safety and efficacy in their hands.

- This study used magnetic resonance images of the upper airway in children of all ages and developed the relationship between age and laryngeal dimensions. It demonstrated that there is no change in relative dimensions of the subglottic structures from birth through adolescence.*
- Practice guidelines for management of the difficult airway: an updated report by the American Society of Anesthesiologists. Task Force on Management of the Difficult Airway. *Anesthesiology* 2003;98:1269-77.
- The most recent guidelines from the American Society of Anesthesiologists for management of the patient with a difficult airway, whether anticipated and unanticipated. Although geared for adult anesthesia, the approach outlined in the algorithm may be applied to children.*
- Rolf N, Coté CJ. Diagnosis of clinically unrecognized endobronchial intubation in paediatric anaesthesia: which is more sensitive, pulse oximetry or capnography? *Paediatr Anaesth* 1992;2:31-5.
- This paper determined that pulse oximetry is more sensitive than capnography in detecting endobronchial intubation. It recommends that when a small but persistent change in oxygen saturation is noted, rather than increase the inspired oxygen concentration, one must first investigate the cause and reassess the position of the endotracheal tube.*
- Weiss M, Dullenkopf A, Gysin C, Dillier CM, Gerber AC. Shortcomings of cuffed paediatric-tracheal tubes. *Br J Anaesth* 2004;92:78-88.
- This paper compares the physical characteristics of the most commonly available pediatric endotracheal tubes (ETTs). It also underscores the shortcomings in ETT design that may affect airway-related patient complications and that should be considered in choosing ETTs for children.*
- Wheeler M. Management strategies for the difficult pediatric airway. *Anesth Clin North Am* 1998;16:743-61.
- A discussion of the management issues specific to children with a difficult pediatric airway. This article expands on the ideas supported by the American Society of Anesthesiologists Task Force on Management of the Difficult Airway as they apply to children.*
- Wheeler M, Roth AG, Dsida RM, et al. Teaching residents pediatric fiberoptic intubation of the trachea: traditional fiberscope with an eyepiece versus a video-assisted technique using a fiberscope with an integrated camera. *Anesthesiology* 2004;101:842-6.
- Lack of proficiency using fiberoptic equipment for pediatric airway management remains a concern. This paper supports two important points: (1) one can achieve a satisfactory proficiency with a pediatric fiberoptic system with relatively few intubations, and (2) a video system can both improve the speed of skill acquisition and shorten the time required for successful intubation.*

# Anesthesia for Thoracic Surgery

GREGORY B. HAMMER

## General Perioperative Considerations

Ventilation and Perfusion during Thoracic Surgery  
Thoracoscopy

## Techniques for Single-Lung Ventilation in Infants and Children

Surgical Lesions of the Chest  
Summary

## General Perioperative Considerations

A thorough preoperative evaluation is essential when caring for the child who is scheduled for thoracic surgery. Appropriate imaging and laboratory studies should be performed according to the lesion involved. Guidelines for fasting, choice of premedication, and preparation of the operating room (OR) are the same as for other infants and children scheduled for major surgery. After induction of anesthesia, placement of an intravenous (IV) catheter, and tracheal intubation, arterial catheterization should be considered for children undergoing thoracotomy as well as those with severe lung disease having thoracoscopic surgery. For thoracoscopic procedures of relatively brief duration in children without significant lung disease, an arterial catheter may not be required. The arterial catheter facilitates monitoring of systemic blood pressure during manipulation of the lungs and mediastinum as well as arterial blood gas tensions during single-lung ventilation (SLV). Placement of a central venous catheter is generally not indicated if peripheral IV access is adequate for projected fluid and blood administration.

Inhalational anesthetic agents are commonly administered in 100% O<sub>2</sub> during maintenance of anesthesia. Isoflurane may be preferred owing to less attenuation of hypoxic pulmonary vasoconstriction compared with other inhalational agents, although this has not been studied in children.<sup>1</sup> Nitrous oxide is avoided. IV opioids have a sparing effect on the concentration of inhalational anesthetics required, and therefore may limit the impairment of hypoxic pulmonary vasoconstriction. Alternatively, total IV anesthesia may be used.

A variety of approaches have been described to prevent and treat pain after videoscopic procedures. Bupivacaine infiltration at incision sites before skin incision has been shown to decrease postoperative pain.<sup>2,3</sup> Bupivacaine infiltration was found to be superior to IV fentanyl or tenoxicam for reducing postoperative pain.<sup>4</sup> The combination of general anesthesia with regional anesthesia that also contributes postoperative analgesia, is particularly desirable for thoracotomy, but may also be beneficial for thoracoscopic procedures. This is especially true when thoracostomy tube drainage, a source of significant postoperative pain, is used after surgery. In addition, regional blockade for postoperative analgesia facilitates deep breathing and coughing, which may limit atelectasis and pneumonia. A variety of regional anesthetic techniques have been described for intraoperative anesthesia and postoperative analgesia, including intercostal and paravertebral blocks, intrapleural infusions, and epidural anesthesia (see Chapters 41, 42, and 43).

## VENTILATION AND PERFUSION DURING THORACIC SURGERY

Ventilation is normally distributed preferentially to dependent regions of the lung, so that there is a gradient of increasing ventilation from the least to the most dependent lung segments. Because of gravitational effects, perfusion normally follows a similar distribution, with increased blood flow to dependent lung segments. Therefore ventilation and perfusion are normally well matched. In infants, however, ventilation is normally distributed to the nondependent areas of the lung and perfusion is more evenly distributed because of their smaller anteroposterior distance that mitigates the effect of gravity. These two effects result in increased ventilation/perfusion ( $\dot{V}/\dot{Q}$ ) mismatch. During thoracic surgery, several factors act to further increase  $\dot{V}/\dot{Q}$  mismatch. General anesthesia, neuromuscular blockade, and mechanical ventilation may cause a decrease in functional residual capacity of both lungs. Compression of the dependent lung in the lateral decubitus position may cause atelectasis. Surgical retraction and/or SLV collapse the operative lung. Hypoxic pulmonary vasoconstriction, which acts to divert blood flow away from underventilated lung, thereby minimizing  $\dot{V}/\dot{Q}$  mismatch, may be diminished by inhalational anesthetic agents and other vasodilating drugs. These factors apply equally to infants, children, and adults. The overall effect of the lateral decubitus position on  $\dot{V}/\dot{Q}$  mismatch, however, is different in infants compared with older children and adults.

In adults with unilateral lung disease, oxygenation is optimal when the patient is placed in the lateral decubitus position with the healthy lung dependent ("down") and the diseased lung nondependent ("up").<sup>5</sup> Presumably, this is related to an increase in blood flow to the dependent, healthy lung and a decrease in blood flow to the nondependent, diseased lung because of the hydrostatic pressure (or gravitational) gradient between the two lungs. This phenomenon promotes  $\dot{V}/\dot{Q}$  matching in the adult patient undergoing thoracic surgery in the lateral decubitus position.

In infants with unilateral lung disease, however, oxygenation is improved with the healthy lung "up."<sup>6</sup> Several factors account for this discrepancy between adults and infants. Infants have a soft, easily compressible rib cage that cannot fully support the underlying lung. Therefore functional residual capacity is closer to residual volume, making airway closure likely to occur in the dependent lung even during tidal breathing.<sup>7</sup> When the adult is placed in the lateral decubitus position, the dependent diaphragm has a mechanical advantage because it is "loaded" by the abdominal hydrostatic pressure gradient. This pressure

gradient is reduced in infants, thereby reducing the functional advantage of the dependent diaphragm. The infant's small size also reduces the hydrostatic pressure gradient between the non-dependent and dependent lungs. Consequently, the favorable increase in perfusion to the dependent, ventilated lung is attenuated in infants.

Finally, the infant's increased oxygen requirement, coupled with a small functional residual capacity, predisposes to hypoxemia. Infants normally consume 6 to 8 mL of  $O_2$ /kg/min compared with adult rates of 2 to 3 mL of  $O_2$ /kg/min.<sup>8</sup> For these reasons, infants are at an increased risk of significant hemoglobin desaturation during surgery in the lateral decubitus position.

A modest increase in  $PaCO_2$  may be beneficial in children during thoracoscopic procedures. In a study of 12 children undergoing video-assisted thoracoscopic surgery for patent ductus arteriosus closure, hypercapnea targeting  $PaCO_2$  values between 50 and 70 mm Hg increased cardiac output, central venous and arterial oxygen tension.<sup>9</sup>

### THORACOSCOPY

With the miniaturization of instruments, progress in video technology, and growing experience among pediatric surgeons, video endoscopic surgery of the chest, or thoracoscopy, is being performed for an increasing number of pediatric surgical indications (Table 13-1). Advantages of thoracoscopy include smaller chest incisions, reduced postoperative pain, and more rapid postoperative recovery compared with thoracotomy (Table 13-2,

Shorter hospitalization
Fewer long-term complications
Cosmetically superior

**FIGURE 13-1** A, Significant chest deformity may occur with growth after thoracotomy. B, Smaller incisions associated with thoracoscopic surgery result in minimal musculoskeletal changes.

Fig. 13-1).<sup>10,11</sup> Endoscopes that can be passed through a needle and trocar system are now manufactured, and digital video signals can be electronically modified to yield sharp, detailed, color images with a minimum light intensity. Digital cameras are designed to maintain an image in an upright orientation regardless of how the telescope is rotated. They are also equipped with an optical or digital zoom to magnify the image or give the illusion of moving the telescope closer to the object of interest. The smallest of telescopes use fiberoptics and are less than 2 mm in diameter (Fig. 13-2). Two-millimeter disposable ports, mounted on a Veress needle, are used for introduction of these small instruments. Larger instruments and ports are used in larger children and for more complex cases.

A second area of major advance in video endoscopic surgery is the development of the endoscopic suite, in which all necessary cables and wiring are located within equipment booms, ceilings, and walls. The manipulation of digital images is controlled by

**FIGURE 13-2** A, Thoracoscopic instruments in situ in an infant. B, Telescopes for use in infants range from 1.2 to 4.0 mm in diameter.

voice or touchscreen command either from the operative field or at a conveniently located station nearby. High-quality digital images are displayed on flat panel monitors that can be positioned within a comfortable viewing range. Remote-controlled cameras can direct any view in the room to any of the monitors or to a remote site. Digital radiographs can be routed from the radiology department to the OR, and consultants in remote locations can be viewed on monitors in the OR so that the surgeon can see to whom he or she is speaking. An additional feature of newer endoscopy suites is voice-controlled bed positioning. Robotic tools can be vocally directed to position telescopes in the surgical field for optimal viewing; these surgical “telemanipulators” facilitate microsurgery in confined spaces, even for small infants. Other endoscopic robots are being developed for a wide range of surgical applications.

Thoracoscopy can be performed while both lungs are being ventilated using CO<sub>2</sub> insufflation and placement of a retractor to displace lung tissue in the operative field. However, SLV is extremely desirable during thoracoscopy because lung deflation improves visualization of thoracic contents and may reduce lung injury caused by the use of retractors. There are several different techniques that can be used for SLV in children.

**FIGURE 13-3** Placement of a single-lumen endotracheal tube (ETT) for left-sided single-lung ventilation results in obstruction of the upper lobe orifice if the distance from the proximal cuff to the tip of the ETT is longer than the main-stem bronchus.

## TECHNIQUES FOR SINGLE-LUNG VENTILATION IN INFANTS AND CHILDREN

### Use of a Single-Lumen Endotracheal Tube

The simplest means of providing SLV is to intentionally intubate the ipsilateral main-stem bronchus with a conventional single-lumen endotracheal tube (ETT).<sup>12</sup> When the left bronchus is to be intubated, the bevel of the ETT is rotated 180 degrees and the child's head is turned to the right.<sup>13</sup> The ETT is advanced into the bronchus until breath sounds on the operative side disappear. A fiberoptic bronchoscope (FOB) may be passed through or alongside the ETT to confirm or guide placement. Alternatively, fluoroscopy may be used to guide and position the ETT.<sup>14</sup> When a cuffed ETT is used, the distance from the proximal cuff to the tip of the ETT must be less than the length of the main-stem bronchus so that the upper lobe orifice is not occluded (Fig. 13-3).<sup>15</sup> This technique is simple and requires no special equipment other than a FOB. This may be the preferred technique of SLV in emergency situations, such as airway hemorrhage or contralateral tension pneumothorax.

Problems can occur when using a single-lumen ETT for SLV. If a smaller, uncuffed ETT is used, it may be difficult to provide an adequate seal of the intended bronchus. This may prevent the operative lung from adequately collapsing or fail to protect the healthy, ventilated lung from contamination by purulent material or blood from the contralateral lung. One is unable to suction the operative lung using this technique. Hypoxemia may occur as a result of obstruction of the upper lobe bronchus, especially when the short right main-stem bronchus is intubated.

Variations of this technique have been described, including intubation of both bronchi independently with small ETTs.<sup>16-19</sup>

**FIGURE 13-4** A variety of balloon-tipped catheters have been used for single-lung ventilation, including an Arrow balloon wedge catheter (A) (Arrow International, Inc., Reading, Pa.), a Cook pediatric bronchial blocker (B) (Cook Medical, Inc., Bloomington, Ind.), and a Fogarty embolectomy catheter (C). (Photographs by Michael Chen, MD.)

**FIGURE 13-5** A bronchial blocker (arrow) is placed in a distal left bronchus (A) and withdrawn into the proximal left main-stem bronchus (B, arrow) under fluoroscopic guidance.

One main-stem bronchus is initially intubated with an ETT, after which another ETT is advanced over a FOB into the opposite bronchus. The disadvantages of these techniques include technical difficulties and trauma to the tracheal and bronchial mucosa. Even after successful bilateral bronchial intubation, the inner diameters of the tubes will be small, limiting gas flow and impeding suctioning of the airways.

#### Use of Balloon-Tipped Bronchial Blockers

A Fogarty embolectomy catheter or an end-hole, balloon wedge catheter may be used for bronchial blockade to provide SLV (Fig. 13-4).<sup>20-23</sup> Placement of a Fogarty catheter is facilitated by bending the tip of its stylet toward the bronchus on the operative side. An FOB may be used to reposition the catheter and confirm appropriate placement. Various techniques for placing an end-hole catheter outside the ETT have been described. Using one such method, the bronchus on the operative side is initially

intubated with an ETT.<sup>20</sup> A guidewire is then advanced into that bronchus through the ETT. The ETT is removed and the blocker is advanced over the guidewire into the bronchus. An ETT is then reinserted into the trachea alongside the blocker catheter. The catheter balloon is positioned in the proximal main-stem bronchus under fiberoptic visual guidance. Alternatively, if an FOB small enough to pass through the indwelling ETT is not available, fluoroscopy may be used (Fig. 13-5). With an inflated blocker balloon the airway is completely sealed, providing more predictable lung collapse and better operating conditions than with an ETT in the bronchus.

One potential problem with this technique is dislodgement of the blocker balloon into the trachea, blocking ventilation to both lungs and/or preventing collapse of the operative lung. The balloons of most catheters currently used for bronchial blockade have low compliance properties (i.e., low volume, high pressure). They require 1 to 3 mL of air or saline to fully inflate.

**FIGURE 13-6** The Cook 5F endobronchial catheter is shown inserted in the multiport adapter. **A**, The adapter has four ports for connection to the breathing circuit, fiberoptic bronchoscope (FOB), endobronchial catheter, and endotracheal tube. After the FOB and endobronchial catheter have been inserted through the multiport adaptor, the FOB is placed through the monofilament loop at the distal end of the catheter (*arrow*). The multiport adaptor is then attached to the indwelling endotracheal tube (**B**) and the breathing circuit (**C**). The FOB is directed into the main-stem bronchus on the operative side. The catheter is then advanced until the monofilament loop slides off the end of the FOB into the bronchus. (Photographs by Elliot Krane, MD.)

ID (mm)*	OD (mm)	Equivalent French Size†
3.0	4.3	13
3.5	4.9	15
4.0	5.5	17
4.5	6.2	19
5.0	6.8	21
5.5	7.5	23
6.0	8.2	25
6.5	8.9	27
7.0	9.6	29
7.5	10.2	31
8.0	10.8	32

*Note:* Cuffed tubes have approximately 0.5-mm additional outer diameter. The external diameter may also vary by manufacturer.

ID, Internal diameter; OD, outer diameter.

\*Sheridan tracheal tubes (Hudson RCI, Arlington Heights, Ill.).

†French (F) size is 3 × OD (mm).

Overdistention of the balloon can damage or even rupture the airway.<sup>24</sup> A recent study, however, reported that bronchial blocker cuffs produced lower “cuff-to-tracheal” pressures than double-lumen tubes.<sup>25</sup> When closed-tip bronchial blockers are used, the operative lung cannot be suctioned and continuous positive airway pressure (CPAP) cannot be provided to the operative lung if needed.

When a bronchial blocker is placed outside the ETT, care must be taken to avoid injury caused by compression and resultant ischemia of the tracheal mucosa. The sum of the catheter diameter and the outer diameter of the ETT should not significantly exceed the tracheal diameter. Outer diameters for pediatric-size ETTs are shown in Table 13-3. These numbers provide an estimate of the predicted tracheal diameter, which should approximate the size of the uncuffed ETT predicted to produce a seal in the trachea.

Recently, adapters have been developed that facilitate ventilation during placement of a bronchial blocker through an

indwelling ETT.<sup>26,27</sup> Use of a 5F endobronchial blocker that is designed for use in children, and has a multiport adapter and FOB, has been described (Cook Medical, Inc., Bloomington, Ind.).<sup>28</sup> The balloon is elliptical so that it conforms to the bronchial lumen when inflated. The blocker catheter has a maximum outer diameter of 2.5 mm (including the deflated balloon), a central lumen with a diameter of 0.7 mm, and a distal balloon with a capacity of 3 mL. The balloon has a length of 1.0 cm, corresponding to the length of the right main-stem bronchus in children approximately 2 years of age.<sup>29</sup> The blocker is placed coaxially through a dedicated port in the adapter, which also has a port for passage of a FOB and ports for connection to the anesthesia breathing circuit and ETT (Fig. 13-6). The FOB port has a plastic sealing cap, whereas the blocker port has a Tuohy-Borst connector that locks the catheter in place and maintains an airtight seal. Because oxygen can be administered during passage of the blocker and FOB, the risk of hypoxemia during blocker placement is diminished, and repositioning of the blocker may be performed with fiberoptic guidance during surgery.

When a FOB is used to guide the placement of a bronchial blocker, both the blocker catheter and FOB must pass through the indwelling ETT. The smallest ETT through which the catheter and FOB can be passed must be larger than the sum of the outer diameters of the catheter and the FOB. The 5F Cook bronchial blocker and an FOB with a 2.2-mm diameter, for example, may be inserted through an ETT with an internal diameter as small as 5.0 mm; for children with an indwelling ETT smaller than this, a blocker catheter can be positioned under fluoroscopy (see Fig. 13-5).<sup>30</sup>

#### Use of a Univent Tube

The Univent tube (Fuji Systems Corporation, Tokyo) is a conventional ETT with a second lumen containing a small blocker catheter that can be advanced into a bronchus (Fig. 13-7).<sup>31,32</sup> A balloon located at the distal end of this small tube serves as a blocker. Univent tubes require a FOB for successful placement. Univent tubes are now available in sizes with internal diameters as small as 3.5 and 4.5 mm, for use in children older than 6 years of age.<sup>33</sup> Because the blocker tube is firmly attached to the main

**FIGURE 13-7** The Univent tube is available in a variety of adult sizes, as well as 3.5 mm internal-diameter and 4.5 mm internal-diameter sizes for use in children (*top*). The adult tubes have a tracheal cuff and an end-hole bronchial blocker, allowing administration of oxygen and suction (*bottom*). The pediatric tubes are uncuffed and have a closed-tip blocker. (Photographs by Michael Chen, MD.)

\*Sagittal/transverse.

ETT, displacement of the Univent blocker balloon is less likely than when other blocker techniques are used. The blocker tube has a small lumen that allows egress of gas and can be used to insufflate oxygen or suction the operated lung.

One disadvantage of the Univent tube is the large cross-sectional area occupied by the blocker channel, especially in the smaller size tubes. Therefore Univent tubes have a large outer diameter with respect to their inner (luminal) diameters (Table 13-4). Smaller Univent tubes have a disproportionately high resistance to gas flow.<sup>34</sup> The Univent tube's blocker balloon has

**FIGURE 13-8** Although the bronchial lumen of a double-lumen tube appears to be round (**A**), both the bronchial and tracheal lumens are D-shaped, as evident in a cross-sectional view (**B**). Their actual lumens have restricted limiting diameters. (Photographs by Michael Chen, MD.)

low-volume, high-pressure characteristics, so mucosal injury can occur during normal inflation.<sup>35,36</sup>

### Use of Double-Lumen Tubes

All double-lumen tubes (DLTs) are essentially two tubes of unequal length molded together. The shorter tube ends in the trachea, and the longer tube ends in the bronchus (Fig. 13-8). DLTs for older children and adults have cuffs located on the tracheal and bronchial lumens. The tracheal cuff, when inflated, allows positive-pressure ventilation. The inflated bronchial cuff allows ventilation to be diverted to either or both lungs and protects each lung from contamination from secretions, purulent material, or blood originating from the contralateral side.

Marraro described a bilumen tube for infants.<sup>37</sup> This tube consists of two separate uncuffed tracheal tubes of different lengths attached longitudinally. This tube is not available in the United States. The smallest cuffed DLT commercially available in the United States is a 26F size (Teleflex Medical, Research Triangle Park, N.C.). This DLT may be used in children as young as 8 years old. DLTs are also available in sizes 28 and 32F (Nelcor brand [Covidien, Mansfield, Mass.]); these are suitable for children 10 years of age and older. Numerous manufacturers produce clear, disposable, PVC Robertshaw-design DLTs, which are available in sizes 35 to 41F (Table 13-5). Essentially, they consist of similar features with small modifications in cuff shape and location. A colored bronchial cuff, commonly blue, permits easy identification by fiberoptic bronchoscopy. In general, the cuffs used in DLTs are high-compliance cuffs that are designed to exert less pressure on the tracheal and bronchial mucosa compared with low-compliance cuffs. For right-sided DLTs, the

**TABLE 13-5 Double-Lumen Tube Dimensions**

Size (F)	Main Body OD (mm)	Limiting Diameter Tracheal Lumen (mm)	Limiting Diameter Bronchial Lumen (mm)
26*	8.7	N/A	N/A
28†	9.4	3.1	3.2
32†	10.6	3.5	3.4
35†	11.7	4.5	4.3
37†	12.4	4.7	4.5
39†	13.1	4.9	4.9
41†	13.7	5.4	5.4

Note: The limiting diameters correspond to the largest suction catheter or fiberoptic bronchoscope that can be placed via the lumen under ideal circumstances (e.g., adequate lubrication). Comparing the data in this table to that in Table 13-3, the OD of the DLTs corresponds to the following tracheal tubes: 26F DLT is equivalent to that of a 6.0-6.5 mm ID tracheal tube; a 28F is equivalent to a 6.5-7.0 mm ID; and a 32F is equivalent to an 8.0 mm ID. Cuff thickness is 0.049 mm; therefore cuff adds 0.10 mm to overall OD of tube.

DLT, Double-lumen tube, ID, internal diameter; OD, outer diameter.

\*Teleflex Medical, Research Triangle Park, N.C.

†Covidien, Mansfield, Mass.

endobronchial cuff is donut shaped and allows the right upper lobe ventilation opening to be positioned at the right upper lobe orifice. Despite this design, right upper lobe occlusion may occur because of the shorter length of the right main-stem bronchus.<sup>1,38</sup> Therefore right-sided DLTs are used infrequently.

DLTs are inserted in children using the same technique as in adults, and left DLTs are almost exclusively used.<sup>39</sup> The tip of the tube is inserted just past the vocal cords, and the stylet is withdrawn. The DLT is rotated 90 degrees to the appropriate side and then advanced into the bronchus. After intubation, the tracheal cuff is inflated first and equal breath sounds should be confirmed. To prevent mucosal damage from excessive pressure applied by the bronchial cuff, the cuff is inflated with incremental volumes to seal air leaks around the bronchial cuff into the trachea. Inflation of the bronchial cuff seldom requires more than 2 mL of air. After inflation of the bronchial cuff, bilateral breath sounds should be rechecked to confirm that the bronchial cuff is not herniating across the carina to impede contralateral lung ventilation. Fiberoptic bronchoscopy can be used to directly visualize the proximal edge of the bronchial cuff in the left bronchus, just distal to the carina. One simple way to verify that the tip of the bronchial lumen is located in the designated bronchus is to clamp the tracheal lumen at the level of the connector and then observe and auscultate left and right lungs. Usually, inspection will reveal unilateral movement of the ventilated hemithorax. With the tracheal lumen clamped, auscultation of the chest will demonstrate air entry in the left lung and no ventilation in the right lung. After auscultation and release of the tracheal clamp, the bronchial lumen is clamped and the tracheal lumen is ventilated to confirm movement and breath sounds of the right lung. Whenever a right-sided DLT is used, ventilation of the right upper lobe must be verified. This can be accomplished by careful auscultation over the right upper lung field or, more accurately, by fiberoptic bronchoscopy. When a left-sided DLT is used, the risk of occluding the left upper lobe bronchus by advancement of the bronchial tip into the distal left main bronchus should be considered.

DLTs may be malpositioned in up to 48% of cases despite careful inspection and auscultation.<sup>40</sup> The simplest way to

evaluate proper positioning of a left-sided DLT is to perform fiberoptic bronchoscopy through the tracheal lumen. The carina is then visualized, and only the proximal edge of the bronchial cuff should be identified just distal to the carina. Herniation of the bronchial cuff over the carina to partially occlude the contralateral main-stem bronchus should be excluded. Fiberoptic bronchoscopy should then be performed via the bronchial lumen to identify the patent left upper lobe orifice. When a right-sided DLT is used, the right upper lobe bronchial orifice must be identified while the bronchoscope is passed through the right upper lobe ventilating slot.

The use of FOB to facilitate positioning of DLTs in children is dependent on the availability of small instruments. FOBs with an external diameter of 3.6 mm are commonly available and will pass through a 35F DLT. Smaller FOBs are needed when 26F, 28F, and 32F DLTs are used (see Table 13-5 for "limiting diameters").

In the adult population, the depth of insertion of the DLT is directly related to the height of the patient.<sup>41</sup> No equivalent measurements are available as yet in children. Fortunately, there are very few reports in children of airway damage from DLTs.

The high-volume, low-pressure cuffs should not damage the airway, provided the cuffs are not overinflated with air or distended with nitrous oxide. Alternatively, saline may be used to inflate the cuffs.

A disadvantage of DLTs is the need to change the DLT to a single-lumen ETT if mechanical ventilation is required after surgery. This is a particular problem for children in whom tracheal intubation was difficult initially because of anatomic or functional limitations. Even when an airway was not classified as difficult preoperatively, it may become difficult secondary to facial and supraglottic edema, the presence of secretions and/or blood in the airway, and laryngeal trauma from the initial intubation. The use of an ETT exchange catheter may facilitate the exchange of a DLT for a single lumen ETT.<sup>42</sup> These devices are commercially available in a variety of sizes (Cook Medical, Inc., Bloomington, Ind.) and allow oxygen insufflation and jet ventilation (see E-Fig. 12-3, A-H).

Several important caveats should be considered before using an ETT exchange catheter. First, it must be small enough to pass through the tracheal lumen of the DLT. This should be tested in vitro before the procedure is performed in vivo. Second, it should never be advanced against resistance, and the clinician must always be cognizant of the depth of insertion; perforations of the tracheobronchial tree have been reported.<sup>43</sup> Third, a jet ventilator should be immediately available in case the new ETT does not follow the exchange catheter into the trachea and oxygenation via the catheter is needed. The jet ventilator should be preset to a peak inspiratory pressure of 25 psi (172 kPa) by an inline regulator. When passing an ETT over an ETT exchange catheter, a laryngoscope should be used to facilitate passage of the ETT into the trachea. It should be noted that the tip of the ETT may hang up on the laryngeal inlet and may require 90 degrees rotation clockwise or counter-clockwise to successfully pass, should this occur.

### General Considerations in the Management of Single-Lung Ventilation

Once the ETT, bronchial blocker, or DLT is in place, airway pressures should be confirmed during SLV. If peak airway pressure is 20 cm H<sub>2</sub>O during two-lung ventilation with a given tidal volume, inflating pressure should not exceed 40 cm H<sub>2</sub>O in SLV when the same tidal volume is delivered during SLV. In general, smaller tidal volumes with increased respiratory rates are used to

deliver a somewhat reduced minute ventilation with SLV as with two-lung ventilation. Some degree of permissive hypercapnia is targeted to minimize lung trauma.

After the child has been placed in the lateral decubitus position, proper ETT, bronchial blocker, or DLT position should be reconfirmed, because malpositioning may occur when turning the patient. Two-lung ventilation should be maintained for as long as possible before switching to SLV. When SLV is required, an  $\text{FiO}_2$  of 1.0 is generally used. Assuming an intact hypoxic pulmonary vasoconstriction response,  $\text{PaO}_2$  during SLV should be between 150 and 210 mm Hg.<sup>44</sup> The lungs should be ventilated with a tidal volume of 8 to 10 mL/kg at a ventilatory rate that maintains the  $\text{PaCO}_2$  between 45 and 60 mm Hg, unless this degree of hypercapnia cannot be tolerated because of other physiologic factors (e.g., concomitant metabolic acidosis). Inadequate tidal volumes may lead to atelectasis in the ventilated lung (reduced functional residual capacity), and increased intrapulmonary shunting, resulting in hypoxemia. Large tidal volumes may force blood to the nondependent lung (similar to the application of positive end-expiratory pressure), thereby increasing the intrapulmonary shunt.<sup>45,46</sup>

After the institution of SLV,  $\text{PaO}_2$  may continue to decrease for up to 45 minutes. Should hypoxemia develop, proper positioning of the indwelling blocker or tube should be reconfirmed by fiberoptic bronchoscopy, if possible. Several techniques can be employed to improve oxygenation. The most effective maneuver for improving  $\text{PaO}_2$  is the application of CPAP to the nondependent lung.<sup>47</sup> Insufflation of oxygen to achieve a CPAP of 10 cm  $\text{H}_2\text{O}$ , for example, produces alveolar inflation and decreases intrapulmonary shunt fraction. This can usually be accomplished without significant expansion of the lung and interference with surgical conditions. If the  $\text{PaO}_2$  continues to decrease despite the application of CPAP to the deflated lung, a malpositioned bronchial blocker or tube should be considered. This may be signaled by a sudden increase in the inflation pressure, a decrease in tidal volume, and/or a change in the capnogram. When a DLT is in place, the surgeon may aid repositioning. The surgeon can palpate the bronchi and manually occlude the main bronchial lumens, thereby guiding the tip of the DLT into the correct position. When the cause of the hypoxemia and/or hypercarbia cannot be readily identified, the balloon or cuff should be deflated and both lungs should be ventilated after informing the surgeon of the problem.

Guidelines for selecting appropriate tubes (or catheters) for SLV in children are shown in Table 13-6. There is significant variability in overall size and airway dimensions in children, particularly in teenagers. The recommendations shown in Table 13-6 are based on average values for airway dimensions. Larger DLTs may be safely used in large adolescents.

## SURGICAL LESIONS OF THE CHEST

### Neonates and Infants

A variety of congenital intrathoracic lesions for which surgery is required may occur in the neonatal or infancy period. These include lesions of the trachea and bronchi, lung parenchyma, and diaphragm, as well as vascular abnormalities.

*Tracheal stenosis* may be acquired or congenital. Tracheal stenosis occurs most commonly because of prolonged tracheal intubation, often in neonates with infant respiratory distress syndrome associated with prematurity. Ischemic injury of the tracheal mucosa may occur as a result of a tight-fitting ETT at the level

<sup>||</sup>Covidien, Mansfield, Mass.

of the cricoid cartilage, which becomes scarred and constricted after a period of time. *Subglottic stenosis* may develop, resulting in stridor after tracheal extubation. Reintubation may be required because of oxygen desaturation and hypercarbia.

Tracheal and/or esophageal compression may occur as a result of a variety of lesions in the chest, including vascular rings and slings (see also Chapters 14 and 31).

A FOB is used to evaluate the severity of the stenosis and exclude other causes of stridor (e.g., vocal cord paralysis or laryngomalacia). When general anesthesia is required, inhalational anesthesia may be administered via a face mask, with the FOB inserted through an adapter in the mask and into the nasopharynx. This is usually performed while the infant breathes spontaneously.<sup>48</sup> Noninvasive imaging studies are being increasingly utilized for the diagnosis of a variety of congenital airway lesions, including vascular rings.<sup>48</sup> Bronchography and “virtual” computed tomography (CT) scanning may also be useful.<sup>49,50</sup>

A cricoid split procedure may be performed for infants with acquired subglottic stenosis. After diagnostic bronchoscopy, the infant is either intubated with an ETT or a rigid bronchoscope is left in place during the operation. Anesthesia may be maintained with inhalational agents or an IV anesthetic technique, such as with propofol and remifentanyl.<sup>51</sup> Typically, an ETT 0.5 mm larger than the original ETT is placed after the repair.

For infants with severe *congenital tracheal stenosis*, a laryngotracheoplasty may be performed. This procedure involves the placement of a costal, auricular, or laryngeal cartilage graft into the anterior and/or posterior trachea.<sup>52</sup> In some cases, a stent may be positioned within the trachea. These infants may require a tracheal tube and mechanical ventilation for a variable period of time postoperatively. In these cases, sedation, analgesia, and at times neuromuscular blockade are maintained after surgery.

*Pulmonary sequestrations* result from disordered embryogenesis, producing a nonfunctional mass of lung tissue supplied by anomalous systemic arteries. Children may present with cough, pneumonia, and failure to thrive; these signs often occur during the neonatal period, and usually before 2 years of age. Diagnostic studies include CT of the chest and abdomen, and arteriography.

Magnetic resonance imaging may provide high-resolution images, including definition of the vascular supply, which may obviate the need for angiography. Surgical resection is performed once the diagnosis is confirmed. Pulmonary sequestrations do not generally become hyperinflated during positive-pressure ventilation. Nitrous oxide administration may result in expansion of these masses, however, and should be avoided.

*Congenital cystic lesions* in the thorax may be classified into three categories.<sup>53</sup> *Bronchogenic cysts* result from abnormal budding or branching of the tracheobronchial tree. They may cause respiratory distress, recurrent pneumonia, and/or atelectasis because of lung compression. *Dermoid cysts* are clinically similar to bronchogenic cysts but differ histologically because they are lined with keratinized, squamous epithelium rather than respiratory (ciliated columnar) epithelium. They usually manifest later in childhood or adulthood. *Cystic adenomatoid malformations* are structurally similar to bronchioles but lack associated alveoli, bronchial glands, and cartilage.<sup>54</sup> Because these lesions

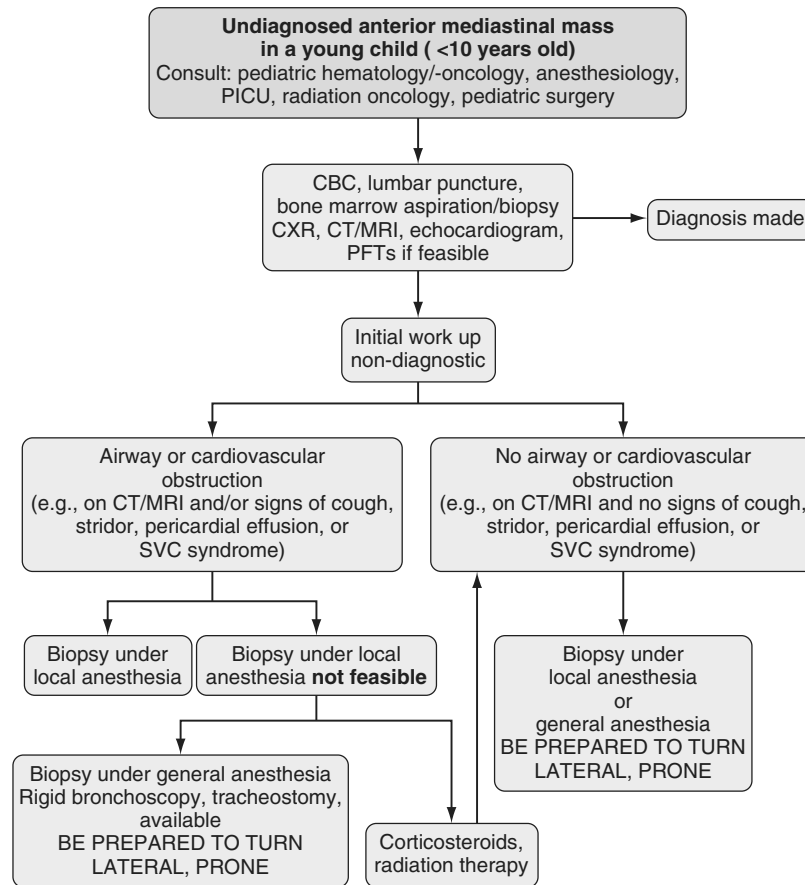

communicate with the airways, they may become overdistended as a result of gas trapping, leading to respiratory distress in the first few days of life. When they are multiple and air filled, cystic adenomatoid malformations may resemble congenital diaphragmatic hernias radiographically. Treatment is surgical resection of the affected lobe. As with congenital diaphragmatic hernias, prognosis depends on the amount of remaining lung tissue, which may be hypoplastic because of compression in utero.<sup>55</sup>

*Congenital lobar emphysema* often manifests with respiratory distress shortly after birth.<sup>56</sup> This lesion may be caused by “ball-valve” bronchial obstruction in utero, causing progressive distal overdistention with fetal lung fluid. The resultant emphysematous lobe may compress lung tissue bilaterally, resulting in a variable degree of hypoplasia. Congenital cardiac deformities are present in about 15% of children with congenital lobar emphysema.<sup>57</sup> Radiographic signs of hyperinflation may be misinterpreted as tension pneumothorax or atelectasis on the contralateral side (Fig. 13-9). Positive-pressure ventilation may exacerbate lung

**FIGURE 13-9** Congenital lobar emphysema of the right lower lobe. Plain radiography illustrates hyperlucency of the right lung on the anteroposterior image (A) and posterior displacement of the heart and mediastinum on the lateral image (B). The computed tomography scan (C) demonstrates compression of the left lung (A) and right upper lobe (C) as well as hyperinflation of the right lower lobe (B).

**FIGURE 13-13** Algorithm for management of a child with a mediastinal mass. CBC, Complete blood cell count; CPB, cardiopulmonary bypass; CT, computed tomography; CXR, chest radiograph; LP, lumbar puncture; MRI, magnetic resonance imaging; PFTs, pulmonary function tests; PICU, pediatric intensive care unit; SVC, superior vena cava.

circulatory collapse.<sup>88</sup> This may occur even in children without signs or symptoms of respiratory or cardiovascular compromise.<sup>93,94</sup> Therefore a preoperative assessment of what position provides the most reliable and consistent good gas exchange should be sought from the child or the parents (nocturnal sleep position). Recommended anesthetic techniques for children with anterior mediastinal masses include inhalation induction or a slow IV induction (with ketamine or propofol), with maintenance of spontaneous respiration. The latter offsets the effect of gravity, which pulls the tumor onto the pulmonary artery, superior vena cava, and tracheobronchial tree, causing life-threatening cardiopulmonary consequences.<sup>87,90,95</sup> The use of continuous positive airway pressure while maintaining spontaneous respiration, maintains functional residual capacity that is otherwise reduced under anesthesia.<sup>96</sup> In adolescents and adults, neuromuscular blockade is commonly used to facilitate tracheal intubation and prevent coughing associated with DLT placement. The morbidity associated with neuromuscular blockade appears to be minimal as long as appropriate precautions are taken. The actual risks in young children, however, have not been studied.<sup>92a</sup> Keeping the head of the bed elevated may decrease the deleterious effects of supine positioning, including cephalad displacement of the diaphragm and secondary reduction of thoracic volume.<sup>97</sup> Placing the child in a partial or even full left lateral decubitus position may help to maintain airway patency and reduce cardiovascular and/or tracheal compression.<sup>87</sup> Performing tracheal intubation while deeply anesthetized, without the use of muscle relaxants and

positive-pressure ventilation, preserves the normal transpulmonary pressure gradient and improves flow through conducting airways.<sup>98-100</sup> The loss of negative intrathoracic pressure associated with neuromuscular blockade increases the risk of severe airway compression and reduction in pulmonary blood flow (i.e., cardiac output).<sup>101</sup> As an alternative to tracheal intubation, use of a laryngeal mask airway has been described.<sup>102</sup> The use of a helium-oxygen (70%/30%) mixture has been recommended to decrease the resistance to breathing and to increase hemoglobin saturation when an anterior mediastinal tumor compresses the trachea and/or bronchi (where turbulent gas flow exists).<sup>102</sup> In the event of tracheal or bronchial collapse under anesthesia, lateral or prone positioning and/or rigid bronchoscopy may be lifesaving.<sup>87</sup> Performing a median sternotomy and cardiopulmonary bypass in this situation has been recommended but is quite impractical unless access for partial bypass has been established before induction of anesthesia.<sup>90</sup>

Institutions should have an algorithm in place for the evaluation of children with anterior mediastinal masses that includes a multidisciplinary approach (Fig. 13-13).

## Summary

The anesthesiologist caring for infants and children undergoing thoracic surgery faces many challenges. An understanding of the primary underlying lesion as well as associated anomalies that may affect perioperative management is paramount. Preoperative

and intraoperative communication with the surgeon is also essential. A working knowledge of respiratory physiology and anatomy in infants and children is required for the planning and execution of appropriate intraoperative care. Familiarity with a variety of techniques for single-lung ventilation suited to the child's size will provide optimal surgical exposure while minimizing trauma to the lungs and airways.
