Dunbar Ivy

This book is dedicated to children and families with congenital cardiac disease for whom I have been privileged to care for and to the teachers and mentors who have provided me the knowledge and skill to do so

James Jaggers

Foreword I

The last thirty years has seen some spectacular advances in the diagnosis and management of children with congenital and acquired heart disease. In the former instance, we have moved from an era of an early palliative surgical approach followed by later repair when mortality of 10 % or higher was common to the modern approach of surgical reconstruction in infancy with a mortality of less than 5 %. Underlying this success story are contributions from all the groups that are involved in the care of children with heart disease including pediatric cardiac nurses, cardiologists and cardiac surgeons, perfusionists, anesthesiologists and pediatric intensivists. They are all members of a team and teamwork is the key ingredient of high performing pediatric cardiac programmes.

My own area of intensive care medicine is an essential part of that team and has now developed into a specialty of pediatric cardiac critical care in it's own rite with an expectation that physicians should have a comprehensive knowledge of cardiac anatomy and physiology as well appropriate training in pediatric intensive care medicine. The newer generation of trainees will also be expected to have expertise in echocardiography, extracorporeal technology and mechanical support. This *Textbook of Pediatric and Congenital Cardiology, Cardiac Surgery and Intensive Care* will be source material for all this because it covers every aspect of heart disease in children and will be an invaluable resource for all team members in the pediatric cardiac programme.

Desmond Bohn, MB FRCPC,
Professor of Anesthesia and Pediatrics
Former Chief, Department of Critical Care Medicine
The Hospital for Sick Children, Toronto
University of Toronto

Foreword II

To say that this text is a monumental undertaking is an understatement. The crux of this work is in the subtitle. It is *comprehensive*, *interdisciplinary*, and, perhaps most importantly, *interactive*. There are several excellent existing textbooks of pediatric cardiology, most of which follow a familiar format of chapters on anatomy and embryology, structural malformations, myocardial/inflammatory diseases, and perhaps heart failure and pulmonary hypertension. None that I know of, cover such a diverse range of subjects as this text: therapeutic hypothermia and tracheal reconstruction; venous thromboembolism and trypanosomiasis; Takayasu disease and Nursing. Authorship is likewise diverse, with contributors from all across the world.

Medicine is an extremely rapidly changing field. The time, often years, between the decision to publish a textbook and the actual publication frequently means that much of what is written is out of date by the time of publication. Thus the decision of the editors and publisher to create both a print and a web version, the latter to be updated frequently and read on a peripheral mobile device help make it both current and accessible. No one carries a large textbook into the ER in the middle of the night, but everyone carries a mobile phone.

Howard P. Gutgesell, MD
Professor of Pediatrics, Emeritus
University of Virginia Medical School
Charlottesville, Virginia

Foreword III

Sixty years ago on May 6 1953 John Gibbon was the first to achieve successful repair of a congenital heart defect using a heart lung machine. What is often forgotten however is that Gibbon's subsequent five patients did not survive. Many other pioneers of cardiac surgery of that era had equally dismal results. Today the outlook for the child with congenital heart disease has improved dramatically. At the top of my list of reasons for that improvement has been the establishment of cohesive interdisciplinary teams of individuals dedicated to the care of patients with congenital heart disease. While these individuals may have expertise in an incredibly specialized area of cardiac surgery, cardiology, cardiac anesthesia, cardiac intensive care, perfusion, cardiac nursing or many of the essential ancillary healthcare support areas, their individual contribution to the successful care of a child with a complex congenital heart problem is only as good as the weakest link in the entire team. This stunning new textbook edited by Eduardo M. da Cruz, Dunbar Ivy and James Jaggers brings together authors from all of the many components of the healthcare team devoted to care of the individual, both adult and pediatric, with congenital heart disease. The primary editors have assembled a team of specialist sub-editors who have each assembled a sub-team of contributors from around the globe. One of the great joys of working within the field of congenital heart disease is that in contrast to many other medical specialties, we are a relatively small family who have come to know each other on a global scale, symbolized by our quadrennial meeting at the World Congress of Pediatric Cardiology and Congenital Heart Surgery.

The authors have brought the reader into the new millennium of publishing by creating an electronic version of this textbook that includes access to videos demonstrating surgical technique as well as diagnostic modalities. The exhaustiveness of the coverage is truly breathtaking. Just reading the list of contents and appreciating the breadth of coverage draws attention to the very considerable care and effort that the editors have put into assembling this unique book. Whether a cardiologist, cardiac surgeon, cardiac intensivist,

a cardiac anesthesiologist or a nurse in the intensive care unit or any one of the many supporting allied healthcare workers in the field of congenital cardiac care, the reader will surely not be disappointed.

Richard Jonas, MD
Professor of Pediatric Cardiac Surgery
Chief of Cardiovascular Surgery and
co-director of the Children's National Heart Institute
Children's National Medical center
Washington, DC, USA

Preface

Pediatric and congenital cardiac patients, from the fetus to the adult, remain in the current century a complex challenge in an ever evolving discipline. Successful cardiovascular programs currently deal with the most critical patients by promoting a horizontal convergence of multiple specialties. Many, if not most, programs have multidisciplinary teams available, and yet the challenge remains to make these teams operate as *interdisciplinary*. Two key goals ought to be pursued in order to achieve successful short and long term outcomes with pediatric cardiac patients. Firstly, the driving force should always be *quality improvement and safety*, and secondly good *communication* shall prevail. There are two main pillars of the latter endeavors, namely individual-based and system-based principles. Individual-based principles are quite subjective and more difficult to manage, since they depend on personalities and behavior. In a balanced environment, individuals should be able to endorse a willingness to develop exhaustive knowledge, team work, trust, self-awareness, capacity to listen, common sense and respect. System-based practices are more objective, and although requiring cultural changes, promote consistency, harmonious interaction and better outcomes. Such practices allow the development of common paths for the team to follow, whilst enhancing good communication and reducing risks, optimizing prevention of complications, better handling fluctuations and identifying outliers, and predicting likely outcomes based on accurate data. The implementation and consolidation of efficient programs require systematic audits, development of sound database platforms, development of plans to address deficiencies, implementation of simulation and quality improvement and safety programs, and the eagerness for transparency and to share the available information with staff, patients and their families in a non-repressive and constructive atmosphere. Such models are not of the realm of utopia, although they are challenging to establish, at least whilst inducing the required cultural changes and promoting the conviction of their usefulness.

The textbook of Pediatric and Congenital Cardiology, Cardiac Surgery and Intensive Care intends to achieve an ultimate objective beyond providing reliable scientific information. It endeavors to symbolize the imperative need for a cohesive and transparent interdisciplinary blend of expertise, by bringing together world renowned authors from different regions around the Globe, and representing the many specialties concerned by and involved in the management of pediatric patients with congenital and acquired cardiac

diseases. We have been privileged to gather many experts from reference programs to whom we will remain forever grateful. As much as we have endeavored to remain consistent, some authors may express personal opinions and hypothesis in a constructive manner, which -as we expect- may help readers understand the many facets and complexities of patient management at different levels. Very importantly, in this project readers will be able to access a website which we see as a source of constantly updated information, including videos dedicated to diagnosis and surgical interventions, and that should evolve overtime into a more interactive tool. We sincerely hope that the Textbook of Pediatric and Congenital Cardiology, Cardiac Surgery and Intensive Care will become a useful tool in the armamentarium of those caring for such complex patients; we aim to provide updated information to help caregivers become better practitioners and human beings. If so, this textbook would have achieved its *raison d'être*.

Acknowledgments

We would like to express our sincere gratefulness to the Section Editors, the Website Editor and to all the authors who dedicated countless hours to produce a work of outstanding quality, with the genuine aim of sharing good practice.

We also want to thank our families for their second-to-none patience and support during the three years of production.

Last but not least, we thank Springer-Verlag, particularly Grant Weston, Mansi Seth and Navjeet Kaur for their advice and collaboration.

About the Editors

Eduardo M. da Cruz, MD, Head of Pediatric Cardiac Critical Care Program, Head of Pediatric Cardiology Inpatient Services, Director of Cardiac Intensive Care Unit, Director of Cardiac Progressive Care Unit, Children's Hospital Colorado and Professor of Pediatrics (Pediatric Cardiology & Intensive Care), University of Colorado Denver, School of Medicine, Aurora, CO, USA

Eduardo M. da Cruz is a Professor of Pediatrics (Pediatric Cardiology and Intensive Care) and the Head of the Pediatric Cardiac Critical Care Program & Inpatient Services at The Heart Institute, Department of Pediatrics, Children's Hospital Colorado, University of Colorado Denver-School of Medicine. He trained in pediatrics, pediatric cardiology and intensive care and has been an attending physician for 20 years in Europe and in the USA. He has extensive experience in the medical and perioperative management of neonates, children and young adults with complex congenital or acquired heart, including heart transplant, mechanical assistance and quality improvement and safety. He is very actively involved in clinical research and teaching in the fields of pediatric cardiology and cardiac intensive care, has delivered hundreds of international lectures and is the editor of various Cardiology and CICU reference textbooks. Eduardo M. da Cruz has published 50 book chapters and dozens of manuscripts in peer-reviewed journals. He is the founder of the Working Group on Pediatric Cardiac Intensive Care of the

Association for the European Paediatric and Congenital Cardiology (AEPC), Deputy Chair and founder of the Section on Hemodynamics and Heart Disease of the European Society of Paediatric and Neonatal Intensive Care (ESPNIC), Board Member of the Congenital Domain of the European Association for Cardio-Thoracic Surgery (EACTS), member of the Society of Pediatric Research (SPR) and of multiple international Societies, and the President of Surgeons of Hope Foundation, based in New York.

Dunbar Ivy, MD, Chief of Pediatric Cardiology, Selby's Chair of Pediatric Cardiology, Co-Director of Children's Hospital Heart Institute, Director of Pediatric Pulmonary Hypertension Program Children's Hospital Colorado and Professor of Pediatrics, University of Colorado School of Medicine Aurora, CO, USA

Dr. Dunbar Ivy began his medical career at Tulane University School of Medicine following his premedical studies at Davidson College. While at Tulane, he became excited about a career in Pediatric Cardiology under the mentorship of Dr Arthur Pickoff. He then obtained training in General Pediatrics at the University of Colorado School of Medicine in Denver, Colorado. Early mentors in Pediatric Cardiology included Drs. Michael Schaffer and Henry Sondheimer. Interest in altitude related illness and pulmonary hypertension in congenital heart disease were fostered by Dr Robert Wolfe on the clinical side and Drs Steve Abman and John Kinsella in the fetal sheep laboratory while a fellow in Pediatric Cardiology at the University of Colorado. Following fellowship, he became a research instructor under the guidance of Dr Mark Boucek, who encouraged him to pursue a career as a clinician scientist. During his time as a Bugher fellow, he obtained early grants from the March of Dimes and American Heart Association regarding the role of endothelin in the perinatal pulmonary circulation. This work transitioned into a National Institutes of Health K-08 award to continue to study molecular derangements in the endothelin pathway in models of pulmonary hypertension. In 2003 Dr Ivy took the position of Chief of Pediatric Cardiology and Selby's Chair of Pediatric Cardiology. His research focus

became more clinical and translational. As Director of the Pediatric Pulmonary Hypertension Program, he began early clinical studies of medical therapy in children, including the use of intravenous epoprostenol, subcutaneous treprostinil, and oral bosentan. He began to work with Dr Robin Shandas regarding measurement of right ventricular afterload in children with pulmonary hypertension in an NIH sponsored Specialized Centers of Clinically Oriented Research grant headed by Dr Kurt Stenmark. Further work on ventricular vascular coupling has continued with NIH funding with Dr Shandas. Dr Ivy was the inaugural Chairman of the first Pediatric Pulmonary Hypertension taskforce at the World Symposium of Pulmonary Hypertension in Nice, France in 2013. Dr. Ivy is a member of multiple societies, and has published over 150 peer reviewed manuscripts.

James Jaggers, MD, Barton-Elliman Chair and Chief of Pediatric Cardiac Surgery, Professor of Surgery, Children's Hospital Colorado, University of Colorado, Aurora, CO, USA

Dr. James Jaggers began his medical career at the University of Nebraska Medical Center as a medical student. He then obtained training in general Surgery at the Oregon Health Sciences University in Portland Oregon and Thoracic Surgery training at the University of Colorado Health Sciences Center in Denver. During this period he also completed a Pediatric Cardiac Surgery Fellowship at the Children's Hospital in Denver. Following this he took a faculty position at Duke University Medical Center in Thoracic and Pediatric cardiac Surgery where he rose to the rank of Associate Professor with tenure. This tenure at Duke was interrupted by a very brief position at the University of Missouri and Mercy Children's Hospital in Kansas City. Following this, he returned to Duke to assume the position of Chief of Pediatric Cardiac surgery and Director of the Duke Pediatric Heart Institute. During his time at Duke, Dr. Jaggers directed the pediatric cardiovascular surgery laboratory and mentored many research fellows. He was principal and co-principal investigator on two basic Science NIH grants and one Pediatric Heart Network NHLBI sponsored multicenter study. In 2010, Dr. Jaggers

moved to the University of Colorado and Children's Hospital Colorado where he is now the Barton Elliman Chair of Congenital Cardiac Surgery and Professor of Surgery. His current research interests include Outcomes research in care of Congenital Heart Disease and investigation into the protein signaling of aortic stenosis and uncompensated cardiac hypertrophy and myocardial dysfunction. Clinical interests include complex neonatal heart surgery, cardiac transplantation and fetal intervention for cardiac defects. Dr. Jaggers is a member of multiple Societies, and has published 117 peer reviewed manuscripts, published 21 book chapters and is a reputed international lecturer with 75 invited lectures.

Genetics of Congenital and Acquired Cardiovascular Disease

1

John L. Jefferies, Hugo R. Martinez, and Jeffrey A. Towbin

Abstract

There has been a growing awareness of genetic triggers and associated cardiovascular disease. The genetic basis for heart and vascular conditions is heterogeneous and includes genomic disorders; de novo dominant and familial dominant mutations; autosomal recessive, X-linked, recurrent copy number variations; complex patterns of inheritance; and mitochondrial inheritance. There are more than 100 genes associated with congenital and/or progressive cardiac abnormalities, and the list is expanding at a rapid rate. These recognized genes encode for ion channels, transcription factors, transduction pathways, mitochondrial proteins, enzymes involved in lysosomal activity, and some other functions that are well recognized to cause genomic disorders with cardiovascular involvement. Advances in genetic analysis have had a significant impact on the current practice of cardiovascular medicine in both children and adults, providing a better understanding of the genetic etiologies for these disorders and assisting in defining clinical phenotypes, ongoing management, and offering potential

insight into long-term prognosis. In this chapter we provide a description of different conditions that encompass single-gene mutations associated with congenital and acquired cardiovascular disease.

Keywords
Cardiovascular genetics • Gene • Genetic syndrome • Mutation

Connective Tissue Disorders

These hereditary disorders include any disease that has the connective tissues of the body as a target of pathology. Connective tissue is a biological tissue with an extensive extracellular matrix that supports and binds organs together. Genetic defects in structural connective tissue proteins or their signaling pathways represent a risk for arterial tortuosity and development of aneurysms with subsequent dissection (i.e., aorta and carotid arteries). In addition to the vasculature involvement, some structural heart defects such as patent ductus arteriosus (PDA), bicuspid aortic valve (BAV), and coarctation of the aorta (CoA) may be present. These disorders include Marfan syndrome (MFS), Loeys-Dietz syndrome (LDS), and Ehlers-Danlos syndrome (EDS) and non-syndromic conditions such as familial thoracic aortic aneurysmal disease, all of which carry varying degrees of risk for dissection. Contact sports and heavy weight training should be avoided in all.

Marfan Syndrome (MFS)

MFS is an autosomal dominant disorder with a high degree of clinical variability and a prevalence of 1 in 5,000–10,000. The typical phenotypic features of MFS involve the ocular, skeletal, and cardiovascular systems. Up to 90 % of individuals with a clinical diagnosis of Marfan syndrome have mutations in FBN1, a gene that codes for fibrillin-1, a structural component of microfibrils, which provides mechanical stability and elastic properties to connective tissues [1–3]. The clinical diagnosis of MFS is based in the recently revised Ghent criteria [94], which places more emphasis on the cardiovascular manifestations and in which aortic root aneurysm and ectopia lentis are the cardinal clinical features. In the absence of any family history, the presence of these two manifestations is sufficient for the unequivocal diagnosis of MFS; in the absence of either of these two, the presence of a bonafide *FBN1* mutation or a combination of systemic score ≥ 7 is required. In the case of a positive family history of MFS, an isolated finding of *ectopia lentis*, aortic root enlargement, or a systemic score ≥ 7 suffices [1]. The major sources of morbidity and early mortality in MFS are related to cardiovascular pathology. These manifestations include dilatation of the aorta, predominantly at the level of the sinuses of Valsalva, mitral valve prolapse with or without regurgitation, tricuspid valve prolapse, and enlargement of the proximal pulmonary artery [4–6]. Ongoing clinical assessment of aortic involvement has revealed that dilatation can occur at any level including the aortic annulus, sinotubular junction, or ascending aorta. Recent guidelines for management of genetic syndromes associated with thoracic aneurysms suggest an echocardiogram at diagnosis and at 6 months thereafter. Subsequently, annual imaging is recommended for patients with stable aortic diameter less than 4.5 cm [7]. This practice may be modified and performed more often in the pediatric population, especially around the time of puberty [8]. Evaluation for surgical repair is recommended at a diameter of 5.0 cm. However, some additional factors may prompt a more thoughtful evaluation which include rapid growth (greater than 0.5 cm/year), family history of aortic dissection at less than 5.0 cm, the presence of significant aortic regurgitation, and the association of mutations within the exons 24–32 in the *FBN1* gene which have been associated with a phenotype that is in the severe end of the clinical spectrum. This genotype is also known as neonatal

MFS [7]. The primary pathology is related to alterations in TGFβ signaling due to loss of fibrillin-1. The increase in active TGFβ signaling has been shown to cause aortic root dilatation, lung bullae, and impaired muscle regeneration. Angiotensin-II receptor blockers antagonize TGFβ signaling. Early trials with losartan showed marked success in ameliorating the effects of elevated TGFβ signaling in a mouse model and in a small trial in patients with MFS [9, 10]. The results of the multicenter Pediatric Heart Network (PHN) study comparing losartan versus atenolol are not yet available but enrollment is complete.

With proper management, the life expectancy of someone with Marfan syndrome approximates that of the general population. However, this good outcome occurs only if the patient receives comprehensive cardiovascular care by a cardiologist knowledgeable and experienced in the care of patients with MFS.

Loeys-Dietz Syndrome (LDS)

LDS is a recently described autosomal dominant syndrome which has features similar to MFS but is caused by mutations in the genes encoding the transforming growth factor beta receptor 1 (*TGFBR1*) or 2 (*TGFBR2*) [11, 12].

The main organ systems affected by mutations in these genes include the skeletal, craniofacial, cutaneous, and vascular. Skeletal manifestations include *pectus excavatum* or *carinatum*, scoliosis, joint laxity, arachnodactyly, and *talipes equinovarus*, but patients do not present significant long bone overgrowth. Craniofacial findings include ocular hypertelorism, bifid uvular/cleft palate, and craniosynostosis. In contrast to MFS, these patients do not develop lens dislocation. Cutaneous features include translucent skin, easy bruising, and dystrophic scars. The vascular findings include arterial aneurysms and tortuosity, which are typically more aggressive than MFS and often present at sites distant from the aortic root [11, 12]. In actuality, arterial disease can present anywhere in the arterial tree making surveillance challenging. Arterial dissection can occur at diameters smaller than those observed in MFS implying that earlier surgical intervention [13]. LDS type 1 patients present more with typical craniofacial features, while LDS type 2 patients mostly lack the craniofacial features but present with more cutaneous findings. However, no set of diagnostic criteria has been established and the diagnosis should thus be confirmed by molecular genetic testing [13]. Elective aortic root replacement is recommended when the maximal diameter reaches 4.0 cm in adults or adolescents. Elective root replacement is recommended in children who show progressive aortic dilatation (>0.5 cm/year) and who have an annulus of sufficient size to accept a graft that will accommodate growth. Frequent evaluation of the aortic root along with annual CT or MR angiography for surveillance of the entire arterial tree is suggested [14].

Thoracic Aortic Aneurysm and Dissection (TAAD)

TAAD is an autosomal dominant disorder without other systemic manifestation. Structural heart defects such as bicuspid aortic valve, aortic coarctation, or patent ductus arteriosus may also be identified [15]. The aortic disease observed is similar to that observed in Marfan syndrome and includes dilatation of the aorta and dissections at either the level of the sinuses of Valsalva or other aortic thoracic segments.

Aortic tissues from affected individuals shows aortic medial degeneration, focal areas of medial hyperplasia, and disarray for which recent guidelines for the management of thoracic aortic disease have been established [7]. Mutations in *MYH11, SMAD3, SLC2A10, ACTA2, TGFBR1, TGFBR2*, and *MYLK* have been associated in individuals with TAAD [13, 16, 17]. These gene mutations cause ~20 % of the TAAD cases, indicating substantial locus heterogeneity in this condition [15]. Positive genetic testing determines whether ongoing cardiac surveillance is necessary. In the absence of an identifiable disease-causing mutation in the index case, aortic imaging is recommended for all first-degree relatives to identify those with asymptomatic

disease. If a pathologic genetic mutation is found, at-risk family members can have targeted testing.

Vascular Ehlers-Danlos Syndrome (EDS)

Vascular EDS, also known as type IV EDS, autosomal dominant manner in individuals with mutations in the *COL3A1* gene thus affecting type-III collagen. About 50 % of affected individuals have a de novo mutation [18]. Typical clinical manifestations of vascular EDS include thin, translucent skin, characteristic facial appearance (large eyes, small chin, sunken cheeks, thin nose and lips, lobeless ears), vascular fragility demonstrated by extensive bruising and easy bleeding, and spontaneous arterial/intestinal/uterine ruptures [19]. The diagnosis of EDS type 4 is based on clinical findings and confirmed by identification of a causative mutation [18–20]. Vascular EDS causes severe fragility of connective tissues with arterial and intestinal ruptures. Following confirmatory genetic testing, long-term follow-up is required, including medical treatment when appropriate.

Osteogenesis Imperfecta (OI)

OI is a group of connective tissue disorders caused by defective synthesis of collagen type I. Clinical features include the blue sclera, pathologic fractures, conductive and sensorineural hearing loss, and dental abnormalities. Cardiovascular involvement is a less common feature but when present may include pathology of left-sided heart valves and enlargement of the aortic root and ascending aorta in up to 12 % [21].

Cardiomyopathies

Cardiomyopathies (CMs) are one of the leading causes of morbidity and mortality in children and neonates and are responsible for a significant percentage of cardiac deaths and heart transplant [22]. It is well established that these disorders are also caused by defects in genes that encode proteins involved in key "final common pathway" that, when disturbed, lead to the clinical phenotypes that define these heart muscle diseases [23].

Cardiomyopathies are subdivided into dilated, hypertrophic, restrictive, arrhythmogenic right ventricular, advised to seek cardiac and genetic clinical evaluation.

Dilated Cardiomyopathy

Idiopathic dilated cardiomyopathy (DCM) is the most common form of cardiomyopathy, accounting for approximately 55 % of cases, and is also the most common cause of cardiac transplantation in children [24]. The pathophysiologic features include increased ventricular volume with ventricular wall thinning and moderate to severe myocardial dysfunction that typically involves the left ventricle [24]. Increasingly, it is being recognized that many of these cases have identifiable genetic mutations that are causative of disease. In advanced practices caring for these patients, genetic testing is playing a larger role in clinical diagnosis and management.

Patients present marked clinical variability. In infants it may be manifested initially by tachypnea, decreased oral intake, and failure to thrive. In older children, symptoms may include diaphoresis, chest pain, palpitations, orthopnea, and decreasing exercise tolerance. Electrocardiographic changes may include conduction system disease, brady- or tachyarrhythmias, atrial enlargement, ventricular hypertrophy, ST segment changes, T wave inversion, or pathologic Q waves. Noninvasive imaging studies such as echocardiography or MRI may reveal cardiomegaly with or without pulmonary edema, impaired systolic and/or diastolic function, and chamber enlargement. Troponin and B-type natriuretic peptide may be elevated and can offer insight into etiology and prognosis.

Familial DCM (FDCM) is defined as the presence of DCM in two or more first-degree relatives. The incidence is likely underestimated due to the diversity of inheritance patterns, timing of presentation, and variable penetrance, as well as a lack of symptoms in some affected individuals [25, 26].

The predominant pattern is autosomal dominant, accounting for at least 30–50 % of cases, and its clinical course may involve heart failure, arrhythmias or conduction disease (commonly associated with fibrosis), or be completely asymptomatic [27].

In FDCM, more than 25 genes have been identified which primarily encode for cytoskeletal (thought to cause defects in force transmission) and sarcomeric proteins (thought to cause defects in force generation). In a smaller number, genes encoding ion channels or channel-interacting proteins, the nuclear membrane, and mitochondrial functions have also been involved [25, 27–29]. In either case, the cardiomyocyte is susceptible to stress due to fragility or dysfunction of mutant proteins, disturbed mitochondrial function leading to inefficient ATP production or utilization, and dysfunction of the contractile apparatus [23].

In X-linked DCM, most cases are caused by mutations in the very large dystrophin gene, DCM with variable severity of skeletal myopathy, in the form of Duchenne (DMD) and Becker (BMD), or isolated, called X-linked cardiomyopathy (XLCM) may be identified. Other less common X-linked forms of DCM are found associated with Barth syndrome, caused by mutations in the tafazzin (TAZ) gene, or Danon disease, caused by LAMP-2 mutations in the dystrophin (*DMD*) gene in young males, showing progressive cardiac disease and elevated serum creatine kinase without the classic features of DMD and BMD [31].

The dystrophin gene is located in the short arm of the X chromosome and encodes for the protein dystrophin, a cytoskeletal protein that provides structural support to the cardiomyocyte and also plays a major role in linking the sarcomeric contractile apparatus to the sarcolemma and extracellular matrix [32]. DMD and BMD are severe muscular dystrophies of childhood onset affecting 1 in 3,500 boys in DMD and 1 in 300,000 boys in BMD [32]. Typically they are characterized by skeletal myopathy, elevated serum creatine kinase, and calf pseudohypertrophy [32, 33]. Among them, DMD is the more severe form, due to an absence of functional dystrophin, which leads to amount or quality of protein expression which leads to muscle weakness by the age 3 and wheelchair dependence by age 12 in DMD. In BMD, the onset of clinical features starts later in life. The cardiac involvement varies with age but it is present at 20 years in all DMD and 70 % of BMD patients [33]. Histological studies show cardiac muscle replacement with fat tissue and fibrosis. The fibrosis eventually leads to ventricular dysfunction and ventricular enlargement. The conduction system can also be affected by fibrosis, thus annual screening for arrhythmias is warranted [33]. Molecular analysis for the *DMD* gene is indicated for diagnosis. If no mutation is detected, skeletal muscle biopsy should be considered for Western blot and immunohistochemistry studies [24, 25, 28] although this is done rarely now in clinical practice.

Female carriers of DMD, BMD, and X-linked DCM are at risk to develop DCM [95]. Although less severe, a complete cardiac evaluation every 5 years starting at late adolescence or early adulthood is warranted [34].

Barth syndrome is an X-linked skeletal mitochondrial myopathy caused by mutations in the *G4.5* gene that encodes for the protein Tafazzin [35]. TAZ gene, previously called G4.5, that encodes for the protein tafazzin. Tafazzin is a key protein required in the synthesis of the membrane phospholipid cardiolipin, which is defective when TAZ is mutated. The condition is typically diagnosed in male neonates with variable cardiomyopathy (DCM with or without endocardial fibroelastosis), LV noncompaction, or hypertrophic cardiomyopathy), with or without and 3-methylglutaconic aciduria [35]. Although some children die in infancy (due to progressive heart failure, sepsis, or sudden death), many survive into childhood. Mutations in the TAZ gene also cause endocardial fibroelastosis, and isolated left ventricular noncompaction cardiomyopathy [36]. Ongoing surveillance of cardiac function is necessary with the use of appropriate medical and surgical therapy, including cardiac transplantation, as indicated.

Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy (HCM) is a primary myocardial disorder with autosomal dominant

pattern of inheritance in most of the cases. HCM is characterized by the presence of hypertrophied and non-dilated ventricular chambers in the absence of another cardiac or systemic disease capable of producing the magnitude of wall thickening. It is histopathologically associated to variable myocyte hypertrophy with disarray and myocardial fibrosis [37]. HCM accounts for ~40 % of childhood cardiomyopathies and has an incidence of 0.47 in 100,000 children [38].

The sarcomere is a protein complex with multiple protein interactions, including the thick myofilament proteins: the β-myosin heavy chain (β-MyHC; MYH7), the ventricular myosin essential light chain 1 (MLC-1s/v), and the ventricular myosin regulatory light chain 2 (MLC-2s/v); the thin myofilament proteins (cardiac actin, cardiac troponin T (cTnT), cardiac troponin I (cTnl), and α-tropomyosin (α-TM)); and one myosin-binding protein or binding protein C (cMyBP-C). There are also proteins involved in the architecture of the sarcomeres like the Z-disc and muscle LIM proteins. One or multiple genes that exhibit tissue-specific, developmental, and physiologically regulated patterns of expression encode each of these proteins.

More than 1,400 mutations in 27 identified genes have been associated with HCM; the vast majority have autosomal dominant transmission, but mitochondrial and autosomal recessive patterns have been also described [37, 39, 40]. The prevalence of causal genes varies among different populations, but overall, the collective results of genetic epidemiology studies suggest that two-thirds of causal genes have been identified. The most common causal genes are *MYH7* and *MYBPC3* accounting for 30 % of all the cases of HCM. Mutation in *TNNT2* and *TNNI3* is less common and accounts for 10–15 % [41].

The majority of the HCM-disease-causing genes identified code for proteins that are part of the sarcomere. It is hypothesized that the genetic defect in a gene encoding a sarcomeric protein disrupts normal contraction and relaxation accumulating calcium in the sarcomere. Thus, reduction of calcium reuptake and reduced stores in the sarcoplasmic reticulum will trigger a remodeling process by several transcription factors resulting in the hypertrophy of the cardiomyocytes and an increased energy demand, which eventually result in ischemia, death, and fibrosis.

The clinical presentation may include multiple clinical abnormalities such as LV outflow tract obstruction (LVOTO), diastolic dysfunction, mitral regurgitation, myocardial ischemia, and arrhythmias [42]. The progression to the "end stage" of the disease is the systolic dysfunction characterized by dilatation of the left ventricle and wall thinning, resembling the phenotype of DCM.

Cardiac examination and noninvasive imaging are the conventional methods to make the diagnosis. Molecular analysis is commercially available and provides important value for early diagnosis, risk stratification, and implementation of preventive measurements. Nonetheless, clinicians should be aware that phenotype-genotype correlation has not been completely deciphered and specific causal mutations can be heterogeneous or clinically modified by environmental factors [37–40, 42–44].

Left Ventricular Noncompaction (LVNC) Cardiomyopathy

LVNC is a relatively new clinical entity classified as a primary cardiomyopathy of genetic origin by the American Heart Association [24]. The developing heart during embryogenesis occurs in different stages, including the formation of two different myocardial layers between the ventricular walls. These include the trabecular layer and the subepicardial compact layer. The endocardium constitutes the cellular base for the trabecular layer, and the compact layer is formed underneath the epicardium. Prior to the development of the coronary circulation, the myocardium is a meshwork of interwoven myocardial fibers with deep intertrabecular recesses, which are responsible for blood supply to the myocardium [45]. During the weeks 5–8 of embryologic development, the large intertrabecular spaces narrow into small capillaries within the trabecular meshwork and parallel establishment of the coronary vessels [45]. Thus regression or

persistence of the deep intertrabecular recesses between the myocardium and the LV cavity originates LVNC [46].

The first genetic cause of isolated LVNC was initially described in 1997 in the gene G4.5/TAZ on Xq28, in patients and carrier females [47]. TAZ, which encodes a novel protein family (tafazzins), is responsible for Barth syndrome and other forms of infantile cardiomyopathies including LVNC [48, 49]. Genes responsible for autosomal dominant LVNC have more recently been identified and encode cytoskeletal and sarcomere proteins most commonly. These include α-dystrobrevin, dystrophin, ZASP, β-myosin heavy chain (MYH7), α-cardiac actin (ACTC), and cardiac troponin T (TNNT2) [49]. Mutation analysis of the mitochondrial genome has also identified gene mutations causing LVNC [50]. Moreover, mutations in genes involved in myocardial genesis such as peroxisome proliferator activator receptor-binding protein (*PBP*), jumonji (*JMJ*), FK506-binding protein (*FKBP12*), and transcription factor specificity protein 10 (*BMP10*) led to congenital LVN in knockout mice [51].

The clinical presentation is variable and it may present as an isolated asymptomatic finding or with signs and symptoms of heart failure during infancy, childhood, adolescence, or adulthood [49]. In some patients, particularly young babies with a dilated and hypertrophic form of LVNC, an "undulating phenotype" where the LV phenotype changes (for instance, from dilated/hypertrophic to hypertrophic and then back to dilated/hypertrophic with systolic dysfunction). Other associated symptoms may include stroke, syncope, and sudden death [36, 45–47]. LVNC has been observed in a variety of neuromuscular disorders, metabolic and mitochondrial disease, structural heart malformations, heterotaxy, and chromosomal abnormalities.

Arrhythmogenic Right Ventricular Cardiomyopathy (ARVC)

ARVC is an inherited cardiac disorder characterized by progressive myocyte loss, which occurs primarily in the right ventricle (RV), and subsequent replacement of the myocardium with fibrofatty tissue [52, 53]. Prevalence has been reported as common as 1 in 5,000 habitants [54]. It is considered a genetic cardiomyopathy since up to 50 % of the patients harbor an identified mutation [55]; nonetheless, infections with coxsackievirus B3 and adenovirus have been reported as well [55, 56]. Genes encoding for desmosome proteins or desmosome interacting proteins such as desmoplakin, plakophilin-2, plakophilin-4, desmocollin-2, desmoglein-2, and plakoglobin have been well described in familial cases [55]. ARVC is generally inherited as an autosomal dominant trait. Autosomal recessive disease is seen frequently in mutations in the (*JUP*) gene which is associated with Naxos disease (diffuse palmoplantar keratosis, arrhythmias, and woolly hair in infancy) and also in desmoplakin gene mutations causing Carvajal syndrome (woolly hair, epidermolytic palmoplantar keratoderma, and cardiomyopathy). When these mutations are present, the functional and structural integrity of the myocytes is disabled, compromising the cell-to-cell adhesion particularly under stress (sports) or infections.

The pathologic features include RV enlargement, frequently with visible aneurysms and thinning of the RV free wall in the region of the infundibulum, apex, or inferior wall (known as the "triangle of dysplasia") associated with fibrosis and inflammatory infiltrate with or without fatty replacement. A spectrum of RV involvement occurs, from no functional impairment to severe impairment; involvement of the LV is less common and is also variable. Classically, patients present with syncope or palpitations secondary to ventricular tachycardia of left bundle branch block morphology, originating from the areas of fibrofatty replacement [53, 55].

Restrictive Cardiomyopathy (RCM)

Restrictive cardiomyopathy (RCM) is a rare entity, accounting for approximately 5 % of cardiomyopathies. RCM is characterized by normal or decreased volume of both ventricles associated

with biatrial enlargement, normal LV wall thickness and atrioventricular valve function and structure, impaired ventricular filling with restrictive physiology, and normal (or near normal) systolic function [24, 58].

Some cases of RCM are inherited, usually with autosomal dominant transmission. Most commonly, these cases are the result of mutations in sarcomere-encoding genes, especially troponin I (cTnI). Other sarcomere genes that cause RCM include troponin T, β-myosin heavy chain, and actin [59]. Another subgroup of patients has been identified with RCM associated with atrioventricular block and skeletal myopathy. These are usually caused by mutations in desmin [59, 60].

The clinical course is characterized by the inability to fill the ventricles; limiting the cardiac output may manifest with exercise intolerance, dyspnea, edema, and atrial fibrillation. Non invasive imaging will reveal normal or concentric mildly thickened ventricles with normal or reduced volumes and enlarged atria. The ECG may show low voltages in cases due to infiltrative causes. Typically, it can also demonstrate large and wide P waves, evidence of ischemia or infarction with ST segment and T wave changes and/or pathologic Q waves. Conduction disease, brady-, and tachyarrhythmias may also be seen.

RCM can be classified based on the underlying process: non-infiltrative, infiltrative, storage disease, endomyocardial causes and idiopathic, or in combination with DCM and HCM [58]. As with DCM, many previous cases termed idiopathic are being found to harbor causative pathologic mutations in sarcomeric genes.

Non-infiltrative causes of RCM include scleroderma and systemic sclerosis with well-described polymorphisms in genes coding for extracellular matrix proteins. Pseudoxanthoma elasticum is an inherited disorder associated with accumulation of mineralized elastic fibers, which may lead to blindness, coronary arterial occlusive disease, and RCM. The *ABCC6* gene on chromosome 16p13.1 is responsible for the calcification of elastic fibers [61].

Infiltrative causes of RCM include amyloidosis, which is a group of diseases characterized by extracellular deposition of insoluble fibrillar proteins with concomitant destruction of normal tissue structure and function. About 20 different proteins are known to cause cardiac amyloidosis, and for the hereditary type, more than 100 mutations are known already but the Val122Ile variant of transthyretin is the most common [62]. Sarcoidosis can also cause systolic dysfunction and arrhythmias. The strongest genetic associations are found within the human leucocyte antigens (HLA) and functional polymorphisms within the butyrophilin-like 2 (*BTNL2*) gene [63].

Lysosomal storage diseases are rare conditions that rarely affect the heart. Gaucher disease, the most prevalent, is an autosomal recessive disorder with more than 180 distinct mutations located in chromosome 1p21. Fabry disease is an X-linked lisosomal disease (the second most common affecting the heart) and may manifest as with HCM or RCM, valvulopathies, coronary artery disease, and aortic enlargement. Mucopolysaccharidoses (Hurler and Hunter diseases) are disorders characterized by the deficiency of enzymes required for the breakdown of glycosaminoglycans. Cardiac manifestations start from childhood and include RCM, endocardial fibroelastosis, and valvular disease including thickening with resultant stenosis and/or insufficiency.

Storage diseases such as hemochromatosis (mutation in the *HFE* gene) cause a mixture of systolic and diastolic dysfunction often accompanied by arrhythmias [64]. Glycogen storage diseases are classified in 12 subtypes. In type II (Pompe disease) and type IIb (Danon disease), cardiac involvement may present as the classic infantile form with HCM and/or RCM phenotype. Pompe disease is caused by more than 200 reported mutations in the *GAA* gene [65]. The diagnosis of idiopathic RCM can only be made by exclusion, and the clinicians should be aware of the genetic and clinical overlap with other cardiomyopathies.

Mitochondrial Cardiomyopathies

Mitochondria represent the main energy source in the cell due to the ability to perform oxidative phosphorylation (OP) by proteins at the

mitochondrial respiratory chain comprising complexes I–IV and ATP synthase. Several genes are involved in the role of energy production. Mutations in these genes may cause consequences in the severe end for those organs heavily dependent of energy production such as the brain, heart, and skeletal muscle. Mitochondrial DNA (mtDNA) is exclusively maternally inherited, whereas nuclear DNA follows Mendelian inheritance. Mutations in the mtDNA typically result in HCM but also DCM and LVNC can occur.

The frequency of cardiac involvement in mitochondrial disease is reported from 17 % to 40 %, and the incidence of mitochondrial cardiomyopathy in the pediatric population is estimated at least 1 in 50,000 [66, 67].

Friedreich's ataxia is an autosomal recessive inherited disease that causes progressive damage to the nervous system, resulting in symptoms ranging from gait disturbance to speech problems. Friedreich's ataxia may also have accompanying HCM and diabetes [68]. Barth syndrome is a serious X-linked disorder, primarily affecting males. It is caused by a mutation in the *tafazzin* gene (*TAZ*, also called G4.5), resulting in an inborn error of lipid metabolism, neutropenia, and skeletal myopathy [69] as discussed above.

MELAS (Mitochondrial Encephalopathy, Lactic Acidosis, and Stroke) is a multisystem clinical syndrome manifested by *m*itochondrial *e*ncephalopathy, *l*actic *a*cidosis, and recurrent *s*troke-like episodes. At least 29 other specific point mutations have been associated with the MELAS; the most commonly described gene is a mitochondrial adenine-to-guanine transition at nucleotide pair 3243 (m.3243A > G) encoding the mitochondrial tRNA (Leu). Cardiac involvement is manifested by nonobstructive concentric hypertrophy, although DCM and Wolff-Parkinson-White syndrome have also been reported [70, 71].

Kearns-Sayre syndrome is characterized by progressive ophthalmoplegia, short stature, mental retardation, increased cerebrospinal fluid protein content, and myopathy. Cardiac involvement consists of severe conductions defects and cardiomyopathy, typically the HCM phenotype [67].

Myoclonic epilepsy and ragged red fibers (MERRF) syndrome is caused by a mtDNA mutation. Clinical manifestations include skeletal myopathy, ataxia, dementia, chronic progressive external ophthalmoplegia, deafness, epilepsy, and dilated cardiomyopathy [72].

Single Gene Disorders Associated with Heart Disease

CHARGE Syndrome

Six cardinal features characterize CHARGE syndrome: ocular coloboma, heart defects of any type, atresia of the choanae, retardation (of growth and/or of development), genital anomalies, and ear anomalies. The chromodomain helicase DNA-binding protein 7 (*CHD7*) gene is mutated in about 60 % of CHARGE cases [73]. The incidence of CHARGE is about 1/8,500–12,500 [74]. Congenital heart defects occur in 75–80 % of patients with CHARGE syndrome, and the most common major heart defect is tetralogy of Fallot (TOF) occurring in ∼ one-third of cases. However, other cardiac anomalies such as double-outlet right ventricle with atrioventricular canal, ventricular septal defect, and atrial septal defect with or without cleft mitral valve can be seen [73].

Townes-Brocks Syndrome

Townes-Brocks syndrome (TBS) is characterized by the triad of imperforate anus and triphalangeal and supernumerary thumbs. TBS is caused by mutations within the SALL1 transcription factor gene at 16q12.1. Cardiac anomalies have been reported in 14 % of cases (2 % of familial cases, 10 % probands, and 59 % of sporadic cases). Major heart defects include truncus arteriosus, tetralogy of Fallot, and atrial or ventricular septal defect [75].

Noonan Syndrome

Noonan syndrome (NS) is a common autosomal dominant disorder with an aggregate incidence of

about 1 in 2,500 live births [76]. It is characterized by short stature, webbed neck, facial dysmorphism, learning disabilities, hearing loss, undescended testes and pubertal delay, variable coagulation defects, and heart defects. There is a significant clinical overlap with cardiofaciocutaneous (CFC), Costello, and LEOPARD syndromes, and thus this group of conditions is often referred to as Noonan spectrum disorders [77]. Sensorineural hearing loss occurs in up to 25 % of patients [78]. The most common congenital heart defect in NS is pulmonary valve stenosis with dysplastic leaflets (50–62 %). HCM is the second most common lesion seen in ~20 % of patients [79]. Other congenital heart defects more often seen in NS are atrioventricular canal defect associated with subaortic obstruction and structural anomalies of the mitral valve.

Up to 50 % of patients with Noonan syndrome have an abnormal electrocardiographic pattern characterized by left axis deviation, an abnormal R:S ratio over the left precordial leads, and an abnormal Q wave [80].

The genes that cause Noonan spectrum disorders encode proteins of the Ras/MAPK signal transduction pathway that regulates cellular proliferation and differentiation [81]. Mutations in PTPN11 are detected in 50 % of individuals with NS. Mutations in the genes *RAF1*, *SOS1*, *KRAS*, *MAP2K1*, *MAP2K2*, *HRAS*, *NRAS*, *SHOC2*, and *BRAF* have also been reported in individuals with NS and the related disorders [81]. Mutations in exons 7, 12, and 13 of PTPN11 have been detected in the majority of individuals with LEOPARD syndrome (90–100 %) who in general manifest cardiac involvement in about 85 % of cases, with being HCM the most common cardiac finding [82, 83]. Costello syndrome is usually more severe and is caused by *HRAS* mutations. Cardiac involvement includes structural anomalies, HCM, and conduction system abnormalities. Approximately 65–75 % of Costello patients have cardiac involvement [84, 85]. Pulmonic stenosis occurs in approximately 25 %, arrhythmia in 42 %, and HCM in 47 %. The arrhythmia most commonly described is supraventricular tachycardia, especially chaotic atrial rhythm/multifocal atrial tachycardia or ectopic atrial tachycardia [26].

In cardiofaciocutaneous syndrome (CFC), ~75 % of patients have cardiac involvement. HCM is identified in 40 % of patients and is most frequently diagnosed in infancy but may be detected at any age. Pulmonary valve stenosis is identified in 25 % of patients. Atrial septal defects, ventricular septal defects, mitral or tricuspid valve dysplasia, and BAV have been described but with lesser frequency [86].

Alström Syndrome

This disorder is characterized by progressive blindness, sensorineural hearing loss, and childhood obesity with insulin resistance [87]. Dilated cardiomyopathy occurs in 70 % of patients and is progressive. LVNC may also be seen. Renal failure develops with age and may result in need for dialysis and/or kidney transplant. The condition exhibits autosomal recessive inheritance resulting from mutations in the *ALMS1* gene [88].

Alagille Syndrome

Alagille syndrome is a multisystem disorder with heart, skeletal, liver, eye, and facial features. It is classically characterized by paucity of bile ducts on liver biopsy, cholestasis, and/or conjugated hyperbilirubinemia. Other findings include skeletal abnormalities such as butterfly vertebrae, eye anomalies such as posterior embryotoxon, and right-sided heart defects. The diagnosis is based on clinical features and molecular testing in the *JAG1* gene account for the majority of cases, occurring in approximately 89 % of patients that fulfill clinical criteria [89, 90]. A second gene, *NOTCH2*, has been shown to cause less than 1 % of cases. The clinical features are highly variable, even within families. Sequence variants in *JAG1* have also been identified in a small number of apparently isolated cases of tetralogy of Fallot, absent pulmonary valve syndrome, or pulmonic stenosis [91]. Right-sided defects predominate, occurring in 75 % of cases. Peripheral and branch pulmonic stenosis are the most common cardiovascular findings. Less frequent cardiac malformations include

ventricular septal defect, atrial septal defect, aortic stenosis, and coarctation [92, 93]. NOTCH and JAG1 are known to be important for vascular development, and at least 10 % of patients with Alagille have documented extra-cardiovascular anomalies including internal carotid artery anomalies, basilar artery aneurysms, middle cerebral artery aneurysm, and Moyamoya disease.

Normal Cardiac Anatomy

2

Robert H. Anderson, Andrew C. Cook, Anthony J. Hlavacek, Horia Muresian, and Diane E. Spicer

Abstract

It is axiomatic that understanding of abnormal anatomy requires a thorough knowledge of normal findings. Nowadays, this knowledge should be based on the appreciation of the location of the heart within the chest, since the basic rule of anatomy is that all structures should be described relative to the anatomical position. The discrepancy between the planes of the heart and the planes of the body should not detract from the importance of abiding by this rule. Having understood the discrepancies between the axes, it is then important to appreciate that the so-called right chambers

are anterior to their allegedly left-sided counterparts, with the left atrium being the most posterior of the cardiac chambers. The atriums possess venous components, appendages, and vestibules, being separated by the septum. The left atrium also has an obvious body. The ventricles are best assessed on the basis of possessing inlet, apical trabecular, and outlet components. The arterial trunks spiral as they extend from the base of the heart into the mediastinum. The cardiac valves are best considered in terms of atrioventricular and arterial complexes, with the leaflets being the working units of all the valves. The atrioventricular valves also have a well-formed tension apparatus, while the arterial valvar leaflets are supported by the valvar sinuses. There are atrial, atrioventricular, and ventricular septal structures. Accounts of the fibrous skeleton are markedly exaggerated, with the so-called central fibrous body being the best formed fibrous element within the heart. This part is perforated by the atrioventricular conduction axis, with the cardiac impulse being generated by the sinus node and slowed in the atrioventricular node. The major coronary arteries and veins occupy the atrioventricular and interventricular grooves, with two coronary arteries arising from the aortic root and most of the veins draining to the coronary sinus located within the left atrioventricular groove.

Introduction

It is axiomatic that to understand abnormal anatomy and to describe it adequately, it is necessary first to understand normal cardiac anatomy, including the relationships of the conduction tissues and coronary arteries to the various components of the heart. We review these features in this chapter, hopefully setting the scene for the subsequent chapters of this book, in which these various anatomical features will be discussed in the setting of congenitally cardiac malformations.

The Heart within the Chest

The basic rules of human anatomy dictate that structures should be described as they are located within the body, the body itself being viewed from the front in the so-called anatomical position. It is unfortunate that this rule has been flaunted consistently over the years, so that cardiac structures are conventionally described in the setting of the heart positioned on its apex. It is only in this "Saint Valentine" orientation that the right atrium and ventricle are seen rightward to their alleged left-sided counterparts. In reality, the so-called right-sided chambers are positioned in front of their partners, the heart itself normally occupying the middle compartment of the mediastinum, with two-thirds of its bulk to the left of the midline. Its long axis shows a considerable obliquity relative to the long axis of the body (Fig. 2.1). This discrepancy between the planes of the body and those of the heart should not disguise the fact that cardiac structures should still be described relative to the bodily coordinates. This is the essence of attitudinally

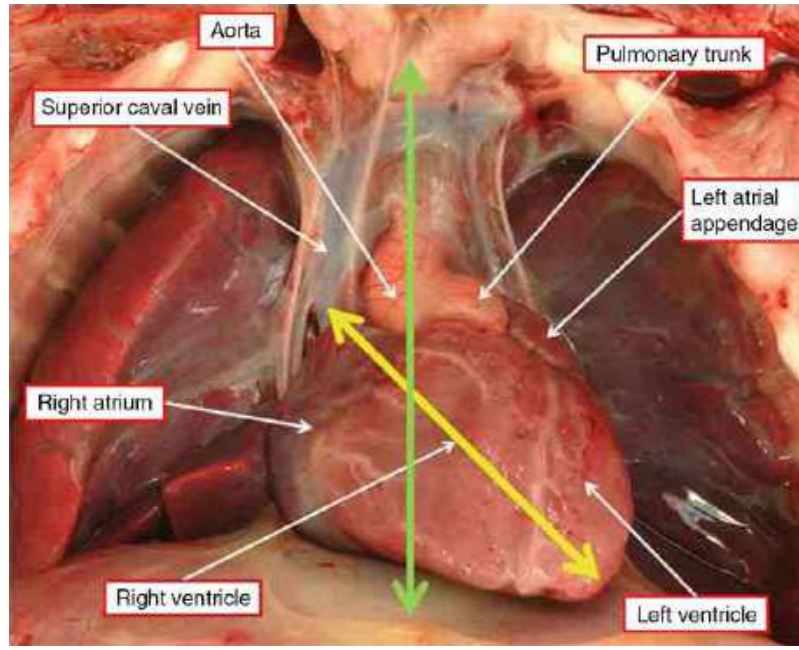

Fig. 2.1 The heart is shown in its usual position within the thorax. Note the gross malalignment between the long axis of the heart (*yellow double headed arrow*) and the long axis of the body (*green double headed arrow*)

appropriate description [1], which we will follow in this chapter. Thus, when considered in attitudinally appropriate fashion, the pulmonary valve is located superiorly and to the left edge of the cardiac silhouette. The locations of the aortic, mitral, and tricuspid valves then overlap when considered in the setting of the cardiac silhouette, with the mitral valve being the most posterior and the tricuspid valve the most inferior. Interrogation of the short-axis section as viewed in left anterior oblique projection then shows the central location of the aortic valve, with appreciation of this relationship being the key to the overall understanding of normal cardiac anatomy (Fig. 2.2). Because of the asymmetric disposition of the heart within the thorax, only some of the general body coordinates can properly be used to describe the interrelationships of the various cardiac components, for example, superior and inferior, left and right, and anterior and posterior, remembering that it is the sternocostal surface of the heart which is anterior and that the posterior parts are those closest to the vertebral column. It also helps to use some coordinates specific to the heart, such as apical and basal. It is the left atrium which is the most posterior chamber within the heart.

The Pericardium

The cardiac chambers, and the proximal parts of the arterial trunks, are enclosed within the pericardial cavity, the pericardium itself being a double-layered sac with fibrous and serous components. The fibrous layer functions as the cardiac seat belt. Its attachments to the diaphragm, along with the entrances and exits of the great veins and arterial trunks, anchor the heart within the mediastinum. The fibrous sac is itself lined with a serous layer, the parietal pericardium, which is reflected onto the surface of the heart at the entrances and exits of the main vascular channels as the epicardium. There are two recesses within the cavity thus formed, namely, the transverse and oblique sinuses. The transverse sinus is the conduit located centrally between the anterior aspect of the atrial chambers and the posterior part of the arterial pedicles, the latter structures themselves being wrapped within a sleeve of serous pericardium (Fig. 2.3). In developmental terms, the conduit is interposed between the venous and arterial poles of the heart. The oblique sinus is the cavity found

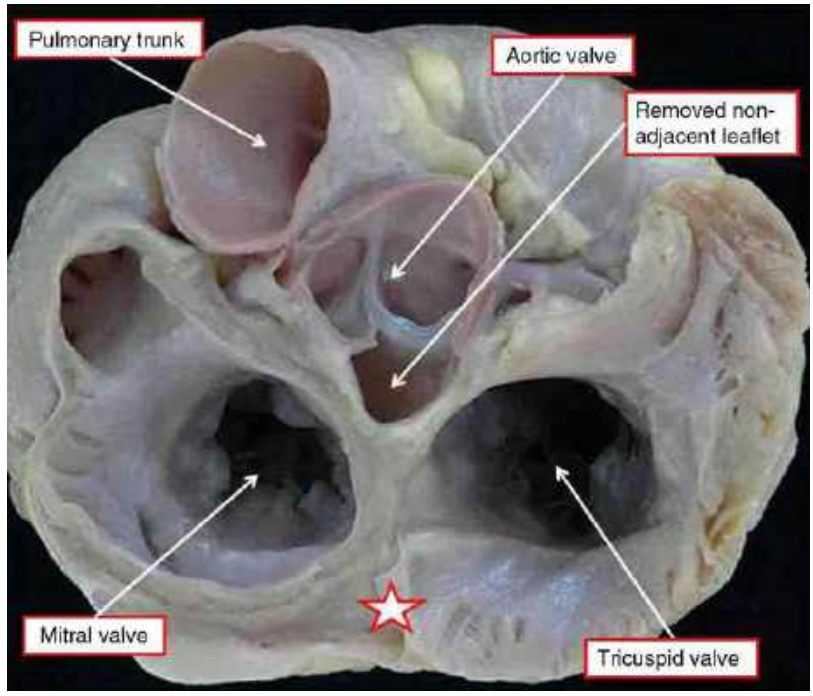

Fig. 2.2 The heart has been dissected by removing the atrial myocardium and the arterial trunks. The short axis is viewed from above. Note the central location of the aortic root. The nonadjacent leaflet has been removed to show how the subaortic outflow tract extends between the ventricular septum and the mitral valve. Appreciation of the relationships of the aortic valve is the key to the understanding of normal cardiac anatomy. The *star* marks the so-called cardiac crux, where the plane of the ventricular septum crosses the inferior atrioventricular groove

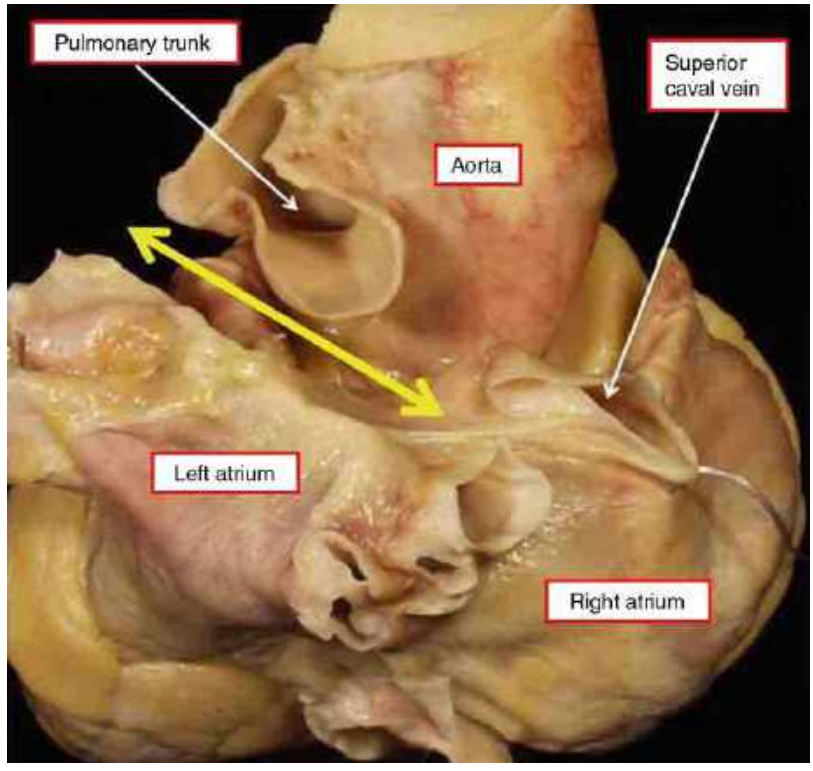

Fig. 2.3 The heart is viewed from above and slightly from the right. The arterial pedicles have been reflected forward to show the transverse sinus of the pericardial cavity (*double-headed arrow*), which interposes between the venous and arterial poles of the heart

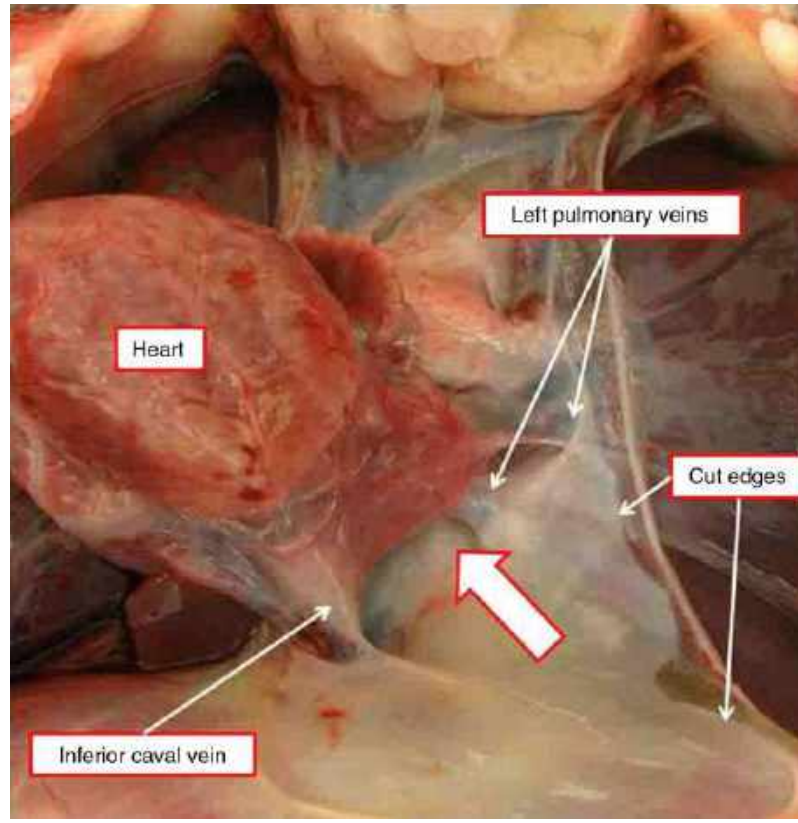

Fig. 2.4 The heart has been reflected from its pericardial cradle, showing how the oblique sinus of the pericardium (*white arrow* with *red* borders) extends posteriorly behind the left atrium, confined by the pericardial reflections round the left pulmonary veins and the right pulmonary veins, the latter reflection extending to include the orifice of the inferior caval vein

behind the left atrium, limited on the left side by entrances of the left pulmonary veins and on the right side by the entrances of the right pulmonary veins along with that of the inferior caval vein (Fig. 2.4).

The Chambers Within the Heart

As we have already explained, although usually described in "Valentine heart" fashion, the heart when viewed during life is not usually positioned on its apex, with the so-called right-sided chambers directly to the right of their left-sided partners [1]. Instead, when seen in frontal projection, the anterior surface of the cardiac silhouette is occupied for the most part by the right atrium and ventricle. The right margin is formed almost exclusively by the right atrium and the caval veins. The left atrium is almost entirely a posterior structure, with only its appendage projecting to the left upper border, while only a strip of left ventricle is seen down the sloping left border. The so-called right chambers of the heart, therefore, are basically anterior, with the ventricles situated to the left and inferiorly relative to their atrial counterparts. The aortic and mitral valves are closely related one to the other within the base of the left ventricle, while the pulmonary and tricuspid valves are separated in the roof of the right ventricle by the extensive supraventricular crest, known classically in its Latin form as the "crista supraventricularis." The crest itself is intimately related posteriorly to the aortic root (Fig. 2.3). The diaphragmatic border of the ventricular mass exhibits a sharp angle anteriorly between its sternocostal and inferior surfaces, known as the acute margin. In contrast, the leftward border has a much gentler curve between the sternocostal and pulmonary surfaces and is called the obtuse margin, albeit that it is not truly a margin. Within the surfaces of the heart, the atrioventricular, or coronary, grooves mark

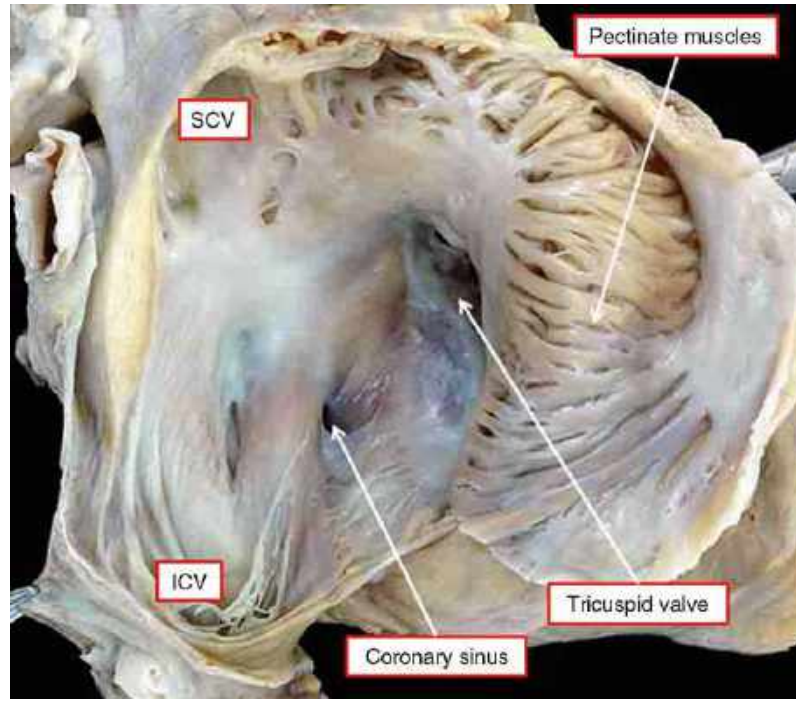

Fig. 2.5 The morphologically right atrium has been opened through a cut along the terminal groove and the wall of the appendage reflected anteriorly and to the right. The image shows the contrast between the pectinated walls of the appendage and the smooth walls of the systemic venous sinus, with the superior and inferior caval veins (SCV, ICV), along with the coronary sinus opening to the venous sinus within the confines of the remnants of the embryonic venous valves

the location of the cardiac short axis, while the interventricular grooves mark the location of the ventricular septum (Fig. 2.1). Although usually described as being posterior, the diaphragmatic surface of the heart is, of course, positioned inferiorly. An important landmark is found on this surface where the interventricular groove joins the atrioventricular groove. This is the cardiac crux (Fig. 2.2).

The Morphologically Right Atrium

Each atrial chamber possesses a venous component, a vestibule leading to the atrioventricular valve, an appendage, and a body, with the septum separating the two atrial chambers. The venous tributaries of the right atrium, the superior and inferior caval vein, and the coronary sinus, enter the smooth-walled systemic venous sinus, the smoothness of its walls contrasting with the pectinated wall of the appendage (Fig. 2.5). The vestibule is also smooth walled, inserting at the atrioventricular junction into the leaflets of the tricuspid valve. The body is not usually obvious in the right atrium, but is the narrow area between the leftward margin of the systemic venous sinus and the septum. It is the appendage which is the most constant and characteristic component, serving to distinguish the chamber as being morphologically right even when the heart is congenitally malformed. Recognition of structures according to their morphology rather than their location, and using their most constant part in final arbitration, is called the "morphological method [2]." It is this principle that provides the basis for logical analysis of congenitally malformed hearts [3]. The right atrial appendage is broad and triangular in shape, having an extensive junction with the smooth-walled venous component, this junction marked externally by the terminal groove, or sulcus terminalis (Fig. 2.6). The pectinate muscles arising from the terminal crest, or crista terminalis, which is the internal counterpart of the groove, extend round the entirety of the parietal part of the right atrioventricular junction. This extent of the pectinate muscles serves to indentify the morphologically right appendage even when the heart is congenitally malformed, as, for example, in the setting of right isomerism [4]. In many hearts, fibrous remnants of the valves of the embryonic sinus venosus mark the boundaries of

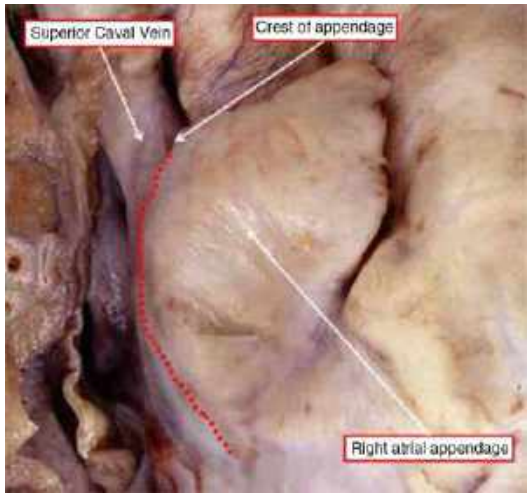

Fig. 2.6 The right atrium is shown anteriorly and from the right. Note the triangular shape of the appendage, which is separated from the posterior systemic venous sinus by the terminal groove (*red dotted line*)

the systemic venous sinus, best seen to the right side, but also on occasion seen to the left side, marking then the boundary of the atrial body. The most prominent of these structures are the Eustachian and Thebesian valves, which guard the orifices of the inferior caval vein and the coronary sinus, respectively (Fig. 2.7). Although the valves themselves are not uniformly present, the insertion of the Eustachian valve into the myocardial wall between the orifice of the coronary sinus and the oval fossa can almost always be found. The continuation from the insertion, buried within the muscular atrial wall, is the tendon of Todaro [5]. Having extended through the atrial wall, the tendon inserts into the fibrous root of the aorta, forming the anterosuperior border of the triangle of Koch. The septal surface of the right atrium, at first sight, seems to be extensive, but this appearance is deceptive. Only the floor of the oval fossa, or fossa ovalis, along with its anteroinferior rim, interposes between the cavities of the two atriums. The superior rim, described as the "septum secundum," is no more than the infolded atrial walls between the attachment of the superior caval vein to the right atrium and the right pulmonary veins to the left atrium (Fig. 2.8) [6]. The floor of the triangle of Koch is the atrial surface of a muscular sandwich, with an extension of the inferior atrioventricular groove serving as the meat in the sandwich, the other layer being the crest of the ventricular muscular septum. The atrial component of the sandwich is confluent with the so-called sinus septum, this being the muscular wall interposed between the orifices of the coronary sinus and the inferior caval vein.

The Morphologically Left Atrium

The left atrium, like its right-sided counterpart, possesses a venous component, an appendage, a vestibule, and a much better formed body (Fig. 2.9). As with the morphologically right atrium, the appendage is the most characteristic and constant component. It is a long tubular structure, usually with several constrictions along its length. Unlike the right appendage, it has a narrow junction with the body of the atrium. Its pectinate muscles are contained within the appendage, so that the entirety of the posterior walls of the atrium is smooth. The coronary sinus is located within the left atrioventricular groove and hence is an integral component of the morphologically left atrioventricular junction, even though it opens into the cavity of the morphologically right atrium. Its walls are separate from those of the left atrium [7]. The pulmonary veins open into the corners of the extensive smooth-walled venous component. The septal surface is formed by the flap valve of the oval fossa. This structure has a characteristically roughened appearance where it overlaps the infolded superior rim, two horns anchoring it to the infolded walls. The body of the left atrium is most obvious in the setting of totally anomalous pulmonary venous connection. In this anomaly, even though the pulmonary venous component is obviously lacking, there is an extensive smooth-walled atrial component forming the site of union between the appendage and vestibule. As with the right atrium, the smooth-walled vestibule inserts at the atrioventricular junction into the leaflets of the atrioventricular valve, in this instance the mitral valve.

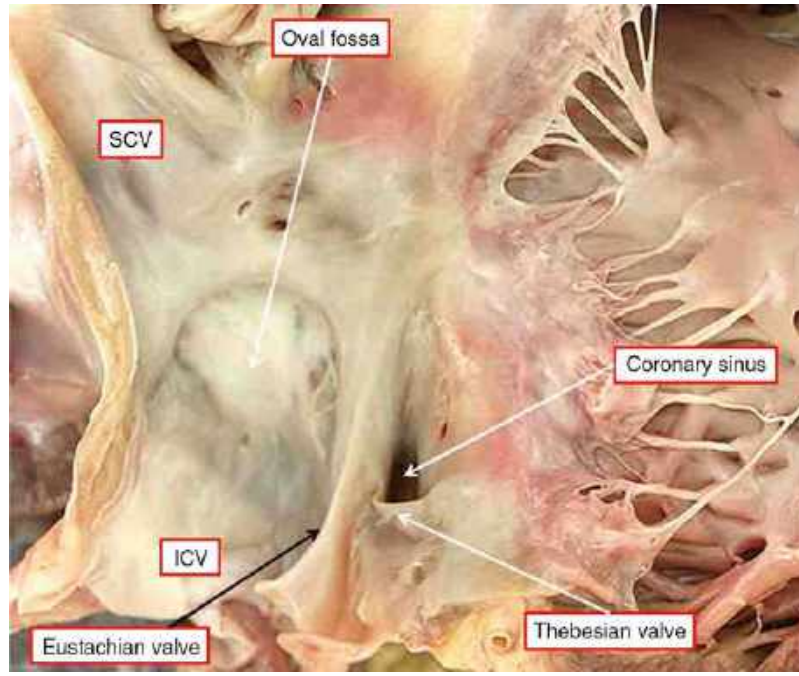

Fig. 2.7 In this heart, the right atrium is opened along a cut through the wall of the appendage, showing how the remnants of the Eustachian and Thebesian valves guard the openings of the inferior caval vein and the coronary sinus, respectively

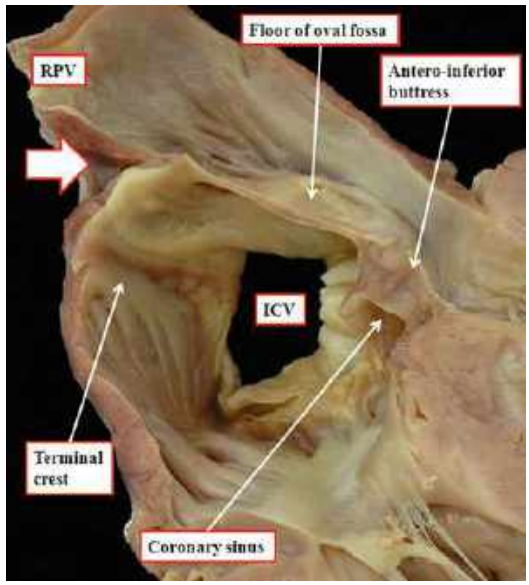

Fig. 2.8 The heart has been sectioned across the oval fossa, showing how its supero-posterior rim is the infolded atrial wall between the attachments of the right pulmonary veins (RPV) to the left atrium and the superior caval vein to the right atrium. The opening of the inferior caval vein (ICV) is well seen

The Morphologically Right Ventricle

The muscular walls of the right ventricle extend from the discrete atrioventricular junction to their union with the walls of the pulmonary trunk at the anatomical ventriculo-arterial junction. Within the cavity thus demarcated, there are three components, the inlet, the apical trabecular, and the outlet parts (Fig. 2.10). The inlet component contains and supports the leaflets of the tricuspid valve, being demarcated distally by the attachments of the valvar papillary muscles. The three leaflets of the valve are located septally, inferiorly, and anterosuperiorly within the atrioventricular junction (Fig. 2.11). The septal leaflet is attached by multiple tendinous cords to the muscular ventricular septum. The inferior leaflet guards the diaphragmatic surface of the junction, albeit that its zone of apposition with the anterosuperior leaflet is often indistinct. The anterosuperior leaflet is the most extensive of the three. Its zone of apposition with the septal leaflet is supported by the medial papillary

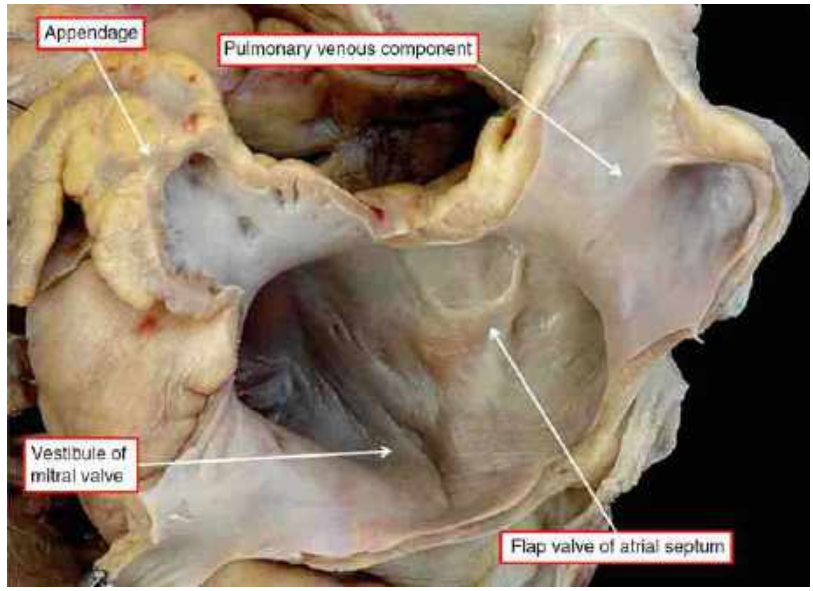

Fig. 2.9 The left atrium is opened through its body, revealing the narrow mouth of the appendage, the vestibule, and the pulmonary venous component. Note that the flap valve of the septum forms its anterior wall

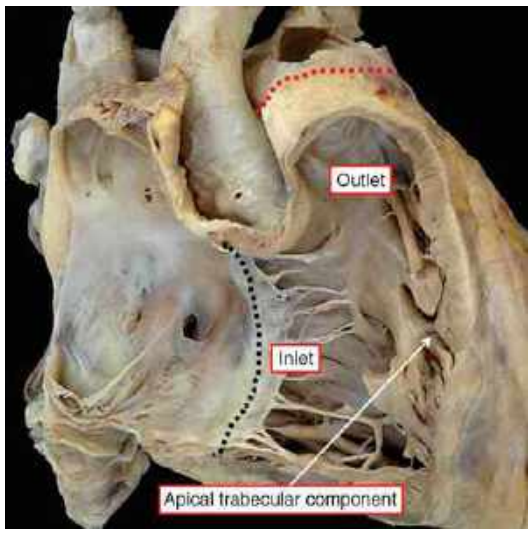

Fig. 2.10 The morphologically right ventricle is shown subsequent to removal of its anterior wall. It extends from the atrioventricular junction (*black line*) to the ventriculo-arterial junction (*red line*). It is best analyzed on the basis of possessing inlet, apical trabecular, and outlet components

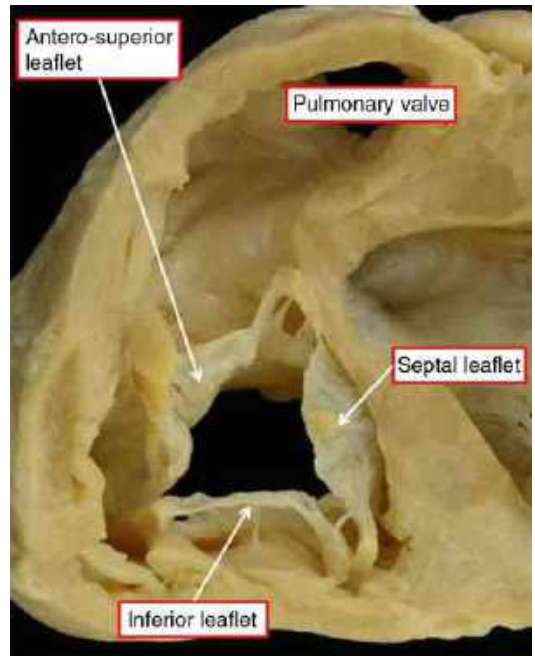

Fig. 2.11 The image shows the right atrioventricular junction as seen in left anterior oblique projection and viewed from the cardiac apex. As can be seen, when viewed as it lies within the chest, the tricuspid valve possesses anterosuperior, inferior, and septal leaflets

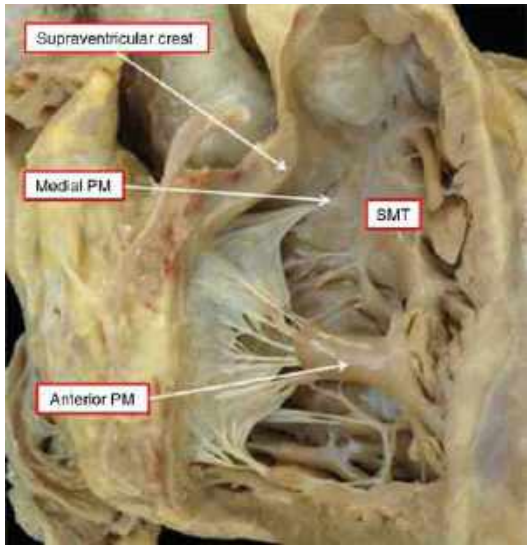

Fig. 2.12 The image shows the septal surface of the right ventricle, where the supraventricular crest inserts between the limbs of the septomarginal trabeculation (SMT), or septal band. Note the origins of the medial and anterior papillary muscles

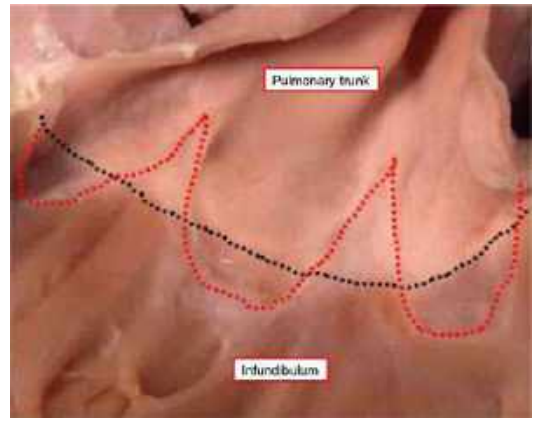

Fig. 2.13 The right ventricular outflow tract has been opened, and the leaflets of the pulmonary valve removed, revealing their semilunar attachments (*red dotted line*) relative to the anatomic ventriculo-arterial junction (*black dotted line*)

muscle, also known as the papillary muscle of the conus, or the muscle of Lancisi (Fig. 2.11). The anterior papillary muscle supports the anterosuperior leaflet, but often times in its middle part rather than at the site of apposition with the inferior leaflet (Fig. 2.11).

The apical trabecular part of the ventricle has particularly coarse trabeculations, this being the most constant feature of the ventricle in malformed hearts. A prominent trabeculation is seen reinforcing the septal surface, forming a prominent Y configuration at the ventricular base where it clasps the supraventricular crest. This is the septomarginal trabeculation, or septal band (Fig. 2.12). The medial papillary muscle arises from the postero-caudal limb of the branch point, the anterior papillary muscle taking origin from the body of the trabeculation towards the ventricular apex. A further series of trabeculations extend from the anterior surface of the septomarginal trabeculation, running into the parietal ventricular wall. One of these septoparietal trabeculations is particularly prominent, joining the anterior papillary muscle and then continuing to the parietal wall. This is the moderator band.

The outlet component of the ventricle is smooth walled, formed by the free-standing sleeve of musculature that supports the leaflets of the pulmonary valve. The valvar leaflets are attached in semilunar fashion within the sleeve, crossing the discrete anatomic ventriculo-arterial junction formed between the ventricular muscle and the walls of the pulmonary trunk (Fig. 2.13). In consequence of the semilunar nature of the hinge of each leaflet, crescents of ventricular musculature are incorporated within the bases of the sinuses of the pulmonary trunk, while triangular areas of arterial wall are incorporated within the ventricular outflow tract [8]. The valvar leaflets, therefore, do not possess an annulus in the sense of a fibrous ring that supports their attachments in circular fashion. Instead, the hinges encircle the outflow tract in crown-like fashion. There are circular junctions to be found within the outflow tract, specifically the anatomical ventriculo-arterial junction and the sinutubular junction between the valvar sinuses and the tubular pulmonary trunk. The so-called annulus identified at the entrance to the pulmonary root, however, is no more than a virtual ring that can be constructed by joining together the most proximal attachments of the leaflets (Fig. 2.13). The component of the subpulmonary infundibular sleeve that interposes

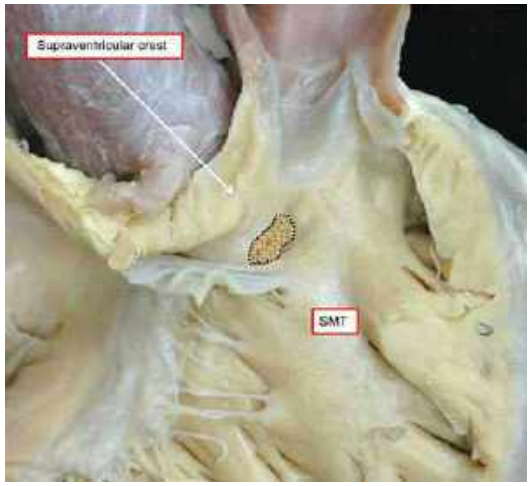

Fig. 2.14 The greater part of the supraventricular crest has been removed, showing that it is no more than the inner curve of the right ventricle. A small part of the musculature inserting between the limbs of the septomarginal trabeculation forms a true muscular outlet septum (hatched area), but its margins cannot be distinguished without dissection

between the leaflets of the pulmonary and tricuspid valves, in other words the supraventricular crest, is often considered to represent a septal structure. In reality, it is no more than the inner curve of the parietal wall of the right ventricle (Fig. 2.12). It is well described as the ventriculo-infundibular fold. A small part of the musculature located at the Y of the septomarginal trabeculation can be removed to provide access to the left ventricle and hence represents a true muscular outlet septum (Fig. 2.14). Without dissection, however, this septal component cannot be distinguished from the remainder of the muscular ventricular septum. Indeed, incisions made outside this restricted area communicate with the outside of the heart.

The Morphologically Left Ventricle

As with the right ventricle, the left ventricle is well described as possessing inlet, apical trabecular, and outlet components (Fig. 2.15). The inlet component surrounds and supports the leaflets of the mitral valve, being limited distally by the attachments of its paired papillary muscles. The valve itself possesses aortic, or anterior, and mural, or posterior, leaflets, which close along a solitary zone of apposition. It has become conventional to describe the fan-shaped tendinous cords supporting the valvar leaflets at the ends of the zone of apposition as "commissural cords." There are, however, similar fan-shaped branching cords that support the slits in the extensive mural leaflet of the valve, usually dividing the leaflet into three scallops. But there can be multiple scallops within the mural leaflet. The zone of apposition between the leaflets, furthermore, does not extend to the atrioventricular junction, or annulus. Further segments of leaflet tissue can be recognized at the ends of the zone of apposition. These components are identified by some as the commissural leaflets. Irrespective of such niceties, when viewed in the closed position, the mural leaflet guards two-thirds of the overall valvar circumference, with slits along its length permitting it to fit snugly against the aortic leaflet (Fig. 2.16). It is the number of slits that determines the number of scallops in this part of the valvar skirt. The other leaflet, positioned anteriorly, but also called the aortic leaflet because of its fibrous continuity, on its ventricular aspect, with parts of the left coronary and nonadjacent leaflets of the aortic valve, guards only one-third of the valvar circumference. Opening the valve, and viewing it in its spread position, shows that the aortic leaflet is much deeper than the mural leaflet. In spite of the different lengths, however, the leaflets have more or less the same surface area. The leaflets of the mitral valve are then supported by the paired papillary muscles. It has become conventional to describe these muscles as being located postero-septally and anterolaterally. Viewing the ventricle in attitudinally appropriate fashion, however, shows that the muscles are located infero-septally and supero-laterally, with the inferior muscle being anterior to its partner (Fig. 2.17). The trabecular component of the left ventricle extends beyond the papillary muscles of the mitral valve, reaching to the relatively thin apical point. The trabeculations themselves are significantly finer than those of the right ventricle and crisscross in characteristic fashion

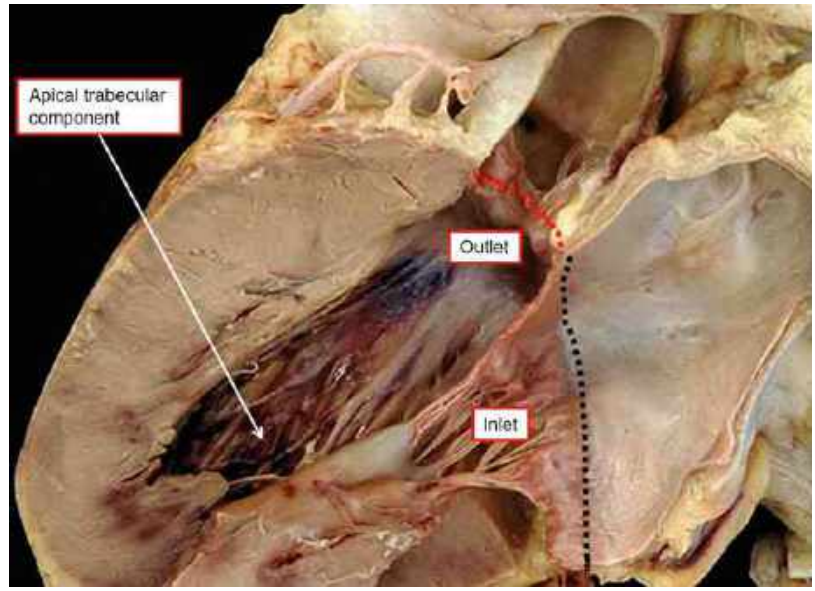

Fig. 2.15 As with the right ventricle, the left ventricle, when defined as extending from the atrioventricular (*black dotted line*) to the ventriculo-arterial (*red dotted line*) junctions, has inlet, apical trabecular, and outlet components

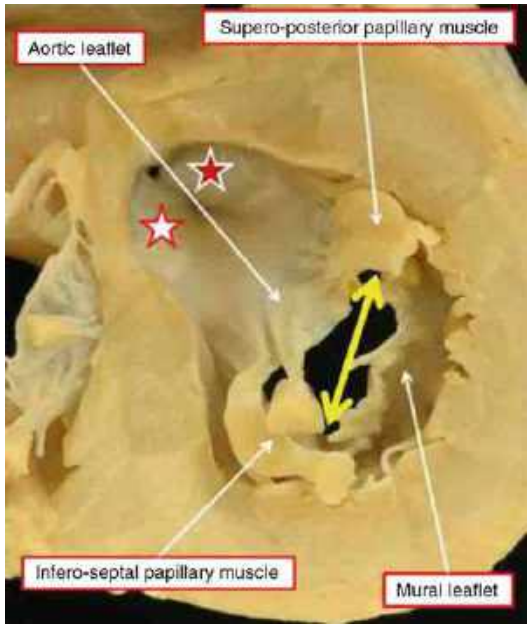

Fig. 2.16 The short axis of the left ventricle is viewed from the cardiac apex in left anterior oblique projection. The view shows well the details of the mitral valve, illustrating the solitary zone of apposition between its aortic, or anterior, and mural, or posterior, leaflets. Note that the papillary muscles are positioned inferiorly and septally, and superiorly and posteriorly

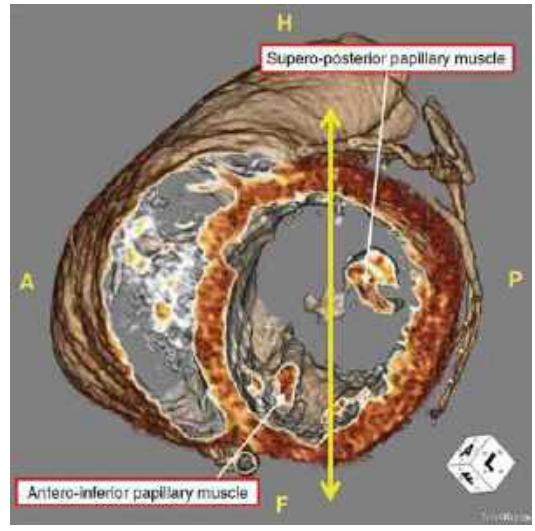

Fig. 2.17 The computed tomographic angiogram confirms the positions of the papillary muscles supporting the leaflets of the mitral valve relative to the bodily coordinates. The double-headed yellow arrow shows the plane from head to feet. Everything to the left hand of this plane is anterior within the body. As shown, therefore, the papillary muscles are located anteriorly and inferiorly, and superiorly and posteriorly, rather than postero-medially and anterolaterally, as they are usually described in current textbooks

(Compare Figs. 2.10 and 2.15). Strands often cross the cavity of the ventricle, particularly from the papillary muscles, as false tendons, or "telegraph wires." They are of no functional significance. The surface of the septal aspect of the trabecular component is smooth, with no evidence of any structure comparable to the septomarginal trabeculation of the right ventricle (Fig. 2.15). The left bundle branch of the atrioventricular bundle descends from the crest of the muscular ventricular septum and fans out in this area.

The outlet component is significantly abbreviated in comparison to its right ventricular counterpart, with the leaflets of the aortic valve supported by musculature only around the anterior quadrants of the outflow tract. Posteriorly, two of the leaflets of the aortic valve are in fibrous continuity with the deep aortic leaflet of the mitral valve. Despite this difference in terms of support, the overall semilunar structure of the aortic valve is comparable to that of the pulmonary valve (Fig. 2.15). As for the right ventricle (Fig. 2.13), the semilunar attachments incorporate crescents of ventricle within the bases of the three aortic sinuses of Valsalva, while three triangles of arterial wall are incorporated within the outflow tract beneath the apices of the zones of apposition between the valvar leaflets. The difference from the situation in the right ventricle is that only two of these crescents are muscular, the third being part of the fibrous continuity between the leaflets of the mitral and aortic valves (Fig. 2.18). The location of the fibrous triangles found beneath the zones of apposition of the leaflets at the sinotubular junction emphasizes the important relationships of the aortic valve [9]. The valvar leaflets are named according to the origin of the coronary arteries from the aortic sinuses. In this way, the sinuses, and the leaflets they support, can be distinguished as being left coronary, right coronary, and nonadjacent. The nonadjacent leaflet is so named because it is furthest away from the pulmonary valve, the two aortic leaflets usually being directly adjacent to pulmonary valvar leaflets if viewed in short axis. The nonadjacent leaflet is also frequently called the non-coronary leaflet. Nonadjacent is the preferable term since, albeit very rarely, the sinus supporting this leaflet can give rise to a coronary artery. In such circumstance, it would obviously then be inappropriate to label the sinus, and leaflet, as being non-coronary. And, as already indicated, use of the term nonadjacent emphasizes that, irrespective of the relationships of the arterial trunks, two of the aortic sinuses are adjacent to corresponding sinuses of the pulmonary trunk. The pulmonary truncal sinuses and valvar leaflets, therefore, can similarly be distinguished as being adjacent or nonadjacent. With regard to the fibrous triangles [9], the one found between the hinges of the left coronary and nonadjacent aortic valvar leaflets forms a wall between the left ventricular outflow tract and the transverse sinus of the pericardium, opening into the space between the posterior wall of the aorta and the anterior atrial walls (Fig. 2.18). The triangle forming the space between the right coronary and nonadjacent aortic valvar leaflets is continuous inferiorly with the membranous septum. When removed, the superior part of the triangle is shown to separate the cavity of the left ventricular outflow tract from the rightward extension of the transverse sinus, specifically with

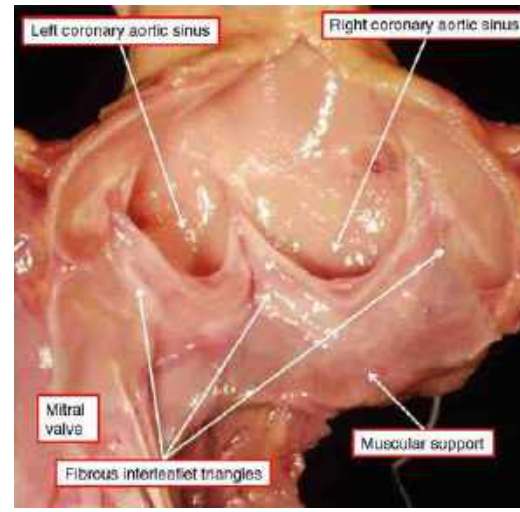

Fig. 2.18 The aortic outflow tract has been opened through the nonadjacent leaflet and sinus of the aortic valve, and the mitral valve reflected to the left. Note the semilunar arrangement of the valvar, with the fibrous interleaflet triangles extending distally to the level of the sinotubular junction

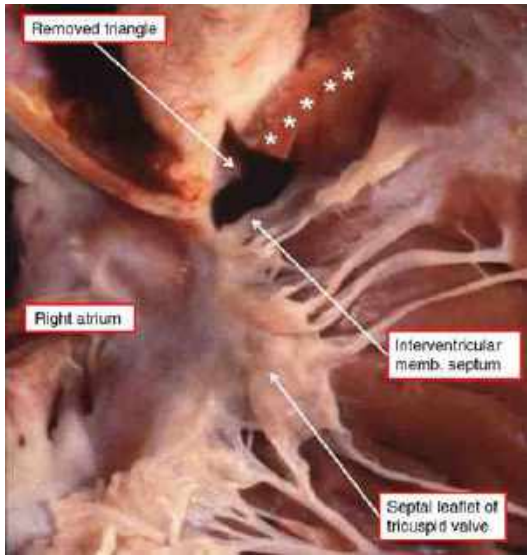

Fig. 2.19 The fibrous triangle interposed between the right and nonadjacent leaflets of the aortic valve has been removed, and the heart photographed from the right side. The triangle incorporates the membranous part of the ventricular septum, but extends superiorly so as to open above the supraventricular crest (*asterisks*) so as to open into the transverse sinus of the pericardium

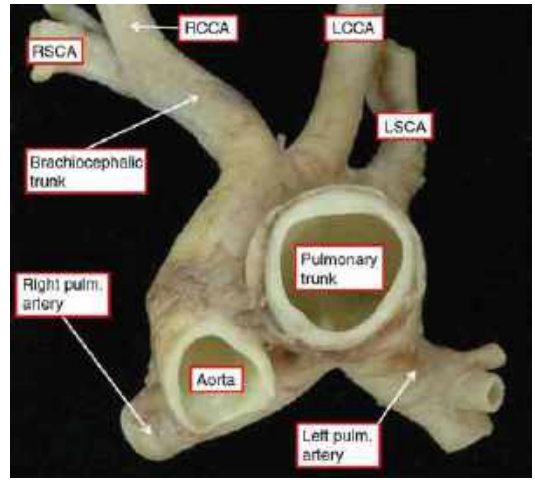

Fig. 2.20 The arterial trunks have been removed from the heart, and photographed from their apical aspect. Note that the pulmonary trunk bifurcates to supply the right and left pulmonary (pulm.) arteries. The brachiocephalic trunk divides to become the right subclavian and common carotid arteries (RSCA, RCCA), while the left common carotid and subclavian arteries (LSCC, LSCA) arise directly from the transverse aortic arch

the space forming the external aspect of the supraventricular crest (Fig. 2.19). The triangle found beneath the hinges of the two coronary aortic valvar leaflets forms the posterior wall of the potential space between the anterior wall of the aortic root and the posterior surface of the free-standing subpulmonary muscular infundibulum.

The Arterial Trunks

The arterial trunks, two in the normal heart, exit from the cardiac base at the ventriculo-arterial junctions, extending superiorly in spiraling fashion into the mediastinum, the pulmonary trunk bifurcating as it moves round the centrally located aorta (Fig. 2.20). Having bifurcated, the right and left pulmonary arteries then extend extrapericardially to reach the pulmonary hilums. When viewed in short axis, each arterial trunk shows a characteristic clover shape at its root, the expanded truncal sinuses supporting at their base the semilunar hinges of the leaflets of the arterial valves, with the pulmonary root usually appearing more dilated and more voluminous when compared to the aortic root. The regions of distal attachment of the leaflets are thickened to form the ring-like sinutubular junctions. The circles forming the distal margins of the arterial valvar complexes are rarely described as annuluses, even though they represent the best formed rings within the arterial roots. The tips of the zones of apposition between the arterial valvar leaflets, usually known as the commissures, are firmly attached to these sinotubular junctions, making them integral components of the valvar complexes. It is frequent to find additional narrowing at this level when the valves themselves are stenotic. Since the junctions are parts of the valvar complexes, it is questionable whether the stenosis should be described as being supravalvar, as is usually the case. The zones of apposition between the leaflets then extend in trifoliate fashion towards the centroids of the valvar orifices (Fig. 2.21). When closed, the centroid itself is positioned approximately

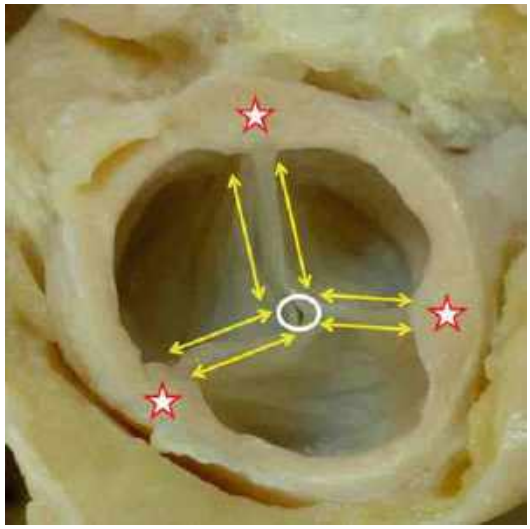

Fig. 2.21 The aortic valve is photographed from above, with the leaflets in the closed position. Note their peripheral attachments at the sinotubular junction (*stars*). The leaflets close along their three zones of apposition (*yellow double-headed arrows*), which join centrally (*white circle*)

halfway between the virtual ring that can be constructed by joining together the basal attachments of the three leaflets and the sinotubular junctions. The pulmonary trunk itself takes only a short course before bifurcating into the right and left pulmonary arteries. The intrapericardial aorta, in contrast, has a more extensive intrapericardial course, exiting from the pericardial cavity to become the transverse aortic arch. The arch usually crosses the left bronchus as it gives rise superiorly to the brachiocephalic trunk, left common carotid, and left subclavian arteries. Distal to the origin of the left subclavian artery, the arch becomes the isthmus, with the site of insertion of the arterial ligament, the remnant of the arterial duct, marking the point where the isthmus becomes the descending aorta. The arterial ligament itself extends from the underside of the isthmus to the upper surface of the left pulmonary artery. The left recurrent laryngeal nerve turns back into the mediastinum round the ligament, or round the arterial duct itself should this structure remain patent in postnatal life.

The Valves of the Heart

We have illustrated already the basic morphological features of the atrioventricular and arterial valves as we described the right and left ventricles. The valves, however, play such important roles in normal and abnormal cardiac function that it is worthwhile reviewing their component parts, the more so since the basic structure of each set of valves is the same for the two ventricles.

The Atrioventricular Valves

Since the atrioventricular valves guard the ventricular inlets, they must withstand the full force of ventricular contraction when in their closed position. Because of this, and unlike the situation with the arterial valves, the atrioventricular valves are furnished with tension apparatus. When considering the overall valvar arrangement, therefore, it is best to describe the valvar complex, which comprises the annulus, the leaflets, the tendinous cords, and the papillary muscles (Fig. 2.22). The annulus, found at the atrioventricular junctions, is better formed for the mitral than the tricuspid valve (Fig. 2.23). Even in the mitral valve, it is unusual to find a complete collagenous ring supporting the leaflets and, at the same time, separating the atrial and ventricular myocardial masses [11]. In the tricuspid valve, it is rare to find collagenous or fibrous cord supporting the hinges of the leaflets. Instead, the leaflets are typically suspended from the endocardial surface of the atrioventricular junction. It is then the fibrofatty tissues of the atrioventricular groove that serve to insulate electrically the atrial from the ventricular musculature (Fig. 2.24). The individual leaflets of the valves are best distinguished according to the way they fit together in their closed position. Examination in this fashion shows that the mitral valve has two leaflets, which close along a single zone of apposition, while the tricuspid valve has three zones of apposition and therefore closes in trifoliate fashion.

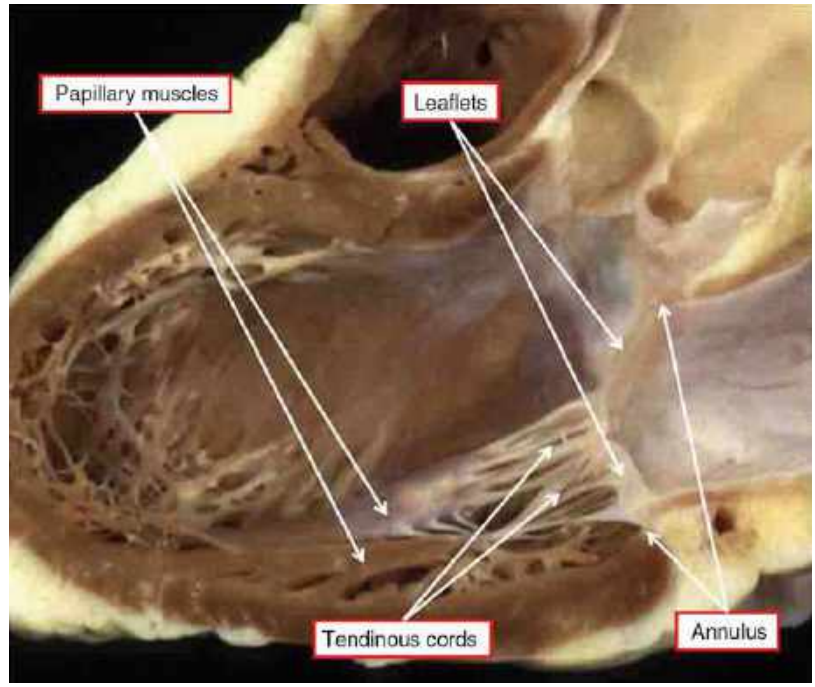

Fig. 2.22 The heart has been sectioned in simulated long-axis parasternal plane, showing the components of the atrioventricular valvar complex

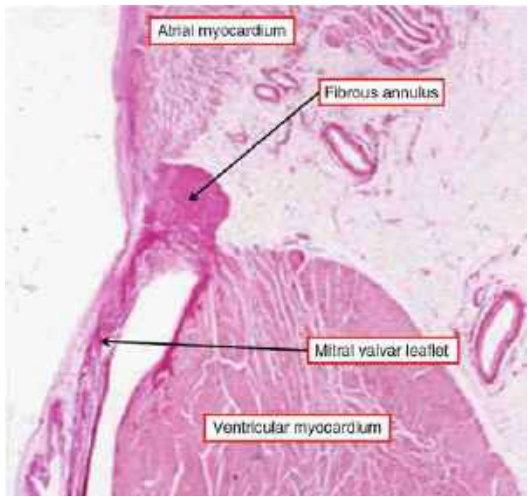

Fig. 2.23 This cross-section across the left-sided atrioventricular junction, stained with the Van Gieson technique, with fibrous tissue colored purple, shows a fibrous annulus supporting the mural leaflet of the mitral valve and interposing between the atrial and ventricular muscle masses

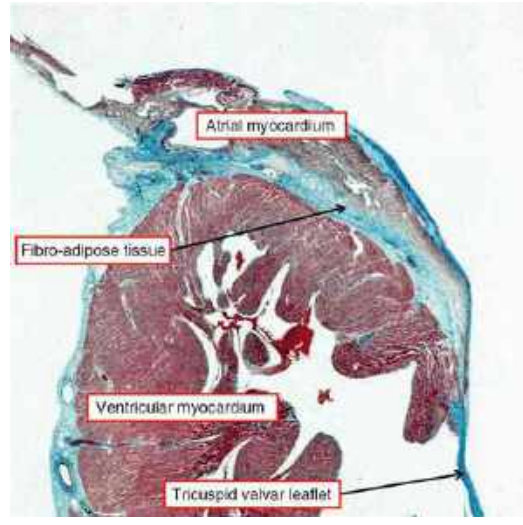

Fig. 2.24 The cross-section across the right-sided atrioventricular junction, stained with the Trichrome technique, with fibrous tissue in green, shows that it is the fibroadipose tissue of the atrioventricular groove, rather than a discrete cord-like annulus, that separates the right atrial and right ventricular muscular walls (compare with Fig. 2.23)

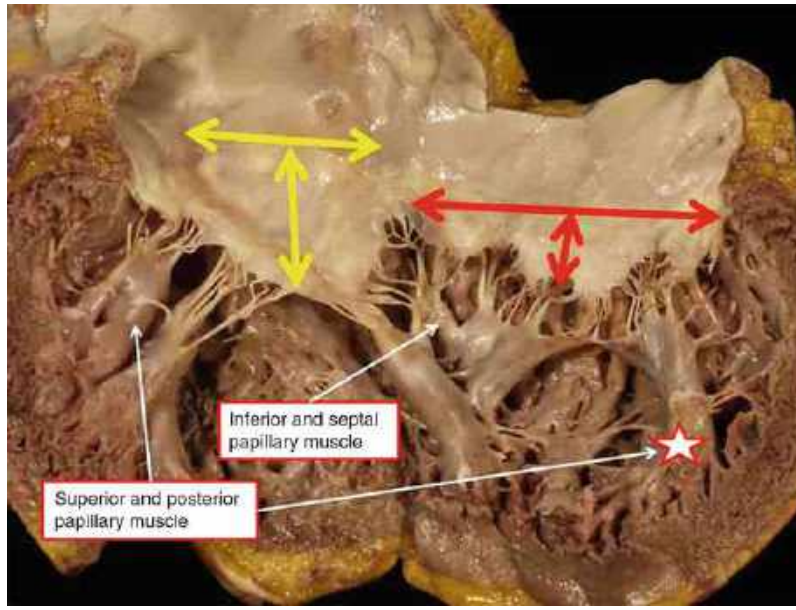

Fig. 2.25 The left atrioventricular junction has been transected across its diaphragmatic aspect, with the cut made close to the obtuse border. The junction has then been opened to show the leaflets of the mitral valve, and their supporting tendinous cords. Note that the mural leaflet guards two-thirds of the valvar orifice, but is shallow, with multiple components (*red arrows*), whereas the aortic leaflet, guarding only one-third of the circumference, is much deeper (*yellow arrows*). Note also that the tendinous cords from the infero-septal papillary muscle support both leaflets, as do those from the superior and posterior muscle, which has been transected during the dissection. One of its heads is shown by the *star*

Various systems have been proposed to describe the arrangement of the tendinous cords that support the leaflets of the atrioventricular valves, some of them relatively complex. It is sufficient for clinical purposes to note that cords are attached uniformly along the leading edges of both valvar leaflets, extending to insert into the supporting papillary muscles. Each papillary muscle supports the adjacent parts of both leaflets (Fig. 2.25). If the leaflets themselves are distinguished on the basis of their pattern of closure, then it becomes unnecessary to describe so-called commissural cords and to seek to distinguish these entities from cleft cords. Fan-shaped cords can be found at the various gaps between the components of the skirt of leaflet tissue in both atrioventricular valves. The cords providing uniform support to the free edges of the leaflets are reinforced by cords attached on the ventricular aspects of the leaflets. These take the form of either strut or basal cords. The strut cords, better formed in the mitral than the tricuspid valve, are attached on the ventricular aspect of the aortic leaflet (Fig. 2.26). The basal cords of the mitral valve support the mural leaflet, extending to insert directly into the ventricular wall (Fig. 2.27), while for the tricuspid valve, such basal cords are found supporting the inferior leaflet. The tricuspid valve, unlike the mitral valve, possesses a septal leaflet. This leaflet is characterized by the multiple cords that attach it directly to the ventricular septum. The mitral valve lacks a septal leaflet, the extensive subaortic outflow tract separating the aortic leaflet of the valve from the smooth septal surface of the left ventricle.

The key to understanding valvar function is to appreciate that, in the normal heart, the entirety of the leading edges of the leaflets should be uniformly supported by tendinous cords. Absence of such uniform support is one of the features underscoring congenital prolapse of leaflets.

The arrangement of the papillary muscles is distinctive for both atrioventricular valves. The tricuspid valve, always found in the morphologically

Fig. 2.26 The outflow aspect of the aortic leaflet of the mitral valve is supported by multiple strut cords

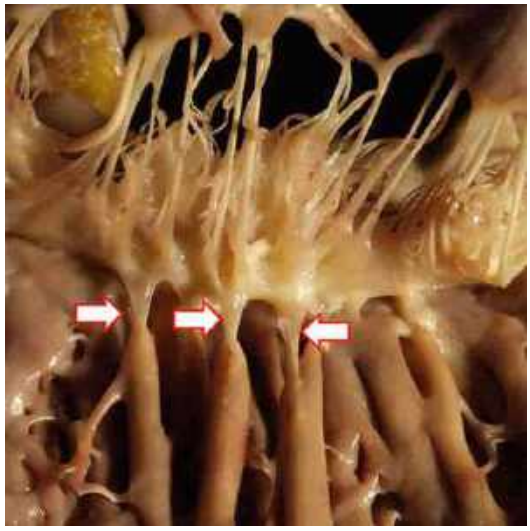

Fig. 2.27 The mural leaflet of the mitral valve has been reflected to show the support provided by multiple basal cords, each cord having its own diminutive papillary muscle, albeit arranged in more bas-relief format relative to the ventricular wall

right ventricle, is supported by the small medial muscle that arises from the postero-caudal limb of the septomarginal trabeculation, a prominent anterior muscle, and an inferior muscle, the latter often being multiple. The prominent anterior muscle itself frequently supports the central part of the anterosuperior leaflet, rather than its zone of apposition with the inferior leaflet. Indeed, the arrangement of the anterior and inferior muscles is remarkably variable. The most distinctive feature of the valve is the multiple direct cordal attachments of the septal leaflet to the ventricular septum.

The papillary muscles supporting the leaflets of the mitral valve, in contrast, have a much more constant arrangement. The muscles are paired and located infero-anteriorly and supero-posteriorly within the ventricular cavity (Fig. 2.17), although the heads of both muscles are frequently multiple. As we have already emphasized, it is a mistake to consider these muscles as being located postero-medially and anterolaterally. This convention of naming the muscles reflects the bad habit of morphologists of describing the heart as though removed from the body and being positioned on its apex. The more appropriate terminology is to describe superior and inferior papillary muscles. The commissures can also better be described in comparable fashion, that is, superior and inferior.

The Arterial Valves

The arterial valves, which guard the outlets of the ventricular mass, extending from the basal to the peripheral attachments of their semilunar leaflets, are just as complex morphologically as the atrioventricular valves. Their components are the supporting ventricular walls, the leaflets, the sinuses, the interleaflet triangles, and the sinotubular junctions. Considered overall, the valvar complex is unequivocally ring-like, but the three-dimensional arrangement of the semilunar suspension of the leaflets within the roots is better described as a crown than a ring (Fig. 2.28). The results of a recent

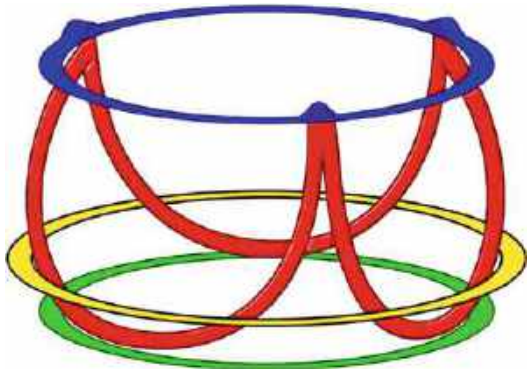

Fig. 2.28 The cartoon shows, in red, how the hinges of the valvar leaflets extend in semilunar fashion through the full length of the arterial roots, which themselves extend from a virtual ring that can be constructed by joining together the basal attachments of the leaflets (*green circle*) to the sinotubular junction (*blue circle*). Within the root, there is then an additional anatomic ring representing the ventriculo-arterial junction (*yellow circle*). The overall suspension of the leaflets, however, is crown-like (*red lines*)

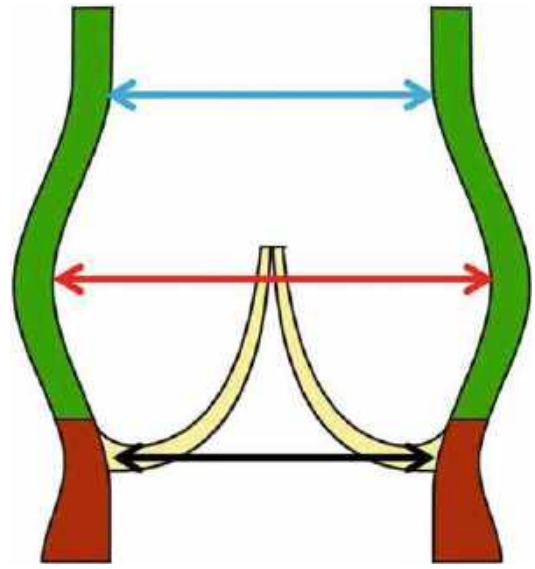

Fig. 2.29 The cartoon shows a cross-section across an arterial root. To provide full information of the dimensions of the root it is necessary to measure diameters at the virtual ring formed at the level of the proximal hinges of the leaflets (*black line*), at mid-sinusal level (*red line*), and at the sinutubular junction (*blue line*). The true anatomic ventriculo-arterial junction, representing the ring where the sinusal walls are supported by the underlying ventricular walls, is not usually measured

extensive questionnaire [10] have revealed a lack of consensus as to how the components of the root should best be described. Suffice it to say that there is no discrete structure that can be dissected from the root as marking a crown-like annulus, although the valvar hinges are themselves attached by collagen to the supporting myocardial or fibrous walls (Fig. 2.13). The key to understanding the overall morphology is to appreciate that at least three zones within the valvar complex can justifiably be described as rings (Fig. 2.28). The first, and most obvious, is the sinutubular junction. The second is the anatomical ventriculo-arterial junction. This junction, best seen in the pulmonary root, where the valvar sinuses are exclusively supported by cardiac muscle (Fig. 2.13), is the locus over which the wall of the arterial trunk joins with the supporting ventricular walls. This anatomical junction is discrete from the hemodynamic boundary between ventricle and arterial trunk, this being represented by the semilunar hinges of the valvar leaflets. This arrangement results in crescents of ventricular wall being incorporated within the truncal sinuses and triangles of arterial wall being incorporated within the ventricular outflow tracts (Figs. 2.13 and 2.18). The entrance to the valvar complex is ring-like, but is a virtual entity, representing the line made by joining the basal attachments of the leaflets within the ventricles. It is this virtual ring, however, that is identified by echocardiographers as the "annulus." The recent questionnaire, answered by surgeons throughout the world [10], showed that this ring was the most popular choice to qualify as the annulus, albeit that many surgeons considered the crown-like remnants seen having removed the leaflets as representing the surgical annulus. It is important, therefore, to recognize the significance of definition of the annulus in such varied fashion. Fully to provide meaningful measurement of the dimensions of the arterial valves, it is also preferable to make such measurements as the levels of the virtual entrance to the root, at mid-sinusal level, and at the sinutubular junction (Fig. 2.29).

The Septal Structures

We have already discussed the basic anatomy of the septal structures. We consider the topic worthy of reemphasis since the precise nature of the walls interposed between the cavities of the cardiac chambers, as we will show, is not as simple as might be imagined from perusal of some current accounts. Clarity can be provided if it is accepted that only those parts of the cardiac walls that separate adjacent chambers, and that can be removed without transgressing of extracardiac space, should be described as being septal [11]. Such a definition does not exclude the fact that walls interposed between adjacent cavities can be folded on themselves, nor that wedges incorporating extracardiac fibroadipose can similarly separate adjacent chambers. Appreciation of the difference between true septal walls, folds, and sandwiches underscores the complete understanding of cardiac anatomy.

These nuances are immediately relevant when we consider the arrangement of the walls that separate the cavities of the atrial chambers. The true atrial septal components are made up by the floor of the oval fossa, and its muscular anteroinferior rim. The so-called septum secundum is no more than the superior rim of the fossa, which is a deep infolding between the attachments of the superior caval vein to the right atrium and the right pulmonary veins to the left atrium (Fig. 2.30). The anterior rim of the fossa is similarly an infolding, which houses the aortic root. The continuation of the anteroinferior muscular buttress into the septal vestibule of the tricuspid valve forms the floor of the triangle of Koch, with dissection revealing this area to be a sandwich incorporating the superior extension of the inferior pyramidal space between its atrial and ventricular walls (Fig. 2.31). The so-called sinus septum is then another fold, forming the branching point of the walls of the coronary sinus and the inferior caval vein.

The apex of the triangle of Koch is made up of fibrous tissue that separates the cavity of the right atrium from the left ventricular outflow tract. This tissue is the fibrous atrioventricular septum, itself a part of the membranous septum of the heart (Fig. 2.32). This structure is the only true atrioventricular septum, since the floor of the triangle of Koch, which previously we had considered to be a muscular atrioventricular septum, is a muscular sandwich (Fig. 2.31). As we have already shown, the membranous septum itself is contiguous with the fibrous triangle that separates the hinges of the nonadjacent and right coronary leaflets of the aortic valve (Fig. 2.19). It is the line of attachment of the tricuspid valve on its right aspect that divides the membranous septum into its atrioventricular and interventricular components (Fig. 2.32), the proportions of the two components varying markedly from heart to heart. In the 4-chamber view, the tricuspid plane is more apical than the mitral plane. The crest or the ventricular septum, furthermore, is not aligned directly with the atrial septum. It is this anatomic arrangement that makes possible the communications seen in malformed hearts between left ventricle and right atrium.

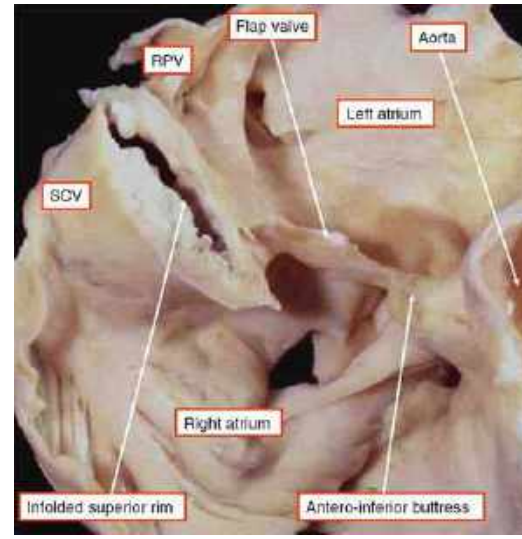

Fig. 2.30 The section, in simulated four-chamber plane, shows how the so-called septum secundum is no more than the infolded atrial walls between the attachments of the right pulmonary veins (RPV) to the left atrium and the superior caval vein (SCV) to the right atrium. It is the flap valve of the oval fossa, along with its muscular anteroinferior buttress, that is the true septal structure

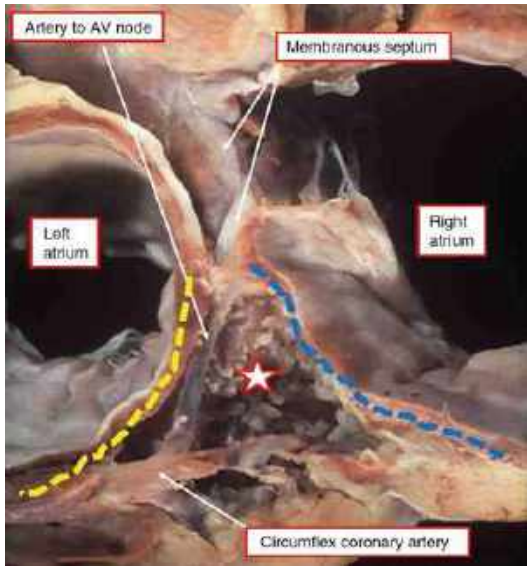

Fig. 2.31 The dissection is made by removing the insertions of the left atrial myocardium into the left atrial vestibule (*yellow dashed line*) and the right atrial myocardium into the tricuspid valvar vestibular (*blue dashed line*). This reveals that the floor of the triangle of Koch (*star*) is a superior continuation of the inferior atrioventricular groove, through which courses the artery to the atrioventricular node, in this heart a branch of the circumflex artery

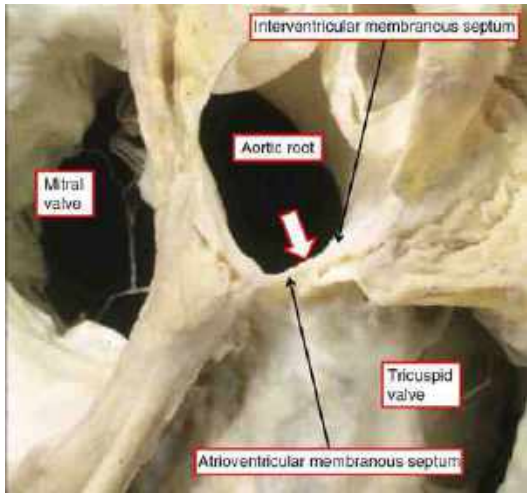

Fig. 2.32 The dissection is comparable to the one shown in Fig. 2.32, but this time made by leaving intact the atrial walls and removing the non-coronary sinus and leaflet of the aortic valve. It shows how the hinge of the septal leaflet of the tricuspid valve (*arrow*) divides the membranous septum into its atrioventricular and interventricular components

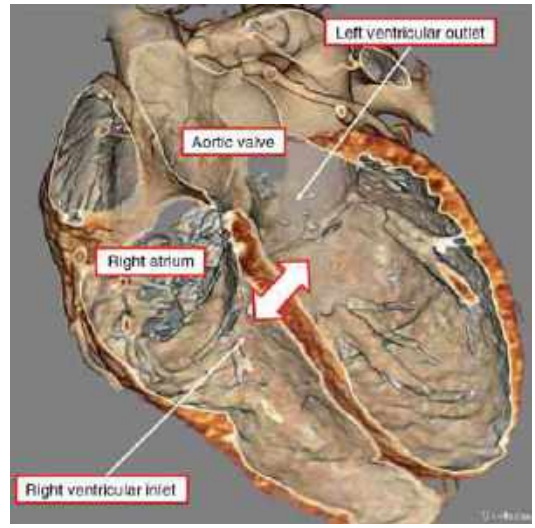

Fig. 2.33 The computed tomographic image shows how the inlet of the right ventricle is separated by the muscular septum from the outlet of the left ventricle (*double-headed white arrow*), so that the inferior part of the muscular ventricular septum is an inlet–outlet septum

The interventricular component of the membranous septum separates the subaortic outflow tract from the cavity of the right ventricle. In terms of size, it is inconspicuous when compared to the bulk of the muscular ventricular septum, but it forms the keystone of the septum within the aortic root. In the past, we had also suggested that the muscular septum itself could be divided into inlet, apical trabecular, and outlet components, illustrating these presumed septal components as matching the corresponding parts of the ventricular cavities [12]. Sectioning across the inlet of the right ventricle, however, shows that this part of the septum borders, in the left ventricle, the subaortic outflow tract (Fig. 2.33). And, because of the free-standing nature of the subpulmonary infundibulum (Fig. 2.34), only a very small part of the muscular septum is a true outlet septum. Furthermore, in the normal heart, there are no boundaries that divide the muscular ventricular septum into component parts. It is preferable, therefore, simply to describe the muscular septum as a whole. A muscular outlet septum, nonetheless, can be seen as an anatomic entity when the septum itself is deficient, and the hole between the ventricles borders the

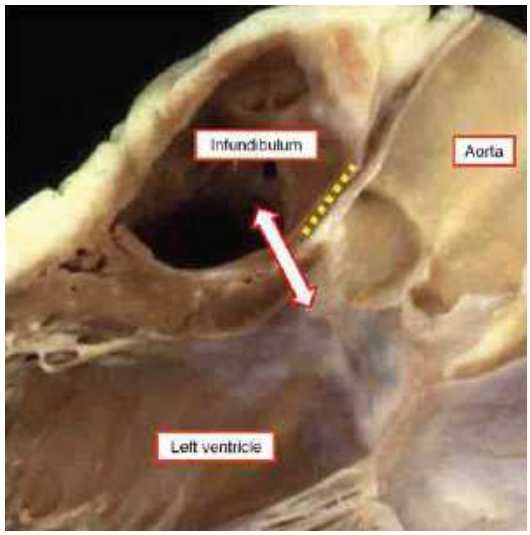

Fig. 2.34 This heart is sectioned to simulate the parasternal long-axis echocardiographic plane. The cut shows that only a small part of the muscular septum separates the ventricular outflow tracts (*double-headed arrow*), since the free-standing muscular infundibular sleeve (*yellow dashed line*) lifts the leaflets of the pulmonary valve away from the cardiac base

persisting parts of the membranous septum. Such perimembranous ventricular septal defects can then appropriately be described as opening to the inlet, apical trabecular, or outlet components of the right ventricle [13], or as being confluent when opening extensively to more than one ventricular component.

The Fibrous Components of the Heart

It is still frequent to find cartoons showing short-axis basal sections of the heart viewed from the atrial aspect as containing a fibrous skeleton that embraces the origins of, and provides the attachments for, the leaflets of all four cardiac valves. Even those textbooks rightly showing the atrioventricular components of the skeleton as being discontinuous show purported fibrous elements supporting the leaflets of the arterial valves [14]. Such arrangements are, of necessity, shown only as cartoons, since there is no foundation in anatomical fact to support the suggested notion. We have already shown how the leaflets of the pulmonary valve are supported on an extensive sleeve of free-standing right ventricular musculature (Fig. 2.13). The leaflets of the aortic valve similarly are hinged in crown-like fashion within the length of the aortic root (Fig. 2.18) and lack any discrete "skeletal" support. It is the zone of fibrous continuity between the aortic leaflet of the mitral valve and the right and nonadjacent leaflets of the aortic valve that forms the strongest component of any fibrous skeleton that does exist within the cardiac base (Fig. 2.35). The ends of the zone of fibrous continuity are thickened, forming the right and left fibrous trigones, and these trigones then anchor the aortic-mitral valvar unit at the base of the left ventricle. The right fibrous trigone itself is continuous with the membranous septum, with the conjoined structure forming the central fibrous body. This is the strongest part of the fibrous skeleton, albeit pierced by the atrioventricular conduction axis as it passes from the apex of the triangle of Koch to reach the crest of the muscular ventricular septum. Cords of fibrous tissue extend from the right and left trigones within the left atrioventricular junction, forming the hinge for the mural leaflet of the mitral valve. It is rare for these cords completely to support the hinge of the mural leaflet and at the same time to insulate the atrial from the ventricular myocardium. Oftentimes the fibrous tissue can be well formed, but as short fibrous strips rather than as a complete encircling cord [15]. In many hearts, the fibrous tissue becomes even more attenuated at various sites around the hinge of the mural leaflet, with the atrial and ventricular muscle masses then being separated by the fibrofatty tissues of the left atrioventricular groove. Such an arrangement, with the valvar leaflets hinged from the ventricular wall rather than a fibrous annulus, is then the rule rather than the exception in the right atrioventricular junction, where it is the fibrofatty tissues of the atrioventricular groove that serve to insulate the atrial from the ventricular musculature (Fig. 2.24). Considered as an entity, therefore, there is very little fibrous tissue in the human heart that serves as a skeleton to support the leaflets of the cardiac valves.

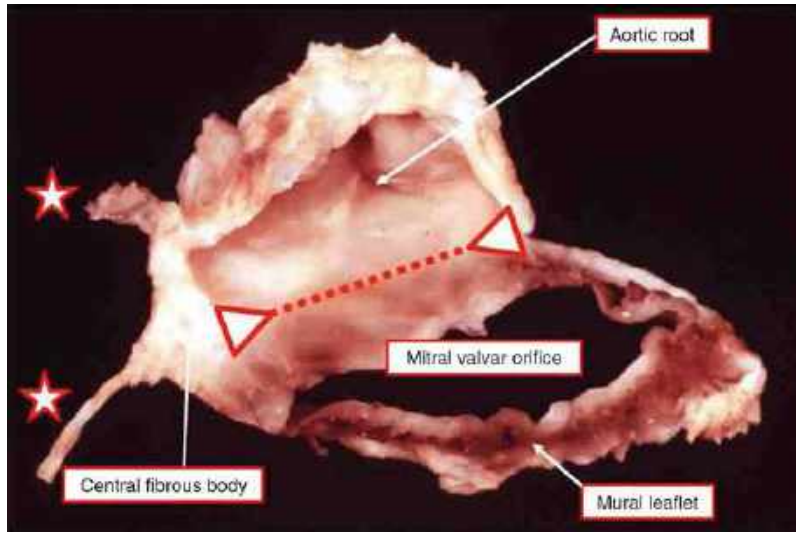

Fig. 2.35 An attempt was made to dissect out the fibrous components of the atrioventricular junctions. As can be seen, it proved possible to remove the aortic root and the mitral valvar orifice. There were limited cords, however, extending into the tricuspid valvar orifice (*stars*), and no connection with the subpulmonary infundibulum. The strongest part of the fibrous support is the area of continuity between the leaflets of the aortic and mitral valves (*red dotted line*), which is thickened at each end to form the fibrous trigones (*triangles*). The right trigone fuses with the membranous septum to form the central fibrous body. The unit is viewed as seen from the ventricular apexes

The Conduction System

The conduction tissues are small areas of specialized myocardium that originate and disseminate the cardiac impulse. Without use of appropriate histological techniques, it is impossible to visualize the tissues directly. Their locations, nonetheless, are sufficiently constant for establishment of accurate anatomical landmarks so that they can be avoided by cardiac surgeons performing intracardiac operative procedures. The cardiac impulse is generated in the sinus node. This small structure is located, in the majority of individuals, subepicardially within the terminal groove, usually being positioned inferior to the crest of the atrial appendage (Fig. 2.36). In about one-tenth of individuals, the node extends across the crest of the appendage at the cavoatrial junction. It then sits like a horseshoe, with one limb in the terminal groove, and the other in the interatrial groove. Equally important to the location of the node is the course of its arterial supply. The artery to the sinus node is the most prominent atrial artery.

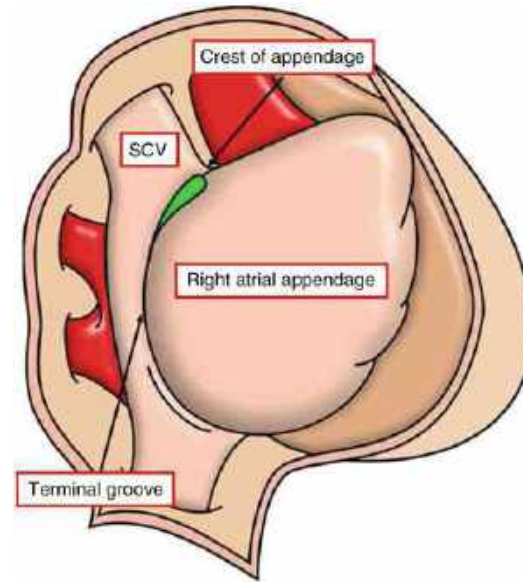

Fig. 2.36 The cartoon shows the usual location of the sinus node, which is shown in green. It lies immediately subepicardially within the terminal groove, and is usually inferior to the crest of the atrial appendage. In one-tenth of individuals, the node extends across the crest in horseshoe fashion. SCV – superior caval vein

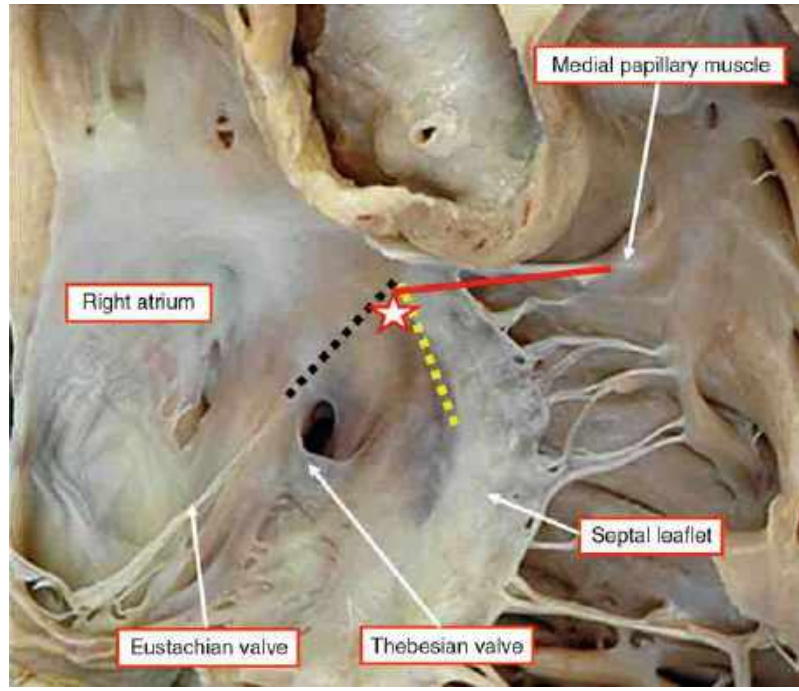

Fig. 2.37 The right atrioventricular junction has been opened in order to reveal the septal structures. The margins of the triangle of Koch are marked, with the location of the tendon of Todaro indicated by the *black dotted line*, and the septal leaflet of the tricuspid valve by the *yellow dotted line*. The atrioventricular node is located at the apex of the triangle (*star*). The location of the atrioventricular conduction axis can then be constructed by extending a line from the apex of the triangle to the medial papillary muscle (*red solid line*)

It arises in most individuals from the initial course of either the right or the circumflex coronary artery. It then runs through the interatrial groove and enters the terminal groove across or behind the cavoatrial junction, with an arterial circle formed in a minority of individuals. In some individuals, the artery arises from the lateral part of the right coronary artery or else from the distal course of the circumflex artery. The nodal artery then runs either across the lateral margin of the right atrial appendage or across the dome of the left atrium. In either event, the major artery supplying the node can be at major risk when a surgeon makes a standard incision to enter the atrial chambers. Because the node frequently receives arterial supply from additional arteries, the risk can be minimized, but it behooves the careful surgeon always to respect major atrial arteries.

The impulse from the sinus node is conducted at the nodal margins into working atrial myocardium, and it is then carried through the working myocardium towards the atrioventricular node. Much has been written in the past concerning the presence of so-called internodal atrial tracts. Anatomical studies have shown unequivocally that there are no narrow and insulated tracts of myocardial cells that join the cells of the sinus node to those of the atrioventricular node that are, in any way, analogous to the insulated ventricular conduction pathways. There are certainly pathways of preferential conduction through the terminal crest, the sinus septum, and round the margins of the oval fossa. The more rapid spread of conduction through these areas, and through the superior interatrial muscular communication known as Bachmann's bundle, is simply a consequence of the more ordered packing of the cardiomyocytes within the prominent muscular bundles.

Having traversed the atrial myocardium, the sinus impulse is delayed in the atrioventricular node, the delay engendered within the node and the ventricular conduction pathways permitting the ventricles to fill during diastole. The atrioventricular node, surrounded by short zones of transitional cells, is positioned at the apex of the triangle of Koch, with the triangle itself delimited by the tendon of Todaro and the attachment of the septal leaflet of the tricuspid valve, its base being formed by the orifice of the coronary sinus (Fig. 2.37). The atrial myocardium forming the

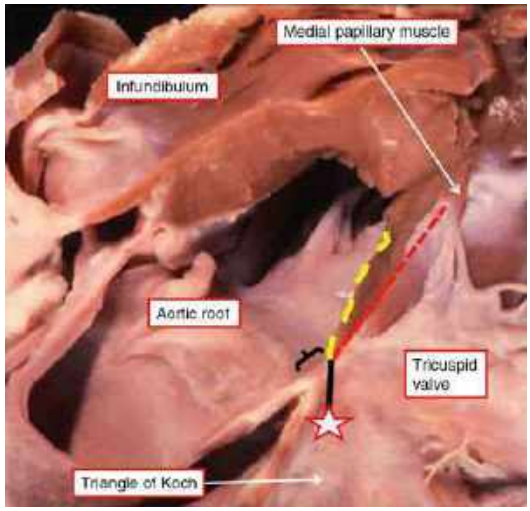

Fig. 2.38 The septal surface of the right atrium and ventricle is seen subsequent to removal of the right coronary aortic sinus and the corresponding leaflet of the aortic valve, the dissection extending inferiorly so as to remove the central part of the muscular ventricular septum. The dissection reveals the short distance between the apex of the triangle of Koch (*star*) and the crest of the muscular ventricular septum. This is the location of the atrioventricular bundle (*black line*) as it traverses the membranous septum (*black bracket*). The bundle then branches, with the right bundle branch (*red dashed line*) emerging beneath the medial papillary muscle. The left bundle branch (*yellow dashed line*) runs in fan-like fashion down the septal surface of the left ventricular cavity

floor of the triangle roofs the inferior pyramidal space, through which courses the artery to the atrioventricular node (Fig. 2.31). There is then but a short distance from the apex of the triangle of Koch to the crest of the muscular ventricular septum. This is the course taken by the atrioventricular bundle, or the bundle of His, as it penetrates the atrioventricular component of the membranous septum. Having penetrated, the atrioventricular bundle branches on the crest of the muscular septum at the base of the fibrous interleaflet triangle found between the nonadjacent and right coronary leaflets of the aortic valve, this being continuous with the membranous septum. The left bundle branch fans out on the smooth left surface of the septum, while the right bundle branch traverses the septum to emerge beneath the medial papillary muscle (Fig. 2.38). It then extends as a thin insulated cord in the substance of the septomarginal trabeculation before ramifying at the ventricular apex, typically crossing the ventricular cavity within the moderator band.

The Blood Supply to the Heart

The Coronary Arteries

The coronary arteries, two in number, are the first branches of the aorta. It is the rule for the arteries to arise from one or other of the sinuses closest to the pulmonary trunk, most usually from both of these adjacent sinuses (Fig. 2.39).

Since there are three aortic sinuses, but only two coronary arteries, the sinuses themselves can be named as the right coronary and left coronary aortic sinuses. In congenitally malformed hearts, the sinuses giving rise to the right and left coronary arteries are not always positioned in rightward and leftward locations, as is the usual situation. It is useful, therefore, to have a convention for naming the sinuses that works irrespective of the origin of the coronary arteries, the more so since the right coronary artery does not always arise from the rightward sinus and since the aorta can have markedly varied relationships to the pulmonary trunk when the heart is congenitally malformed. Such a convention is provided when the aortic sinuses are assessed from the stance of the observer positioned in the nonadjacent sinus and looking towards the pulmonary trunk (Fig. 2.40). One facing sinus is then to the right hand of the observer and is now known as sinus #1 [16]. In the normal heart, this sinus usually gives rise to the right coronary artery. The other sinus, to the left hand of the observer, and known as sinus #2, usually gives rise to the main stem of the left coronary artery. The system holds good for naming the aortic sinuses, and the origin of the coronary arteries, when the arterial trunks are abnormally disposed in congenitally malformed hearts.

In the normal situation, the coronary arteries arise within their appropriate sinuses, but it is not uncommon to find origins above the sinutubular junction, and oftentimes the arteries are eccentrically positioned within the sinuses. Additional

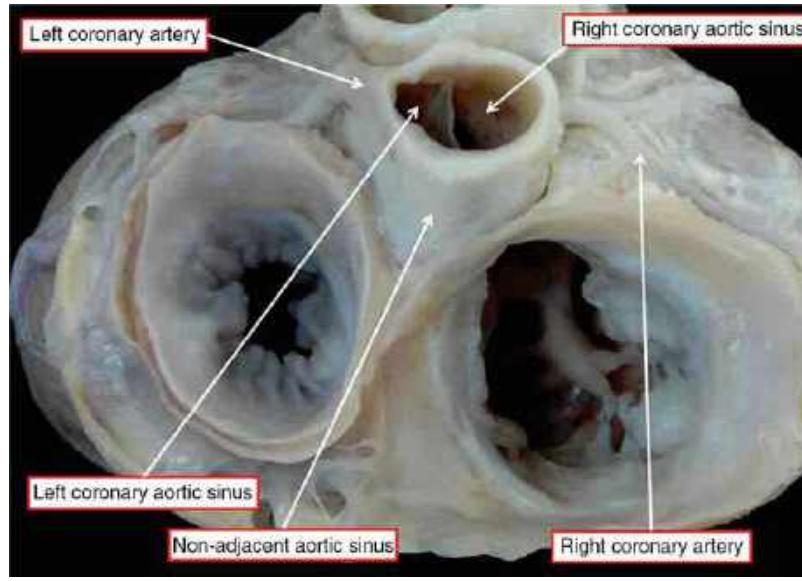

Fig. 2.39 The base of the heart is shown from the atrial aspect having removed the atrial walls and the aortic trunk. The right and left coronary arteries arise from the sinuses adjacent to the pulmonary root, permitting these sinuses to be named as being right aortic and left aortic coronary sinuses. The nonadjacent sinus does not give rise to a coronary artery

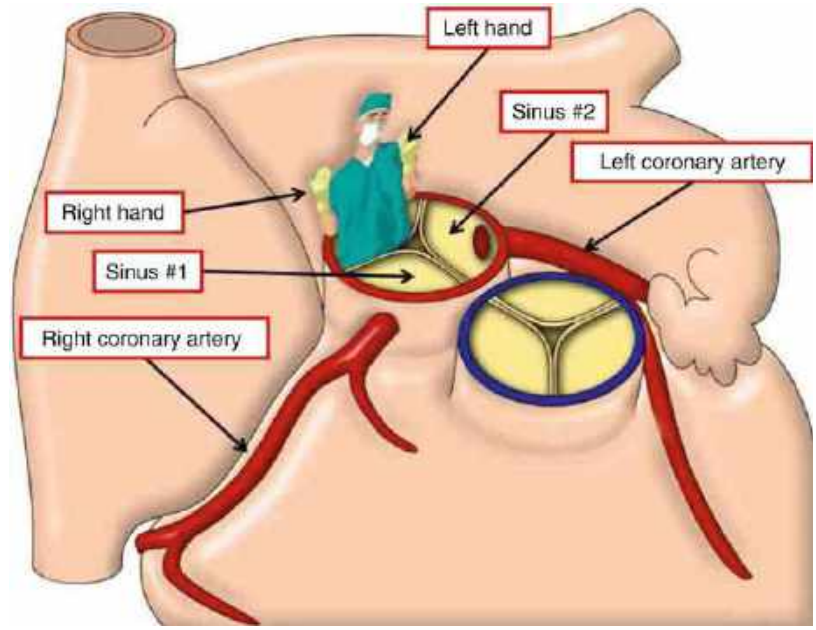

Fig. 2.40 The cartoon shows how, irrespective of the location of the aorta, with the observer positioned in the nonadjacent aortic sinus and looking towards the pulmonary trunk, one sinus will always be to the right hand and the other to the left hand. The right-handed sinus is conventionally described as #1 and the left-handed sinus as #2. In the normal heart, sinus #1 gives rise to the right coronary artery, while the main stem of the left coronary artery arises from sinus #2

arteries can also arise directly within the sinus, most frequently the infundibular artery, or the artery to the sinus node.

Having taken origin from the aorta, the right coronary artery is able to pass directly into the right atrioventricular groove and then run round the tricuspid valvar orifice. From this position within the atrioventricular groove, the artery gives rise to ventricular and atrial branches. The infundibular and acute marginal arteries are the major ventricular branches, while in just over half the population the artery to the sinus node is the major atrial branch (Fig. 2.41).

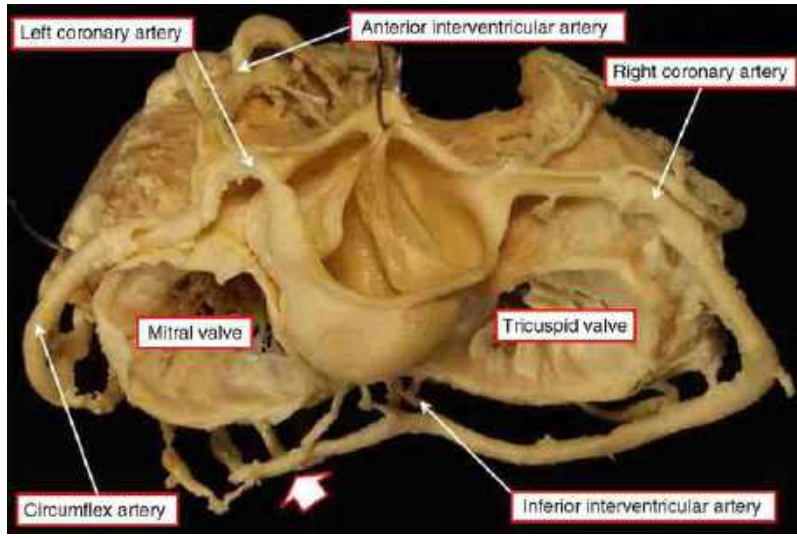

Fig. 2.41 The heart has been dissected to show the contents of the atrioventricular grooves, revealing the branches of the right coronary artery, which arises from the right coronary aortic sinus to pass directly into the right groove. In this specimen, as in nine-tenths of the population, the artery continues beyond the crux (*arrow*) to supply the diaphragmatic, or inferior, surface of the left ventricle. The short course of the left coronary artery is also seen subsequent to its origin from the left coronary aortic sinus, along with its anterior interventricular and circumflex branches

Having given rise to the acute marginal branch, the right coronary artery itself extends through the diaphragmatic aspect of the right atrioventricular junction and, in about nine-tenths of individuals, gives rise to the inferior interventricular artery. This artery is still described as being posterior in most current textbooks, but is unequivocally positioned inferiorly when the heart is viewed as it is positioned within the chest (Fig. 2.42). Having supplied the inferior interventricular artery, the right coronary artery usually continues beyond the crux, supplying branches to variable portions of the diaphragmatic surface of the left ventricle and hence producing right coronary arterial dominance.

The main stem of the left coronary artery is short, rarely being more than 1–2 cm in length. It passes from the left coronary aortic sinus directly into the left atrioventricular groove, being located beneath the orifice of the left atrial appendage. In this position, it branches into the anterior interventricular and circumflex arteries. In many

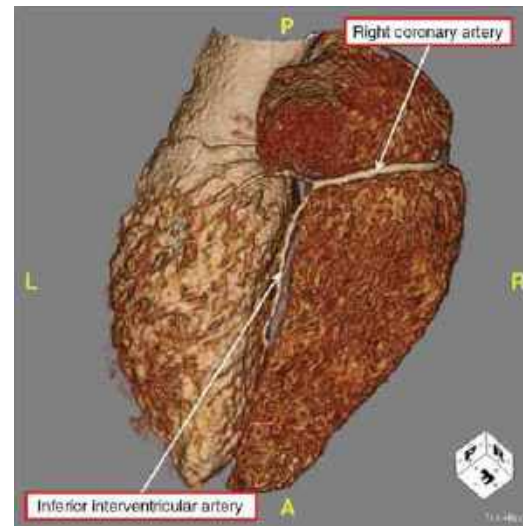

Fig. 2.42 The computed tomogram shows that, although usually described as being posterior and descending, the coronary artery arising at the crux and running through the inferior interventricular groove, occupies the inferior rather than the posterior surface of the ventricular mass. Note the compass

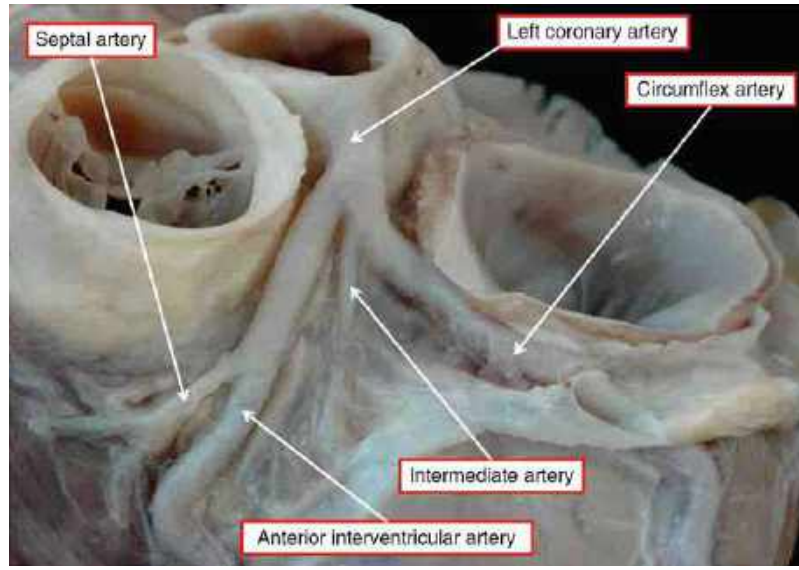

Fig. 2.43 The main stem of the left coronary artery is short, and rarely exceeds 2 cm in length. In this specimen, the artery gives rise not only to the anterior interventricular and circumflex branches, but also a small intermediate branch

individuals, rather than bifurcating in this fashion, the artery supplies a third intermediate artery, which supplies directly the obtuse marginal surface of the left ventricle (Fig. 2.43).

The anterior interventricular artery, also known as the left anterior descending artery, gives diagonal branches to the adjacent surfaces of the right and left ventricles as it runs within the interventricular groove, although right-sided diagonal branches are rare, along with the septal arteries, which pass perpendicularly into the ventricular septum. Usually called the perforating arteries, these vessels penetrate the septum rather than perforate it. There can be several such branches, but one or two are usually larger than the others. The largest may be the first of the series, but frequently is the second septal branch. This main septal branch, or two branches if of equal size, supplies the greater part of the ventricular septum, including the muscular portion of the aortic root. This artery, or arteries, is the target for ablation in the interventional treatment of hypertrophic cardiomyopathy. It enters the muscular septum immediately beneath the free-standing sleeve of subpulmonary infundibular musculature (Fig. 2.43).

The circumflex artery varies in its extent depending on whether the right coronary artery is dominant. In the setting of right coronary arterial dominance, the circumflex artery can terminate abruptly, having given rise to the obtuse marginal branch or branches. In one-tenth of individuals, nonetheless, it is the circumflex artery which is dominant. It then encircles the mural component of the left atrioventricular junction, continuing beyond the crux to supply part of the diaphragmatic surface of the right ventricle. In this setting, it is the circumflex artery that gives rise to the inferior interventricular artery, along with the artery to the atrioventricular node (Fig. 2.44). Taken overall, therefore, there are three major coronary arteries, these being the right coronary artery and the anterior interventricular and circumflex branches of the left coronary artery. With regard to dominance, it is the amount of myocardium vascularized by the right and circumflex arteries that is of major significance.

The Coronary Veins

The major cardiac veins, running alongside the coronary arteries in the interventricular and atrioventricular grooves, bring the larger part of the coronary arterial blood back to the right atrium (Fig. 2.45). The great cardiac vein accompanies the anterior interventricular artery, becoming the

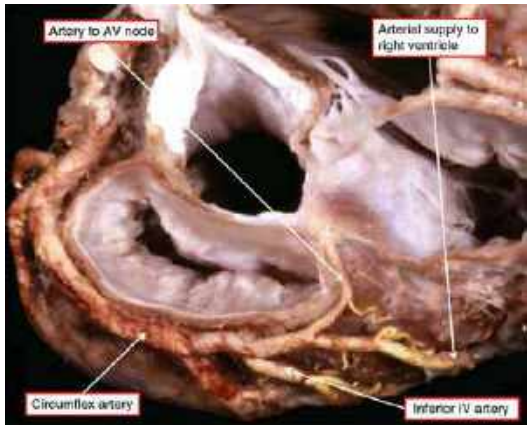

Fig. 2.44 The diaphragmatic surface of the heart is shown in the setting of left coronary arterial dominance. The circumflex artery gives rise to the inferior interventricular (IV) artery, continuing to supply branches to the right ventricle. The artery to the atrioventricular (AV) node also arises from the dominant circumflex artery

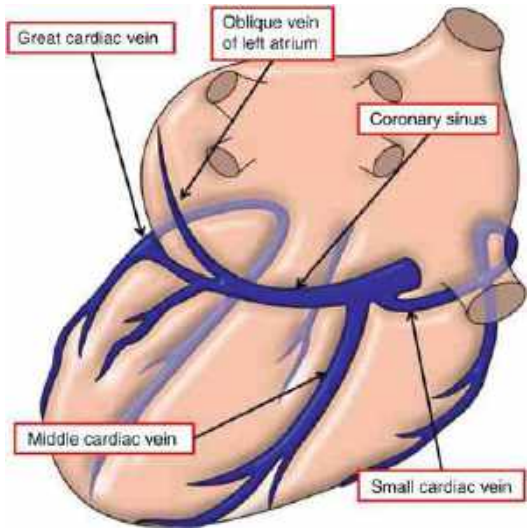

Fig. 2.45 The cartoon shows the arrangement of the cardiac veins that empty into the coronary sinus

coronary sinus in the left atrioventricular groove. The sinus begins at the point of entrance of the oblique vein of the left atrium, the sinus and vein representing the remnants of the embryonic left sinus horn. The junction usually corresponds with the site of a prominent venous valve, the valve of Vieussens. The terminal portion of the coronary sinus possesses its own muscular walls [7], which are extensions of the musculature of the right atrium, although also possessing connections with the left atrial walls. The initial walls of the sinus, however, are extremely thin and prone to rupture during surgical procedures. Taken overall, the sinus runs within the left atrioventricular groove and drains to the right atrium. Prior to entering the right atrium, it collects the middle cardiac vein, which runs in the inferior interventricular groove along with inferior interventricular artery. The small cardiac vein, which runs in the right atrioventricular groove, also usually enters the right atrium via the coronary sinus. When there is persistence of the left superior caval vein, it usually drains into the coronary sinus along the route normally occupied by the oblique vein, extending along the roof of the left atrium between the left pulmonary veins and the left atrial appendage. An additional series of veins, the minor cardiac veins, usually three to four in number, drain the blood from the anterior surface of the right ventricle and enter directly the infundibulum. Minimal cardiac veins, or Thebesian veins, drain the blood from the walls of the right and left atriums, opening directly into the atrial cavities.

Copyright to the Figures

The intellectual copyright in all the images, and the rights to each of the images, are retained by the authors. Most of the images have been newly prepared and labeled specifically for inclusion in this textbook. We are indebted to Gemma Price, nonetheless, who prepared the original cartoons for some of the figures and permitted us to relabel them or use them in this publication.

Chromosomal Anomalies Associated with Congenital Heart Disease

3

Kathryn C. Chatfield and Matthew A. Deardorff

Abstract

For medical practitioners who care for children with congenital heart disease, it is very evident that chromosomal disorders are commonly associated with heart defects. In fact, chromosomal disorders account for up to 10–12 % of cases presenting with cardiac disease in infants, and overall, genetic syndromes may account for 20 % [Hartman et al. (Pediatr Cardiol 32:1147–1157, 2011), Goldmuntz et al. (Congenit Heart Dis 6:592–602, 2011), Pierpont et al. (Circulation 115:3015–3038, 2007)]. Down syndrome is the most common chromosomal cause of congenital heart disease, followed by Turner syndrome, trisomy 18, and the 22q.11.2 deletion syndromes. This chapter will address the relationship between congenital heart disease (CHD) and chromosomal disorders to familiarize the medical practitioners who care for these patients. We will discuss aspects of the most common chromosomal disorders, including autosomal trisomies, a sex-chromosome anomalies, and microdeletion syndromes. The cardiac practitioner should be able to recognize distinctive features and cardiac lesions associated with these syndromes, appreciate the necessity of a complete medical genetics evaluation, and understand the risk of CHD for a patient with a particular syndrome. The cardiac medical team should be familiar with the outcomes associated with medical, palliative, or corrective treatments, and need for ongoing cardiac surveillance.

Introduction

It has been long recognized that chromosomal abnormalities are a leading cause of CHD in children. The purpose of this chapter is to describe each of the common chromosomal syndromes that present to pediatric cardiologists and cardiovascular surgeons. It is essential that the cardiology practitioner be able to recognize common syndromes, know when to suspect a chromosomal disorder based solely on a specific type of heart defect, and delineate the steps necessary to ensure appropriate care of the patient with regard to their heart disease and their general health. The ability to appropriately counsel and educate patients, families, and other care providers is based on relevant knowledge of the underlying syndrome. It is especially important that the cardiologist be prepared to address noncardiac issues associated with care of a child with a chromosomal syndrome, as they are not only likely to be in a position to make a genetic diagnosis in an infant who presents with suspected CHD but also to manage initial care. Knowledge about the common features of a specific syndrome the guide workup that extends beyond cardiac-specific care, to identify and minimize comorbidities. In addition, understanding the underlying genetic diagnosis may predict surgical outcomes and inform expectations for neurodevelopment and medical outcome. The cardiology practitioner should use the information in this chapter and included references to serve as a guide as to when and what types of other specialist referrals should be considered, as well as to engage clinical geneticists to assist with diagnostic workup beyond the cardiac assessment and to deliver family education and counseling.

An Introduction to Genetics of Chromosomal Anomalies

This chapter details aspects of syndromes that are caused by aneuploidy or an abnormal number of chromosomes or genetic material that can include the sex chromosomes or autosomal nonsex chromosomes. These abnormalities can be observed via conventional microscopy-based karyotyping to identify whole or partial chromosome loss or gain. They can also be detected by molecular techniques that have enabled the identification of submicroscopic microdeletions or microduplications. In this chapter, we discuss the chromosomal basis, clinical features, and management of several of the more common disorders. A tabular listing of less common microdeletion and microduplication syndromes is provided at the end of the chapter (Table 3.1).

Trisomies/Monosomies: Other than the sex chromosomes in males, the human genome is disomic, comprised of two nearly identical copies. Aneuploidy results when there is deviation from the normal disomic state. Trisomies represent an additional copy of a chromosome, whereas monosomy describes the loss of a chromosome. Both result in pathology due to aberrant, either *excess* or *insufficient*, dosage of genetic material contained within critical chromosome segments. Most commonly, trisomies and monosomies result from meiotic nondisjunction or failure of duplicated chromosomes to segregate into separate gametes, such that two or zero copies are carried in an ova or sperm. Thus, after fertilization, abnormal copies of the chromosome are present during embryogenesis. Of the possible whole chromosome aneuploidies, trisomy 21, 18, and 13, and sex-chromosome

Table 3.1 Deletion/duplication syndromes with associated congenital heart disease

Chromosome anomaly (syndrome name)	Frequency estimate	Associated cardiac lesions (in order of frequency)	Proportion of patients with CHD	References
1p36 deletion	1:5,000	DCM, PDA, VSD, dilated Ao, ASD, BAV, Ebstein anomaly	43 %	Heilstedt et al. [1]

aneuploidies are the only ones viable to term in a pregnancy, with a very few rare exceptions.

Microdeletions and Duplications: A deletion of a region of a chromosome and the genes contained within can result in a partial chromosome monosomy causing a deletion or microdeletion syndrome. The term *microdeletion* has come into popular usage with the advent of microarray-based technologies, which have permitted detection of chromosome deletions (and duplications) that were not detectable by traditional chromosomal karyotype analysis, typically less than 5 megabases in size [19]. Microdeletions are more likely to cause abnormal fetal development and congenital anomalies, compared to small duplications which often have a mild or inconsistent phenotype. However, as a general rule, the larger the loss or gain of genetic material, and therefore more reduced or duplicated genes, the more severe the impact on fetal development. With increasing usage of array-based technologies to find a diagnosis in children with multiple congenital anomalies, phenotypes associated with specific microdeletions and some duplications are becoming better recognized [20, 21]. As additional children with these rare microdeletion/duplication syndromes are diagnosed, the frequency of associated congenital anomalies will become clearer, and the natural history of these diseases better understood.

Unbalanced Translocations: Another type of genetic change that can cause multiple congenital anomalies including CHD is *unbalanced translocations*. An unbalanced translocation is usually the result of inheritance of an abnormal chromosome from a normal parent who carries a *balanced translocation*, where all of the normal genomic material is present, but in abnormal locations. Individuals with balanced translocations typically do not have disease, unless the translocation disrupts an essential gene. However, these individuals are at high risk of multiple miscarriages and/or children with multiple congenital anomalies as the result of inheriting an aneuploid or unbalanced complement of genetic material. Because of the large number of possible combinations and the rarity of each, the spectrum of unbalanced translocations seen in children with congenital heart disease is beyond the scope of this chapter. Often these children will have a phenotype that results from combination of deletion of one chromosome and/or duplication of another. Cardiology providers should seek genetics consultation in these cases, as medical workup is unstandardized and predicting medical and neurodevelopmental outcome is extremely complex. Due to the potential risk for CHD in any child with an unbalanced translocation, screening for cardiac disease is warranted.

Mosaicism: Mosaicism refers to the presence of aneuploidy, an atypical complement of chromosomes, in only a subpopulation of cells within the individual. A mosaic diagnosis can be made by conventional karyotype or by microarray, depending on the nature of the aneuploidy. In other words, some cells (from any given tissue) will have a normal karyotype, while others will contain the chromosomal abnormality. In many cases this leads to a milder phenotype in the affected individual. However, the medical practitioner should exercise equal caution in a mosaic individual since the exact extent and tissue localization of mosaicism cannot be accurately measured. Generally, an individual with a mosaic form of a syndrome should undergo the same cardiac screening and surveillance as an individual with the "full" nonmosaic syndrome.

Chapter Organization

This chapter is organized by diagnosis. Each syndrome is presented in a similar format to allow cardiac practitioners to locate pertinent information with ease. Each syndrome is listed by accepted chromosomal nomenclature as well as by its familiar name, referring to the physician credited with its first description. Characteristic features (dysmorphology) are described to assist the clinician with making a diagnosis based on the physical characteristics of the patient. Population epidemiology of each syndrome is

presented with the overall prevalence of CHD. For each, there is a brief discussion of the inheritance pattern and de novo occurrence rate. A listing of affected organ systems is discussed in brief to further assist with diagnosis, as well as medical workup for the newly diagnosed or presurgical patient. It is beyond the scope of this chapter to cover all medical surveillance issues for each syndrome. Nonetheless, pertinent medical aspects are covered as they can contribute to early and late morbidity and mortality after cardiac interventions. For example, airway abnormalities and atlantoaxial instability may be important considerations for the cardiac anesthesiologist caring for a child with Down syndrome or 22q deletion syndrome. Immune dysfunction may likewise be relevant to care of cardiac postoperative fever, and attention to endocrine dysfunction may prevent cardiovascular compromise. The most common types of CHD in each syndrome will be discussed, as some syndromes should be considered based on the cardiac lesion alone. The cause of CHD for each syndrome will be mentioned if it is currently understood, with genes named that are suspected to have a causative role in development of the heart. General medical and surgical outcomes will be detailed where these have been studied in larger groups.

The following syndromes will be discussed in detail: trisomies 21, 18, and 13, Turner syndrome, and the 22q11.2 and Williams Syndrome microdeletion syndromes. A summary of other well-known microdeletion and duplication syndromes is provided in Table 3.1. Referenced literature and consensus guidelines for medical and cardiac care are provided where available. The National Center for Biotechnology Information/National Library of Medicine sponsors Online Mendelian Inheritance in Man (OMIM; http://www.ncbi.nlm.nih.gov/omim), an online catalog of human genes and genetic disorders, as well as the GeneTest Reviews (http://www.genetests.org). Both are an excellent resource for medical practitioners seeking current expert information on chromosome syndromes, microdeletion syndromes, and single-gene disorders.

Syndromes

Trisomy 21: Down Syndrome

Epidemiology and Genetics

Trisomy 21, commonly known as Down syndrome, is the result of three copies of chromosome 21 transmitted to an embryo. It is the most common chromosomal anomaly in live born infants. Although others described the syndrome prior to 1845, it is named for British physician John Langdon Down, who described the features in 1866. Trisomy 21 was identified as the cause by Dr. Jérôme Lejeune in 1959 [22]. It is estimated to occur in 12 per 10,000 live births in the United States and may be increasing in frequency [23] due to trends in advanced maternal age which may be modified by the increase in the rate of termination for this diagnosis [24]. Trisomy 21 is most often de novo and not inherited from a parent. Full trisomy 21 is present in 95 % of individuals with Down syndrome. However, the syndrome can also be the result of a translocation event (4 %) and can be found in mosaic form (1 %). In rare cases a translocation can be inherited [25]. Individuals with Down syndrome generally have decreased fertility but would have a 50 % recurrence rate in their progeny.

Physical and Medical Features

The syndrome can usually be recognized in an infant by typical features that include the following findings: short stature, hypotonia, flattened occiput (brachycephaly), epicanthal folds (skin fold covering the inner edge of the eye), upslanting palpebral fissures, low-set rounded ears, open mouth with prominent tongue, broad hands with short digits (brachydactyly), fifth digit curvature (clinodactyly), single palmar crease, wide 1st–2nd toe (sandal) gap, ligamentous laxity, diastasis recti, and small genitalia [26]. Typical facial features are depicted in Fig. 3.1. Cardiac malformations are present in 50 % of individuals with Down syndrome and are the most important medical issues in infancy

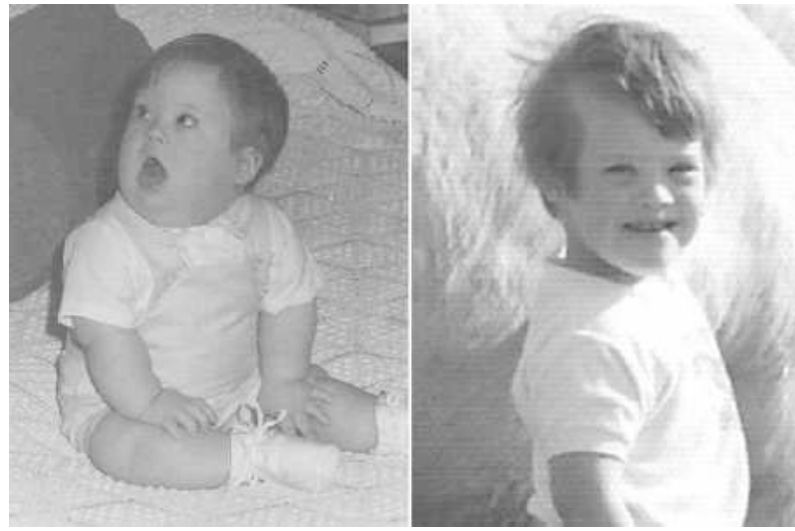

Fig. 3.1 Boy with Down syndrome as a 9-month-old infant and as a young child. Notable features include upslanting eyes, epicanthal folds, open mouth, macroglossia, low-set rounded ears, brachydactyly (short fingers), and fifth digit clinodactyly (curved digit) (*Photographs courtesy of family*)

contributing to significant morbidity and mortality in infancy [27]. Other affected organ systems include the GI system (in 12 %), with common anomalies including duodenal atresia, annular pancreas, Hirschsprung's disease, and other anorectal anomalies. Celiac disease is also frequent (7–16 %). Endocrine abnormalities occur with increased frequency, with hypothyroidism in 15 % of individuals, and an increased rate of insulin-dependent diabetes mellitus. Reproductive problems result from low testosterone in males and ovarian/pituitary dysfunction in females. Ear, nose, and throat issues include obstructive sleep apnea, enlarged tonsils, conductive hearing loss, and frequent otitis media related to anomalies of the eustachian tube. Macroglossia, small jaw and palate with cleft soft palate often occur and contribute to feeding difficulties. The otolaryngology issues combined with low tone can contribute to upper airway obstruction in infants and children. Hematologic and immune system abnormalities include increased relative risk for leukemias (10–20 times that of general population), and increased prevalence of immune system disorders, which can contribute to a higher incidence of upper respiratory infections and chronic hepatitis. Central nervous system involvement ranges from mild to severe but predominantly results in moderate intellectual disability. Other CNS involvement includes atlantoaxial instability, seizure disorders such as infantile spasms (5–10 %), autistic features, and a very high rate of early onset Alzheimer's disease. The American Academy of Pediatrics health supervision guidelines for children with Down syndrome is an excellent resource for guidance in treatment of these and other medical concerns that arise in Down syndrome (http://pediatrics.aappublications.org/content/128/2/393.full.pdf) [28].

CHD in Down Syndrome

Congenital heart disease is present in 40–55 % of individuals with Down syndrome. Accordingly, all children with Down syndrome should undergone screening echocardiography soon after birth. Several large population-based studies performed since the 1970s have shown very similar overall prevalence rates and indicated the preponderance of certain defects, including atrioventricular septal defects (AVSD), atrial and ventricular septal defects (ASD and VSD), tetralogy of Fallot, and persistent patent ductus arteriosus (PDA) [29–33]. The strong association between AVSD and Down syndrome is well recognized, with AVSD (all forms included) being identified in 30–47 % of Down syndrome individuals with CHD. Common AVSD is by far the most common subtype of AVSD in Down syndrome, followed by ventricular component and atrial

component only types. Unbalanced, single-ventricle types of AVSD are reported, but are relatively rare. Furthermore, the diagnosis of AVSD raises the question of a diagnosis of Down syndrome, as its prevalence is as high as 85 % among all those diagnosed with an AVSD [34]. Combined VSD and ASD are common lesions reported in 17–44 % of those with CHD, and ASD alone only in 15–42 %. Estimates of the prevalence of tetralogy of Fallot and persistent PDA are similar between studies, with both of these defects being present in roughly 3–7 % of patients with CHD.

There is a growing body of literature that also indicates altered risk for acquired cardiovascular disease in individuals with Down syndrome. Pulmonary arterial hypertension has long been recognized as a problem in children and adults with Down syndrome, both with and without CHD, often predisposed by contributing upper airway and pulmonary risk factors [35]. Pulmonary hypertension may be more frequent due to reduction of alveolar count, persistence of the fetal double capillary network in the lung and reduction in the cross sectional area of the vascular bed [36, 37]. Further, the severity and incidence of alveolar simplification (decreased alveolar septal formation) is increased in children with Down syndrome and congenital heart defects [38, 39]. Persistent pulmonary hypertension is more frequent in infants with Down syndrome with and without structural heart disease [40]. Due to the multifactorial nature of this problem, a multidisciplinary approach is appropriate to monitor and treat pulmonary hypertension in infants, children, and adults with Down syndrome [41]. Interestingly, a vascular phenotype that is notably *absent* in Down syndrome is atherosclerotic coronary artery disease, which has been recognized since a series of autopsies in the 1970s on older individuals with Down syndrome revealed a notable lack of atheroma [42]. Correspondingly, there is a scarcity of reports of myocardial infarction in patients with Down syndrome in the literature likely as a result of some coronary protective effect of trisomy 21 [43].

The genes that cause endocardial cushion defects in Down syndrome are under active investigation [24]. Clues have been provided through analysis of patients with partial chromosome 21 duplication and CHD, narrowing the region responsible to a 1.77-Mb "DSCHD" critical region, which contains 10 genes including the promoter and a portion of the Down syndrome cell adhesion molecule (*DSCAM*) gene [44]. Given that only 50 % of individuals with Down syndrome have CHD, it is also likely that familial modifier genes alter a "threshold" for cardiac malformation [45]. Ethnic background also appears to influence the prevalence and type of CHD, enforcing the theory that other modifier genotypes are important in endocardial cushion formation. More expansive genomic analyses and animal models may lead to a clearer understanding of the impact of genes present on chromosome 21 and throughout the genome on the development of the heart in Down syndrome.

Outcomes

Population-based studies indicate that children with Down syndrome have a decreased survival rate compared to the general population that is primarily attributed to the presence of CHD, GI abnormalities, or both [46]. Survival of children with Down syndrome has improved dramatically over the past decades due to improvements in both medical treatment and surgical interventions. Risk factors for early death include prematurity (<30 weeks gestation) and very low birth weight. Evidence suggests that 10-year survival of Down syndrome children *without* major malformations is similar to that of the general population.

When specifically considering cardiac surgical outcomes in Down syndrome, the current evidence indicates that trisomy 21 is not a significant risk factor for postoperative mortality [47–49]. Some studies even suggest that there are better outcomes of biventricular and palliative AVSD repair in children with Down syndrome compared to nonsyndromic children with similar lesions [50]. There are, however, differences in the postoperative course of infants and children with Down syndrome compared to patients without. A large retrospective cohort study using the Society of Thoracic Surgeons

Congenital Heart Surgery Database revealed that patients with Down syndrome were on average younger at surgery, except those undergoing AVSD or tetralogy of Fallot repair [48]. The length of hospitalization for post surgical Down syndrome patients was longer, by a matter of a day(s) for most surgeries, and was more often associated with respiratory and infectious complications. Patients with Down syndrome also had higher rates of heart block requiring pacemaker placement with ventricular septal defect repair.

Trisomies 18 and 13: Edwards Syndrome and Patau Syndrome

Epidemiology and Genetics

Trisomy 18, also known as Edwards syndrome, was first described in a 1960 article published in the Lancet by JH Edwards et al. in the same issue where trisomy 13 was reported by Klaus Patau and colleagues [51, 52]. Trisomies 18 and 13 are the second and third most common autosomal trisomies, respectively, in live born infants. This section will combine the discussions of epidemiology, genetics, and outcomes of both syndromes, as they are similar. Most large population studies have analyzed and reported on data about the two syndromes in parallel given the similarities in epidemiology and natural history, with similar implications for medical care and family counseling.

Trisomy 18 occurs in 1–4 per 10,000 live births, and trisomy 13 in between 0.6 and 1.4 per 10,000 live births [53, 54]. Recent large retrospective studies evaluating epidemiology and outcomes in both trisomies 18 and 13 show that the fetal prevalence of both trisomy syndromes has also increased over a 20-year period correlating with increases in advanced maternal age, while concurrently the rate of live births has decreased. This decrease in the number of live births is attributed to increases in both fetal diagnosis and elective terminations as a result of prenatal diagnosis. Up to 50 % of pregnancies with trisomy 13, and 72 % of those with trisomy 18, result in miscarriage or stillbirth [53, 55]. Of the trisomy 18 fetuses that survive to term, 60 % are female, a difference not accounted for by differential rates of termination. Full trisomies 18 and 13 are generally de novo events, not inherited from a parent [56]. Partial duplication of either chromosome or mosaic trisomies 18 or 13 is also seen and can produce features of that syndrome to be present and may result in attenuated forms of the syndromes. Partial trisomies 18 or 13 is often the result of triplication of the long arms of either chromosome, as the consequence of an unbalanced translocation event, found in 2–3 % of trisomy 18 and 5–10 % of trisomy 13 cases. While partial trisomy 13 may have better survival, the same may not be true for partial forms of trisomy 18. Mosaicism is the cause in roughly 5 % of cases. The degree of mosaicism identified from blood karyotypes is not predictive of the degree mosaicism in other tissues or clinical severity in either syndrome. Robertsonian unbalanced translocations 13;14 are the most common form of trisomy 13 due to an unbalanced translocation. In the event that a parental balanced translocation or inversion is the cause of the unbalanced karyotype in the child, there is a significant recurrence risk. In rare cases these trisomies result from inheritance from a mosaic parent. So although trisomies 13 and 18 are rarely inherited, there is an increased recurrence risk above the general population for parents of children with one of these syndromes [57].

Physical and Medical Features of Trisomy 18

Edwards et al. and Smith et al. both described the features associated with three copies of chromosome 18 in 1960 [51, 58] (Fig. 3.2). The pattern of dysmorphology and malformations is well defined by the following features: pre- and postnatal growth deficiency, dolichocephaly (scaphocephaly), short palpebral fissures, micrognathia, abnormally formed external ear, and redundant skin at the back of the neck [26, 56]. Other characteristic physical findings include clenched fists with second and fifth digits that override, small, underdeveloped thumbs, short sternum, and radial aplasia/hypoplasia and clubbed feet. Dermatoglyphics (finger print pattern) often reveal a simple arch pattern. Cardiac defects are the most common major

Fig. 3.2 Girl with trisomy 18 as an infant. Same individual shown as a young child. Notable features include mild dolichocephaly, short palpebral fissures, micrognathia, abnormally formed external ear (*Photographs courtesy of family*)

Fig. 3.3 Girl with trisomy 13 as an infant. Same individual shown at 13 years of age. Notable features include cleft lip (later repaired), postaxial polydactyly, hypotelorism, and flat nasal bridge (*Photographs courtesy of family*)

organ malformation, while genitourinary anomalies, such as horseshoe kidney, are also frequent (25–75 % of individuals). Less frequent findings (5–25 %) include gastrointestinal malformations such as omphalocele, esophageal atresia and tracheoesophageal fistula, pyloric stenosis, and Meckel diverticulum. Central nervous system abnormalities include cerebral hypoplasia, agenesis of the corpus callosum, polymicrogyria, and spina bifida. In the less frequent category are craniofacial defects including orofacial clefts, microphthalmia, coloboma, and cataract of the eye.

Physical and Medical Features of Trisomy 13

The classic pattern of malformations associated with Patau syndrome caused by full trisomy 13, mosaic and partial forms, is well recognized and present in 60–70 % of cases [26, 56] (Fig. 3.3). The classic phenotype consists of variable degrees of midline defects with postaxial polydactyly: extra fingers on the ulnar side of hand and lateral aspect of feet. The syndrome can present as holoprosencephaly or cyclopia at one end of the spectrum, but features may be less dramatic and demonstrate microphthalmia/anophthalmia, orofacial clefts, and hypotelorism. In the absence of obvious midline defects, the presence of frontal capillary malformations and frontal hair upsweep on the forehead, ear malformations, and cutis aplasia over the posterior fontanelle can assist with diagnosis. Major malformations in infants diagnosed with trisomy 13 include cardiovascular malformations in up to 70 %, cleft lip or palate (73 %), abdominal wall defects (20–25 %), abnormal external genitalia in females and males (30 % and 71 %, respectively), and central nervous system abnormalities (11 %) [59, 60]. Both trisomies 18 and 13 are associated with severe intellectual disability.

CHD in Trisomy 18 and Trisomy 13

Congenital heart disease is nearly universal in children with trisomy 18, with estimates between

90 % and 100 % based on a series of postmortem specimens performed by Van Praagh et al. in the 1980s and a few case series of echocardiographic evaluations performed in live infants [61–63]. In the Van Praagh series, all 41 cases were noted to have ventricular septal defect, with tricuspid valve anomalies in 80 %, pulmonary valve anomalies in 70 %, aortic valve anomalies in 68 %, and mitral valve anomalies in 66 %. Malformation of more than one valve (polyvalvar disease) was present in 93 % of subjects. Double-outlet right ventricle (all with mitral atresia) was seen in 10 % of cases, and 15 % had tetralogy of Fallot (2 of 6 with pulmonary atresia). In smaller series based on echocardiography, similar observations were made with 76–80 % of patients having ventricular septal defects, 75 % with atrial septal defects, 50–90 % with patent ductus arteriosus, with a majority having more than one lesion. These series also noted valvar abnormalities in nearly 100 %, with most individuals having involvement of at least two valves. Other common findings include bicuspid aortic valve (up to 30 %) and aortic coarctation (10 %). Based on these studies, between 10 % and 25 % of patients will have more complex cardiac lesions. In these patients the patent ductus arteriosus was usually large with bidirectional shunting. This finding in addition to right heart dimensions, pathology of pulmonary arterioles, and more recent population surveys indicates a high incidence of pulmonary hypertension in trisomy 18 [64]. Evidence to date demonstrates that all individuals with trisomy 18 likely have cardiac pathology with large ventricular septal defect and patent ductus arteriosus occurring commonly. Complex CHD is much less frequent, but pulmonary atresia with intact septum, AVSD, and hypoplastic left heart syndrome have all been reported.

Trisomy 13 also has a high frequency of CHD, present in between 50 % and 85 % of individuals, making heart abnormalities as common as the classic limb or orofacial defects [26, 60, 63]. Common types are very much like what has been reported in trisomy 18, with patent ductus arteriosus, ventricular septal defect, and atrial septal defect being common (each seen in 50–85 % of patients). Tetralogy of Fallot is the most frequent reported complex defect, with a range of others reported in the literature, including endocardial cushion defects, transposition of the great arteries, truncus arteriosus, tricuspid atresia, Ebstein anomaly, and hypoplastic left heart syndrome. In the largest case series of 16 patients, over one third of infants with trisomy 13 had complex CHD. A more recent large population-based study published from the United States Healthcare Cost and Utilization Project reports a lower prevalence of CHD in both trisomy 18 (45 %) and trisomy 13 (35 %) in over 1,000 individuals with each diagnosis [59]. A lower prevalence of all major malformations in this report is likely due to the fact that the database does not reflect a universal screening for CHD or other anomalies, as well as a low rate of autopsy in deceased individuals.

The genes that cause abnormal heart development in Edwards and Patau syndromes have not been systematically investigated to date.

Outcomes

Many population studies performed over the last three decades have demonstrated that lifespan is drastically reduced in infants born with trisomies 18 and 13 [65]. Median survival in trisomy 18 is reported to be between a few days to 2 weeks and in trisomy 13 between 3 and 30 days [54, 66–70]. Based on cumulative data from several studies, for infants with trisomy 18, 36–52 % survive the first week, 25–38 % the first month, and 2–8 % the first year. Estimates for survival in trisomy 13 are similar with 38–61 % surviving the first week, 13–30 % the first month, and 0–9 % the first year [60, 66, 70–72]. For reasons not yet understood, survival in female infants with trisomy 18 is better than that of males. Comparison between the first large-scale analyses of survival and those performed more recently indicates no significant change in survival over the last 30 years [73].

The conventional approach to these trisomy syndromes largely discouraged any type of intervention, citing the "hopeless" outlook for these patients who ought not be subjected to needless interventions, and that intensive treatment heavily consumes societal resources. Be that as it may, instances of management have resulted in recent studies suggesting prolonged survival with

intensive medical and surgical interventions including neonatal resuscitation, respiratory support with or without tracheostomy, gastrointestinal surgeries, and inotropic medications. Some groups have reported median survival of up to 152 days in trisomy 18, with 25 % surviving to 1 year, and median survival over 700 days in trisomy 13, with 35 % surviving to 1 year [74, 75]. These two studies only included a very limited number of cardiac surgeries in a few cases of trisomy 13. There have been other publications specifically studying cardiac surgery in both trisomies 13 and 18, which have demonstrated prolonged mean survival in a selected group of patients who received palliative procedures to correct overcirculation (pulmonary artery banding, patent ductus arteriosus ligation), shunts to provide pulmonary blood flow in tetralogy of Fallot, and repair of coarctation of the aorta [64, 76, 77]. Some patients have had primary intracardiac repairs including ventricular septal defect patching and repair of tetralogy of Fallot, performed electively. Due to the observation that death in patients with trisomies 13 and 18 is correlated with congenital heart disease and heart failure, these studies suggest that palliation of overcirculation, protecting the pulmonary vasculature, and preventing heart failure can impact survival in these syndromes. Of note, complex repairs have not been attempted in more complex lesions. The Support Organization for Trisomies (SOFT) maintains a database of types of surgeries and medical facilities that have offered them to patients with trisomies 18 and 13 as reported by participating families and providers (www.trisomy.org). The discussion surrounding when and whether to perform palliation or repairs of congenital heart disease in trisomies 18 and 13 is beyond the scope of this chapter, and it is important to note that many families will choose "comfort care" for their infants with Edwards or Patau syndrome. Attitudes related to interventions will continue to evolve in the medical and biomedical ethics communities, with greater focus on family-centered care and joint medical decision making. The discussion surrounding care of infants with trisomies 18 and 13 has been well framed by Dr. John Carey in recent literature for interested readers [65].

Turner Syndrome: Monosomy X

Epidemiology and Genetics

Turner syndrome is named for Dr. Henry Turner who described a triad of "infantilism, webbing of the skin of the neck, and cubitus valgus" in 1938 [78]. Credit must also be attributed to Dr. Privatdozent Ullrich who provided an equally descriptive report in 1930 [79]. The Turner syndrome (TS) is now well recognized for its physical characteristics, endocrine abnormalities, typical heart defects, and chromosome anomalies of a single copy of chromosome X in a female with these clinical features. The syndrome affects approximately 1 in 2,000–2,500 live born females, with higher prevalence of 1 in 600 fetal life [80, 81]. Although the classic definition of TS includes the karyotype of 45,X which denotes complete absence of a second X chromosome, partial X chromosome deletions, ring X chromosomes, and other X abnormalities can present with typical features [82, 83]. Mosaicism is common and may be present in greater than 50 % of females with X chromosome abnormalities. Some women with mosaicism will have classic TS, and many are likely to a "milder" or attenuated phenotype. There is a greater likelihood that mosaic individuals will be diagnosed at a later age or evade detection entirely. The most common form of mosaicism is 45,X/46,XX, but many other combinations of sex-chromosome mixtures have been reported. In a population of girls with TS referred for a growth hormone trial, those with mosaicism were more likely to have been detected incidentally, and nonmosaic patients were more likely to demonstrate classic features [84]. Small distal short arm deletions of the X chromosome (Xp-) and distal long arm deletions are also seen. Depending on the size of the deletion and the genes that are deficient, these women can have some TS features but are not typically given the diagnosis of TS. Genetic counseling may be necessary when X chromosome abnormalities are detected pre- or postnatally to determine the significance and potential impact on health, including cardiovascular impact. As a rule, when typical TS heart lesions are identified and an abnormality of the X chromosome is found,

the patient should be followed as any patient with TS. Karyotype testing is recommended in all suspected cases of TS for diagnosis and prognosis is based on presenting features and genetic heterogeneity as described above.

The genetic etiology of vascular malformation in TS is still under investigation [85]. *Haploinsufficiency* (lower gene dosage) of the SHOX transcription factor has been implicated in growth and skeletal findings in TS and may impact on cardiovascular development through downstream affects on brain natriuretic peptide (BNP) and fibroblast growth factor receptor 3 (FGFR3). However, other gene interactions are likely necessary since isolated *SHOX* gene mutations have been identified in humans with growth and skeletal features, but typically without CHD or known vascular disease.

Physical and Medical Features

Increased rates of prenatal testing have led to more prenatally diagnosed TS which is considered in pregnancies with hydrops fetalis, increased nuchal translucency, cystic hygroma, or lymphedema, with or without associated CHD. Similar findings may be present in the newborn, where cystic hygroma may result in webbing of the neck, and lymphedema in the extremities is a key to diagnosis in over 95 % of those detected as infants [86]. Other classic findings include low posterior hairline, misshapen, prominent or rotated ears, narrow palate with subsequent crowding of dentition, a broad chest with wide-spaced nipples, cubitus valgus, and hyperconvex nails. In children without significant CHD or neonatal features, the diagnosis is often made in girls who present with short stature, lack of breast development, amenorrhea with elevated follicle stimulating hormone levels, and/or infertility [87].

The most serious medical concerns in TS are related to the cardiovascular system as discussed below. Malformations of the urinary system are identified in 30–40 % of TS patients, with structural kidney defects being more common in nonmosaic TS, and collecting system malformations occurring more often with mosaic and other structural X chromosome abnormalities. Autoimmune thyroiditis occurs in up to 25 % of children with TS, and celiac disease is present in approximately 5 %. Growth hormone therapy to augment short stature has become common for girls with TS. One third will have strabismus and hyperopia among other eye anomalies. Hearing problems and ear malformations are common, along with otitis media. Distinct dental/craniofacial features can be noted with narrow maxilla and broad retrognathic mandible. Abnormalities of tooth development are common, placing girls at risk of tooth loss during orthodontic treatment or intubation procedures.

CHD in Turner Syndrome

CHD is the major cause of morbidity and mortality in TS from fetal life into adulthood. All children with Turner syndrome should have a cardiology evaluation and an echocardiogram to evaluate for a bicuspid aortic valve and aortic dilation (http://pediatrics.aappublications.org/content/111/3/692.full.html). Cardiac defects significantly impact prenatal viability, with over 60 % of affected fetuses having CHD. Many of which do not survive early gestation, and in combination with electively terminated fetuses, this accounts for the discrepancy between fetal and live birth incidence rates [81, 88]. Hypoplastic left heart occurs in 13 % of fetuses with TS, and coarctation in 45 %.

Of all infants and children with TS, it is estimated that between 22 % and 70 % have some cardiovascular manifestation with 70 % of those presenting as structural or vascular abnormalities, and 30 % with functional defects including conduction abnormalities and hypertension [85, 89, 90]. In surveys of children and adults with TS and CHD, 15–30 % had bicuspid aortic valve, and 17–18 % had a history of coarctation of the aorta. Other types of CHD are seen including partial pulmonary venous return in up to 13–15 %, left superior vena cava in 8–13 %, septal defects in 2–6 %, and mitral valve abnormalities in approximately 5 %. More complex lesions, including hypoplastic left heart syndrome, aortic valve stenosis, and atrioventricular septal defects, are seen in some, which reinforces the need for regular electrocardiogram screening in infants. Recent literature evaluating

differences between girls with incidentally detected TS and clinically suspected TS suggests that incidentally discovered TS is more likely to be mosaic and less likely to have cardiovascular findings (31 % had cardiovascular finding) compared with clinically detected TS, where the prevalence of cardiac findings was 64 % [84]. This data suggests that "milder" TS caries a lower, but significant, risk of CHD.

Aortopathy is a recognized feature of Turner syndrome, which can occur in the absence of congenital heart disease, although there is greater risk in those with known bicuspid aortic valve, history of coarctation, and/or known aneurism [89, 91, 92]. The exact prevalence and natural history of aortopathy in TS is actively under investigation, but wider use of cardiovascular MRI in screening of older individuals with TS has led to better detection of vascular abnormalities [93–95]. These data show some degree of aortic dilation in 23–30 % of adults and an elongated transverse arch in 50 %, with coarctation detected in 12 % adults. Bicuspid aortic valve is associated with accelerated growth of the aortic root, while age, aortic valve morphology, and blood pressure each correlate with thoracic aortopathy. Patients with Turner syndrome are at risk for aortic dissection and rupture. In a recent study, of patients with spontaneous aortic dissections, 18 of 19 (95 %) had an associated cardiac malformation that included a bicuspid aortic valve. A recent study suggested that individuals with Turner syndrome who are >18 years of age with an ascending aortic size index >2.5 cm/m^2 should be considered for an aortic operation to prevent aortic dissection [96]. Hypertension affects 25 % of girls and approximately 50 % of adult women with TS. Careful surveillance and control of blood pressure is important to reduce the risk of aortic dissection.

Conduction abnormalities are also common in TS [97]. Sinus tachycardia is seen in all stages of life, accelerated atrial and atrioventricular conduction are observed, and risk of atrial tachycardia may be increased. The myocardial action potential can be prolonged with delayed repolarization, and a pathologically prolonged corrected QT interval is seen in one third of patients. It is as yet unclear if this confers risk for sudden death in this population. Health surveillance guidelines from the Turner Syndrome Consensus Study Group provide recommendations regarding care of all medical issues associated with TS [82].

Outcomes

Estimating the impact of cardiovascular disease in TS is complicated by comorbid conditions, but CHD is estimated to account for 8 % and acquired cardiovascular disease 41 % of all cause mortality [98]. In regard to CHD, there is evidence that repair of hypoplastic left heart syndrome as well as partial anomalous pulmonary vein repair in TS has less favorable outcomes compared to the general population of patients with these lesions [99–101]. However, data from the Pediatric Cardiac Care Consortium indicates that for most other interventional and surgical procedures, there is no difference in length of hospital stay or mortality between TS and non-TS patients.

Aortopathy is a significant cause of morbidity and mortality in adolescent and adult women with Turner syndrome [102]. The estimated risk of aortic dissection in young and middle-aged women with TS is 100-fold over that of age-matched controls. Surveillance through adulthood is likely to decrease morbidity and mortality in Turner syndrome. Most women with Turners syndrome are not fertile, but in the age of assisted reproduction, some women with TS are able to carry a pregnancy, and aortic dissection during pregnancy has been documented [103]. These pregnancies should be considered high risk and monitored very carefully by obstetricians and cardiologists for potential pregnancy-related aortic dissection. Overall mortality is threefold greater in women with TS compared to the general population and higher in nonmosaic TS compared to mosaic and other forms. Based on data from a Danish national registry study, mean life expectancy in all forms of TS is 69 years, and 64 years in nonmosaic, 45,X TS [104]. The decreased life expectancy in nonmosaic TS appears to be multifactorial, related to acquired cardiovascular disease, stroke, diabetes, and metabolic syndrome.

22q11.2 Deletion Syndrome: DiGeorge Syndrome, Velocardiofacial Syndrome (VCFS), Shprintzen Syndrome, Conotruncal Anomaly Face Syndrome

Epidemiology and Genetics

The syndrome now termed the "22q deletion syndrome" is the most common microdeletion syndrome in humans. Often referred to as DiGeorge syndrome, the 22q phenotype was described by several different groups as early as the late 1960s and 1970s who each noted a distinctive phenotype observed in families [105]. The association between conotruncal heart defects, characteristic facies, learning differences, and palate anomalies was recognized by Dr. Robert Shprintzen, a speech pathologist, and by Dr. Angelo DiGeorge, an endocrinologist at St. Christopher's Hospital for Children in Philadelphia, who described the same characteristic heart findings with thymic deficiency, hypocalcemia, and cleft palate. A Japanese group concurrently described the features of "conotruncal anomaly face syndrome" (CTAF). In the early 1980s, improvements in chromosome analysis led to the initial discovery of an abnormality on the long "q" arm of chromosome 22 [106, 107]. Fluorescent in situ hybridization (FISH) technology allowed more sensitive detection of the deletion, and recognition that most individuals diagnosed with DiGeorge, VCFS, Shprintzen, CTAF, and some with Opitz G/BBB syndrome actually carried the same unifying genetic diagnosis [108]. Current testing will detect the deletion in >95 % of patients with the clinical syndrome.

The genetic etiology of the 22q deletion syndrome is typically due to a loss of ~3 megabases of genetic material within the long arm of chromosome 22 and is estimated to occur in between 1 in 4,000 and 1 in 6,500 live births, but may be underestimated due to lack of recognition in individuals with a milder phenotype [109, 110]. Recent large population-based studies agree with older prevalence estimates and predict that 700 children per year are born with the 22q11.2 deletion in the United States, with equal male-to-female prevalence, and some suggestion that the deletion may be more common in the Hispanic population [111]. It is inherited in an autosomal dominant fashion but occurs de novo in 93 % of cases (ergo, 7 % of cases are inherited from a parent with the deletion). Interestingly, in familial cases the deletion is more likely to be inherited from the mother [112]. A common deletion occurs in 85 % of individuals, although smaller and larger atypical deletions can occur. Unbalanced translocations in which the 22q11.2 critical region is absent can also manifest typical features of the syndrome. There is no clear genotype-phenotype relationship recognized currently. One cannot predict based on the presence or size of the deletion, and exact breakpoints, whether an affected person will be more or less severely affected. There is some evidence that intellectual disability may be more significant in familial cases, but the reasons for this are not clear and may reflect both environmental causes and ascertainment biases. There is no evidence of anticipation; an affected parent is not at increased risk of having a child more significant cardiovascular or other organ system manifestations.

The mechanism by which loss of one copy of the 22q11.2 region results in malformation of the heart is currently under active investigation. There are over 20 genes known in the typical DiGeorge chromosome region (DGCR), but the transcription factor *TBX1* may be primarily involved in cardiac development [113, 114]. Absence of one or both copies of *TBX1* in a genetically modified mouse recapitulates cardiac features of 22q deletion syndrome, with abnormal development of the pharyngeal arches, and abnormal septation of outflow tracts in the heart. Subsequent to the discovery of an important role for TBX1 in cardiac development, mutations in the *TBX1* gene were identified in some patients that had a DiGeorge phenotype with conotruncal heart defects, and no detectable 22q11.2 deletion [115]. Nonetheless, it is likely that modifier genes or variation in downstream targets of *TBX1* lead to variability among individuals with the 22q11.2 deletion or with isolated *TBX1* mutations. It is also likely that the 22q deletion affects other genes involved in embryogenesis and heart development, as patients with

Fig. 3.4 Boy with 22q deletion syndrome. Notable features include hooding of the eyelids and bulbous nasal tip with hypoplastic ala nasi (*Photographs courtesy of family*)

more terminal deletions that do not include *TBX1* can also have complex conotruncal heart defects [116].

Physical and Medical Features

Physical characteristics among individuals with the 22q11.2 deletion can be variable, but distinctive facial characteristics are detectable in most and include hooding of the eyelids, a bulbous nasal tip with underdeveloped ala nasi, and thickening of the helices of the ears [109] (Fig. 3.4). These features may be more easily recognized in Caucasians compared to individuals of other races. Fingers and toes can be long and tapered in appearance. The other classic findings include congenital heart disease in 75–80 %, palate anomalies in 70 % (cleft or submucuos cleft, velopharyngeal insufficiency), intellectual disability (70–90 %), and immune deficiency (77 %) [111, 117, 118]. Other common features include hypocalcemia (50 %); feeding difficulties (30 %); hearing impairment (sensory and conductive, ~30 %); renal abnormalities (37 %); abnormalities of the upper airway, esophagus (including tracheoesophageal fistula), and lower gastrointestinal tract (including malrotation and abnormal motility); cervical spine anomalies (atlantoaxial instability); growth hormone deficiency; and central nervous system abnormalities and seizures (unrelated to hypocalcemia). Because of the immune dysregulation in the 22q11.2 deletion syndrome, neonates and infants who require surgery and need a blood transfusion are at increased risk for graft-versus-host disease, and all blood should be irradiated to kill living white blood cells.

CHD in 22q11.2 Deletion Syndrome

In the current era, the association between conotruncal heart malformations and 22q11.2 deletion is well recognized in the field of pediatrics. The 22q11.2 deletion accounts for a significant percentage of all conotruncal defects diagnosed in children, with 50–60 % of all children with interrupted aortic arch (almost all type B) carrying this deletion [119, 120]. Other conotruncal defects are similarly largely the result of the 22q syndrome, with 35 % of truncus arteriosus, one third of posterior misalignments VSD, 25 % of VSD/coarctation, 16 % of tetralogy of Fallot, and 5 % of all double-outlet right ventricle diagnoses deleted for the 22q11.2 region. Up to 25 % of individuals with isolated arch anomalies will have a 22q11.2 deletion [121]. Presentation with any conotruncal heart anomaly or arch anomaly is indication enough to strongly consider testing for 22q11.2 deletion. When a conotruncal heart anomaly is found with other vascular abnormalities, including right-sided aortic arch, abnormal branching of peripheral arteries, and pulmonary valve or pulmonary artery atresia, the likelihood of diagnosing the 22q deletion is further increased [122]. Several population-based and national registry studies

validate earlier appraisals of the frequency of 22q deletion in patients with CHDs, although they are still likely underestimates, as they do not reflect universal genetic screening [111, 119, 122, 123]. These larger studies estimate that 10 % of infants with conotruncal defects and approximately 2 % of patients with CHD (all types) carry the 22q11.2 deletion.

Given the prevalence of this microdeletion syndrome in the population and the frequency in which it is found in conotruncal heart defects, it is not surprising that a large majority (~80 %) of patients with 22q deletion have some form of CHD. Among those with 22q deletion and CHD, 17–22 % have tetralogy of Fallot, 10–15 % have pulmonary atresia/ventricular septal defect (VSD), 15 % have interrupted aortic arch (typically type B, but type A has also been seen), ~15 % have VSD, 7–9 % have truncus arteriosus, 4 % have VSD/atrial septal defect (ASD), a few percent have isolated ASD, and a few percent will have pulmonary stenosis [109, 111, 118]. Other complex lesions have been reported including hypoplastic left heart syndrome, transposition of the great arteries, double-outlet right ventricle/interrupted aortic arch, and heterotaxy/atrioventricular canal/interrupted aortic arch, but these are all relatively rare. Up to 50 % will have some type of vascular abnormality, including right-sided aortic arch, mirror image head and neck vessels, vascular ring, aberrant origin of the subclavian artery, and left superior vena cava.

Outcomes

CHD is the major cause of morbidity and mortality in the 22q deletion syndrome, with over 85 % of deaths attributed to CHD, and a majority of occurring in the first 6 months of life [118]. Overall the mortality rate for infants has been estimated at 8 %. Several groups have looked at postoperative outcomes in patients with conotruncal defects and have found that overall mortality and complication rates are higher in patients with the 22q deletion syndrome compared to other syndromic and nonsyndromic patients with similar cardiac lesions [47, 124–127]. Specifically, 22q11.2 deletion has been identified as a risk factor for immediate postoperative mortality in pulmonary atresia/ventricular septal defect with major aortopulmonary collaterals and in interrupted aortic arch repairs. Some surgical outcome studies have indicated that children with 22q deletion syndrome require surgery at a younger age and more frequently show signs of heart and respiratory failure as well as pulmonary vascular disease. Increased rates of sepsis, pneumonia, postoperative stridor, and hypocalcemia, with prolonged intubation times and longer hospitalizations were seen in some series. However, other groups have not shown statistically significant differences in age, weight, length of mechanical ventilation, or overall mortality between surgical patients with 22q and patients with similar cardiac defects [128]. Multiple factors are likely to contribute to higher postsurgical morbidity and possibly mortality in patients with 22q deletion syndrome, including certain types and complexity of cardiac anatomy, airway and parenchymal lung disease, and immunodeficiency.

Morbidity and mortality in infants and young children with 22q deletion primarily associated with CHD are recognized, but given that individuals without CHD may escape detection, the overall life expectancy is not truly known. Overall survival in individuals with 22q deletion may be shorter than the general population based on one cohort study to date, which showed increased mortality rate (11.8 %) in individuals with the deletion compared to their unaffected siblings [129]. No common cause of death was evident in this series, but sudden cardiac death was reported in 50 % of deaths and occurred in individuals with and without any underlying CHD. Other factors that may contribute to longevity include a very high rate of neuropsychiatric disease in adults with 22q deletion. The median age of death in this cohort was 42 years overall, 47 years for those with no significant CHD. Overall life expectancy may be significantly reduced

in this population, but further natural history studies are needed.

A complete updated review of the 22q11.2 deletion syndrome can be found in NCBI GeneReviews™ [109] (http://www.ncbi.nlm.nih.gov/books/NBK3823).

Williams Syndrome: Williams-Beuren Syndrome, 7q11.23 Deletion

Epidemiology and Genetics

Williams syndrome is one of the most common contiguous gene deletion syndromes with a prevalence of 1 in 7,500 [130]. A New Zealand physician, J. C. P. Williams, first described the association between super-valvar aortic stenosis (SVAS) and "mental deficiency" in four patients in 1961 [131]. Three more patients with the same cardiovascular findings, developmental differences, and characteristic facial features were reported a year later by the German physician A. J. Beuren [132]. What became known as the "Williams-Beuren" syndrome was subsequently defined as a loss of 1.55 megabases of a critical region (WBSCR) on chromosome 7q11.23, identified in 99 % of affected individuals [133–135]. The WBSCR contains at least 25 genes and includes the elastin gene (*ELN*), which is known to be responsible for the cardiovascular phenotype in this group of patients [136]. Williams syndrome typically occurs de novo, although familial cases have been reported; the inheritance is autosomal dominant. Males and females are equally affected, and the deletion is equally likely to be of maternal or paternal origin. Atypical deletions do occur, and there are genotype-phenotype correlations that have helped investigators to better understand how individual genes in the WBSCR contribute to the clinical presentation [137]. Larger deletions (2–4 megabases) are typically associated with a more severe phenotype notable for more significant intellectual disability. Smaller deletions have also been described that contain the *ELN* gene with the vascular phenotype and a characteristic cognitive phenotype with minimal intellectual disability. The primary role for elastin in the arteriopathy associated with Williams syndrome is further evidenced by the finding that dominant familial nonsyndromic SVAS can occur due to mutations in one copy of the *ELN* gene [138, 139]. Testing for *ELN* mutations should be considered in all cases of familial or sporadic SVAS. *ELN* gene alterations have been found in roughly a third of cases of isolated, nonsyndromic SVAS, and testing sensitivity is likely to increase over time [140, 141]. There is *incomplete penetrance* and *variable expressivity* of elastin gene defects, leading to some family members with severe SVAS, while others who carry the same gene change can have no or minor vascular manifestations.

Physical and Medical Features

Clinical diagnostic criteria have been established for Williams syndrome by the AAP Committee on Genetics, and excellent reviews of the disorder have been written by Drs. Colleen Morris and Barbara Pober [136, 137]. The diagnostic criteria employ a scoring system based on the presence of growth features, behavioral traits, facial dysmorphisms, calcium abnormalities, and cardiovascular features. Although the facial features and developmental/behavioral characteristics become more distinctive with age, a diagnosis of Williams syndrome can easily be made clinically and should always be considered in an infant with SVAS. Associated findings in the infant can include hypercalcemia, with subtle facial features including periorbital fullness, a short nose with a broad tip, full checks and full lips, and a long philtrum. In children with blue or green eyes, a starburst or "stellate" pattern of the iris can be noted. With age these and other features become more notable, with wide mouth, hypodontia, and what some describe as an "elfin" appearance.

Cardiovascular findings are the most common medical complications in Williams syndrome, seen in 80 % of infants and children [142]. Failure to thrive is present in 70 % of infants during the first year of life, attributed to poor feeding, while

Fig. 3.5 Angiogram of the aorta in a child with Williams syndrome. From *left to right*, inferior to superior, *arrows* indicate the aortic annulus, area of severe super-valvar aortic stenosis, and area of mild coarctation

obesity becomes common in older children and adults (30 %). Central hypotonia is present in 80 %, with hyperactive deep tendon reflexes and peripheral hypertonia in 75 % and 50 %, respectively. Idiopathic hypercalcemia is identified in 15 % of infants and typically resolves by childhood but can contribute to irritability, poor feeding, and constipation in the infant. Joint and integumentary involvement is also common, with soft lax skin and joint hypermobility present in 90 %, although 50 % will also have contractures. Inguinal and umbilical hernias occur in 40–50 % and rectal prolapse in 5 %. Half of children have ocular and visual abnormalities (esotropia, hyperopia), and half will have chronic otitis media. Other less common findings include structure abnormalities of the genitourinary tract (20 %), recurrent urinary tract infections (30 %), and Chiari I malformation (10 %). Other endocrinopathies occur and include hypothyroidism, early puberty, and short stature. Intellectual disability is present in 95 % and is moderate to severe in 75 %, mild in 20 %. Behavioral phenotypes have been well documented, with 80 % being diagnosed with generalized anxiety disorder and 70 % with attention-deficit hyperactivity disorder.

CHD in Williams Syndrome

Arteriopathy is identified in 80 % of all patients with Williams syndrome, with an even higher percentage of those diagnosed in the first year of life having cardiovascular involvement (96 %) [143]. SVAS is the most common finding, in 45–60 % of individuals, while valvar and supravalvar pulmonary stenosis (SVPS) is seen in 40–45 % [134, 144–146] (Fig. 3.5). Peripheral pulmonic stenosis (PPS) is also very common, seen in 50–60 % of infants with Williams syndrome, but often improves with age. Combined left and right obstructive lesions are seen in 20–35 % of patients. In general, pulmonary artery stenosis improves, whereas SVAS can worsen over time. Other vascular stenoses also occur and include renal artery in 10–45 %, the thoracic aorta in ~15 %, coronary anomalies in 6–10 %, and other arterial stenoses in 20 % [144, 147]. SVAS is mild in the majority of patients (64 %), with 12 % having moderate and 25 % severe narrowing. The percentages for PPS are similar with 62 % classified as mild, 16 % moderate, and 22 % severe. When coarctation of the aorta or SVPS is present, roughly 50 % will be mild, 25 % moderate, and 25 % severe. Stenosis of the thoracic aorta in Williams syndrome is more often long segment, but discreet narrowings and coarctation of the aorta do occur. In patients with thoracic aorta stenosis, 50 % have mild narrowing, and roughly 25 % moderate, and 25 % severe involvement. Intracardiac disease can be seen in Williams syndrome but is less common with ventricular septal defects, aortic valve and mitral valve abnormalities each being seen in up to 10 % of all patients, and atrial septal defect in 5 % [148]. Percentages for each of these anomalies increase to 20 % in those diagnosed as infants. Rare complex heart defects, including tetralogy of Fallot, have been reported. Hypertension is very common, occurring in 50 %, and can be related to renal artery stenosis in some cases, but will occur in the absence of identifiable vascular disease, and has been linked to a gene in the WBSCR, *NCF1* [149]. Hypertension develops

with age and is seen in 50 % of individuals, necessitating screening in children and adults regardless of known vascular disease.

Outcomes

Outcomes in the prognosis for patients with Williams syndrome are largely dependent on the presence and severity of cardiovascular disease [150]. A few large cohorts have provided natural history data that describe the frequency and types of cardiovascular interventions for which children with Williams syndrome have required. Pham et al. and Collins et al. recently reported on large cohorts of Williams syndrome patients (each greater than 240) from the Pediatric Cardiac Care Consortium and the Children's Hospital of Philadelphia, respectively [143, 151]. The Philadelphia study found that 21 % of Williams syndrome patients required surgery or intervention. Freedom from intervention was 91 %, 81 %, 78 %, 72 %, and 62 % at 1, 5, 10, 20, and 40 years, respectively. Gender was not identified as a risk factor in these series. These data indicate that of patients with SVAS, approximately 25 % will require surgical intervention, and these patients typically fall in the severe category. Of the surgeries performed in Williams syndrome, 50–80 % are for SVAS or combined outflow obstruction and just over 25 % of all patients with SVAS required intervention. Most patients in the mild and moderate categories of SVAS do not require intervention, and a significant portion (16 %) show spontaneous improvement with time. Conversely some SVAS progresses in severity (9 %), and if intervention is needed, it is usually necessary within the first 5 years of life. High rates of PPS are detected in infants, with intervention required in 80 % of severe, 50 % of moderate, and over 20 % of mild cases. A majority of catheter-based intervention in Williams syndrome is to treat PPS, and repeat catheterizations are more common in patients with this lesion. Intervention for stenosis of the thoracic aorta has been required in less than 5 % of patients when narrowing was considered to be severe by echocardiogram indices, with 2/3 undergoing a surgical repair, and 1/3 an interventional approach [152].

Overall mortality in these studies was low and primarily attributed to cases with combined SVAS and SVPS, where baseline mortality is approximately 5 %, and surgical mortality as high as 20–35 %. Several cases of sudden cardiac death have also been described, associated with other causes including coronary ostial stenosis, pulmonary hypertension, ventricular arrhythmia, and anesthesia [153]. Life expectancy in Williams syndrome has not been well studied to date, but individuals are known to live into their 60s.

A complete updated review of Williams syndrome can be found in NCBI GeneReviews™ [155] (http://www.ncbi.nlm.nih.gov/books/NBK1249).

Genetic Testing for Chromosome Syndromes, Microdeletion and Duplication Syndromes

Only brief mention will be made about common types of genetic tests currently in use for diagnosis of chromosomal abnormalities since the preferred types of testing, and associated costs are rapidly evolving. High-resolution chromosome analysis is useful in the diagnosis of aneuploidy, i.e., trisomies and monosomies; it can detect mosaicism and is necessary for diagnosis of suspected balanced and unbalanced translocations. Fluorescent in situ hybridization (FISH) is a fast and accurate method for diagnosis of specific trisomies and common microdeletions such as 22q11.2 and the Williams syndrome deletion. Although this technique is no longer cutting edge, it is extremely useful due of the speed with which results can be obtained and relatively low cost. Array-based technologies (types include BAC, oligonucleotide, and SNP) are, at present, the preferred modality for the diagnosis of all types of aneuploidy, mosaicism, and deletions and duplications. These high-resolution chromosome analyses cover nearly all of the genome to detect missing or extra segments of material (referred to as copy number variants or CNVs). These approaches permit diagnosis of more common, very rare, and very small pathologic deletions in the genome.

It allows more precise location of chromosome break points and mapping of absent or extra genetic material. However, it is not uncommon for "variants of unknown significance" to be detected, which may be unrelated to the cardiovascular phenotype and can be confusing to clinicians and families. Array-based testing is more expensive and typically requires several weeks for results and interpretation.

Choosing the correct type of genetic test has become increasingly complex for the general and subspecialty practitioner, even for more commonly recognized syndromes. Turnaround times, expense, and interpretation of unexpected results are important considerations and appropriate reasons to consult a clinical geneticist or genetic counselor working in a cardiology practice before ordering tests. In some cases it is important to collect blood samples before a surgical procedure in order for genetic testing to be initiated before possible blood transfusion, which can introduce donor genetic material that could interfere with accurate test results. It is also important to consider the impact that a test will have on a family, the medical team, and surgical team, before and after the birth of an infant. When and if a diagnosis will influence management decisions, it is very important to expedite testing. The importance of including the family in the decisions about genetic testing cannot be overemphasized. Genetics professionals are critical team members; their role in education of families and cardiology practitioners can assist in decision making that best serves the affected child and facilitates ethical practice.

Acknowledgements Recognition and thanks to Dr. Robert Bone, Donna McDonald-McGinn, and members of the Support Organization For Trisomy (SOFT) for their contributions to this chapter.

Outcomes Analysis and Quality Improvement for the Treatment of Patients with Pediatric and Congential Heart Disease

4

Jeffrey P. Jacobs

Abstract

Important advances have been made in the science of outcome analysis and quality improvement for the treatment of patients with pediatric and congenital heart disease. These advances have been made in seven domains: nomenclature, database standardization, complexity adjustment, data verification, subspecialty collaboration, longitudinal follow-up, and quality improvement.

Keywords

Complexity stratification • Congenital cardiac surgery • Congenital heart disease • Data verification • Databases • Deterministic matching • EACTS Congenital Heart Surgery Database • Japan Congenital Cardiovascular Surgery Database (JCCVSD) • Linking databases • Longitudinal follow-up • Nomenclature • Outcomes analysis • Patient safety • Pediatric cardiac surgery • Pediatric heart disease • Probabilistic matching • Quality assessment • Quality improvement • Risk adjustment • STS Congenital Heart Surgery Database • United Kingdom Central Cardiac Audit Database (UKCCAD)

Introduction

In order to perform meaningful multi-institutional outcome analyses and quality improvement, any database must incorporate the following seven essential elements [1–4]:

1. Use of a common language and nomenclature [5]
2. Use of a database with an established uniform core dataset for collection of information [6–10]
3. Incorporation of a mechanism of evaluating case complexity [11–19]
4. Availability of a mechanism to assure and verify the completeness and accuracy of the data collected [20]
5. Collaboration between medical and surgical subspecialties [21–24]
6. Standardization of protocols for life-long follow-up [25–28]
7. Incorporation of strategies for quality assessment and quality improvement [29–32]

Nomenclature

Substantial effort has been devoted to the standardization of nomenclature and definitions related to surgery for pediatric and congenital cardiac disease. During the 1990s, both the European Association for Cardio-Thoracic Surgery (EACTS) and the Society of Thoracic Surgeons (STS) created databases to assess the outcomes of congenital cardiac surgery. Beginning in 1998, these two organizations collaborated to create the International Congenital Heart Surgery Nomenclature and Database Project. By 2000, a common nomenclature and a common core minimal dataset were adopted by EACTS and STS and published in the Annals of Thoracic Surgery [5]. In 2000, The International Nomenclature Committee for Pediatric and Congenital Heart Disease was established. This committee eventually evolved into the International Society for Nomenclature of Paediatric and Congenital Heart Disease (ISNPCHD). By 2005, members of the ISNPCHD cross mapped the nomenclature of the International Congenital Heart Surgery Nomenclature and Database Project of the EACTS and STS with the European Paediatric Cardiac Code (EPCC) of the Association for European Paediatric Cardiology (AEPC) and therefore created the International Paediatric and Congenital Cardiac Code (IPCCC) [4], which is available for free download from the internet at [http://www.IPCCC.NET].

Most international databases of patients with pediatric and congenital cardiac disease use the IPCCC as their foundation. Two versions of the IPCCC are used in the overwhelming majority of multi-institutional databases throughout the world:

1. The version of the IPCCC derived from the nomenclature of the International Congenital Heart Surgery Nomenclature and Database Project of the EACTS and the STS
2. The version of the IPCCC derived from the nomenclature of the EPCC of the AEPC

These two versions of the IPCCC are also often referred to with the following abbreviated short names:

1. EACTS–STS-derived version of the IPCCC
2. AEPC-derived version of the IPCCC

The STS Congenital Heart Surgery Database and the EACTS Congenital Heart Surgery Database use the EACTS–STS-derived version of the IPCCC.

This common nomenclature, the EACTS–STS-derived version of the IPCCC [2, 4, 5], and the common minimum database dataset created by the International Congenital Heart Surgery Nomenclature and Database Project [1] are now utilized by the STS Congenital Heart Surgery Database, the EACTS Congenital Heart Surgery Database, and the Japan Congenital Cardiovascular Surgery Database (JCCVSD). Between 1998 and January 1, 2012, inclusive, this nomenclature and database were used by STS and EACTS to analyze outcomes of 339,002 operations.

Database

The STS Congenital Heart Surgery Database is the largest database in North America dealing with congenital cardiac malformations [6, 7]. It has grown annually since its inception, in terms of both the number of participating centers submitting data and the number of operations analyzed (Figs. 4.1, 4.2, and 4.3). As of March 1, 2012, the STS Congenital Heart Surgery Database currently has 103 participating centers: 100 out of an estimated 125 centers from the United States of America that perform pediatric and congenital heart surgery and 3 out of 8 centers from Canada that perform pediatric and congenital heart surgery [33, 34]. The Report of the 2005 STS Congenital Heart Surgery Practice and Manpower Survey, undertaken by the STS Workforce on Congenital Heart Surgery, documented that 122 centers in the United States of America perform pediatric and congenital heart surgery and 8 centers in Canada perform pediatric and congenital heart surgery [33]. The Report of the 2010 STS Congenital Heart Surgery Practice and Manpower Survey, undertaken by the STS Workforce on Congenital Heart Surgery, documented that 125 centers in the

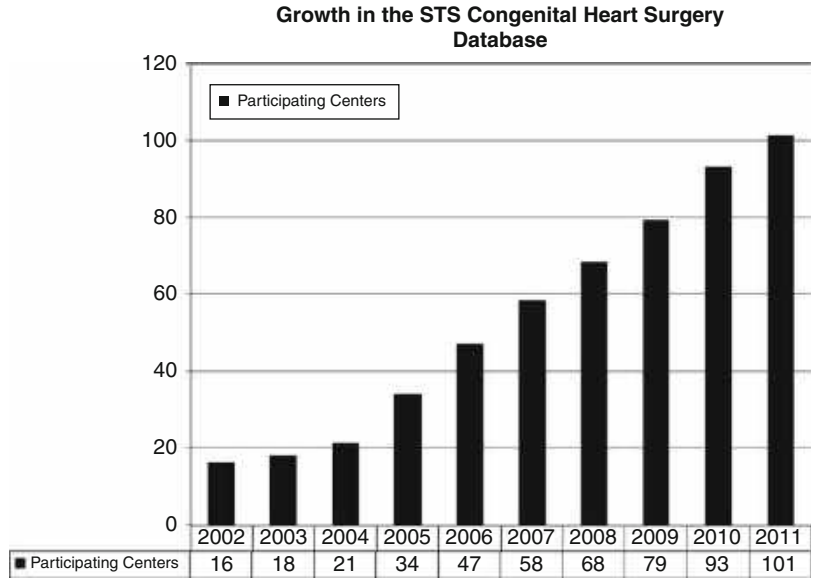

Fig. 4.1 The graph documents the annual growth of the STS Congenital Heart Surgery Database by the number of participating centers submitting data. The aggregate report from Fall 2011 Harvest of the STS Congenital Heart Surgery Database [8] includes data from 101 Congenital Heart Surgery Centers in the United States of America and Canada

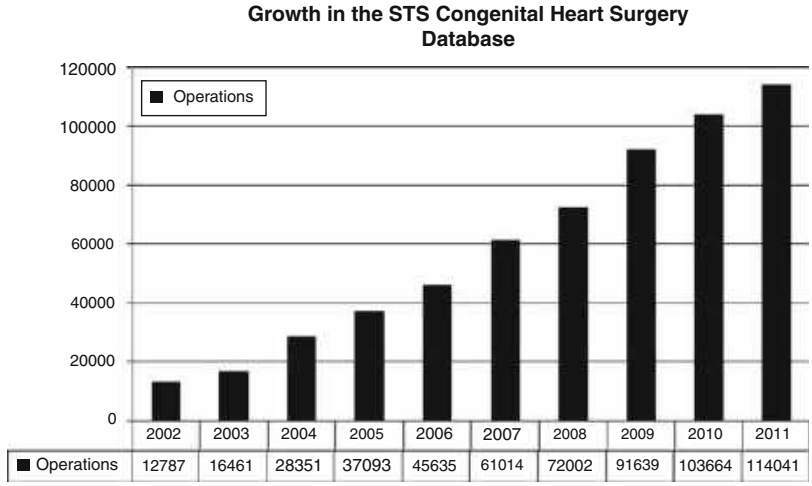

Fig. 4.2 The graph documents the annual growth of the STS Congenital Heart Surgery Database by the number of operations per averaged 4-year data collection cycle. The aggregate report from the Fall 2011 Harvest of the STS Congenital Heart Surgery Database [8] includes 114,041 operations performed in the 4-year period of July 1, 2007, to June 30, 2011, inclusive, submitted from 101 centers in North America, 100 in the United States of America, and 1 in Canada. Operations per averaged 4-year data collection cycle

United States of America perform pediatric and congenital heart surgery and 8 centers in Canada perform pediatric and congenital heart surgery [34]. As of July 2012, the number of cumulative total operations in the STS Congenital Heart Surgery Database is 213,416 [8]. In collaboration with EACTS, the STS has developed standardized methodology for tracking mortality and morbidity associated with the treatment of patients with congenital and pediatric cardiac disease [9, 10].

The EACTS Congenital Heart Surgery Database is the largest database in Europe dealing with congenital cardiac malformations

	2000	2001	2002	2003	2004	2005	2006	2007	2008	2009	2010	2011
Cumulative Operations	4237	9747	16537	26404	39988	58181	79399	98406	119266	148110	179697	213416

Fig. 4.3 The graph documents the annual growth of the STS Congenital Heart Surgery Database by the cumulative number of operations over time. The current number of cumulative total operations in the STS Congenital Heart Surgery Database is 213,416. The aggregate report from the Fall 2011 Harvest of the STS Congenital Heart Surgery Database [8] includes 114,041 operations performed in the 4-year period of July 1, 2007, to June 30, 2011, inclusive, submitted from 101 centers in North America, 100 in the United States of America, and 1 in Canada. Cumulative operations over time

(Fig. 4.4) [5, 6]. By January 2012, the EACTS Congenital Heart Surgery Database contained 125,606 operations performed in 105,004 patients. As of January 2012, the EACTS Congenital Heart Surgery Database has 390 registered centers from 69 countries, with 161 active centers from 41 countries submitting data.

The JCCVSD has recently been operationalized based on identical nomenclature and database standards as that used by EACTS and STS [6]. The JCCVSD began enrolling patients in 2008. By November 2011, 82 hospitals were submitting data, 20 more were ready to start submitting data, and over 16,000 operations were entered into the JCCVSD, in just over 3 years of data collection (Fig. 4.5). In Japan, it is mandatory for specialists to enroll in this benchmarking project in order to objectively examine their own performance and make efforts for continuous improvement. In the future, certification is to be performed solely on the basis of empirical data registered by the project. The developers of the JCCVSD hope to collaborate with their colleagues across Asia to create an Asian Congenital Heart Surgery Database.

In the United Kingdom, the United Kingdom Central Cardiac Audit Database (UKCCAD) uses the AEPC-derived version of the IPCCC as the basis for its national, comprehensive, validated, and benchmark-driven audit of all pediatric surgical and transcatheter procedures undertaken since 2000 [7]. All 13 tertiary centers in the United Kingdom performing cardiac surgery or therapeutic cardiac catheterization in children with congenital cardiac disease submit data to the UKCCAD. Data about mortality is obtained from both results volunteered from the hospital databases and by independently validated records of deaths obtained by the Office for National Statistics, using the patient's unique National Health Service number, or the general register offices of Scotland and Northern Ireland. Efforts are underway to link the UKCCAD to the EACTS Congenital Heart Surgery Database. Linkage of the UKCCAD to the EACTS Congenital Heart Surgery Database will require use of the cross

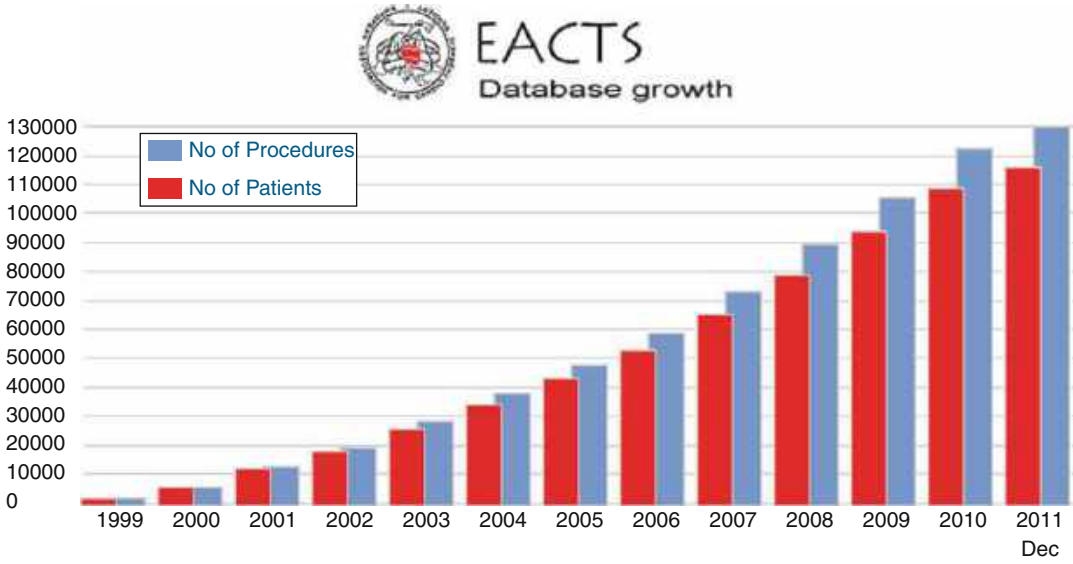

Fig. 4.4 The graph documents the annual growth in the European Association for Cardio-Thoracic Surgery Congenital Database by both number of patients and number of operations. As of January 2012, the EACTS Congenital Heart Surgery Database contained 125,606 operations performed in 105,004 patients. In January 2012, the EACTS Congenital Heart Surgery Database has 390 centers from 69 countries registered, with 161 active centers from 41 countries submitting data. This graph is provided courtesy of Bohdan Maruszewski of the Children's Memorial Health Institute in Warsaw, Poland, Director of the European Association for Cardio-Thoracic Surgery Congenital Database, and President of the European Congenital Heart Surgeons Association (ECHSA)

Fig. 4.5 The graph documents the initial growth of the Japan Congenital Cardiovascular Surgery Database (JCCVSD). The JCCVSD has recently been operationalized based on identical nomenclature and database standards as that used by EACTS and STS. The JCCVSD began enrolling patients in 2008. By November 2011, 82 hospitals were submitting data, 20 more were ready to start submitting data, and over 16,000 operations were entered into the JCCVSD, in just over 3 years of data collection. The developers of the JCCVSD hope to collaborate with their colleagues across Asia to create an Asian Congenital Heart Surgery Database. This graph is provided courtesy of Arata Murakami, MD, of the University of Tokyo in Tokyo, Japan

map of the AEPC-derived version of the IPCCC (used by the UKCCAD) to the EACTS–STS-derived version of the IPCCC (used by the EACTS, STS, and JCCVSD).

As of January 2102, the STS Congenital Heart Surgery Database contains data about 213,416 operations, and the EACTS Congenital Heart Surgery Database contains data about 125,606 operations. Therefore, the combined dataset of the STS Congenital Heart Surgery Database and the EACTS Congenital Heart Surgery Database contains data about 339,002 operations, all coded with the EACTS–STS-derived version of the IPCCC [2, 3, 5] and all coded with identical data specifications [1].

Complexity Stratification

The importance of measurement of complexity derives from the fact that analysis of outcomes using raw measurements of mortality, without adjustment for complexity, is inadequate. The mix of cases can vary greatly from program to program. Without stratification of complexity, the analysis of outcomes will be flawed [11–19].

The analysis of outcomes after surgery requires a reliable method of estimating the risk of adverse events. However, formal risk modeling is challenging for rare operations. Complexity stratification provides an alternative methodology that can facilitate the analysis of outcomes of rare operations. Complexity stratification is a method of analysis in which the data are divided into relatively homogeneous groups (called strata). The data are analyzed within each stratum.

Three major multi-institutional efforts that have attempted to measure the complexity of congenital heart surgery operations are the following:

1. *R*isk *A*djustment in *C*ongenital *H*eart *S*urgery-1 methodology (RACHS-1) [11, 18]
2. *A*ristotle *B*asic *C*omplexity Score (ABC Score) [11, 13–17]
3. ***ST***S–E***A***C***T***S Congenital Heart Surgery Mortality Categories (STS–EACTS Mortality Categories) (STAT Score) [12]

RACHS-1 and the ABC Score were developed at a time when limited multi-institutional clinical data were available and were therefore based in a large part on subjective probability (expert opinion). The STAT Categories are a tool for complexity stratification that was developed from an analysis of 77,294 operations entered into the EACTS Congenital Heart Surgery Database (33,360 operations) and the STS Congenital Heart Surgery Database (43,934 patients) between 2002 and 2007. Procedure-specific mortality rate estimates were calculated using a Bayesian model that adjusted for small denominators. Operations were sorted by increasing risk and grouped into five categories (the STS–EACTS Congenital Heart Surgery Mortality Categories) that were designed to be optimal with respect to minimizing within-category variation and maximizing between-category variation.

Table 4.1 compares RACHS-1, the ABC Score, and the STS–EACTS Mortality Categories. Table 4.2 shows the application in the STS Congenital Heart Surgery Database of the STAT Congenital Heart Surgery Mortality Categories [30]. STS has transitioned from the primary use of Aristotle and RACHS-1 to the primary use of the STAT Categories because of three reasons:

1. STAT Score was developed primarily based on objective data while RACHS-1 and Aristotle were developed primarily on expert opinion (subjective probability).
2. STAT Score allows for classification of more operations than RACHS-1 or Aristotle.
3. STAT Score has a higher c-statistic than RACHS-1 or Aristotle.

Data Verification

Collaborative efforts involving EACTS and STS aim to enhance mechanisms to verify the completeness and accuracy of the data in the databases [1, 20]. A combination of three strategies

Table 4.1 Table 4.1 shows the results of comparing the STS–EACTS Categories (2009) to the RACHS-1 Categories and the Aristotle Basic Complexity Score using an independent validation sample of 27,700 operations performed in 2007 and 2008. In the subset of procedures for which STS–EACTS Category, RACHS-1 Category, and Aristotle Basic Complexity Score are defined, discrimination was highest for the STS–EACTS Categories (C-index = 0.778), followed by RACHS-1 Categories (C-index = 0.745), and Aristotle Basic Complexity Scores (C-index = 0.687)

Method of modeling procedures	Model without patient covariates	Model with patient covariates	Percent of operations that can be classified (%)
STS–EACTS Congenital Heart Surgery Mortality Categories (2009)	C = 0.778	C = 0.812	99
RACHS-1 Categories	C = 0.745	C = 0.802	86
Aristotle Basic Complexity Score	C = 0.687	C = 0.795	94

Table 4.2 Table 4.2 shows the discharge mortality in an analysis of patients in the STS Congenital Heart Surgery Database who underwent surgery between January 1, 2005, and December 31, 2009, inclusive [30], stratified by STS–EACTS Congenital Heart Surgery Mortality Categories

	Total number of operations	Discharge mortality (%)
STS–EACTS Category 1	15,441	0.55
STS–EACTS Category 2	17,994	1.7
STS–EACTS Category 3	8,989	2.6
STS–EACTS Category 4	13,375	8.0
STS–EACTS Category 5	2,707	18.4

may ultimately be required to allow for optimal verification of data:

1. Intrinsic data verification (designed to rectify inconsistencies of data and missing elements of data)
2. Site visits with "Source Data Verification" (in other words, verification of the data at the primary source of the data)
3. External verification of the data from independent databases or registries (such as governmental death registries)

Subspecialty Collaboration

Under the leadership of the Multi-Societal Database Committee for Pediatric and Congenital Heart Disease [2, 3], further collaborative efforts are ongoing between congenital and pediatric cardiac surgeons and other subspecialties including:

1. Pediatric cardiac anesthesiologists, via the Congenital Cardiac Anesthesia Society
2. Pediatric cardiac intensivists, via the Pediatric Cardiac Intensive Care Society
3. Pediatric cardiologists, via the Joint Council on Congenital Heart Disease, the American College of Cardiology, and the Association for European Paediatric Cardiology

Strategies have been developed to link together databases [21–24]. By linking together different databases, one can capitalize on the strengths and mitigate some of the weaknesses of these databases and therefore allow analyses not possible with either dataset alone. Linked databases have facilitated both comparative effectiveness research [23, 24] and longitudinal follow-up [27, 28]. Under the leadership of the Multi-Societal Database Committee for Pediatric and Congenital Heart Disease [2, 3], further collaborative efforts are ongoing between congenital and pediatric cardiac surgeons and other subspecialties.

Longitudinal Follow-Up

The transformation of the STS Database to a platform for longitudinal follow-up will ultimately result in higher quality of care for all cardiothoracic surgical patients by facilitating longitudinal comparative effectiveness research on a national level [25–28]. Several potential

strategies will allow longitudinal follow-up with the STS Database, including the development of clinical longitudinal follow-up modules with the STS Database and linking the STS Database to other clinical registries, administrative databases, and national death registries:

1. Using probabilistic matching, the STS Database can be linked to administrative claims databases (such as the CMS Medicare Database [27] and the Pediatric Health Information System (PHIS) database [22–24]) and become a valuable source of information about long-term mortality, rates of rehospitalization, long-term morbidity, and cost.
2. Using deterministic matching with shared unique identifiers, the STS Database can be linked to national death registries like the Social Security Death Master File (SSDMF) and the National Death Index (NDI) in order to verify life-status over time [28].
3. Through either probabilistic matching or deterministic matching [12], the STS Database can link to multiple other clinical registries, such as the National Cardiovascular Data Registry (NCDR) of the American College of Cardiology (ACC), in order to provide enhanced clinical follow-up.
4. The STS Database can develop clinical longitudinal follow-up modules of its own to provide detailed clinical follow-up [21, 25, 26, 28].

Quality Assessment and Quality Improvement

The STS Database is increasingly used to document variation in outcomes [29, 30] and measure quality [31, 32]; STS has collaborated with the Congenital Heart Surgeons' Society to develop and endorse metrics to assess the quality of care delivered to patients with pediatric and congenital cardiac disease [34]. Tables 4.3, 4.4, and 4.5 present 21 "quality measures for congenital and pediatric cardiac surgery" that were developed and approved by the Society of Thoracic Surgeons (STS) and endorsed by the Congenital Heart Surgeons' Society (CHSS). These quality measures are organized according to Donabedian's triad of structure, process, and outcome [35]. It is hoped that these quality measures can aid in congenital and pediatric cardiac

Table 4.3 Quality measures for congenital and pediatric cardiac surgery

1.	Participation in a **National Database** for Pediatric and Congenital Heart Surgery
2.	**Multidisciplinary rounds** involving multiple members of the healthcare team
3.	Availability of institutional **pediatric ECLS (Extracorporeal Life Support) Program**
4.	**Surgical volume** for pediatric and congenital heart surgery: total programmatic volume and programmatic volume stratified by the **five STS–EACTS Mortality Categories**
5.	**Surgical volume** for **eight pediatric and congenital heart benchmark operations**
6.	Multidisciplinary **preoperative planning conference** to plan pediatric and congenital heart surgery operations
7.	Regularly scheduled **Quality Assurance and Quality Improvement Cardiac Care Conference**, to occur no less frequently than once every 2 months
8.	Availability of **intraoperative transesophageal echocardiography (TEE)** and epicardial echocardiography
9.	**Timing of antibiotic administration** for pediatric and congenital cardiac surgery patients
10.	Selection of **appropriate prophylactic antibiotics and weight-appropriate dosage** for pediatric and congenital cardiac surgery patients
11.	Use of an **expanded preprocedural and postprocedural "time-out"**
12.	Occurrence of new postoperative **renal failure** requiring dialysis
13.	Occurrence of new postoperative **neurological deficit** persisting at discharge
14.	Occurrence of arrhythmia necessitating **permanent pacemaker** insertion
15.	Occurrence of **paralyzed diaphragm** (possible phrenic nerve injury)
16.	Occurrence of need for **postoperative mechanical circulatory support** (IABP, VAD, ECMO, or CPS)
17.	Occurrence of **unplanned reoperation** and/or interventional cardiovascular catheterization procedure
18.	**Operative mortality** stratified by the five STS–EACTS Mortality Levels
19.	**Operative mortality** for eight benchmark operations
20.	Index cardiac **operations free of mortality and major complication**
21.	Operative **survivors free of major complication**

Table 4.4 Definitions of quality measures for congenital and pediatric cardiac surgery

	Definitions of Quality Measures for Congenital and Pediatric Cardiac Surgery			
	Number	**Type**	**Title of Indicator**	**Description**
1	S-1	Structure	Participation in a National Database for Pediatric and Congenital Heart Surgery	Participation in at least one multi-center, standardized data collection and feedback program that provides regularly scheduled reports of the individual center's data relative to national multicenter aggregates and uses process and outcome measures.
2	S-2	Structure	Multidisciplinary rounds involving multiple members of the healthcare team	Occurrence of daily multidisciplinary rounds on pediatric and congenital cardiac surgery patients involving multiple members of the healthcare team, with recommended participation including but not limited to: cardiac surgery, cardiology, critical care, primary caregiver, family, nurses, pharmacist and respiratory therapist. Involvement of the family is encouraged.
3	S-3	Structure	Availability of Institutional Pediatric ECLS (Extracorporeal Life Support) Program	Availability of an institutional pediatric Extracorporeal Life Support (ECLS) Program for pediatric and congenital cardiac surgery patients. Measure is satisfied by availability of ECMO equipment and support staff, but applies as well to Ventricular Assist Devices (including extracorporeal, paracorporeal, and implantable).
4	S-4	Structure	Surgical volume for Pediatric and Congenital Heart Surgery: Total Programmatic Volume and Programmatic Volume Stratified by the Five STS-EACTS Mortality Categories	Surgical Volume for Pediatric and Congenital Heart Surgery STS version 2.5: All Index Cardiac Operations (A Cardiac Operation is defined as an operation of Operation Type "CPB" or "No CPB Cardiovascular".) STS version 3.0: Same Surgical volume for pediatric and congenital heart surgery stratified by the five STS-EACTS Mortality Levels, a multi-institutional validated complexity stratification tool See *J Thorac Cardiovasc Surg* 2009;138:1139–1153. O'Brien et al. **An empirically based tool for analyzing mortality associated with congenital heart surgery. Table 1, pp 1140-1146.**
5	S-5	Structure	Surgical Volume for Eight Pediatric and Congenital Heart Benchmark Operations	Surgical Volume for Eight Benchmark Pediatric and Congenital Heart Operations: These 8 Eight Benchmark Pediatric and Congenital Heart Operations are tracked when they are the Primary Procedure of an Index Cardiac Operation. (A Cardiac Operation is defined as an operation of Operation Type "CPB" or "No CPB Cardiovascular".)

Procedure type	**Abbreviation**	**STS–CHSDB Diagnostic and Procedural Inclusionary and Exclusionary Criteria**
1. VSD Repair	VSD	**Procedural Inclusionary Criteria**: 100 = VSD repair, Primary closure 110 = "VSD repair, Patch" 120 = VSD repair, Device* *(Please note that this measure is applicable when one or more septal occluder devices are implanted in the course of a surgical operation for which the Primary Procedure of an Index Cardiac Operation is VSD repair. [A Cardiac Operation is defined as an operation of Operation Type "CPB" or "No CPB Cardiovascular".] A VSD device that is placed as a purely transcatheter technique and not as a component of a cardiac operation is classified as an Interventional Cardiology Procedure and is not tracked as part of this measure.) **Diagnostic Inclusionary Criteria:** 71 = VSD, Type 1 (Subarterial) (Supracristal) (Conal septal defect) (Infundibular) 73 = VSD, Type 2 (Perimembranous) (Paramembranous) (Conoventricular) 75 = VSD, Type 3 (Inlet) (AV canal type) 77 = VSD, Type 4 (Muscular) 79 = VSD, Type: Gerbode type (LV-RA communication) **Diagnostic Exclusionary Criteria:** 80 = VSD, Multiple
2. TOF Repair	TOF	**Procedural Inclusionary Criteria:** 350 = "TOF repair, No ventriculotomy" 360 = "TOF repair, Ventriculotomy, Nontransanular patch" 370 = "TOF repair, Ventriculotomy, Transanular patch" 380 = TOF repair, RV-PA conduit

(*continued*)

Table 4.4 (continued)

Definitions of Quality Measures for Congenital and Pediatric Cardiac Surgery			
Number	**Type**	**Title of Indicator**	**Description**
			Diagnostic Inclusionary Criteria: 290 = TOF 2140 = TOF, Pulmonary stenosis **Diagnostic Exclusionary Criteria** 300 = TOF, AVC (AVSD) 310 = TOF, Absent pulmonary valve 320 = Pulmonary atresia 330 = Pulmonary atresia, IVS 340 = Pulmonary atresia, VSD (Including TOF, PA) 350 = Pulmonary atresia, VSD-MAPCA (pseudotruncus) 360 = MAPCA(s) (major aortopulmonary collateral[s]) (without PA-VSD)
			3. Complete AV Canal Repair — AVC **Procedural Inclusionary Criteria** 170 = AVC (AVSD) repair, Complete (CAVSD) **Diagnostic Inclusionary Criteria:** 100 = AVC (AVSD), Complete (CAVSD) **Diagnostic Exclusionary Criteria:** 110 = AVC (AVSD), Intermediate (transitional) 120 = AVC (AVSD), Partial (incomplete) (PAVSD) (ASD, primum) 300 = TOF, AVC (AVSD)
			4. Arterial Switch — ASO **Procedural Inclusionary Criteria**: 1110 = "Arterial switch operation (ASO)" **Procedural Exclusionary Criteria**: 1120 = Arterial switch operation (ASO) and VSD repair 1123 = Arterial switch procedure + Aortic arch repair 1125 = Arterial switch procedure and VSD repair + Aortic arch repair 1050 = Congenitally corrected TGA repair, Atrial switch and ASO (double switch)
			5. Arterial Switch + VSD repair — ASO+VSD **Procedural Inclusionary Criteria**: 1120 = "Arterial switch operation (ASO) and VSD repair" **Procedural Exclusionary Criteria**: 1110 = Arterial switch operation (ASO) 1123 = Arterial switch procedure + Aortic arch repair 1125 = Arterial switch procedure and VSD repair + Aortic arch repair 1050 = Congenitally corrected TGA repair, Atrial switch and ASO (double switch)
			6. Fontan — Fontan **Procedural Inclusionary Criteria**: 950 = Fontan, Atrio-pulmonary connection 960 = Fontan, Atrio-ventricular connection 970 = "Fontan, TCPC, Lateral tunnel, Fenestrated" 980 = "Fontan, TCPC, Lateral tunnel, Nonfenestrated" 1000 = "Fontan, TCPC, External conduit, Fenestrated" 1010 = "Fontan, TCPC, External conduit, Nonfenestrated" 1030 = Fontan, Other 2340 = Fontan + Atrioventricular valvuloplasty **Procedural Exclusionary Criteria**: Exclude patients age ≥7 years 1025 = Fontan revision or conversion (Re-do Fontan)
			7. Truncus Repair — Truncus **Procedural Inclusionary Criteria**: Primary procedure must be: 230 = "Truncus arteriosus repair" **Procedural Exclusionary Criteria**: Exclude any operation if any of the component procedures is: 240 = Valvuloplasty, Truncal valve 2290 = Valvuloplasty converted to valve replacement in the same operation, Truncal valve 250 = Valve replacement, Truncal valve 2220 = Truncus + Interrupted aortic arch repair (IAA) repair
			8. Norwood — Norwood **Procedural Inclusionary Criteria**: 870 = "Norwood procedure"

(*continued*)

Table 4.4 (continued)

	Definitions of Quality Measures for Congenital and Pediatric Cardiac Surgery			
	Number	**Type**	**Title of Indicator**	**Description**
6	P-1	Process	Multidisciplinary preoperative planning conference to plan pediatric and congenital heart surgery operations	Occurrence of a pre-operative multidisciplinary planning conference to plan pediatric and congenital heart surgery cases. This conference will involve multiple members of the healthcare team, with recommended participation including but not limited to: cardiology, cardiac surgery, anesthesia, and critical care. This measure will be coded on a per operation basis. Reporting of compliance will be as a fraction of all Cardiac Operations. A Cardiac Operation is defined as an operation of Operation Type "CPB" or "No CPB Cardiovascular".
7	P-2	Process	Regularly Scheduled Quality Assurance and Quality Improvement Cardiac Care Conference, to occur no less frequently than once every two months	Occurrence of a regularly scheduled Quality Assurance and Quality Improvement Cardiac Care Conference to discuss care provided to patients who have undergone pediatric and congenital cardiac surgery operations, including reporting and discussion of all major complications and mortalities, and discussion of opportunities for improvement. Reporting of compliance will be by reporting the date of occurrence. Annual compliance of 100 % equals no fewer than six conferences per year.
8	P-3	Process	Availability of intraoperative transesophageal echocardiography (TEE) and epicardial echocardiography	Availability of intraoperative transesophageal echocardiography (TEE) and appropriate physician and sonographer support for pediatric and congenital cardiac operations. Epicardial echocardiography and appropriate physician and sonographer support should be readily available for those patients in whom TEE is contraindicated or less informative. Availability means presence and availability of equipment and staff. This measure will be coded on a per operation basis. Reporting of compliance will be as the fraction of all Cardiac Operations with availability (as opposed to use) of TEE and/or epicardial echocardiography. (A Cardiac Operation is defined as an operation of Operation Type "CPB" or "No CPB Cardiovascular".)
9	P-4	Process	Timing of Antibiotic Administration for Pediatric and Congenital Cardiac Surgery Patients	Measure is satisfied for each Cardiac Operation, when there is documentation that the patient has received prophylactic antibiotics within the hour immediately preceding surgical incision (two hours if receiving vancomycin). (A Cardiac Operation is defined as an operation of operation type "CPB" or "No CPB Cardiovascular".)
10	P-5	Process	Selection of Appropriate Prophylactic Antibiotics and Weight-Appropriate Dosage for Pediatric and Congenital Cardiac Surgery Patients	Measure is satisfied for each Cardiac Operation, when there is documentation that the patient received body weight appropriate prophylactic antibiotics as recommended for the operation. (A Cardiac Operation is defined as an operation of operation type "CPB" or "No CPB Cardiovascular".)
11	P-6	Process	Use of an expanded pre-procedural and post-procedural "time-out"	Measure is satisfied for each Cardiac Operation when there is documentation of performance and completion of an expanded pre-procedural and post-procedural "time-out" that includes the following four elements (A Cardiac Operation is defined as an operation of operation type "CPB" or "No CPB Cardiovascular".): 1. The conventional pre-procedural "time-out", which includes identification of patient, operative site, procedure, and history of any allergies. 2. A pre-procedural briefing wherein the surgeon shares with all members of the operating room team the essential elements of the operative plan; including diagnosis, planned procedure, outline of essentials of anesthesia and bypass strategies, antibiotic prophylaxis, availability of blood products, anticipated or planned implants or device applications, and anticipated challenges. 3. A post-procedural debriefing wherein the surgeon succinctly reviews with all members of the operating room team the essential elements of the operative plan, identifying both the successful components and the opportunities for improvement. This debriefing should take *place prior to the patient leaving the operating room or its equivalent,*and may be followed by a more in-depth dialogue involving team members at a later time. (The actual debriefing in the operating room is intentionally and importantly brief, in recognition of the fact that periods of transition may be times of instability or vulnerabilityfor the patient.) 4. A briefing and execution of a hand-off protocol at the time of transfer (arrival) to the Intensive Care Unit at the end of the operation, involving the anesthesiologist, surgeon, physician staff of the Intensive Care Unit (including critical care and cardiology) and nursing.

(*continued*)

Table 4.4 (continued)

	Definitions of Quality Measures for Congenital and Pediatric Cardiac Surgery			
	Number	**Type**	**Title of Indicator**	**Description**
12	O-1	Outcome	Occurrence of new post-operative renal failure requiring dialysis	For each surgical admission (Index Cardiac Operation) code whether the complication occurred during the time interval beginning at admission to operating room and ending 30 days post-operatively or at the time of hospital discharge, whichever is longer (A Cardiac Operation is defined as an operation of operation type "CPB" or "No CPB Cardiovascular".): STS version 2.5: 220 = Acute renal failure requiring temporary dialysis 230 = Acute renal failure requiring permanent dialysis STS version 3.0: 230 = Renal failure - acute renal failure, Acute renal failure requiring dialysis at the time of hospital discharge 223 = Renal failure - acute renal failure, Acute renal failure requiring temporary dialysis with the need for dialysis not present at hospital discharge 224 = Renal failure - acute renal failure, Acute renal failure requiring temporary hemofiltration with the need for dialysis not present at hospital discharge Please note: Unless a patient requires dialysis prior to surgery, renal failure that requires dialysis after surgery constitutes an operative complication, despite the fact that pre-operative diminished renal perfusion may have contributed to the development of this complication. This measure will be reported as percentage of all Index Cardiac Operations. This measure will also be reported stratified by the 5 STS-EACTS Congenital Heart Surgery Mortality Categories. (STS is developing Congenital Heart Surgery Morbidity Categories. When these STS Congenital Heart Surgery Morbidity Categories are published and available, this metric will be stratified by the STS Congenital Heart Surgery Morbidity Categories instead of the STS Congenital Heart Surgery Mortality Categories.)
13	O-2	Outcome	Occurrence of new post-operative neurological deficit persisting at discharge	For each surgical admission (Index Cardiac Operation) code whether the complication occurred during the time interval beginning at admission to operating room and ending 30 days post-operatively or at the time of hospital discharge, whichever is longer (A Cardiac Operation is defined as an operation of operation type "CPB" or "No CPB Cardiovascular".): 320 = Neurological deficit, Neurological deficit persisting at discharge This measure tracks "new post-operative neurological deficits" that (1) occur during the time interval beginning at admission to operating room and ending at the time of hospital discharge and (2) persist at discharge. Such new post-operative neurological deficits may or may not be related to a stroke. If the new post-operative neurological deficit is the result of a stroke (that occurs during the time interval beginning at admission to operating room and ending at the time of hospital discharge) and the neurological deficit persists at discharge, then the following two complications should both be selected: 320 = Neurological deficit, Neurological deficit persisting at discharge 420 = Stroke Thus, thiscomplication (320 = Neurological deficit, Neurological deficit persisting at discharge) should be coded in situations where a patient has a stroke (during the time interval beginning at admission to operating room and ending at the time of hospital discharge) and the neurological deficit persists at discharge. This measure does not include a neurologic deficit (which may or may not be related to a stroke) that does not persist at discharge. Please note that this complication (320 = Neurological deficit, Neurological deficit persisting at discharge) should be coded even in the situation where the patient has a neurological deficit that is present prior to admission to operating room and this neurological deficit worsens (or a new neurological deficit develops) during the time interval beginning at admission to operating room and ending at the time of hospital discharge. This measure will be reported as percentage of all Index Cardiac Operations. This measure will also be reported stratified by the 5 STS-EACTS Congenital Heart Surgery Mortality Categories. (STS is developing Congenital Heart Surgery Morbidity Categories. When these STS Congenital Heart Surgery Morbidity Categories are published and available, this metric will be stratified by the STS Congenital Heart Surgery Morbidity Categories instead of the STS Congenital Heart Surgery Mortality Categories.)

(*continued*)

Table 4.4 (continued)

	Definitions of Quality Measures for Congenital and Pediatric Cardiac Surgery			
	Number	**Type**	**Title of Indicator**	**Description**
14	O-3	Outcome	Occurrence of arrhythmia necessitating permanent pacemaker insertion	For each surgical admission (Index Cardiac Operation) code whether the complication occurred during the time interval beginning at admission to operating room and ending 30 days post-operatively or at the time of hospital discharge, whichever is longer (A Cardiac Operation is defined as an operation of operation type "CPB" or "No CPB Cardiovascular".): STS version 2.5: 60 = Postoperative AV block requiring permanent pacemaker STS version 3.0: 74 = Arrhythmia necessitating pacemaker, Permanent pacemaker This measure will be reported as percentage of all Index Cardiac Operations. This measure will also be reported stratified by the 5 STS-EACTS Congenital Heart Surgery Mortality Categories. (STS is developing Congenital Heart Surgery Morbidity Categories. When these STS Congenital Heart Surgery Morbidity Categories are published and available, this metric will be stratified by the STS Congenital Heart Surgery Morbidity Categories instead of the STS Congenital Heart Surgery Mortality Categories.)
15	O-4	Outcome	Occurrence of paralyzed diaphragm (possible phrenic nerve injury)	For each surgical admission (Index Cardiac Operation) code whether the complication occurred during the time interval beginning at admission to operating room and ending 30 days post-operatively or at the time of hospital discharge, whichever is longer (A Cardiac Operation is defined as an operation of operation type "CPB" or "No CPB Cardiovascular".): STS version 2.5: 300 = Phrenic nerve injury/paralyzed diaphragm STS version 3.0: 300 = Paralyzed diaphragm (possible phrenic nerve injury) This measure will be reported as percentage of all Index Cardiac Operations. This measure will also be reported stratified by the 5 STS-EACTS Congenital Heart Surgery Mortality Categories. (STS is developing Congenital Heart Surgery Morbidity Categories. When these STS Congenital Heart Surgery Morbidity Categories are published and available, this metric will be stratified by the STS Congenital Heart Surgery Morbidity Categories instead of the STS Congenital Heart Surgery Mortality Categories.)
16	O-5	Outcome	Occurrence of need for Postoperative mechanical circulatory support (IABP, VAD, ECMO, or CPS)	For each surgical admission (Index Cardiac Operation) code whether the complication occurred during the time interval beginning at admission to operating room and ending 30 days post-operatively or at the time of hospital discharge, whichever is longer (A Cardiac Operation is defined as an operation of operation type "CPB" or "No CPB Cardiovascular".): STS version 2.5: 40 = Postoperative mechanical circulatory support (IABP, VAD, ECMO, or CPS) STS version 3.0: 40 = Postoperative/Postprocedural mechanical circulatory support (IABP, VAD, ECMO, or CPS) Please note that this complication should be coded even in the situation where the patient had preoperative mechanical circulatory support if the patient has mechanical circulatory support postoperatively at any time until 30 days post-operatively or the time of hospital discharge, whichever is longer. This measure will be reported as percentage of all Index Cardiac Operations. This measure will also be reported stratified by the 5 STS-EACTS Congenital Heart Surgery Mortality Categories. (STS is developing Congenital Heart Surgery Morbidity Categories. When these STS Congenital Heart Surgery Morbidity Categories are published and available, this metric will be stratified by the STS Congenital Heart Surgery Morbidity Categories instead of the STS Congenital Heart Surgery Mortality Categories.)
17	O-6	Outcome	Occurrence of unplanned reoperation and/or interventional	For each surgical admission (Index Cardiac Operation) code whether the complication occurred during the time interval beginning at admission to operating room and ending 30 days post-operatively or at the time of hospital discharge, whichever is longer (A Cardiac Operation is defined as an operation of operation type "CPB" or "No CPB Cardiovascular".):

Table 4.4 (continued)

	Definitions of Quality Measures for Congenital and Pediatric Cardiac Surgery			
	Number	**Type**	**Title of Indicator**	**Description**
			cardiovascular catheterization procedure	STS version 2.5: 20 = Reoperation during this admission (unplanned reoperation) 240 = Bleeding requiring reoperation STS version 3.0: 22 = Unplanned cardiac reoperation during the postoperative or postprocedural time period 24 = Unplanned interventional cardiovascular catheterization procedure during the postoperative or postprocedural time period 26 = Unplanned non-cardiac reoperation during the postoperative or postprocedural time period 240 = Bleeding, Requiring reoperation *n.b. does not include delayed sternal closure* This measure will be reported as percentage of all Index Cardiac Operations. This measure will also be reported stratified by the 5 STS-EACTS Congenital Heart Surgery Mortality Categories. (STS is developing Congenital Heart Surgery Morbidity Categories. When these STS Congenital Heart Surgery Morbidity Categories are published and available, this metric will be stratified by the STS Congenital Heart Surgery Morbidity Categories instead of the STS Congenital Heart Surgery Mortality Categories.) This measure counts all patients who require any additional unplanned cardiac or non-cardiac operation and/or interventional cardiovascular catheterization procedure occurring (1) within 30 days after surgery or intervention in or out of the hospital, or (2) after 30 days during the same hospitalization subsequent to the operation or intervention. A cardiac operationis defined as any operation that is of the Operation Type of “CPB” or “No CPB Cardiovascular”. The following operations will always be coded as “Planned Reoperation”: (1) Delayed Sternal Closure, (2) ECMO Decannulation, (3) VAD Decannulation, (4) Removal of Broviac catheter. The following operations will always be coded as “Unplanned Reoperation”: (1) Reoperation for bleeding, (2) Reoperation for infection, (3) Reoperation for hemodynamic instability, (4) Reoperation for initiation of ECMO or VAD, (5) Reoperation for residual or recurrent lesion.
18	O-7	Outcome	Operative Mortality Stratified by the Five STS-EACTS Mortality Levels	Operative mortality stratified by the five STS-EACTS Mortality Levels, a multi-institutional validated complexity stratification tool See *J Thorac Cardiovasc Surg* 2009;138:1139–1153. O’Brien et al. **An empirically based tool for analyzing mortality associated with congenital heart surgery. Table 1, pp 1140-1146.**
19	0-8	Outcome	Operative Mortality for Eight Benchmark Operations	Operative Mortality for Eight Benchmark Pediatric and Congenital Heart Operations: These 8 Eight Benchmark Pediatric and Congenital Heart Operations are tracked when they are the Primary Procedure of an Index Cardiac Operation. (A Cardiac Operation is defined as an operation of Operation Type “CPB” or “No CPB Cardiovascular”.) (These 8 Eight Benchmark Pediatric and Congenital Heart Operationsare listed and described in this table in Measure Number S-5.)
20	O-9	Outcome	Index Cardiac Operations Free of Mortality and Major Complication	“Index Cardiac Operations free of mortality and major complication” is defined as the percent of pediatric and congenital heart surgery Index Cardiac Operations free all of the following: (1) Operative mortality, (2) any one or more of the following major complications occurring or diagnosed during the time interval beginning at admission to operating room and ending 30 days post-operatively or at the time of hospital discharge, whichever is longer: *a) Renal failure.* Acute renal failure requiring temporary or permanent dialysis (220, 230, 223, 224) STS version 2.5: 220 = Acute renal failure requiring temporary dialysis 230 = Acute renal failure requiring permanent dialysis STS version 3.0: 230 = Renal failure - acute renal failure, Acute renal failure requiring dialysis at the time of hospital discharge 223 = Renal failure - acute renal failure, Acute renal failure requiring temporary dialysis with the need for dialysis not present at hospital discharge 224 = Renal failure - acute renal failure, Acute renal failure requiring temporary hemofiltration with the need for dialysis not present at hospital discharge

				d) ECMO/VAD. Postop mechanical circulatory support (IABP, VAD, ECMO or CPS) (40) STS version 2.5: 40 = Postoperative mechanical circulatory support (IABP, VAD, ECMO, or CPS) STS version 3.0: 40 = Postoperative/Postprocedural mechanical circulatory support (IABP, VAD, ECMO, or CPS) *e) Paralyzed diaphragm (possible phrenic nerve injury).* STS version 2.5: 300 = Phrenic nerve injury/paralyzed diaphragm STS version 3.0: 300 = Paralyzed diaphragm (possible phrenic nerve injury) *f) Unplanned reoperation.* (20, 22, 26 or 240) STS version 2.5: 20 = Reoperation during this admission (unplanned reoperation) 240 = Bleeding requiring reoperation STS version 3.0: 22 = Unplanned cardiac reoperation during the postoperative or postprocedural time period, exclusive of reoperation for bleeding 24 = Unplanned interventional cardiovascular catheterization procedure during the postoperative or postprocedural time period 26 = Unplanned non-cardiac reoperation during the postoperative or postprocedural time period 240 = Bleeding, Requiring reoperation This measure will be reported as percentage of all Index Cardiac Operations. This measure will also be reported stratified by the 5 STS-EACTS Congenital Heart Surgery Mortality Categories. (STS is developing Congenital Heart Surgery Morbidity Categories. When these STS Congenital Heart Surgery Morbidity Categories are published and available, this metric will be stratified by the STS Congenital Heart Surgery Morbidity Categories instead of the STS Congenital Heart Surgery Mortality Categories.)

Table 4.5 Consensus definitions of the morbidities

Measure	Organ system	Complication	Definitions
12	Renal	Renal failure – acute renal failure, acute renal failure requiring dialysis at the time of hospital discharge	Renal failure – acute renal failure (ROOT Definition) + with new postoperative/postprocedural requirement for dialysis, including peritoneal dialysis and/or hemodialysis. Code this complication if the patient requires dialysis at the time of hospital discharge or death in the hospital. (This complication should be chosen only if the dialysis was associated with acute renal failure.) {"Renal failure – acute renal failure" ROOT definition = acute renal failure is defined as new onset oliguria with sustained urine output <0.5 cc/kg/h for 24 h and/or a rise in creatinine >1.5 times upper limits of normal for age (or twice the most recent preoperative/preprocedural values if these are available), with eventual need for dialysis (including peritoneal dialysis and/or hemodialysis) or hemofiltration. Acute renal failure that will be counted as an operative or procedural complication must occur prior to hospital discharge or after hospital discharge but within 30 days of the procedure. (An operative or procedural complication is any complication, regardless of cause, occurring (1) within 30 days after surgery or intervention in or out of the hospital or (2) after 30 days

(*continued*)

Table 4.5 (continued)

Measure	Organ system	Complication	Definitions
			during the same hospitalization subsequent to the operation or intervention. Operative and procedural complications include both intraoperative/intraprocedural complications and postoperative/postprocedural complications in this time interval.) The complication is to be coded even if the patient required dialysis, but the treatment was not instituted due to patient or family refusal}
12	Renal	Renal failure – acute renal failure, acute renal failure requiring temporary dialysis with the need for dialysis not present at hospital discharge	Renal failure – acute renal failure (ROOT definition) + with new postoperative/postprocedural requirement for temporary dialysis, including peritoneal dialysis and/or hemodialysis. Code this complication if the patient does not require dialysis at the time of hospital discharge or death in the hospital. (This complication should be chosen only if the dialysis was associated with acute renal failure.) {"Renal failure – acute renal failure" ROOT definition = acute renal failure is defined as new onset oliguria with sustained urine output <0.5 cc/kg/h for 24 h and/or a rise in creatinine >1.5 times upper limits of normal for age (or twice the most recent preoperative/preprocedural values if these are available), with eventual need for dialysis (including peritoneal dialysis and/or hemodialysis) or hemofiltration. Acute renal failure that will be counted as an operative or procedural complication must occur prior to hospital discharge or after hospital discharge but within 30 days of the procedure. (An operative or procedural complication is any complication, regardless of cause, occurring (1) within 30 days after surgery or intervention in or out of the hospital or (2) after 30 days during the same hospitalization subsequent to the operation or intervention. Operative and procedural complications include both intraoperative/intraprocedural complications and postoperative/postprocedural complications in this time interval.) The complication is to be coded even if the patient required dialysis, but the treatment was not instituted due to patient or family refusal}
12	Renal	Renal failure – acute renal failure, acute renal failure requiring temporary hemofiltration with the need for dialysis not present at hospital discharge	Renal failure – acute renal failure (ROOT definition) + with new postoperative/postprocedural requirement for temporary hemofiltration. Code this complication if the patient does not require dialysis at the time of hospital discharge or death in the hospital. (This complication should be chosen only if the hemofiltration was associated with acute renal failure.) {"Renal failure – acute renal failure" ROOT definition = acute renal failure is defined as new onset oliguria with sustained urine output <0.5 cc/kg/h for 24 h and/or a rise in creatinine >1.5 times upper limits of normal for age (or twice the most recent preoperative/preprocedural values if these are available), with eventual need for dialysis (including peritoneal dialysis and/or hemodialysis) or hemofiltration. Acute renal failure that will be counted as an operative or procedural complication must occur prior to hospital discharge or after hospital discharge but within 30 days of the procedure. (An operative or procedural complication

(*continued*)

Table 4.5 (continued)

Measure	Organ system	Complication	Definitions
			is any complication, regardless of cause, occurring (1) within 30 days after surgery or intervention in or out of the hospital or (2) after 30 days during the same hospitalization subsequent to the operation or intervention. Operative and procedural complications include both intraoperative/intraprocedural complications and postoperative/postprocedural complications in this time interval.) The complication is to be coded even if the patient required dialysis, but the treatment was not instituted due to patient or family refusal}
13	Neurologic	Neurological deficit, neurological deficit persisting at discharge	Newly recognized and/or newly acquired deficit of neurologic function leading to inpatient referral, therapy, or intervention not otherwise practiced for a similar unaffected inpatient, with a persisting neurologic deficit present at hospital discharge. In other words, new (onset intraoperatively or postoperatively – or intraprocedurally or postprocedurally) neurological deficit persisting and present at discharge from hospital
13	Neurologic	Stroke	"Stroke" ROOT definition = a stroke is any confirmed neurological deficit of abrupt onset caused by a disturbance in blood flow to the brain, when the neurologic deficit does not resolve within 24 h
13	Neurologic	Spinal cord injury, neurological deficit persisting at discharge	Spinal cord injury (ROOT definition) + with a persisting neurologic deficit present at hospital discharge. {"Spinal cord injury" ROOT definition = newly acquired or newly recognized deficit of spinal cord function indicated by physical exam findings, imaging studies, or both}
13	Neurologic	Peripheral nerve injury, neurological deficit persisting at discharge	Peripheral nerve injury (ROOT definition) + with a persisting neurologic deficit present at hospital discharge. {"Peripheral nerve injury" ROOT definition = newly acquired or newly recognized deficit of unilateral or bilateral peripheral nerve function indicated by physical exam findings, imaging studies, or both}
14	Arrhythmia – Arrhythmia necessitating pacemaker	Arrhythmia necessitating pacemaker, permanent pacemaker	Implantation and utilization of a permanent pacemaker for treatment of any arrhythmia including heart block (atrioventricular [AV] heart block)
15	Neurologic	Paralyzed diaphragm (possible phrenic nerve injury)	Presence of elevated hemidiaphragm(s) on chest radiograph in conjunction with evidence of weak, immobile, or paradoxical movement assessed by ultrasound or fluoroscopy
16	Mechanical support utilization	Postoperative/ postprocedural mechanical circulatory support (IABP, VAD, ECMO, or CPS)	Utilization of postoperative/postprocedural mechanical support, of any type (IABP, VAD, ECMO, or CPS), for resuscitation/CPR or support, during the postoperative/ postprocedural time period. Code this complication if it occurs (1) within 30 days after surgery or intervention regardless of the date of hospital discharge or (2) after 30 days during the same hospitalization subsequent to the operation or intervention.
17	Operative/procedural	Unplanned cardiac reoperation during the	Any additional unplanned cardiac operation occurring (1) within 30 days after surgery or intervention in or out

(*continued*)

Table 4.5 (continued)

Measure	Organ system	Complication	Definitions
		postoperative or postprocedural time period, exclusive of reoperation for bleeding	of the hospital or (2) after 30 days during the same hospitalization subsequent to the operation or intervention. A cardiac operation is defined as any operation that is of the operation type of "CPB" or "No CPB Cardiovascular". The following operations will always be coded as "planned reoperation": (1) delayed sternal closure, (2) ECMO decannulation, (3) VAD decannulation, (4) removal of Broviac catheter. The following operations will always be coded as "unplanned reoperation": (1) reoperation for bleeding, (2) reoperation for infection, (3) reoperation for hemodynamic instability, (4) reoperation for initiation of ECMO or VAD, (5) reoperation for residual or recurrent lesion
17	Operative/procedural	Unplanned interventional cardiovascular catheterization procedure during the postoperative or postprocedural time period	Any unplanned interventional cardiovascular catheterization procedure occurring (1) within 30 days after surgery or intervention in or out of the hospital or (2) after 30 days during the same hospitalization subsequent to the operation or intervention
17	Operative/procedural	Unplanned noncardiac reoperation during the postoperative or postprocedural time period	Any additional unplanned noncardiac operation occurring (1) within 30 days after surgery or intervention in or out of the hospital or (2) after 30 days during the same hospitalization subsequent to the operation or intervention

surgical quality assessment and quality improvement initiatives. These initiatives will take on added importance as the public reporting of cardiac surgery performance becomes more common [36, 37].

Pediatric Risk Adjustment for Congenital Heart Disease

5

Kathy Jenkins, Kimberlee Gauvreau, Lisa Bergersen, Meena Nathan, and Ravi Thiagarajan

Abstract

Infants and children with congenital heart disease are a very diverse clinical population and vary considerably in size, anatomy, and physiology. Despite this, over the past decade risk adjustment tools have been developed that account for this diversity in a variety of settings, including the cardiac operating room, intensive care unit, and catheterization laboratory, to allow meaningful comparisons of outcomes among practitioners and institutions. Increasingly reliable methods, along with multicenter data repositories, will allow more accurate benchmarking, and guide improvement.

Introduction

Each year in the United States, about 40,000 children are born with congenital heart defects (CHD) [1]. Between 1999 and 2006, CHD was listed as the primary cause of death in 27,960 people; 48 % of deaths occurred in infants, often following complex expensive surgeries and prolonged intensive care unit (ICU) stay [1]. Congenital heart lesions are characterized by diversity, and differences in anatomy are an important source of variation in risk of death and other adverse outcomes. Judging relative performance among institutions or practitioners requires an understanding of differences in case-mix complexity. Risk factors incorporated in adjustment methods should be limited to intrinsic vulnerabilities of patients, not to vulnerabilities that can vary based on practice patterns or setting of care. Procedure type can be used as a surrogate for anatomic diagnosis in cases where specific diagnoses are universally treated with a single type of procedure.

Risk Adjustment for Cardiac Surgery Outcomes

Most prior work to create risk adjustment models has been done to allow outcome comparisons for short-term mortality after congenital heart surgery. The Aristotle Complexity Adjustment Method is based on the primary procedure of an operation as defined by the Society of Thoracic Surgeons-European Association for Cardiothoracic Surgery (STS-EACTS) Derived Procedure Short List [2, 3] and has been the most commonly used risk adjustment method for mortality in Europe [4, 5]. The Aristotle Basic Complexity Score (ABC Score) defines the complexity of a given operation through three factors: the potential for mortality, the potential for morbidity, and the technical difficulty of the operation. The ABC Score was created from a survey of 50 congenital heart surgeons. Participants were asked to rank all procedures from the STS-EACTS Minimum Database Procedure Short List. Each procedure was scored a value from 0.5 through 5 for mortality, for morbidity, and for technical difficulty. The sum of the three median values ranges from 1.5 to 15, and is the final ABC Score for a procedure [4, 5]. Four ABC Levels were created from the Complexity Scores: 1.5–5.9 = 1, 6.0–7.9 = 2, 8.0–9.9 = 3, and 10.0–15.0 = 4 [4, 5]. A more complicated scoring system, known as the Aristotle Comprehensive Complexity Score, adds additional clinical risk factors.

The Risk Adjustment for Congenital Heart Surgery (RACHS-1) method was developed to adjust for baseline case-mix differences in risk when comparing in-hospital mortality among groups of patients <18 years of age undergoing congenital heart surgery [6, 7]. A nationally representative 11-member panel of pediatric cardiologists and cardiac surgeons used clinical judgment to place surgical procedures defined by the Current Procedural Terminology 4 (CPT-4) and International Classification of Diseases, Ninth Revision, Clinical Modification (ICD-9-CM) codes into six groups with similar risk for in-hospital mortality. These risk categories were then refined using empirical data from the Pediatric Cardiac Care Consortium (PCCC, 1996) and three statewide hospital discharge databases (Illinois, 1994; Massachusetts, 1995; California, 1995). The final method includes six risk categories as well as four additional clinical factors: age at operation (<30 days, 31 days to 1 year, 1–17 years), prematurity, the presence of a major non-cardiac structural anomaly (e.g., tracheoesophageal fistula), and the presence of combinations of cardiac surgical procedures. The mortality rates for congenital heart surgery by RACHS-1 risk category in the Kids' Inpatient Database 2006 are shown in Fig. 5.1. The RACHS-1 model has shown excellent performance characteristics in a variety of settings and does not rely on any particular coding framework [7–11].

RACHS-1 can be used to evaluate differences in in-hospital mortality among groups of patients within a single data set, or to adjust for case mix differences when evaluating the performance of a single institution in comparison to a benchmark

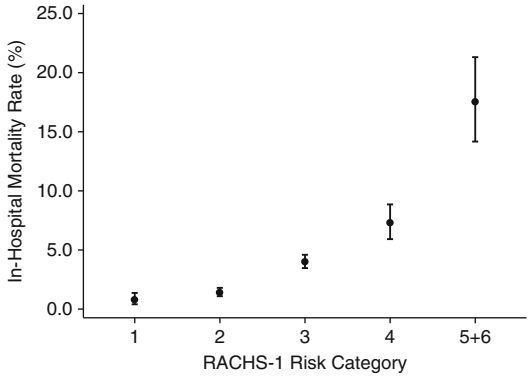

Fig. 5.1 Mortality rates for congenital heart surgery by RACHS-1 risk category

data set. The methodology can be applied in two different ways. A simple approach is to evaluate mortality rates within each of the six risk categories separately. This method, however, can make it difficult for a program to determine how it is doing overall, evaluating its entire caseload. A preferable approach which incorporates cases from all risk categories into a single measure is to calculate a standardized mortality ratio (SMR). The model containing risk category, age group, prematurity, presence of a major non-cardiac structural anomaly, and presence of combinations of cardiac surgical procedures is used to generate an expected in-hospital mortality rate for a program given its case mix. The SMR is then calculated as the program's observed mortality rate divided by its expected mortality rate. A value greater than 1.0 indicates that a program's mortality is higher than would be expected given its case mix, while a value less than 1.0 means that its mortality rate is lower than would be expected.

Recently, the National Quality Forum approved a risk adjustment method that harmonized the RACHS-1 method with a concurrently existing measure administered by the Agency for Healthcare Research and Quality (AHRQ). The AHRQ methodology incorporated some elements of the validated RACHS-1 method including its six risk categories, but other model parameters differed. Developers of the two methodologies worked together to create a new model with improved performance and face validity.

Table 5.1 RACHS-1 final model

	Odds ratio	95 % Confidence interval	P value
RACHS-1 risk category			
1	1.00	–	–
2	1.09	(0.65, 1.82)	0.75
3	2.28	(1.31, 3.94)	0.003
4	2.78	(1.57, 4.93)	<0.001
5 + 6	5.16	(2.91, 9.14)	<0.001
Age group			
0–28 days	6.28	(4.54, 8.69)	<0.001
29–90 days	2.96	(2.16, 4.07)	<0.001
91–364 days	1.19	(0.89, 1.59)	0.23
1–17 years	1.00	–	–
Birth weight 500–2,499 g	1.96	(1.49, 2.59)	<0.001
Multiple procedures	2.19	(1.81, 2.66)	<0.001
Major non-cardiac structural anomaly	1.27	(1.06, 1.51)	0.008
Transfer-in	0.96	(0.76, 1.21)	0.73

SID 2008: $n = 17{,}525$; model c statistic = 0.82

The final model contained RACHS-1 risk category, age (0–28 days, 29–90 days, 91–364 days, 1–17 years), low birth weight (<2,500 g), non-cardiac congenital anomalies, multiple cardiac procedures during the admission, and transfer into the hospital. The final model applied to the 2008 State Inpatient Databases (SID), which included 17,525 cases of congenital heart surgery, is shown in Table 5.1. This model showed excellent discrimination, with an area under the receiver-operator characteristic (ROC) curve of 0.82. The SID includes hospital discharges from 46 states and encompasses 97 % of US procedures. Beginning in spring of 2013, institutions can find algorithms that allow a comparison of their own standardized mortality ratios or adjusted mortality rates to the SID 2011 benchmark as a reference on the AHRQ website.

The Society of Thoracic Surgeons (STS) maintains a national registry that collects information for all cardiovascular procedures performed by cardiovascular surgeons at participating institutions [12]. These institutions receive regular reports about their own mortality and major complications compared to other institutions. Mortality outcomes are stratified by age

and procedural complexity category using the ABC Levels, RACHS-1 risk categories, and more recently by five categories empirically derived from the STS-EACTS registries known as the STS-EACTS Congenital Heart Surgery Mortality Categories (STAT) [13]. Methodology to adjust for other clinical variables to calculate standardized mortality ratios is currently under development. Complication data are also stratified by age and other variables in these reports, and risk adjustment methodology for complications is being developed [14, 15].

Measuring Technical Performance for Congenital Heart Surgery

Outcomes in congenital cardiac surgery are multifactorial, with success being dependent on several components that include (1) preoperative status, complexity of the defect, and adequacy of the diagnostic evaluation and appropriate surgical plan; (2) intraoperative conduct of the operation, which includes conduct of anesthesia, cardiopulmonary bypass, and the actual operative procedure; and (3) postoperative course, which in turn is dependent on the physiological status of the patient, adequacy of the repair, and the delivery of care in the ICU. While all of these components are important and interactive, the technical adequacy of the repair may well be the single most important component in determining a successful outcome.

Technical Performance Score (TPS) is a novel, expert opinion-based and echocardiographically-derived tool for assessing operative performance [16, 17]. This tool was developed and validated at Boston Children's Hospital, and scores have currently been developed for 90 % of congenital cardiac operations covering the entire spectrum of RACHS-1 risk categories. Technical performance of various congenital cardiac operations is categorized into three classes: class 1 (optimal – no residual defect), class 2 (adequate – minor residual defect), and class 3 (inadequate – major residual defect or unplanned surgical or catheter reintervention prior to discharge from index operation). Surgical procedures are subdivided into individual components/sub-procedures and each sub-procedure is assigned one of the aforementioned scores based on specific echocardiographic criteria. If all sub-procedures are assigned an optimal (class 1) score, the overall score for the entire procedure would be optimal (class 1). If individual sub-procedures are scored a mixture of class 1 and class 2, the overall score for the entire procedure would be adequate (class 2). If any sub-procedures are scored as inadequate (class 3), or if there is a need for surgical or catheter-based reintervention in the anatomic area of interest prior to discharge, the overall score would be inadequate (class 3). Only the anatomic areas initially intervened upon are scored.

Ongoing work has shown that inadequate technical performance (class 3) has a strong association not only with worse early outcomes such as higher in-hospital mortality, higher occurrence of major adverse events, and increased resource utilization (longer post-operative length of stay in the hospital), but also with worse midterm outcomes such as higher post-discharge mortality and a greater rate of unplanned midterm reinterventions [18–21].

Risk Adjustment for Cardiac Intensive Care Outcomes

In the pediatric intensive care unit (PICU), severity of illness scores can help objectively assess risk of death and prognosis, and are integral to provision of modern pediatric intensive care. These scores provide objective measures of critical illness and risk of death that can guide better clinical care, help better understand structures and process of care for improvement, guide resource allocation, and improve the quality and efficiency of care provided [22, 23]. Although severity of illness scores specifically for children with cardiac disease receiving intensive care are not available, currently available generic PICU scores have been used in this population for purposes for risk adjustment when assessing outcomes.

Table 5.2 Comparison of current pediatric severity of illness scores for mortality

Score	Year	Site of origin	Collection time	Variables	ROC
PELOD	2003	France, Canada	Entire PICU admission	12	0.980
PIM 2	2003	Australia, UK	At admission	10	0.900
PRISM-III	1996	USA	12-h	PRISM-III	1996

PRISM, Pediatric Risk of Mortality Score (current version PRISM-III); PIM 2, Paediatric Index of Mortality (current version PIM 2); PELOD, Pediatric Logistic Organ Dysfunction score; ROC, Receiver operating characteristic

Development of severity of illness measures in the PICU began with the "Clinical Classifications Scoring System" that helped categorize patients based on their clinical need of requiring routine to more frequent care [22, 23]. This was followed by the development of the "Therapeutic Intervention Scoring System (TISS)" by Cullen et al. [24]. The TISS method categorized patients by the number and complexity of therapeutic interventions received during hospitalization. The increasing recognition that death in the ICU was due to multiple organ failure and that organ failure in turn was related to physiological instability in the ICU led to the use of vital signs upon ICU admission or during the first 24 h of ICU care stay in development of modern severity of illness scoring systems [22, 25]. Commonly used pediatric severity of illness methods in PICUs include the Pediatric Risk of Mortality score (current version PRISM-III), the Pediatric Index of Mortality score (current version PIM2), and the Pediatric Logistic Organ Dysfunction score (PELOD) [26–29].

The currently available pediatric scoring systems were developed using large datasets containing patients admitted to PICUs and included children with acquired and congenital heart disease [26]. Variables for inclusion in these scoring systems were derived from either datasets used for score development or from expert opinions. A comparison of score characteristics, site of development, timing of data collection, number of variables, and performance characteristics of the current pediatric severity of illness scores are shown in Table 5.2. The ability of PRISM-III score to discriminate mortality was evaluated in the Cardiac Intensive Care Unit (CICU) at Boston Children's Hospital using data collected from 1,113 admissions for cardiac medical and surgical indications, during the calendar year 2003. Score performance for discriminating mortality was assessed using the area under the receiver operating characteristic curve (ROC). The ROC was 0.82 for the whole CICU admission cohort, 0.84 for 278 cardiac medical, and 0.87 for 615 surgical patients (unpublished data). Thus, the PRISM-III score was found to accurately discriminate mortality in this cohort of CICU admissions.

Severity of illness measures can potentially be used for the following purposes in PICUs: [22, 25, 30] (1) *Benchmarking and Performance Assessment*: Perhaps the most important use of the severity of illness scores is to help adjust for severity of illness-based differences in case-mix when comparing performance of PICUs (external benchmarking) and for comparing performance of a single PICU over time (internal benchmarking). Internal benchmarking can be used to determine strengths and weaknesses within a PICU and can provide opportunities for improvement in care. External benchmarking can be performed by calculating a standardized mortality ratio; this measure is commonly used by regulatory agencies to identify underperforming PICUs after adjusting for differences in case mix index. (2) *Efficiency of Care Assessment*: One potential method to compare efficiency is using standardized length of ICU stay as a proxy for resource utilization and combining it with SMR. Among PICUs with comparable SMR, more efficient PICUs may have shorter lengths of stay and less efficient PICUs may have longer lengths of stay [30]. (3) *Clinical Research*: Severity of illness can help adjust for differences in case-mix based on severity of illness when comparing population for purposes of research. They can also be used to select populations of subjects with a more homogenous risk of mortality for randomization in clinical trials. (4) *Allocation of Resources in*

the ICU: Estimation of illness severity can aid planning and allocation of scarce ICU resources to areas of high risk or patients that are at higher risk of mortality. (5) *Clinical Decision Making*: Knowledge of the risk of mortality can help provide physicians and families with information regarding prognosis and help decision-making in the choice of treatments. The use of severity of illness scores in clinical decision-making is only of limited value because predicting individual prognoses based on severity of illness scores is usually not accurate [22, 23].

Although assessing severity of illness is a very valuable tool in modern PICUs, several limitations need to be considered prior to their use [25, 31, 32]. Decreased predictive performance may be due to errors in data collection due to either incorrect entry or incorrect interpretation of variable definitions. Scores derived from the general PICU population may not be applicable to specialized populations (e.g., the accuracy of generic PICU scores has not been well characterized in children with cardiac disease). Similarly, these scores may not be applicable to populations from a different geographic region remote from the population used to derive the score. Improved care and change in practice over time may result in a higher predicted mortality than observed and thus result in falsely low SMRs. Thus, these scores may require constant recalibration to preserve their precision. As previously discussed, these scores are not accurate enough to guide provision or withdrawal of therapies at an individual patient level. Finally, the scores are only designed to predict short-term outcomes, such as mortality, and are not useful for prediction of important long-term outcomes, such as functional outcomes or quality of life.

Severity of illness scores are thus valuable tools for assessing the performance and improving quality of care delivered in PICUs. Their performance depends on accurate data collection using established variable definitions. Future development of prognostic models and severity of illness scores should focus on improving ease of use, generalizability to many diseases and populations, and ability to predict longer-term outcomes beyond PICU mortality.

Risk Adjustment for Cardiac Catheterization

With the advancement of cardiac catheterization procedures and techniques and the subsequent increase in size of the patient population, it has become critical to gain a deeper knowledge of the risks of adverse events associated with common catheterization procedures. In 2011, a method to adjust for baseline risk in pediatric cardiac catheterizations was developed. The Catheterization for Congenital Heart Disease Adjustment for Risk Method (CHARM) allows for an equitable comparison of adverse event rates among physicians or institutions by accounting for factors that contribute to the risk assessment of each patient: procedure type, hemodynamic vulnerability, and age [33].

In 2008, a retrospective analysis using data from a single center examined the frequency, severity, and attributability of adverse events (AEs) during cardiac catheterization, and looked for associations between patient and procedural characteristics and occurrence of AEs. An expert panel of 11 interventional cardiologists from 6 institutions participated, and defined attributes of risk by consensus methodology. All AEs were characterized using previously defined severity levels from 1 (none) to 5 (catastrophic). In addition to AE classification, procedures were grouped into 6 different categories based on risk of a high-severity AE [34, 35].

To further classify risk during congenital catheterization procedures, the Congenital Cardiac Catheterization Project on Outcomes (C3PO) is a multi-center registry that began prospectively collecting data from 8 participating centers in 2007 [36]. The prior single-center analysis had demonstrated a strong association between higher procedure type categories defined by consensus and high severity adverse events, defined as level 3 (moderate), 4 (major), and 5 (catastrophic) events [34, 35]. With the larger dataset, the C3PO investigators further refined the procedure type risk categories and improved generalizability by employing both consensus and empirical methods utilizing the multi-center

	Risk Group 1	Risk Group 2	Risk Group 3	Risk Group 4
Diagnostic Case	Age ≥ 1 year	Age ≥ 1 month < 1 year	Age < 1 month	
Valvuloplasty		Pulmonary Valve ≥ 1 month	Aortic Valve ≥ 1 month Pulmonary valve < 1 month Tricuspid valve	Mitral Valve Aortic Valve < 1 month
Device or Coil Closure	Venous collateral LSVC	PDA ASD or PFO Fontan Fenestration Systemic to Pulmonary Artery collaterals	Systemic Surgical Shunt Baffle Leak Coronary Fistula	VSD Perivalvar leak
Balloon Angioplasty		RVOT Aorta dilation < 8 ATM	Pulmonary artery < 4 vessels Pulmonary artery ≥ 4 vessels all < 8 ATM Aorta > 8 ATM or CB Systemic Artery (not aorta) Systemic Surgical Shunt Systemic to Pulmonary Collaterals Systemic vein	Pulmonary Artery ≥ 4 vessels Pulmonary vein

Fig. 5.2 CHARM risk categories

data. Ultimately, four procedure type risk categories were created (Fig. 5.2) [37].

In order to assess the contribution of indicators of hemodynamic vulnerability, data from the multi-center registry were used to examine eight separate hemodynamic variables for inclusion in the risk adjustment method: cardiac index, right ventricular (RV) systolic pressure, RV to systemic pressure ratio, systemic ventricle end-diastolic pressure, mixed venous saturation, systemic arterial saturation, main pulmonary artery systemic pressure, and main pulmonary artery mean pressure. Multivariable modeling identified four indicators of hemodynamic vulnerability which were independently related to the occurrence of high-severity AEs: systemic ventricular end-diastolic pressure ≥18 mmHg, systemic arterial saturation <95 % (or <78 % if single ventricle (SV)), mixed venous saturation <60 % (or <50 % if SV), and pulmonary artery systolic pressure ≥45 mmHg (or mean ≥17 if SV) [33]. Cases were categorized as having none, one, or two or more of these four indicators.

The final CHARM model combined procedure type risk category, number of indicators of hemodynamic vulnerability, and age <1 year [33].

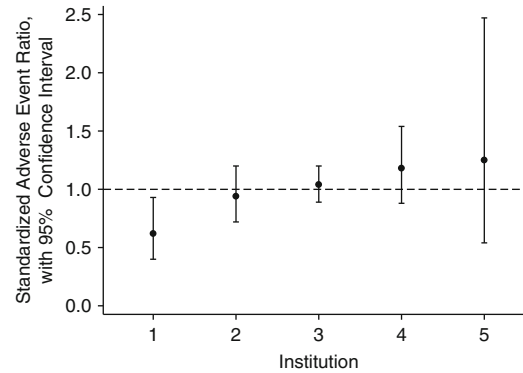

Fig. 5.3 Standardized adverse event ratios (SAERs)

This model can be used to make comparisons across programs or practitioners by calculating standardized adverse event ratios (SAER) (Fig. 5.3). Similar to an SMR, an SAER value greater than 1.0 indicates a program for which the observed rate of high severity adverse events is higher than would be expected given its case mix, while a value less than 1.0 indicates that the observed rate of high severity adverse events is lower than would be expected. The CHARM model received full endorsement from the

National Quality Forum in 2012 as a pediatric quality measure.

The National Cardiovascular Disease Registry® (NCDR®) IMPACT Registry™ has recently begun collecting information about pediatric and congenital cardiac catheterization procedures [38]. Version 2, expected in 2014, will incorporate the CHARM methodology.

Summary

Infants and children with congenital heart disease are a very diverse clinical population, and vary considerably in size, anatomy, and physiology. Despite this, over the past decade risk adjustment tools have been developed that account for this diversity in a variety of settings, including the cardiac operating room, ICU, and catheterization laboratory, to allow meaningful comparisons of outcomes among practitioners and institutions. These increasingly reliable methods, along with multicenter data repositories, allow more accurate benchmarking and guide improvement.

Transport of the Critically Ill Cardiac Patient

6

Aaron G. DeWitt and John R. Charpie

Abstract

This chapter discusses the unique challenges encountered when transporting critically ill pediatric patients with cardiac disease. Whether they have congenital or acquired heart disease, ensuring adequate tissue oxygenation is the primary goal when transporting these patients. Typical strategies have to be modified for the transport process, but this is still accomplished by adopting strategies that (1) optimize systemic oxygen delivery and (2) limit systemic oxygen demand.

When considering transporting these patients, it is of paramount importance to have a well-trained team whose members are skilled with all ages of pediatric patients, but especially neonates. There are further challenges when transporting children on extracorporeal membrane oxygenation. Communication between the referring and accepting institutions must be complete but efficient and should be repeated several times throughout the process in order to adjust management plans.

There are several specific diagnoses in pediatric cardiac critical care that warrant special consideration. Extreme cyanosis associated with D-transposition of the great arteries, requires optimization of systemic oxygen delivery, but requires timely transit in order for balloon atrial septostomy. Obstructed total anomalous pulmonary venous return requires timely transit in order for surgical decompression of the obstructed pulmonary veins. Patients with single ventricle physiology and impaired systemic perfusion often require steps that limit pulmonary blood flow in order to maximize systemic blood flow. Lastly, children with severely impaired ventricular function are often very tenuous, and when considering any intervention, the benefits and risks should be weighed carefully.

Introduction

From the neonate with a suspected cyanotic heart lesion to the adolescent with newly diagnosed cardiomyopathy, pediatric patients with cardiac disease often present specific diagnostic and management challenges that may require referral and transport to centers with highly specialized medical and surgical knowledge necessary to provide care for these patients. Transport of critically ill children with heart disease, in particular, requires close communication and coordination of care between centers and an experienced transport team able to manage the unique physiology of this patient population. The purpose of this chapter is to discuss fundamental principles to consider when transporting critically ill children with either congenital or acquired heart disease. Further, though this chapter is not intended to discuss any particular diagnosis in depth, there are a few specific clinical situations that merit special consideration.

General Principles

The wide range of potential anatomic diagnoses in critically ill children with heart disease makes initial management a daunting task, which is made even more difficult during the transport process. First, transporting these patients adds a layer of complexity given the limited manpower, equipment, and medications available when en route. Second, since echocardiography is the mainstay for diagnosis of the majority of pediatric heart disease, and high-quality imaging and accurate diagnosis may not be readily available at outlying institutions, many patients are transported without a definitive cardiac diagnosis or with only suspected cardiac disease as part of the differential diagnosis. Despite these challenges, clinicians managing and transporting patients with confirmed or suspected complex cardiac disease should focus on one major basic physiologic tenant, namely, the provision of adequate tissue oxygenation. Therefore, this chapter focuses on oxygen metabolism, specifically, the balance between oxygen supply and demand and application of these fundamental principles to transport of critically ill patients with cardiac disease.

Oxygen Supply

Oxygen supply (or oxygen delivery) is determined by both cardiac output and systemic arterial oxygen content.

Cardiac Output

The primary determinants of cardiac output (CO) are heart rate (HR) and stroke volume (SV), and this relationship may be expressed as: $CO = HR \times SV$. The variables that determine stroke volume are preload (e.g., ventricular diastolic filling), afterload (wall stress as determined by aortic pressure or systemic vascular resistance), and contractility. To increase cardiac output, one must optimize at least one of these three parameters.

Perturbations in heart rate and rhythm are not uncommon in pediatric patients. These disturbances occur in isolation or may be associated with congenital heart disease. Symptomatic bradycardia, observed in neonates with congenital complete heart block due to maternal systemic

lupus erythematosus or in adolescents with sick sinus syndrome after Fontan palliation, may require interventions aimed at increasing heart rate prior to and during transport. Cardiac transport teams should universally have epinephrine available, which can be utilized for its β-adrenergic effects. However, if the diagnosis is known in advance, the transport team could consider a more selective chronotropic agent like isoproterenol. Transvenous pacing may not be feasible during transport but, with proper sedation, transcutaneous pacing can be applied if the patient's heart rate does not respond adequately to pharmacologic intervention.

Despite the direct relationship between HR and CO, atrial or ventricular tachycardias may *impair* cardiac output, particularly at fast ventricular rates. Lack of atrioventricular synchrony and impaired ventricular diastolic filling associated with many tachycardias may lead to a reduction in stroke volume and CO. Furthermore, a disproportionately shortened diastole may impact coronary artery blood flow that could be important in certain patients with increased myocardial oxygen demand. Specific therapeutic approaches for tachyarrhythmias include both pharmacologic and/or electrical cardioversion, depending on the degree of hemodynamic compromise, the particular arrhythmia substrate, and any underlying cardiac disease. A complete discussion of therapeutic approaches to tachyarrhythmias is beyond the scope of the chapter. However, if patients can maintain good perfusion and pulses, then treating the tachycardia may not be necessary prior to transport. In general, given the potential for important side effects from certain antiarrhythmic medications, the transport team should try to avoid treating stable, hemodynamically tolerated arrhythmias if possible so that a catastrophic rhythm disturbance does not occur during transport.

Preload, or ventricular diastolic filling, is generally reflected in a patient's intravascular volume status and may be further guided by cardiac ultrasound if available. It is important for the transport team to note the amount of fluid already given by the referring center and the patient's response to fluid boluses. Clinicians who are unfamiliar with caring for critically ill pediatric cardiac patients may be too conservative or too liberal with fluid resuscitation. Physical examination and chest roentgenogram become paramount in monitoring fluid resuscitation when ultrasound is not readily available. While giving intravenous fluid resuscitation as crystalloid or colloid will likely be institutional specific, infusing packed red blood cells may have additional benefits in this population (see Arterial Oxygen Content below).

Limiting afterload in order to improve cardiac output is rarely feasible (or perhaps necessary) in the acute setting of interhospital transport. In fact, often times the vasoactive medications used to support blood pressure during transport cause vasoconstriction and increased afterload. Initiating afterload reduction may induce hypotension and should be done judiciously in a more closely monitored in-hospital setting rather than during transportation. This is especially true for patients with intravascular dehydration, ventricular outflow tract obstruction, pulmonary hypertension, or severe ventricular dysfunction.

There is one major exception to avoiding afterload reduction. In critically ill patients with systemic to pulmonary arterial connections (ductus arteriosus, surgical shunt, etc.), acute afterload reduction may be beneficial. These patients may show evidence of pulmonary overcirculation and some degree of systemic underperfusion, leading to decreased systemic oxygen delivery. Initiation of a peripheral vasodilator (e.g., a phosphodiesterase-3 inhibitor like milrinone) prior to transport may be highly beneficial by improving the pulmonary to systemic blood flow balance.

Improving contractility is readily accomplished by the addition of inotropic medications. The clinical indications for these medications are similar to many intensive care settings and primarily related to evidence for decreased systemic ventricular systolic function. However, there are a few specific considerations in pediatric cardiac patients. First, when selecting inotropic medications for transport, the transporting team should keep in mind the side effects of the medications. For instance, a patient with impaired ventricular

diastolic filling may not tolerate the chronotropic effects of certain adrenergic agents. Second, inotropic agents are generally sympathomimetic drugs. Patients with catecholamine sensitive tachyarrhythmias may have increasing dysrhythmias with infusion of these positive inotropic agents. Third, many newly diagnosed critically ill cardiac patients are neonates and young infants. Neonates and infants have relatively immature calcium handling, and their myocardium relies more heavily on extracellular calcium concentration for adequate contractility. Thus, they may be more responsive to calcium repletion than older children or adults. Lastly, metabolic acidosis can be detrimental to optimal cardiac function and aiming for a normal pH should be a goal prior to transport.

Arterial Oxygen Content

Optimizing arterial oxygen content may be one of the most important interventions made by the referring hospital or transport team, but it is imperative that the pathophysiology is well understood before specific therapies are considered. For example, supplemental oxygen, while detrimental in lesions with pulmonary overcirculation, is essential in patients with pulmonary hypertension and prohibitively cyanotic patients with transposition physiology or obstructed total anomalous pulmonary venous connection.

The first consideration should be the patient's hemoglobin concentration. Extrapolating from the equation for oxygen content, the greatest amount of oxygen delivered to the tissues is derived from oxygen bound to hemoglobin. Since blood transfusion is impractical during transport, if one desires to increase the oxygen-carrying capacity, one must rely on the referring institution to transfuse the patient prior to transport. Since blood transfusion carries some incremental risk, this decision needs to be considered carefully and should not be performed routinely in every patient with cyanotic or acyanotic congenital heart disease. However, if there is significant hemodynamic instability or the systemic arterial oxygen saturation is prohibitively low, blood transfusion is of paramount importance to tissue oxygenation.

If systemic arterial saturation remains low, the next consideration should be the presence of and degree of lung disease. In this regard, the clinical exam and chest X-ray should help guide management decisions. In general, it is best to address clinically significant respiratory issues prior to transport. If there is respiratory distress in the setting of a large pneumothorax or pleural effusion, for example, then it should be evacuated prior to transporting the child. Additionally, if there is significantly increased work of breathing or apnea, then the patient should be intubated and mechanically ventilated for transport.

Supplemental oxygen administration is perhaps the most controversial component of optimizing arterial oxygen content. It is important to remember that supplemental oxygen can range from potentially harmful (e.g., shunt-dependent single ventricle patients) to life saving, and a rational approach to its administration should be used on a case-by-case basis in consultation with the accepting hospital.

Unfortunately, the greatest dilemma occurs in neonates with suspected congenital heart disease, and the definitive diagnosis is unknown. This dilemma was examined retrospectively [1] and patients on high levels of supplemental oxygen were found to be most at risk for metabolic acidosis and arterial hypoxemia upon arrival to the accepting institution. This association, however, does not imply causality. While one could conclude that high levels of supplemental oxygen led to pulmonary overcirculation, systemic underperfusion, and the observed metabolic derangements, one could also surmise that the patients who are more critically ill required higher levels of supplemental oxygen. What this study did show was that there were no differences in outcomes between groups who, during transport, had SpO2 of <75 %, 75–85 %, or >85 %. Thus, empirically aiming for oxygen saturations in the 70s when the diagnosis is unknown is likely an adequate goal during transport.

Prostaglandin E1 Therapy

The final way to increase arterial oxygen content is to increase effective pulmonary blood flow, or the amount of deoxygenated systemic venous blood that is pumped to the pulmonary capillaries for exchange of alveolar oxygen. For certain patients with congenital heart disease, this may be accomplished with prostaglandin E1 (PGE_1) therapy. Pharmacologically, PGE_1 maintains patency of the ductus arteriosus, and it can increase pulmonary blood flow with right-sided obstructive lesions (such as pulmonary atresia). PGE_1 may also be used to increase systemic blood flow in left-sided obstructive lesions.

PGE_1 therapy is indicated whenever a ductal-dependent cardiac lesion is suspected. This generally occurs in one of two settings. The first setting is a nursery or neonatal intensive care unit in a patient with known congenital heart disease by prenatal ultrasound or in a patient with central cyanosis and suspected congenital heart disease. The second setting is an emergency room when a patient presents with cardiogenic shock or cyanosis following ductal closure. For the first situation, initial PGE_1 dose is generally 0.03 mcg/kg/min (to maintain ductal patency), while in the latter setting, higher doses up to 0.1 mcg/kg/min may be required to open a previously closed or closing ductus arteriosus. Higher doses are associated with higher rates of adverse side effects [2]. When accepting the initial transport request, the transporting team will often recommend starting prostaglandin immediately. However, on rare occasions, the medication isn't readily available. Thus, PGE_1 should be a medication carried by the transport team accepting the patient. It should be remembered that PGE_1 can be given intravenously or intra-arterially, if necessary.

Most infants can be started on PGE_1 infusion safely, but it should not be initiated universally. In fact, it may be detrimental to start PGE_1 in patients with or with the potential for pulmonary venous hypertension. One such example is total anomalous pulmonary venous return (TAPVR) with obstruction which is discussed below in more detail. Briefly, in TAPVR there is a pulmonary venous confluence which does not connect to the left atrium, but rather returns oxygenated blood to the right side of the heart through connection to a systemic venous pathway. If this pathway is obstructed anywhere along its course, pulmonary venous hypertension develops leading to pulmonary venous congestion. In this circumstance, the addition of prostaglandins can further exacerbate pulmonary venous obstruction and potentially worsen hypoxemia. In infradiaphragmatic TAPVR, it is theoretically possible that PGE_1 may relax the ductus venosus and improve obstruction, but this remains controversial. Another example where PGE_1 may be counterproductive is severe aortic stenosis without an atrial septal defect. While patients with severe aortic stenosis may require patency of the ductus arteriosus for adequate systemic blood flow, a patent ductus arteriosus can also increase pulmonary blood flow and raise left atrial pressure due to insufficient egress of blood from the left ventricle. Similar to TAPVR, this may lead to worsened pulmonary venous hypertension and pulmonary edema. Thus, initiation of PGE_1 in these circumstances must be carefully considered on a case-by-case basis.

PGE_1 has many side effects [3]. Generally, side effects are well tolerated and are most likely to occur during initiation of the drug. Conversely, if patients have been stable on the PGE_1 infusion prior to transport, side effects during transport are much less likely. The two most important side effects to consider during transport are hypotension and apnea. PGE_1 can cause peripheral vasodilation which can lead to profound hypotension. The transport team should be prepared to administer fluid and/or vasoactive medications to counteract this effect.

Aminophylline can mitigate the risk of apnea in patients on PGE_1 [4]. If, however, they become apneic, the patient should be intubated. The question of whether to prophylactically intubate neonates on PGE_1 is controversial. One retrospective study showed that neonates who were intubated had a higher risk for a major complication (defined as an acute change in cardiovascular, respiratory, or neurologic status) than those who

were not intubated [2]. This held true even when the authors excluded those neonates who were intubated emergently. Thus, the decision to intubate a neonate on prostaglandin should be based on the entire clinical picture, not merely the risk of apnea with PGE_1 infusion.

Oxygen Demand

Although improving oxygen delivery is an important principle for clinicians involved in transporting pediatric patients with heart disease, limiting oxygen demand is an equally important strategy for the most critically ill children. However, it is important to consider each patient on a case-by-case basis because not every patient requires all of these strategies.

There are several strategies employed to reduce oxygen consumption and decrease demand. Common strategies include sedation, intubation, and mechanical ventilation. Patients with increased work of breathing and respiratory distress, in particular, may benefit from sedation, intubation, and mechanical ventilation.

Tachypnea alone is not an appropriate indication for intubation. Many patients, particularly neonates with unrepaired congenital heart disease and pulmonary overcirculation, are tachypneic (but not in distress). Typically, these patients are able to regulate their own minute ventilation and maintain a normal pH and pCO_2 without the need for intubation and mechanical ventilation. Intubating these patients prophylactically can lead to unnecessary complications, and the patients may actually be more difficult to medically manage on the ventilator.

It should be noted that there are a few important groups of patients in whom sedation, intubation, and mechanical ventilation may be detrimental and should be used with caution. For example, patients with severe systemic ventricular dysfunction can be very tenuous with their circulation dependent on high endogenous catecholamines. Any disturbance could cause circulatory collapse and should be avoided unless medically necessary. If sedation is necessary, then sedative choice should be aimed at combating this risk. These patients are discussed in more detail later in the chapter under the Special Considerations section. Another group of patients who merit careful consideration prior to sedation, intubation, and mechanical ventilation are single ventricle patients palliated with cavo-pulmonary connections. Since pulmonary blood flow relies on passive blood flow from the systemic venous circulation, positive pressure ventilation and the loss of negative intra thoracic pressure may have significant detrimental effects on cardiac output.

Another strategy to limit oxygen demand is neuromuscular blockade. This is generally reserved for the most critically ill patients and necessitates the above strategies of sedation, intubation, and mechanical ventilation.

Perturbations in core body temperature can lead to increased oxygen demand. Thus, the usual goal during transport should be to maintain normothermia. This is a challenge for neonates (especially premature neonates) with immature thermoregulation. Hypothermia is a risk not only for neonates but also for any patient due to environmental exposure during the transport process. This risk should be minimized with thermal blankets, layering, hats, etc. Hypothermia produces a stress response, but it also can lead to shivering, which causes increased oxygen demand by skeletal muscles. Hyperthermia also leads to increased metabolic demands, so fevers should be treated aggressively.

Finally, critically ill patients should not have enteral feeds to minimize any aspiration risk during transport and in order to avoid the additional metabolic demand of increased mesenteric blood flow.

Preparing for Transport

The transport process begins when the call is received from the referring institution. In rapid succession, several decisions have to be made: how urgent is the transport, which institution should provide the transport team, what mode of transportation should be used, what transport personnel and equipment are needed, and to which

unit or procedural suite within the accepting institution will the patient be brought. The answers for many of these questions, while critically important, are often institution specific and will not be addressed in this chapter. However, in general, these decisions should be made through a collaborative process involving clinicians from both the referring and accepting institutions.

Communication with the Referring Hospital

Communication between the referring provider and accepting provider is critical in understanding the underlying pathophysiology involved. This should be accomplished in a quick and efficient manner so that the transport process can be initiated appropriately. Table 6.1 describes the typical information that should be obtained. The focus should be on using precise language.

When communicating with referring institutions, it is also important to avoid jargon. Language that is used every day in a pediatric cardiac intensive care unit may not be routine in other units. For instance, instead of using language like "pre-ductal" and "post-ductal," say "right arm" and "leg." This can avoid confusion on the part of the referring institution and avoid false conclusions on the part of the transporting institution.

For the most critical transports, there will be lag time between the initial call and when the transport team arrives. The referring institution should be instructed on what additional information should be obtained and what therapies should be initiated. A focus should be on the referring institution's available resources and what they can do in the interim while they wait for the transport team to arrive. Electrolytes and blood glucose should be optimized. As noted above, this is the only practical time when blood can be transfused. Central venous access can often be obtained depending on the unit in which the child resides – neonatologists are adept at umbilical lines while pediatric intensivists and emergency medicine doctors are skilled at femoral and other forms of central venous access. If patients will require intubation, and the referring physicians are comfortable, then patients can be intubated.

Table 6.1 Initial information necessary for the transport of critically ill patients with cardiac disease

Age of the patient and any known cardiac diagnoses/ surgeries
Brief HPI and pertinent historical data
Physical exam findings with cardiorespiratory exam and pertinent other findings with focus on:
• General appearance including color and perfusion
• Vital signs including heart rate, respiratory rate, temperature, blood pressure (where obtained), and oxygen saturation (where obtained)
• Presence or absence of dysmorphic features
• Work of breathing
• Cardiac exam including palpation and auscultation
• Presence of organomegaly (or jugular venous distension in older individuals)
• Pulses: femoral and radial/brachial
Further diagnostic assessment
• Chest X-ray including heart size and pulmonary vascular markings
• ECG or other assessment of heart rhythm
• Echocardiogram if available
• Laboratory results with close attention to blood gas (including lactate) and hemoglobin/hematocrit
Initial stabilization measures
• Venous and arterial access obtained
• Medications given including drip rates of cardiovascular medications
• Respiratory interventions with close attention to FiO2

Assembling a Team

The training attained by Emergency Medical Service personnel is generally inadequate for the transport of pediatric patients with congenital and acquired heart disease. Even the attention paid to this subject in Pediatric and Neonatal Advanced Life Support training is highly limited compared to the focus on more common pediatric respiratory illnesses.

At least one nurse and one respiratory specialist are necessary for transport of the critically ill child with cardiac disease. Each should have several years of experience caring for pediatric

patients. In particular, they should have experience in caring for critically ill neonates. It is not, however, a prerequisite that they work in a unit dedicated to pediatric cardiac critical care. However, if they lack that experience, then further instruction in cardiac pathophysiology may be necessary.

The decision to send a mid-level provider or attending depends on the referring institution, the accepting institution, to which unit the child will be admitted, and illness severity. For instance, a critically ill neonate for whom the diagnosis is unclear maybe best served by the neonatal transport team. Who goes on the transport is perhaps not as important as the communication between the transport team and the cardiac team (see below).

Finally, the team should bring any vascular access devices and catheters that are appropriate for the size of the patient. The decision whether or not to obtain additional vascular access by the transport team is patient specific. There is a delicate balance between the additional time necessary to obtain access and the time lost getting the patient back to the accepting institution. Therefore, to reiterate above, if the referring institution is able to obtain vascular access while the transport team is en route, they should do so.

Communicating with the Accepting Hospital

Once the transport team arrives and makes their initial assessment, there should be communication with the senior cardiologist, intensivist, or cardiac intensivist at the accepting institution. A joint decision should be made for further stabilization or to proceed with the transport. Prior to the trip back to the accepting institution, there should be an update to the senior physician. This will serve as a way to answer questions he/she may have had after the initial phone call, a way to assess any interventions that had been performed, and provide a chance for any last minute advice. Similarly, updates from transport nurse to the accepting nurse at the accepting institution may be helpful to assure that the appropriate equipment and staffing are readily available on arrival.

Communication with Family

Lastly, it is imperative that members of the transport team communicate with the family prior to transporting an ill child. Usually the parents are quite nervous and scared, and it is important that the transport team explains the process and to briefly let them know what they can expect once they arrive at the accepting institution.

In addition, there are a few practical considerations to discuss. First, obtain general informed consent for transport and for any typical procedures that might be anticipated such as intubation, central venous or arterial line placement, and transfusion. If a cardiac catheterization, balloon atrial septostomy, or ECMO may be required, informed consent should be obtained for these procedures as well. This will prevent treatment delay at the accepting institution.

Second, as many contact phone numbers as possible should be obtained from the parents or guardians. Often times, a single family member can go with the child. However, if not, and the patient needs to go to the operating room after arrival to the accepting institution, then the surgeon will need to be able to contact them. Likewise, the ICU team at the accepting institution will need to be able to reach the family if there is a change in status.

Special Considerations

Practically speaking, there are two primary situations in which a pediatric patient might need to be transported to an institution with a higher level of cardiac care. The first is when there is hemodynamically significant congenital heart disease and a diagnostic and/or therapeutic procedure is required. If pediatric echocardiography is not available at the referring institution, then that procedure can be as simple as an echocardiogram. Even though fetal echocardiography and prenatal diagnosis of congenital heart disease has led to planned deliveries of neonates at specialized centers, there often is still a need for transport [5, 6]. Many times, these patients require further stabilization and/or an intervention only available at the accepting institution.

The second situation encountered is poor cardiovascular function. This could be for a myriad of reasons in patients with either known or highly suspected congenital or acquired heart disease, including cardiomyopathy, myocarditis, and arrhythmia. The care of these patients, from the neonates and infants to the older children and adolescents, can be accomplished by applying the principles outlined above combined with disease-specific principles outlined elsewhere in this book. This section will bring attention to some specific disease processes. They deserve extra attention because patients with these disease processes can be especially ill and appropriate decision making can be the difference between life and death. The approach to three specific situations in neonates and infants will be outlined, followed by ventricular dysfunction most commonly observed in older children. Lastly, transport on extracorporeal membrane oxygenation (ECMO) will be briefly discussed.

Extreme Cyanosis and Dextro-Transposition of the Great Arteries

When dextro-transposition of the great arteries is suspected or confirmed and the atrial septum is restrictive preventing adequate mixing of oxygenated and deoxygenated blood, affected patients can be severely cyanotic and hypoxemic. If the referring institution is comfortable with transporting the patient, and they are otherwise hemodynamically stable, then that can be advantageous to expedite transfer. Prohibitively cyanotic patients (PaO_2 <30 Torr) can be palliated with the following measures, but the required intervention is an emergent balloon atrial septostomy. Patients should be sedated and intubated in order to provide 100 % inspired oxygen. Prostaglandins should be initiated to maintain the ductus arteriosus. Mild respiratory alkalosis may decrease pulmonary vascular resistance and promote pulmonary blood flow. To improve oxygen-carrying capacity, target hematocrit levels should be 45–50 %. Consideration should be given to neuromuscular blockade to decrease metabolic demand. Hypotension, hypocalcemia, metabolic acidosis, and hypoglycemia should be managed aggressively. A small subset of patients with transposition physiology will have increased pulmonary vascular resistance and reverse differential cyanosis (i.e., right arm arterial oxygen saturation will be lower than that of the leg). If this is indeed the case, inhaled nitric oxide should be considered.

Extreme Cyanosis and Lung Disease

The care of cyanotic neonates with evidence of pulmonary parenchymal disease usually falls to the neonatologist, and the differential diagnosis is broad. One potential congenital cardiac cause is obstructed total anomalous pulmonary venous return (TAPVR). The pulmonary venous hypertension and pulmonary venous congestion that develop can mimic pulmonary disease, and thus the diagnosis of TAPVR with obstruction requires a high degree of clinical suspicion.

When transporting these neonates, there are a few important considerations. The first is that sedation, mechanical ventilation, and high amounts of supplemental oxygen may be required. Gas exchange can be limited by pulmonary edema, and this can somewhat be overcome by increasing respiratory support and inspired oxygen. Further, such universal measures as transfusion to increase oxygen-carrying capacity and sedation/paralysis to limit oxygen demand can be employed. However, measures that would increase pulmonary blood flow (starting PGE_1) can serve to exacerbate pulmonary venous obstruction and hypoxemia. Right ventricular dysfunction can ensue secondary to suprasystemic pressures, and severe hypoxemia and metabolic acidosis may impact on left ventricular function as well. Thus, inotropic medications may be required.

The second, and most important consideration, is that TAPVR with obstruction should be considered a surgical emergency. Even if the patient is fully supported on ECMO with normal oxygenation saturations, there is unrepaired pulmonary venous obstruction, progressive pulmonary venous hypertension, and elevated pulmonary vascular resistance. Timely surgical decompression of the veins is necessary to limit irreversible damage.

Single Ventricle Physiology with Impaired Systemic Blood Flow

Patients with single ventricle physiology can have systemic arterial oxygen saturations that are too low, too high, or appropriate (relative to mixed venous oxygen saturations). This section will not discuss patients who have been surgically palliated who present with severe cyanosis secondary to acute thrombosis or stenosis of their systemic to pulmonary artery connection. Rather, it will focus on those pre- and postoperative patients whose systemic to pulmonary artery connections are too prominent. Whether through a ductus arteriosus or surgical shunt, these patients can develop systemic underperfusion at the expense of pulmonary overcirculation. Vascular resistance that is too high in the systemic vascular bed relative to the resistance in the pulmonary arterioles drives this.

These patients often have relatively high arterial oxygen saturations, metabolic acidosis, and possibly elevated lactate levels. The first steps should include limiting oxygen demand – sedate, paralyze, intubate, and mechanically ventilate. Concurrently, the patient's oxygen-carrying capacity should be optimized by assuring the hemoglobin is optimized to at least 15 mg/dL. The transporting team should optimize cardiac output by correcting metabolic acidosis and hypocalcemia.

Since the underlying problem is the inappropriate balance between pulmonary and systemic vascular resistance, the transporting team can use several methods to shift that balance in favor of systemic perfusion. Supplemental oxygen, a potent vasodilator, should be avoided. Inhaled nitrogen, which can lower the fraction of inspired oxygen causing pulmonary vasoconstriction, can often be equipped in transport vehicles. Thus, the respiratory therapist should be alerted prior to transport if nitrogen will be required. Ventilation strategies achieving hypercarbia and mild respiratory acidosis (and thus pulmonary vasoconstriction) can also be utilized.

In the transport setting, decreasing systemic vascular resistance may be more difficult. Phosphodiesterase-3 inhibitors such as milrinone can be used; however, initiation of this medication can lead to systemic hypotension. Ideally, milrinone infusion is started well before the transport team arrives so that the patient is hemodynamically stable before leaving the referring institution. Furthermore, the transport team must be confident in its ability to monitor systemic blood pressure during transport if vasoactive drugs are used.

Severe Ventricular Dysfunction

From older infants to adolescents, children can present with severe ventricular dysfunction at any age from a myriad of etiologies. Those who develop this dysfunction acutely or have an acute on chronic process are those who appear most ill. As far as the transport process is concerned, they should be stabilized as any critically ill patient should: hypotension should be treated with gentle fluid resuscitation and vasoactive agents, and respiratory failure should be treated with respiratory support. If the underlying etiology can be effectively treated (e.g., arrhythmia), then it should.

However, patients with severe dysfunction may be "stable" and not require invasive support. This is where very difficult decisions must be made. If the patient decompensates en route, vascular access and intubation can be exceedingly difficult in an ambulance or helicopter. However, patients who have severe chronic ventricular dysfunction can be very tenuous. That is, their limited cardiac output may be maintained by very high sympathetic tone and endogenous catecholamines. Anything that disrupts this compensatory process, namely, certain types of sedatives and analgesics, can precipitate cardiovascular collapse. Therefore, the decision to sedate a patient for intubation or central venous access should not be taken lightly. Before doing so, initiating a low dose of an inotropic agent such as dopamine or epinephrine may be indicated.

Transporting on ECMO

Sometimes, medical management is inadequate to maintain cardiac output in pediatric patients with severe cardiac disease. Extracorporeal membrane oxygenation may become the only

way to safely transport these patients to a higher level of care. Transporting patients on ECMO involves a well-coordinated plan with the cooperation of a large team.

Certainly there are problems that can occur during transport. However, published data would support this practice as safe. Complication rates of patients transported on ECMO are similar to any patient on ECMO [7–10]. ECMO circuits can be designed specifically for the transport process.

The complexity of transporting patients on ECMO comes when assembling and transporting the medical/surgical team. At minimum, the team should consist of six members. A medical provider with experience caring for critically ill pediatric patients with cardiac disease should serve as the team leader – this may be a senior fellow, an experienced mid-level provider, or attending. A surgeon with experience in neck and groin cannulation is necessary to initiate ECMO. Two perfusionists are necessary to initiate and manage the ECMO circuit. Usually, at least one perfusionist should have experience as a respiratory therapist in order to manage the ventilator. Lastly, two nurses are recommended as well.

The above-described team cannot all fit on a single ambulance or helicopter along with the patient and the ECMO circuit. Thus, two vehicles are necessary to transport the team. At least one perfusionist, one nurse, and the team leader should return with the patient to the accepting hospital.

Conclusion

Transporting critically ill patients with cardiac disease can be anxiety provoking, especially when the diagnosis is unknown. The primary goal is to get the patient from the referring institution to the accepting institution as swiftly and as safely as possible. This involves having an experienced transport team in place, appropriately utilizing the resources of the referring institution and optimizing the balance of systemic oxygen delivery to demand. The latter requires basic knowledge in cardiac pathophysiology, knowing what interventions are available and how those interventions impact the physiology of the individual patient.

General Pre-Operative and Post-Operative Considerations in Pediatric Cardiac Patients

7

Heather A. Dickerson and Antonio G. Cabrera

Abstract

The care of children with cardiac disease who require intensive care requires a thorough understanding of anatomy, fetal and neonatal physiology, and an organized approach to the patient's organ systems. An organized approach to potential pathophysiologic states will enable the caregiver to develop a proactive and, as much as possible, goal-oriented therapeutic plan. The objective of this chapter is to provide clinically relevant aspects on pre- and postoperative intensive care management of children with cardiac disease.

Introduction: Clinical Presentation

Neonates and infants with congenital heart disease (CHD) can present with the following clinical syndromes:

1. *Congestive heart failure*: children and especially neonates will present with congestive heart failure due to volume and/or pressure overload. In neonates, the decline on pulmonary vascular resistance will increase the proportion of left-to-right shunting. Septal defects (i.e., patent arterial duct, large ventricular septal defects) can become evident in the first weeks of life. Other lesions such as truncus arteriosus will become manifest as the pulmonary vascular resistance decreases and mild cyanosis ensues. Neonates and small infants will present with tachypnea and difficulty feeding. BNP levels have been found to be elevated in patients with suspected critical cardiac disease and can serve as an adjuvant in the diagnosis of these critically ill patients. Using a cutoff of 100 pg/mL, B-type natriuretic peptide had a sensitivity of 100 % and a specificity of 98 % identifying critical cardiac lesions [1].
2. *Low cardiac output*: children with left-sided obstructive lesions (i.e., mitral stenosis,

Fig. 7.1 12-lead electrocardiogram demonstrating retrograde atrial capture after a single dose of intravenous adenosine on a patient with atrioventricular reentrant tachycardia (*AVRT*) due to the presence of a concealed accessory pathway

critical aortic stenosis, Shone's complex, and hypoplastic left heart syndrome) can present with signs and symptoms that resemble sepsis. Studies have shown the overlap between these two clinical syndromes [2]. A child with cold extremities, sinus tachycardia with little beat-to-beat variability, diminished arterial pulse volume, hypotension, and acidosis should raise the suspicion of decreased systemic output due to myocardial dysfunction or left ventricular outflow obstruction. Fluid boluses and antibiotics may be important adjuvants for the care of these patients but should not delay the start of prostaglandins. Specifically, children with aortic atresia may have the arterial duct as the only source of coronary blood flow through retrograde flow across the hypoplastic aortic arch.

Children with incessant arrhythmias or complete heart block with profound bradycardia may also present in low cardiac output. A 12-lead EKG that confirms upright P waves in lead I and aVF would confirm sinus rhythm or sinus tachycardia. If supraventricular tachycardia is suspected, intravenous adenosine (0.1 mg/kg/dose) administration can be an important diagnostic tool that will uncover the mechanism of the arrhythmia (Fig. 7.1).

3. *Cyanosis*: persistent cyanosis in neonates and young infants may be due to congenital heart disease with right-to-left shunting or pulmonary venous desaturation secondary to parenchymal lung disease. Clinical determination of cyanosis is possible when there is at least 3–5 g/dL of reduced hemoglobin. Importantly, desaturation (<95 % in the right arm or a more than 3 % difference between right arm and lower extremities) has been found to be highly sensitive and specific when diagnosing critical cardiac disease [3].

Physical Examination

Although the entire physical examination is important when evaluating the cardiovascular system, the following are key aspects of the exam that enhance the individuals' ability to determine abnormalities.

Pulses: the brachial and femoral pulse should be felt together for delay and amplitude; also both brachial pulses should be felt together.

Skin color: nail beds and conjunctivae should be assessed for cyanosis.

Liver palpation: this can be a very helpful finding when trying to identify volume overload. It is best done by feeling lightly from above the costal margin and tracking down; this prevents guarding specially from younger children. A soft 3 cm liver that does not cross the midline may be normal, but a 4 cm tense liver that crosses the midline likely due to enlargement of the left lobe, also called the "failure lobe," is a significant finding. Measuring the liver span with a tape measure provides a more accurate indicator of differences in liver size when assessing and following loading conditions and right ventricular dysfunction. Palpation should extend to the pelvis, as the liver can be enlarged to this level.

Lungs: rales in the infant and even young children may be more a marker of infection than pulmonary edema. Tachypnea and grunting may be present in the absence of rales.

Cardiac: it is important to provide a framework which, if applied rigorously, would improve the accuracy derived from physical examination. First, the examiner should aim to determine the presence of right or left ventricular impulse. This is done by positioning the palm of the right hand over the left sternocostal margin and extending the fingers towards the apex. Right ventricular impulse is normal during the first few days of life and as the pulmonary vascular resistance becomes less prominent. Right ventricular impulse later in life should make the clinician suspicious of elevated pulmonary pressures. Also, in patient with dextroposition or cardiac malposition, an abnormal precordial impulse can alert the clinician to direct a specific search on abnormal findings. In order to auscultate, caregivers may adopt the technique of "dissection" previously described by Liebman [4]. First, it is useful to listen to the entire cardiac cycle in order to get an appreciation for the cadence and to determine what is systolic and what is diastolic. After some practice, it is generally not necessary to feel the arterial pulse to determine what is the first sound (S_1) and what is systole. After that, the auscultator listens to each possible sound and murmur, everywhere and in everyone with discipline. Hence, initially the examiner listens only to S_1, nothing else. After listening on the same manner over the aortic and pulmonary areas for ejection clicks, midsystolic clicks, the second heart sound (S_2), opening snaps, the third heart sound (S_3), and the fourth heart sound (S_4) if present, the auscultator ends with listening to systole and diastole for murmurs with both the diaphragm and the bell.

Chest Radiograph

Plain chest films are used as a screening modality to evaluate for the presence of congenital heart disease or acquired cardiovascular abnormalities. They can provide anatomical and physiological information. The practitioner should develop and organized approach to the description of the chest radiograph. Seven methodic steps may be suggested: technique, situs, heart size and chamber enlargement, pericardium, great vessel anatomy, and pulmonary vascularity. The chest radiograph can be helpful to exclude lung pathology and if the concern for congenital heart disease is high and there is no echocardiography available. Chest x-ray is unlikely better than the physical examination in defining disease severity. It exhibits good accuracy and reproducibility to identify significantly abnormal pulmonary vascularity in children with congenital heart disease. However, with a sensitivity of 24–68 %, its ability to detect decreased pulmonary vascularity is low [5]. In neonates undergoing evaluation for congenital heart disease, the chest film has also low sensitivity for structural heart disease (26–59 %) with a negative predictive value of 46–52 %. Among neonates less than 2 kg or younger than 35 weeks of gestation, the chest film had even lower sensitivity for detecting congenital heart disease [6]. Although caregivers should consider chest films with "classic patterns" ("egg on a string" for transposition, "boot-shaped heart" for tetralogy of Fallot, among other), there are few "classic" films that represent a specific diagnosis in neonates.

Fig. 7.2 Chest radiograph demonstrating a "massive cardiomegaly" in an infant with Ebstein's anomaly of the tricuspid valve

When "massive cardiomegaly" is present, Ebstein's anomaly of the tricuspid valve could be evoked (Fig. 7.2). Massive cardiomegaly in older children should raise the suspicion for dilated cardiomyopathy or pericardial effusion.

12-Lead Electrocardiogram

The 12-lead electrocardiogram (ECG) is the best diagnostic tool to determine the presence of sinus rhythm. It is the gold standard for initial arrhythmia evaluation but is unlikely to be better than the physical exam in defining serious versus benign heart disease. Although the rhythm strip from the monitor in the intensive care can be helpful, it is often insufficient when attempting to discern rhythm characteristics and ischemia. A 12-lead electrocardiogram can be helpful in patients with myocardial ischemia and redirects the diagnosis search (Fig. 7.3). In patients who remain hemodynamically stable, a consultation with an arrhythmia specialist is recommended before antiarrhythmic therapy is started, as the initial treatment choice would affect the efficacy of the additional therapies needed.

Stabilization and Transport

The transport of acutely ill infants and children between facilities requires a specialized team. Physicians, nurse practitioners, nurses, and respiratory therapists play an important role when planning and executing the safe transport of these patients. A report from Yeager et al. showed that although transports to the cardiac intensive care can be carried out without mortality, acidosis (pH $<$ 7.25) and desaturation ($<$70 %) are not uncommon [7]. Start of prostaglandins should take place if there is shock and sepsis is unlikely, or when persistent cyanosis is unresponsive to standard ventilatory management in the absence of significant lung disease. A specific chapter elsewhere in this textbook provides a detailed discussion on this topic.

Prostaglandins

The determination of prostaglandin dependency can be suspected from the fetal echocardiogram. Having the neonatal team place umbilical vascular access may prove capital and may prevent delays in initiating therapy with PGE_1. PGE's are as a continuous intravenous infusion at 0.05–0.1 mcg/kg/min; once therapeutic response is achieved, the rate is reduced to its lowest effective dosage. Maintenance doses are between 0.01 and 0.04 mcg/kg/min; higher doses may be required in patients receiving ECMO support [8]; apnea may be less likely to occur at doses $<$0.015 mcg/kg/min [9]. In emergent situations, PGE_1 may be started at an infusion rate of 0.1 mcg/kg/min, but it is often possible to reduce the dosage to $^1/_2$ or even $^1/_{10}$ without losing the therapeutic effect [10].

Acyanotic infants who have abnormal pulses, poor systemic perfusion, cardiomegaly on chest radiograph, and acidosis are more likely to have a prostaglandin-sensitive lesion [11]. Also, the presence of a murmur increases the likelihood of a prostaglandin-sensitive lesion with the chest radiograph typically showing normal or oligemic lung fields due to reduced pulmonary

Fig. 7.3 12-Lead electrocardiogram of a neonate with myocarditis due to enterovirus demonstrating ST elevation in II, III, aVF, and V6, consistent with injury and QS patterns in V5–V7 suggesting acute lateral wall infarct

blood flow. And be more likely to starting PGE_1 in a critically ill neonate is less likely to harm the child stabilize a child with serious congenital heart disease.

Preoperative Inotropes

The use of preoperative inotropes in children with cardiac disease has not been well studied. There is evidence that dopamine is more effective than dobutamine in the short-term treatment of hypotension in premature infants [12]. These authors' group reported that outcomes of children less than 2 years of age with higher inotrope scores, including dopamine, and with lymphopenia (absolute lymphocyte count <3,000 cell/mcL) are associated with higher mortality and longer length of hospital stay [13]. Dopamine use is known to suppress the production of prolactin, which is thought to play an important role in lymphocyte proliferation; its absence can lower the number of circulating lymphocytes [14].

If perfusion is adequate and end-organ function preserved, inotropes are not necessary. Special attention should be paid when treating poor perfusion in children with ductal-dependent systemic circulation and significantly diminished systemic blood flow. Preoperative use of milrinone could be deleterious as it decreases systemic and pulmonary vascular resistance potentially exacerbating low systemic cardiac output. Additionally, milrinone may prove helpful improving ventricular function and atrioventricular valve regurgitation in patients with hypoplastic left heart syndrome when presenting with pulmonary overcirculation and systemic underperfusion. It may be recommended trying to avoid preoperative inotropes in small children with cardiac disease, even if the mean arterial pressure is slightly lower than the gestational age.

Echocardiogram

The essence of preoperative echocardiography is an accurate and complete diagnosis. Appropriate surgical planning cannot be accomplished without this data. The diagnosis can be made by transthoracic or transesophageal echocardiography.

Preoperative echocardiography must be structured and complete so that cardiac anatomical abnormalities are not missed, as lesions may not occur in isolation. Postoperative outcome is

significantly worse if lesions are missed and thus residual lesions remain.

In addition to specific anatomic considerations below, echocardiography will determine ventricular function which will impact timing of surgical intervention and medical management both before and after surgery. Evaluation of systolic and diastolic function of both the left and right ventricle is important in congenital heart lesions.

Important aspects to evaluate in patients with single-ventricle anatomy include:

1. The anatomy and competency of the atrioventricular valves, analysis of the presence of straddling/overriding and the likelihood of septation, and assessment of obstruction or atresia of either atrioventricular valve. Significant atrioventricular valve insufficiency can also impact surgical candidacy and medical management in the perioperative period.
2. Determination of characteristics leading to biventricular repair or single-ventricle palliation.
3. Assessment of obstruction of either or both semilunar valves or outflow tracts.
4. Determination of the need for a shunt, a pulmonary arterial band, neither (balanced), or a Damus-Kaye-Stansel- or Norwood-type reconstruction to assure systemic outflow.
5. Evaluation of the status of the atrial septal defect and restrictive physiology.

In children with heterotaxy syndrome, it is extremely important to not only elucidate the intracardiac anatomy but also fully evaluate the systemic and pulmonary veins. Frequently, these patients can have bilateral superior vena cavae (especially important to document in case of cannulation and for proceeding with a bidirectional Glenn anastomosis) or else an interrupted inferior vena cava. Hepatic vein entrance into the heart should also be investigated in those patients with an interrupted inferior vena cava with azygous continuation. Pulmonary veins are frequently anomalous, and it is especially important to rule out obstruction in order to determine surgical timing.

When children are undergoing biventricular septation with closure of a ventricular septal defect, it is important to assure that there are no additional defects that require closure. Missing a ventricular septal defect can occur as the ventricular pressures can be equal in defects such as tetralogy of Fallot. Evidence of elevated right-sided pressures by echocardiography can also aid in the postoperative care of patients with congenital heart disease. In children with double outlet right ventricle, care should be taken to delineate the location of the ventricular septal defect as this can determine the possibility of baffling/septation.

Cardiac Catheterization

With improvement in noninvasive diagnostic modalities such as echocardiography, cardiac CT, and MRI, diagnostic cardiac catheterization is not indicated preoperatively in most congenital heart lesions. Below are discussed some lesions in which preoperative cardiac catheterization can be helpful and/or indicated [15].

Balloon atrial septostomy may be needed in neonates with *transposition of the great arteries* to stabilize intracardiac mixing and thus tissue perfusion prior to surgical intervention if there is significant cyanosis due to atrial septal restriction, or in patients with moderate to severely restrictive atrial septal communication and hypoplastic left heart syndrome.

In patients with *pulmonary atresia with intact ventricular septum*, cardiac catheterization can determine the coronary artery distribution and whether there is right ventricular-dependent coronary circulation, as occurs if there are proximal stenoses of the coronary arteries with fistulae to the right ventricle. In this case, decompressing the right ventricle incurs significant risks of coronary ischemia. Catheterization can also aid in assessing the size of the right ventricle and thus whether perforation of the pulmonary valve and decompression of the right ventricle would benefit the patient and allow the possibility of a biventricular circulation or eventual one and a half ventricle repair.

Patients with *pulmonary atresia*, *ventricular septal defect*, *and multiple aortopulmonary collaterals* may also undergo preoperative cardiac

catheterization to determine the anatomy of their collateral flow. In addition to determining the location of collaterals, catheterization determines whether there is dual supply to lung segments, and in this case, collaterals can be occluded to limit this dual supply and promote supply from the pulmonary arteries. Limiting collateral flow also limits return to the heart when on bypass that complicates surgical intervention.

If there is concern for *pulmonary hypertension*, cardiac catheterization can be helpful to confirm the severity and also test reactivity with oxygen, nitric oxide, and medications. This information can help with perioperative treatment of these patients.

In children scheduled to undergo a *Fontan completion*, cardiac catheterization can determine the pulmonary artery pressure (pulmonary vascular resistance), pulmonary artery anatomy, ventricular end-diastolic pressure, and presence of collateral vessels. Collaterals can be coiled at the time of the catheterization, and distal pulmonary artery stenoses not amenable to surgical intervention at the time of the Fontan can be ballooned or stented. Intrapulmonary arteriovenous malformations can be diagnosed and eventually embolized in order to limit postoperative cyanosis. In children with *heterotaxy syndrome*, it is also important to investigate the systemic veins and rule out any connections in the abdomen that could lead to cyanosis postoperatively, if not occluded. Separate hepatic vein drainage should be evaluated as they would need to be incorporated in the Fontan circuit. The pulmonary veins should also be investigated to assure that there is no obstruction as this would negatively impact outcome in children undergoing a Fontan completion.

CNS Evaluation

There is increasing evidence that children with cardiac disease should have evaluation of their neurologic status before surgical intervention as lesions can precede bypass or circulatory arrest [16–19]. These neurologic abnormalities can be anatomic (congenital abnormalities), due to alterations in intrauterine blood flow or ischemia from perinatal instability. Evaluation has traditionally been done by head ultrasound which can evaluate for intraventricular and intracerebral hemorrhage and at times infarction or ischemia. Structural lesions can also be elucidated by ultrasonography. Ultrasonography is portable and noninvasive and does not require sedation/anesthesia to perform, making it an attractive modality in these children. There is recent data promoting MRI evaluation as a more definitive test to evaluate neurologic status [20]. The benefits of the information obtained from a preoperative MRI need to be weighed against the risk of transport and the anesthesia or sedation required to perform the test. If there are significant hemorrhagic and/or ischemic lesions on neurologic evaluation, the patient may benefit from delaying surgery and the associated requirements for heparinization on bypass. In addition, in the presence of neurologic anomalies, patients can be screened for seizure activity that would benefit from treatment. Research continues into the long-term sequelae of these neurologic findings and means to diminish further insults associated with cardiac surgical intervention.

Renal Evaluation

Preoperative evaluation of the structure and function of the kidney is important as acute kidney injury (AKI) is not infrequent in the postoperative care of children with cardiac disease [21, 22]. Renal ultrasonography can rule out structural lesions that would complicate the care of these children [23]. It is important to know if the child has vesicoureteral reflux and requires antibiotic prophylaxis or has other anatomic abnormalities that can impact renal function. Children with AKI preceding surgery are at higher risk for further deterioration with cardiopulmonary bypass and especially with circulatory arrest. These children are more likely to benefit from postoperative peritoneal dialysis, and a catheter can be placed at the time of surgery. Peritoneal dialysis can lessen the effects of AKI in the postoperative period by controlling hyperkalemia and volume overload.

Gastrointestinal Preoperative Management

Preoperative feeding of neonates is a highly debated topic. Children with prostaglandin-dependent systemic circulation (HLHS, interrupted aortic arch, coarctation), truncus arteriosus, and aortopulmonary window are at a significant risk for developing necrotizing enterocolitis (NEC) [24]. These cardiac lesions are associated with limited systemic blood flow, increased pulmonary blood flow and resultant risk for mesenteric ischemia, and decreased intestinal oxygen delivery. There remains significant debate with limited available literature in relation to enteral feeding in these neonates preoperatively [25, 26]. There is a theoretical risk for increasing gastrointestinal metabolic demands, but benefits from early institution of enteral feeding may also be considerable, particularly if applying consistent and standardized feeding algorithms. It is imperative, when instituting enteral feeds in these patients, to monitor for early signs of NEC, including feeding intolerance, temperature instability, abdominal distension, and/or bloody stools. If these signs occur, feeds should be stopped, abdominal radiography should be performed serially, and antibiotics should be instituted if there is concern for NEC.

Feeding Issues in Children with Heterotaxy Syndrome

The primary issue in children with heterotaxy syndrome is the presence of defects in organ laterality associated with significant congenital heart lesions that often require intervention in the neonatal period. These children have a significant risk of malrotation or non-rotation of the bowel, and therefore, feedings should be instituted with caution, especially in the critical period after cardiac surgery when there can also be limited splanchnic blood flow. As the bowel is not attached in a normal fashion, there is the risk of volvulus which can lead to necrosis of the bowel. Children should be evaluated by abdominal ultrasound (identification of the orientation of the superior mesenteric vessels) and an upper GI series (position of the duodenojejunal junction) to rule out malrotation. Feedings should be instituted slowly with a high index of suspicion for feeding intolerance and signs of obstruction. There is controversy of utility and timing of a Ladd procedure to diminish the risk of volvulus. Data from several institutions would recommend expectant management in the neonatal period and elective Ladd procedure when the child has stabilized [27, 28].

Management of Oxygen Delivery

The main goal in intensive care both pre- and postoperatively is maintaining adequate oxygen delivery to the patient's organs. This becomes a paramount issue in the postoperative cardiac patient, especially as they have a nadir in cardiac output approximately 6–12 h after cardiopulmonary bypass. Increasing oxygen delivery (increased cardiac output and/or increased oxygenation) but also decreasing oxygen demands (sedation, cooling) can be beneficial. Oxygen delivery is dependent on systemic cardiac output, oxygen saturation, and hemoglobin concentration as delivery of oxygen (DO_2) is dependent on the product of arterial oxygen content (CaO_2) and cardiac output (CO): $DO_2 = CO \times CaO_2$. The importance of tissue capacity to extract and consume oxygen and the role of microcirculation cannot be overstated. Though much of the discussion will involve means to monitor cardiac output and oxygen delivery and extraction, physical examination remains an important tool, although there is evidence to state that the accuracy of the latter to detect early changes is poor and operator dependent. It is therefore of utmost importance to follow markers that aim to detect changes in anticipation of shock, allowing caregivers to address management timely enough to avoid decompensation.

Basic means of monitoring cardiac output and tissue perfusion include a comparison of core versus peripheral temperature (an increased differential can mean diminished peripheral

perfusion) and evaluation of pulse wave amplitude with pulse oximetry. Trending heart rate pulse wave characteristics can help determine volume status. Noninvasive blood pressure monitoring can be helpful but tends to overestimate low blood pressure and underestimate high blood pressure. End-tidal CO_2 monitoring can be a sign of acute changes in pulmonary blood flow. Inadequate oxygen delivery can be demonstrated by a metabolic lactic acidosis as tissue hypoxia favors anaerobic glycolysis. Prolonged increased lactate levels can be associated with worse perfusion and outcomes.

Mixed venous oxygen saturation (SVO_2) is a measure of oxygen extraction, and if low, can be a sign of inadequate oxygen delivery. It is especially important to monitor trends in mixed venous saturation. This can be monitored invasively (samples from a central venous line in the superior vena cava or right atrium) or by a surrogate measure – near-infrared spectroscopy (NIRS) monitoring which has been shown to correlate with invasive testing [29].

Near-Infrared Spectroscopy

Near-infrared spectroscopy (NIRS) will be extensively discussed in a specific chapter elsewhere in the textbook. NIRS displays a measurement of capillary-venous oxyhemoglobin saturation centimeters below the skin. Measurements are displayed in real time and are noninvasive, thus making the monitor an attractive means of monitoring critically ill patients. Monitoring has been studied both with cerebral and flank measurements with flank measurements being higher than cerebral measurements. A difference of less than 10 between the flank and cerebral measurements indicates a redistribution of perfusion away from the somatic circulation and can be a predictor of anaerobic metabolism. Decreased flank saturations and a decrease in this differential may be an early predictor of necrotizing enterocolitis. The relationship between hypoxia on NIRS monitoring and organ injury has been established with a normothermic threshold of 45 % being associated with cerebral injury [30].

Increasing systemic oxygen delivery can be accomplished by increasing cardiac output (volume resuscitation, inotropes, treatment of pulmonary hypertension, ventilation, assurance of atrioventricular synchrony) or by increasing oxygen content (increased supplemental oxygen, increased hemoglobin). Specifics of management in patient with single- or two-ventricle physiology follow.

Single-Ventricle Physiology

In patients with single-ventricle physiology, it is important to balance systemic and pulmonary blood flow as their combined cardiac output is divided between these two systems and thus more pulmonary blood flow leads to compromised systemic blood flow. Patients with single-ventricle physiology are also more dependent on hemoglobin concentration as they are desaturated at baseline and therefore their systemic oxygen delivery is more dependent on their oxygen-carrying capacity.

NIRS monitoring revealing a cerebral saturation less than 45 % and flank saturations less than 60 % with the difference in the two values approaching zero can predict shock, complications, and a longer ICU stay in single-ventricle patients [30]. The real-time display of NIRS monitoring aids in prospective management and the ability to more closely assure an appropriate balance of the systemic and pulmonary circulations. It is generally more helpful to decrease systemic vascular resistance (SVR) (Milrinone, Nipride, or ACEI in some circumstances) rather than increase pulmonary vascular resistance (PVR) to balance the circulations and maintain oxygen delivery. Increases in SVR in neonates after stage-1 palliation for hypoplastic left heart syndrome are especially dangerous as these may lead to increased pulmonary blood flow and thus cardiac output is stolen from the systemic circulation. Studies have shown that to balance the systemic and pulmonary circulations in patients with single-ventricle physiology, it is more beneficial to increase delivered CO_2 than provide a hypoxic gas mixture as this provided better

systemic oxygen delivery with the same fall in pulmonary blood flow, thus balancing the circulations without compromising systemic oxygenation [31]. This is the case in preoperative patients with hypoplastic left heart syndrome and in those after stage-1 palliation. Children after bidirectional Glenn anastomosis also benefit from hypoventilation or a higher end-tidal CO_2 to improve oxygen delivery as increased CO_2 leads to increased cerebral blood flow, increased return to the Glenn circulation, and thus improved oxygenation. This needs to be carefully counterbalanced by the risks of respiratory acidosis that would compromise PVR. Negative pressure ventilation can significantly increase cardiac output in patients after a Fontan procedure and thus improve systemic oxygen delivery. In patients with a Fontan fenestration, it is important that measures are undertaken to decrease PVR as this leads to less shunting across the fenestration and thus better systemic oxygenation.

Two-Ventricle Physiology

The following are special considerations not discussed above in patients with two-ventricle physiology. In patients with left ventricular failure, it can be helpful to provide respiratory support, as noninvasive positive pressure or else as invasive ventilation (depending on severity and risks), since it decreases left ventricular afterload and end-diastolic pressure (LVEDP) promoting a better cardiac output and oxygen delivery. Patients with two-ventricle physiology and a shunting lesion can have issues with pulmonary overcirculation as in the case with a ventricular septal defect; this can overload the failing left ventricle and lead to decreased systemic flow. Limiting supplemental oxygen can diminish pulmonary blood flow and augment systemic flow. Pulmonary overcirculation can lead to pulmonary edema and resultant pulmonary venous desaturation. Increasing PEEP in these cases can improve pulmonary venous saturation and thus systemic oxygen delivery.

Catecholamine-Resistant Hypotension

Initial therapy to treat low cardiac output syndrome should involve careful volume replacement, adequate management of respiratory status and cardiopulmonary interactions, and inotropic and lusitropic support, but when this fails, other management strategies need to be used to maintain systemic perfusion and oxygen delivery. There are also significant concerns with catecholamine administration including increased myocardial oxygen consumption, increased systemic vascular resistance/afterload, tachycardia, and risk of arrhythmias that can be ameliorated with alternative therapies. Catecholamine-resistant hypotension is not an infrequent issue in postoperative cardiac patients, especially neonates. Options for therapy include vasopressin, corticosteroids, and thyroid hormone replacement.

Vasopressin is an endogenous hormone that is released in response to increases in osmolality or decreases in blood pressure or blood volume. Vasopressin stimulates the V_{1a}, V_{1b}, V_2, and V_3 receptors in the body, resulting in vasoconstriction, water retention, pulmonary arteriolar vasodilation, and activation of various clotting factors. Vasopressin can increase the sensitivity of the vasculature to the vasoconstrictive effects of intrinsic catecholamines, through the V_{1a} receptor [32]. Vasopressin has also been shown to be effective in the face of cellular acidosis and is not affected by local vasodilators. In addition, vasopressin does not cause tachycardia. Activation of the V_3 receptors also augments ACTH production and thus increases cortisol production [32]. Low-dose vasopressin infusions can reverse hypotension and improve end-organ perfusion and urine output in pediatric cardiac surgical patients [33, 34], and the effectiveness may be due to a deficiency that can occur in catecholamine-resistant hypotension [35]. Infusions can range from 0.01 to 0.04 units/kg/h. There are concerns with splanchnic and peripheral ischemia, though this is infrequent at the above doses. The infusion can be associated with significant hyponatremia secondary to its effects on the

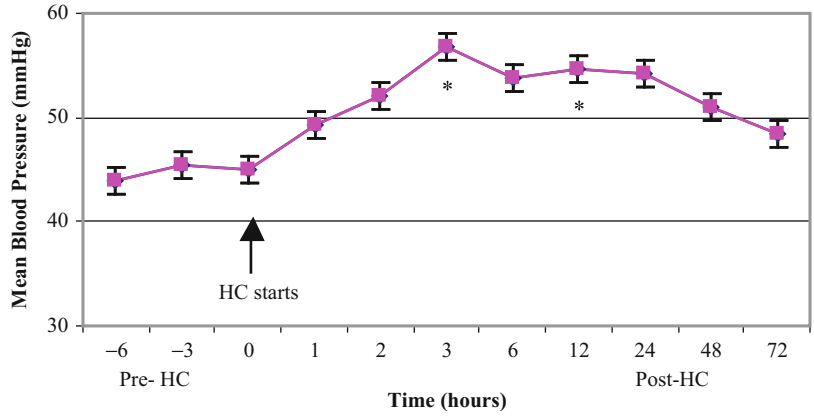

Fig. 7.4 Impact of hydrocortisone administration in patients with catecholamine-resistant hypotension after surgery for congenital heart disease. Changes in the mean arterial blood pressure in patients treated with hydrocortisone (*HC*). Time (hours) before and after the initiation of HC administration and the time when HC administration started are indicated (time points, mean, SE; $*p < .05$ vs. the value at the time of initiation of HC treatment)

V_2 (aquaporin) receptors which lead to an increase in free water retention. Paradoxically, vasopressin infusions in catecholamine-resistant hypotension often lead to increased urine output as there is constriction of the efferent arteriole to a greater extent than the afferent arteriole leading to an increase in the glomerular filtration rate.

Corticosteroids are another potentially effective treatment for catecholamine-resistant hypotension (Figs. 7.4 and 7.5), the most frequently used being hydrocortisone. The probable mechanisms of action of corticosteroids in improving hemodynamics in critically ill children include reversing the downregulation of the adrenergic receptors, increasing the plasma concentration of norepinephrine and cytosolic calcium in myocardial and vascular smooth muscle cells, treating adrenal suppression, limiting inflammatory capillary permeability and systemic vasodilation, and improving the balance of pro- and anti-inflammatory proteins [36–40]. Corticosteroids are active, even if the child does not have adrenal insufficiency (assessed with a cosyntropin stimulation test). Hydrocortisone administration has been shown to increase blood pressure and allow for weaning of catecholamines in pediatric patients after cardiopulmonary bypass [38, 40]. Hydrocortisone is given as a stress dose (50–100 mg/m^2/day) and tapered so there is not acquired adrenal insufficiency. Concerns with steroid administration are hyperglycemia, increased infection risk, gastrointestinal bleeding, spontaneous intestinal perforation, and neurodevelopmental concerns.

Another option therapy for catecholamine-resistant situations is thyroid hormone replacement. Initial data suggest that T_3 replacement increases cardiac index (especially in those with longer bypass times), increases cardiac contractility, increases systolic blood pressure, and decreases systemic vascular resistance without changing diastolic blood pressure [41–44]. The heart rate in patients increased or was unchanged, but there were no serious dysrhythmias. T_3 replacement corresponded to reduced inotrope requirements, decreased mean treatment scores, and a decrease in the time to a negative fluid balance [41–44]. Thyroid replacement can be effective in cases when the thyroid axis has been blunted by the administration of dopamine.

There have also been case reports of the utility of methylene blue for catecholamine-resistant hypotension leading to restoration of peripheral vascular tone and weaning of inotropes. It works through inhibiting the guanylate cyclase enzyme blunting the vasodilation caused by release of nitric oxide [45].

The mean dose of epinephrine at the time of initiation of hydrocortisone treatment and within the next 72 h (*$p < 0.05$ vs. the value at the time hydrocortisone treatment was started)

Bleeding

Bleeding is a frequent issue after cardiac surgery. Not only are there extensive surfaces that can bleed with multiple suture lines but also an inherent level of coagulopathy from multiple reasons. There is dilution of coagulation factors secondary to cardiopulmonary bypass, consumption of coagulation factors and platelets by activation secondary to contact with the bypass circuit, hypothermia leading to less effectiveness of the clotting cascade, fibrinolysis activated by bypass, and residual effects of the heparin required on bypass. Sources of surgical bleeding should be ruled out and intervened upon if necessary. Patients should be warmed to normothermia as this can improve the effectiveness of the patient's intrinsic coagulation system. Protamine should be given if there are residual heparin effects. It should be administered slowly, and patients should be monitored for elevations in pulmonary artery pressure, bronchospasm, and hypotension which appear to be an immune-mediated response. Laboratory evaluation should include assessment of PT, PTT, fibrinogen, and platelet count. A thromboelastogram (TEG) with and without heparinase can also be helpful in targeting therapy. If the TEG is abnormal but normal with heparinase, then protamine should be administered. If both samples are abnormal, blood product administration steered by the TEG profile can be helpful. A prolonged R is consistent with a need for factors (fresh frozen plasma and cryoprecipitate), and decreases in the maximal amplitude suggest a need for platelets [46]. It is important to remember that neonates should receive CMV-negative blood and blood should be radiated, especially if there is a concern that the patient may have DiGeorge syndrome. Activated factor VII can also be used if other measures are not successful. It converts prothrombin to thrombin and reacts with activated platelets which can lead to fibrin clot formation at site of incisions/trauma and lead to a cessation of bleeding [47].

Conclusion

Pre- and postoperative management of pediatric cardiac patients is complex and multifactorial. Successful outcomes cannot be achieved without a well-coordinated interdisciplinary effort. Main therapeutic goals concentrate on maintenance of proper cardiac output and tissue perfusion,

prevention and aggressive management of multiorgan dysfunction, nutritional support, and reduction of morbidity. With critically ill cardiac patients, anticipation matters and the use of tools to identify early signs of decompensation allowing to timely address therapeutic deficiencies is of paramount importance.

Special Considerations in the Medical and Surgical Management of the Premature Infant

8

S. Adil Husain

Abstract

Continued improvements in prenatal diagnosis, preoperative stabilization, surgical techniques, and postoperative management strategies have produced improved outcomes and a more aggressive approach to the treatment of congenital heart disease. These improvements are impacting the decision-making algorithms in the premature infant with congenital heart disease dramatically. A further understanding of this topic requires an analysis of the impact of prematurity upon noncardiac organ system maturation, the challenges of diagnosis and monitoring this particular patient population, and finally an understanding of its association with surgical decision making and outcomes.

Introduction: Definitions and General Implications of Prematurity

Advances in the medical and surgical treatment of congenital heart disease (CHD) have led to improved outcomes and the ability to successfully manage highly complex disease entities. As surgical techniques have evolved and perioperative management strategies have become refined, the ability of multidisciplinary teams to successfully provide care to the infant with CHD has become commonplace. The premature neonatal population has perhaps benefited the most as a result of these advancements.

A discussion of prematurity and its impact upon CHD requires a distinction between prematurity and other neonatal classifications also often discussed and analyzed such as low birth weight (LBW) and small for gestational age (SGA). The entity of prematurity is commonly correlated with LBW as well as SGA. Prematurity is defined as birth prior to 37 weeks gestation, whereas LBW is defined as <2.5 kg and SGA as birth weight less than 10 % predicted. Several studies have demonstrated infants with CHD are more likely to be SGA or of LBW when compared with normal weight infants [1–3].

Prematurity rates have increased most within the subset of late preterm births as defined by 34–36 weeks gestation. Overall, the rates of premature births in the United States continue to grow and were upwards of 13 % of all births in 2006 [4]. In regard to LBW, single institution retrospective studies have consistently described increased hospital mortality rates for neonates undergoing cardiac surgery. These mortality rates range from 15 % to 21 % [5]. In comparison, overall mortality rates for all children undergoing surgical intervention for congenital heart disease are near 4.0 % [6]. Multicenter, large database-related studies have also identified birth weight less than 2.5 kg as an independent risk factor for surgical mortality across a broad spectrum of disease entities [7] (Table 8.1).

Surgical literature on this topic has focused more on birth weight rather than gestational age. However, certain studies have looked at gestational age directly in regard to an association with management principles for CHD. For instance, in a large single-center study of neonates with critical CHD, infants born at 37–38 weeks had a 2.3-fold greater adjusted odds risk of hospital mortality when compared to a reference group born at 39–40 weeks gestation [8] (Fig. 8.1).

Cnota and colleagues investigated infants born 34–40 weeks gestation to determine if any relationship existed between degree of prematurity and risk of death from CHD [9]. They studied the national linked birth/infant death cohort datasets and analyzed over 14.9 million records. CHD deaths were noted to occur in 4,736 patients or 0.04 % of the study population. Comparisons across 1 and 2 week intervals were investigated. All 2-week intervals were statistically significant ($p < .01$). The group argued that knowledge regarding a clear decrease in CHD death rates, as gestational age approaches 40 weeks, should impact decision making regarding elective delivery for the sole indication of prenatally diagnosed CHD. Such data clearly identifies the impact of even mild prematurity upon prognosis.

The exact etiology for poor outcomes in neonates with CHD who are born prematurely is neither well defined nor understood. Incomplete maturation of noncardiac organ systems, challenges regarding both diagnosis and management in the preoperative and postoperative settings, as well as the inherent surgical decision-making controversies in this patient population are all contributors to these poor outcomes. As such, all of these topics will be the focus of this review.

Impact of Prematurity on Specific Non Cardiac Organ Systems

Neurologic

Neurologic development has been found to have direct correlations with CHD. More specifically, term newborns with CHD are known to have an increased incidence of underdeveloped neurologic function. Although brain development occurs

throughout pregnancy, the most distinct and significant embryological changes occur within the third trimester [5].

Oxygen delivery is of paramount importance during this period of neurologic maturation. This is likely the product of increased brain metabolic demands during this fetal period. More specifically, increased neuronal activity is associated with an increased dependency upon appropriate oxygen and substrate delivery. The presence of CHD, and its associated impact upon oxygen delivery, can thus create a detrimental environment for appropriate brain maturation [10].

The most common form of brain injury observed in premature infants is white matter injury. This is also the most prevalent finding in term infants with CHD. Inappropriate development of oligodendrocytes, and the associated lack of myelination, has been attributed to white matter injury. Preoperative brain injury in the form of white matter abnormalities has been noted in 28–39 % of children with CHD. In addition, 40–63 % of newborns with CHD develop perioperative white matter injury [5].

Disease entities, which perhaps best support the hypothesis of cerebral oxygen delivery as

being the main variable impacting brain maturation, include transposition of the great arteries (TGA) and hypoplastic left heart syndrome (HLHS) or other single-ventricle physiology conditions. Newborns with these forms of CHD have brains that receive lower levels of oxygen-saturated blood from the right ventricle as a consequence of disordered fetal circulation. As a result, these forms of CHD have attracted the most focus in respect to investigational attempts at better understanding the impact of CHD upon neurodevelopmental maturation.

Miller and colleagues published their findings of abnormal brain development in newborns with CHD by focusing upon newborns with TGA and those with single-ventricle physiology [11]. They studied 41 term newborns (29 with TGA and 12 with single-ventricle physiology) and compared them to a control cohort of 16 patients. They employed magnetic resonance imaging (MRI), magnetic resonance spectroscopy (MRS), and diffusion tensor imaging (DTI) before cardiac surgical intervention. The group focused upon N-acetylaspartate to choline ratio, lactate to choline ratio, and average diffusivity, and the fractional anisotropy of white matter tracts as metrics to evaluate brain maturation. As compared to control newborns, those with CHD displayed findings consistent with widespread brain abnormalities prior to undergoing heart surgery. In fact, the imaging findings were consistent with those in premature newborns and as such may reflect abnormal brain development in utero.

Studies have also focused upon the possible variations in cerebral growth within infants who have CHD. Ortinau and colleagues studied 67 infants with CHD who underwent preoperative MRI for analysis of brain development and injury [12]. Their study population consisted of 26 children with single-ventricle physiology (10 with right-sided and 16 with left-sided disease), 27 children with TGA, and 14 children with two functioning ventricles but associated aortic arch anomalies. There were 36 control patients. Focal white matter abnormalities were noted in 28 (42 %) of the patients. CHD infants also displayed smaller brain tissue measurements than control infants in the frontal and parietal lobes as well as in the cerebellum and brainstem. When cardiac groups were compared, those with single-ventricle physiology had a smaller brainstem area than those with a two-ventricle circulation. Overall, the group described a 4-week delay in brain developmental by use of a maturation scoring system. In addition, they noted regional variation in impaired growth with the frontal and parietal lobes being most affected, independent of white matter injury.

The concept of brain maturation scoring derived by MRI-obtained data was also employed by Licht and colleagues who studied children with TGA and single-ventricle physiology in regard to brain maturation [13]. Scoring for maturation was a combination of four parameters including myelination, cortical infolding, involution of glial cell migration bands, and the presence of germinal matrix tissue. The authors studied 29 neonates with single-ventricle physiology (all HLHS) and 13 with TGA. Mean gestational age was 38.9 weeks. The mean total maturation score obtained was significantly lower than reported normative data in infants without CHD, corresponding to a delay of 1 month in structural brain development.

Risk factors for pre- and postoperative brain injury in this already susceptible and fragile patient population include hypoxia, hypotension, and physiologic parameters related to low cardiac output. Mechanisms by which these insults can be avoided in the perioperative setting are of significant importance. Focused strategies on peri- and postoperative risk factors have allowed for the development of techniques involving cardiopulmonary bypass and the use of cerebral near-infrared spectroscopy (NIRS) to best recognize and manage risk factors for brain injury. In spite of this understanding and the many technologic and therapeutic advances made in the care of the neonate with CHD, the issue of preoperative brain maturation delay is perhaps of most importance. In fact, preoperative delayed brain development has emerged as the most significant risk factor for subsequent acquired brain injury. The dramatic difference in neurologic development seen in infants with CHD suggests that novel and focused strategies on neuroprotection may be required in this population.

Pulmonary

Respiratory maturation begins early in pregnancy. By the 16th–18th week of gestation, bronchiolar branching is completed with primitive alveoli initiating gas exchange at approximately 24 weeks. Saccules form between 25 and 36 weeks and these saccules mature into alveoli beginning at approximately 36 weeks gestation [14]. By term, the alveolar count reaches approximately 80 % of adult levels. Alveolar simplification is frequently noted in this population if lung biopsy is performed. Furthermore, pulmonary interstitial glycogenosis frequently accompanies immature alveolar development.

The association of neurologic developmental concerns and its affiliation with respiratory function is of significance. Maturation of brainstem regions and control patterns of breathing are impacted in the moderate and late preterm infant. The brainstem increases in length and volume throughout gestation with initial growth during the first half of pregnancy, but with continued increments occurring later [15].

Several studies have described higher frequencies of pulmonary disorders in the preterm infant [16, 17]. Regarding all forms of respiratory morbidity and overall respiratory failure, each week gained until 39 weeks gestation reduces the risk of respiratory morbidity. The Burgandy study, a French epidemiologic study of singleton liveborn babies, evaluated this phenomenon in a population of 173,058 moderate to late preterm infants [17].

Twenty-four studies published between 2000 and 2009 consistently revealed that infants born at 32–36 weeks experience respiratory-related morbidity and mortality at higher rates than term infants [18]. Of the 24 studies identified, 16 were retrospective population-based cohort studies and 8 were observational. Levels of morbidity were comparable to those observed in very preterm infants. This study also focused upon a discussion of infectious variables and the increased overall incidence of RSV within this patient population as well as an understanding of the possible persistence of diminished lung function into adulthood.

Respiratory distress syndrome (RDS) is reported to be five times more prevalent in the premature infant and is the consequence of both a qualitative and quantitative deficiency in pulmonary surfactant in association with an overall immature cardiopulmonary system [19]. The surfactant pool surges at approximately 35 weeks gestation and continues to rise to a peak at term. Increased surfactant, released from type II cells into the alveoli, are also the product of maternal uterine contractions and endogenous steroids, both of which are decreased in prevalence within preterm infants [14].

Bronchopulmonary dysplasia (BPD) is a more chronic form of lung disease, most often found in premature infants who developed RDS. It is readily accepted as the most common lung disease of infancy [20]. Surgical morbidity and mortality are both increased in infants with an established diagnosis of BPD. Mechanical ventilation is frequently necessary in the management strategy for the preterm neonate with CHD. This is especially true in patients with anomalies that are associated with increased pulmonary blood flow. Pulmonary venous engorgement can often lead to decreased pulmonary compliance and the increased work of breathing associated with these anatomic challenges is not well tolerated. Chest wall and airway compliance exceeds that of their noncompliant lung counterparts, and this in turn further decreases tidal volumes and minute ventilation. Although the need for mechanical ventilation is well accepted, its detrimental impact upon lung inflammation and the release of inflammatory mediators, both contributors to BPD, may create a challenging clinical cycle. In addition, high levels of inspired oxygen are a source of significant pulmonary toxicity and thus associated with worsening BPD. The currently accepted definition for BPD is a requirement for supplemental oxygen at 28 days of life, and its severity is graded at 36 weeks corrected gestation based on the persistence of an oxygen requirement [21]. Although this definition is imprecise, it is widely accepted that oxygen use at 36 weeks correlates with a greater than 50 % chance of poor pulmonary and neurodevelopmental outcomes [5].

Following cardiac surgery, mechanical ventilation is often required for significant periods of time. This is especially true in the preterm, low weight neonate who often has an open chest in the immediate recovery period. Spontaneous ventilation can be quite challenging secondary to chest wall instability. Re-intubation rates are noted to be higher in the preterm population following cardiac surgery, upwards of 15–25 % in comparison to <5 % in the term patients [22]. The importance of either phrenic nerve injury with its associated impact upon diaphragm functionality or thoracic duct injury leading to chylous effusions cannot be underestimated. Their incidence is higher in the premature and low birth weight population and, as a result, often leads to more prolonged periods of mechanical ventilation and its associated detrimental sequelae. In addition, challenges with long-term central venous catheters in the upper venous system can also increase the risk of venous congestion and thrombosis, both of which are associated with increased pleural effusions.

There has been a tremendous focus placed upon the prevention of BPD, and the administration of antenatal steroids has been shown to improve survival of these infants and reduce morbidities such as necrotizing enterocolitis (NEC). However, while antenatal steroids increase surfactant pools, they do not consistently decrease the incidence of BPD. Although they may improve short-term adaptation to air breathing, they may also interfere with normal lung developmental patterns. Exogenous surfactant administration has also been suggested as a successful preventative strategy. Although it has a role in treatment for early RDS, its use has not had a major impact on the incidence of chronic lung disease in surviving infants [5].

Gastrointestinal

Understanding gastrointestinal issues associated with prematurity are often limited to intestinal anatomy and pathophysiology. Although gut motility and feeding intolerance are of importance, challenges associated with hypoglycemia, as well as hepatic immaturity and jaundice, are also of significance. The most often described clinical challenge in the preterm neonate regarding gastrointestinal physiology is the management of necrotizing enterocolitis (NEC).

Hypoglycemia

An expert panel convened by the National Institutes of Health in 2008 concluded that there lacked an evidence based process in defining what constitutes neonatal hypoglycemia and in particular, how it relates to brain injury [23]. Low plasma glucose defined as less than 40 mg/dl is reported in upwards of 15 % of term newborns. The frequency and severity of this complication is higher in preterm infants. Following delivery, the fetal blood glucose concentration falls due to the interruption of placenta-driven glucose supply. In low birth weight infants, gluconeogenesis is active, accounting for 30–70 % of endogenous glucose production. However, decreased glycogen stores, immaturity of insulin response in the beta islet cells of the pancreas, as well as increased energy demands all found in the premature infant lead to hypoglycemic states [24, 25].

Unfortunately, there is no single concentration of plasma glucose associated with clinical signs that may be attributed to neonatal hypoglycemia or the direct causation of cerebral injury. Treatment must thus be based upon a flexible approach guided by clinical assessment and not solely on plasma glucose concentrations. In the premature neonate with CHD, increased metabolic demands and challenges with cerebral and systemic perfusion only compound this ill-defined issue. Care must be taken to include an aggressive strategy focused upon serum glucose monitoring and treatment for hypoglycemic episodes when necessary.

Hyperbilirubinemia

Jaundice is the most common reason for hospital re admission in the preterm infant. Severe neonatal hyperbilirubinemia is defined as serum total bilirubin levels >17 mg per 100 ml. The risk of neurologic insult associated with

hyperbilirubinemia is also increased in the preterm infant. There is an approximate eightfold increased risk in the development of total serum bilirubin greater than 20 mg per 100 ml in infants born at 36 weeks gestation (5.2 %) versus those born at 41 or 42 weeks gestation (0.7 % and 0.6 %, respectively) [26].

As with all infants, increased bilirubin is secondary to increased production as well as diminished metabolism and elimination. However, in the preterm infant, production of bilirubin is higher, perhaps due to a higher proportion of senescent red blood cells. The placenta is the primary route of fetal bilirubin excretion. Unlike term infants, the hepatic conjugation system remains immature to a greater degree and for longer durations in the preterm infant [14]. Associated feeding difficulties also lead to a delay in the enterohepatic recirculation of bilirubin, further exacerbating the hepatic bilirubin load.

Preterm infants must be monitored aggressively for the potential toxicity of hyperbilirubinemia. Rare cases occur, involving a progression from elevated bilirubin levels to a state of acute bilirubin encephalopathy. Kernicterus is a devastating and debilitating condition described by the clinical tetrad of the following:

(a) Choreoathetoid cerebral palsy
(b) High-frequency central neural hearing loss
(c) Palsy of vertical gaze
(d) Dental enamel hypoplasia

The US Pilot Kernicterus Registry, a database of voluntarily reported cases of kernicterus, has created a set of recommendations regarding prevention of severe hyperbilirubinemia [27]. In addition, the American Academy of Pediatrics Subcommittee on Hyperbilirubinemia has created phototherapy guidelines that include definitions for management strategies based on level of prematurity as well as those with associated higher risks, including infants with CHD. The Netherlands Neonatal Research Network has published treatment nomograms which can be downloaded from http://www.babyzietgeel.nl/index.php?id=135.

Recognition of these guidelines regarding definitions and management strategies is necessary for the multidisciplinary team caring for children with CHD as the neurologic sequelae of neonatal hyperbilirubinemia may be profound.

Feeding Intolerance and Necrotizing Enterocolitis (NEC)

Feeding intolerance is a common challenge in the preterm infant. Contributing factors include issues with immature oral coordination and swallowing mechanisms, as well as findings of hypotonia and poor strength. In fact, the need for supplemental parenteral nutrition is commonplace as recommended protein and caloric requirements are unattainable with enteral nutrition alone. Unfortunately, this approach increases the risk of intestinal atrophy, hepatic failure, as well as generalized bacteremia. Preterm infants often fail to achieve intrauterine growth rates. In addition, all preterm infants have an increased risk of gastroesophageal reflux disease, which further detracts from adequate caloric intake and weight gain [28].

The intestinal tract not only functions as an organ for digestion and absorption, it also has responsibilities in the areas of immunity as well as endocrine and exocrine functions. The intestinal barrier plays a significant role in the prevention of bacterial translocation and the initiation of its associated inflammatory response. NEC is associated with a host of inflammatory mediators, which in concert are thought to promote the development of intestinal injury. Intestinal permeability is also higher in immature neonates in comparison with term infants. In fact, the permeability of the preterm intestine to carbohydrate markers such as lactulose, exhibits a developmental pattern of improved permeability with maturation.

NEC is one of the most worrisome disease entities in the neonatal population. This is due both to the rapid manner in which it may present and intensify as well as the associated high incidence of mortality (20–50 %). The incidence of morbidity associated with long-term motility difficulties may be the product of stricture formation, short bowel syndrome, and the development of chronic adhesions. Alarmingly, upwards of 90 % of NEC cases occur in

premature infants, and thus NEC is rarely observed in older infants and children. Interestingly, the more premature the infant, the later NEC appears to occur subsequent to birth. It is important to distinguish spontaneous intestinal perforation from NEC. This form of gastrointestinal insult is not accompanied by intestinal necrosis and is associated with the use of glucocorticoids and indomethacin and not likely with enteral feeding [29].

The association between CHD and NEC has been well described. One of the most extensive studies to focus on this association is from McElhinney and colleagues who studied a cohort of 643 neonates with heart disease at a single institution [30]. Of note, 40 % of these patients had single-ventricle physiology. Data was recorded retrospectively in 21 patients with NEC and 70 control neonates matched by diagnosis and age at admission. In particular, the diagnosis of HLHS and truncus arteriosus was independently associated with the development of NEC by multivariate analysis. In addition, earlier gestational age and episodes of low cardiac output were also factors significantly associated with NEC by multivariate analysis. Interestingly, hospital mortality was not increased in the NEC cohort, although it was the direct cause of death in nearly 20 % of patients in whom it did develop.

The mechanism by which CHD predisposes a patient to NEC has also been investigated. Carlo and colleagues support the postulate that diastolic runoff in the abdominal aorta and the subsequent circulatory mesenteric insufficiency are associated with NEC [31]. Their group conducted a case control study of infants with CHD and proven NEC and consisted of a cohort of 18 patients. They compared this group with an age and diagnosis matched cohort of 20 control subjects. They concluded that persistent diastolic flow reversal in the abdominal aortic Doppler profile was associated with an increased risk of NEC in infants with CHD irrespective of gestational age or anatomic type of CHD.

There is a prevailing lack of consensus regarding preoperative enteral nutrition to prostaglandin-dependent neonates. A recent retrospective review suggested that it was likely safe in term neonates [32]. In a worldwide survey, fewer United States caregivers (56 %) reported routine preoperative enteral feeding in prostaglandin-dependent infants when compared with caregivers outside the United States (93 %). Of those respondents willing to feed, approximately two-thirds did not base their decision on the ductal flow direction [33]. Less is known of the safety and role of preoperative feeding of preterm prostaglandin-dependent neonates.

Clearly, several noncardiac organ systems are prone to significant challenges in the preterm infant. More specifically, the challenges posed by circulatory insufficiency create an increased set of risks in patients with CHD. Several associations are important to be recognized. The impact of prematurity and hypoglycemia both play an important role in the concerns for neurologic morbidity. When considering the impact of CHD upon cerebral perfusion and oxygenation, neurodevelopmental variables require further important and focused discussion. In addition, the need for pharmacologic and possible mechanical mechanisms of intervention to treat pulmonary dysfunction creates a significant challenge for the patient with CHD. These therapies may be essential; however these can also have a detrimental impact on the overall management of issues related to prematurity. Finally, the importance of nutritional stability and gastrointestinal maturation in the preoperative optimization and postoperative recovery for patients with CHD is impacted by the challenges of prematurity in regard to feeding intolerance, gut motility, and risk factors associated with NEC. Understanding this complex set of associations lends strongly to a system where multidisciplinary expertise is employed in the management of such patients. Involvement of neonatologists, cardiologists, anesthesiologists, surgeons, pediatric intensivists, as well as other subspecialists is essential in creating management strategies to best care for these complex infants throughout their hospital course.

Diagnostic Challenges in the Preterm Infant

Diagnostic modalities employed in the neonatal population regarding anatomic and physiologic characterization of CHD include echocardiography, CT, MRI, and cardiac catheterization. There exist several challenges regarding these modalities in the premature and LBW infant. Issues surrounding vascular access, sedation, and transportation, as well as overall diagnostic accuracy, all play prominent roles in the ability to perform diagnostic studies and obtain accurate results with all of these aforementioned modalities.

Echocardiography has long been considered the goal standard as the diagnostic test along the entire spectrum of CHD. It has been shown to be highly accurate in both infants and children. However, its accuracy has been found to be more challenging in the low birth weight population. A paucity of studies exist which have focused upon accuracy rates for diagnostic procedures in the premature or LBW population. In addition, the challenges of safely performing these studies have not been well described.

Dorfman and colleagues examined the diagnostic accuracy of echocardiography in 251 infants with weight <2.5 kg with CHD compared to a control cohort of 319 patients matched for diagnosis [34]. The results of initial echocardiograms were compared for diagnostic accuracy with consensus diagnosis on the basis of all confirmatory data available. The group noted 13 major diagnostic errors in LBW infants (5.2 %) compared to 6 in the control group (1.6 %). In comparison, 20 minor errors were found in the LBW group (8.0 %) versus 21 in the control subjects (6.6 %). The technical quality of the studies was not statistically different in the two groups; however, a higher proportion of the studies in the LBW group were categorized as "poor" or "borderline" quality (40 % vs. 28 %). As a result, the group concluded that as surgical- and catheter-based interventions are extended, an increased awareness of the diagnostic limitations of echocardiography was warranted.

The requirement of a multidisciplinary approach with anesthesia as well as cardiology and radiology is essential when planning other diagnostic forms of evaluation such as CT or MRI. These modalities are not only of significance regarding cardiovascular structural issues such as aortic and pulmonary artery anatomy but also becoming increasingly employed as tools to risk stratify patients preoperatively for neurologic related structural concerns. The transportation of these fragile patients, required sedation which may also include ventilator-related management as well as the planning of the radiologic technique employed, all require a very concerted and structured plan for the best chance at obtaining an accurate test within the safest of environments.

As the ability of employing earlier therapeutic strategies becomes more prevalent, the importance of obtaining the most accurate and precise diagnosis with limited risk is becoming a key component in the overall success of managing premature and LBW patients with CHD.

Monitoring Challenges in the Preterm Infant

The monitoring of preterm infants with CHD is essential as seen by the multi-organ issues in this fragile patient population. Hemodynamic monitoring presents challenges as evidenced by small patient size and a very labile hemodynamic and physiologic environment. Costello and colleagues describe an ideal comprehensive hemodynamic profile to have specifically defined characteristics and focus their discussions on the difficulties associated with maintenance of these characteristics across the entire spectrum of gestational age and in the presence of intra- and extracardiac shunting [5] (Table 8.2).

Table 8.2 Characteristics of an ideal monitoring method for preterm infants Costello et al. [5]

Validated against an existing gold standard

Safe
Noninvasive
Feasible: practical, reliable, easily interpreted, cost-effective
Accurate throughout the spectrum of patient populations

Currently, most NICU settings are limited to noninvasive monitoring techniques which allow for the assessment of continuous heart rate, blood pressure, and oxygen saturation in addition to various indirect measures such as capillary refill time, pulse examination, central versus peripheral temperature difference, and serum lactate levels. Normative ranges for all of these monitored variables, blood pressure in particular, lack established definitions in the premature patient population.

Several monitoring modalities are worthy of discussion, which address these challenges. They include bedside limited echocardiography and associated measurement of superior vena cava (SVC) flow, as well as near-infrared spectroscopy (NIRS). Echocardiography has the ability to provide longitudinal assessment of myocardial function, systemic and pulmonary blood flow, and the status of ductal patency. Quantified SVC blood flow has been shown to have a moderate correlation with cardiac output and avoids the challenges associated with cardiac output measurements made at the level of semilunar valve annulus in patients with known intra- or extracardiac shunting. In particular, inappropriate SVC flow has been associated with increased morbidity, mortality, and worse neurodevelopmental outcomes.

NIRS measures regional tissue oxygen saturation by quantifying the differential red and infrared light absorption by oxygenated and deoxygenated hemoglobin. Unfortunately, much like blood pressure, normative data in the premature infant has yet to be defined. In addition, NIRS does not provide direct information regarding tissue oxygen consumption. More specifically, it provides an insight into regional oxygen delivery. There continues to be an evolving and growing acceptance of this modality in the peri- and postoperative CHD patient population. Disagreement still exists as to the impact its use has on long-term outcomes, most specifically neurodevelopmental [35]. Unfortunately, upwards of 25 % of patients undergoing a two-ventricle repair have low cardiac output syndrome, and this is undoubtedly higher in the SVP population. Due to the lack of an accepted and conventional postoperative monitoring technique to assess cardiac output and oxygen delivery, NIRS continues to gain acceptance as a standard of care modality. Its strength is derived in the focus on goal-directed therapy to improve outcomes via a low-risk and noninvasive means of collecting continuous data [36].

Surgical Decision Making and Outcomes for the Preterm Infant

The manner in which to approach operative decision making in the premature and LBW infant has long been a topic of much discussion and controversy. Discrepancies in philosophy have involved many issues. Does prematurity or LBW have a larger impact on surgical survival rates? Does a strategy of delaying surgery to allow for growth and development increase surgical survival rates? How does one answer these questions with limited patients investigated and the inability to truly construct a prospective study? These questions are important not only to recognize but perhaps more importantly to try and answer.

The impact of LBW upon cardiac surgical mortality rates in infants with CHD has been well documented. Curzon and colleagues published a comprehensive analysis based upon the Society of Thoracic Surgeons Database and described a statistically significant increase in mortality for infants with CHD weighing less than 2.5 kg undergoing operative intervention [7].

Table 8.3 Mortality data by complexity scoring Curzon et al. [7]

	Mortality rate, 1–2.5 kg ($n = 517$)	Mortality rate, 2.5–4 kg ($n = 2{,}505$)	Risk ratio (95 % CI)	P
RACHS-1				
2	5.0 (139)	2.4 (709)	2.1 (0.89–4.97)	.03
3	14.2 (183)	5.6 (840)	2.5 (1.62–3.99)	<.01
4	21.9 (105)	9.7 (462)	2.3 (1.43–3.55)	<.01
6	30.0 (90)	21.1 (494)	1.4 (1.00–2.04)	.03
Aristotle				
1	80.0 (5)	26.7 (15)	3.0 (1.16–7.73)	.32
2	11.7 (222)	5.5 (876)	2.1 (1.36–3.37)	<.01
3	13.6 (88)	5.2 (544)	2.7 (1.40–5.01)	<.01
4	20.78 (178)	13.6 (965)	1.5 (1.10–2.13)	<.01
Risk level missing	16.7 (24)	1.9 (105)	8.75 (1.7–45.04)	.08

RACHS-1 risk adjustment for congenital heart surgery 1

The interventions cited included Stage I palliation for SV disease, arterial switch procedure, repair of total anomalous pulmonary venous return, creation of a shunt for Stage I repair of pulmonary atresia with intact ventricular septum, as well as aortic coarctation repair. In addition, mortality rates were shown to be higher within each risk adjustment for congenital heart surgery 1 (RACHS-1) category of patients (Table 8.3).

Recently, Hickey and colleagues reported a very comprehensive analysis comparing LBW with prematurity as variables impacting surgical outcomes [37]. This was within a further investigation into the question of delayed surgical intervention to allow for a period of growth and maturity. Several important conclusions were reached. This study analyzed 1,618 patients admitted to a single institution within 30 days of birth for CHD over a 10 year time period. The group began by employing univariate and subsequently multivariable analyses to investigate the impact of prematurity and birth weight on survival. Both were associated with poor outcome ($p < .0001$ for each) (Figs. 8.2 and 8.3). Gestational age strongly influenced subsequent risk of death and the relationship was nonlinear. In particular, a gestational age <36 weeks was associated with a disproportionately worse survival and was especially marked in infants born less than 32 weeks. In fact, a sub-analysis of the 1,320 children born at 37–42 weeks still described a significant survival association with age ($p = .0027$). Infants born at 42 weeks were predicted to have an 11 % increased survival in comparison to those born at 37 weeks.

When directly comparing prematurity to LBW, the latter revealed a more reliable association with poor outcomes as based upon bootstrap re-samples (53 % versus 99.6 %). The clinical impact of prematurity was largely represented by other factors with strong associations such as unfavorable diagnoses, syndromic findings, and clinical status. In contrast, LBW was associated with a higher early surgical risk over and above other markers of poor prognosis (Table 8.4).

When analyzing LBW, the group found its nonlinear association with death to have an inflection point at approximately 2.0 kg (Fig. 8.3). As such, a further analysis was performed upon the 149 infants who had a birth weight <2.0 kg to investigate the merits of delaying intervention to permit growth and maturation. The group divided this patient population into several categories based upon a thorough retrospective review of

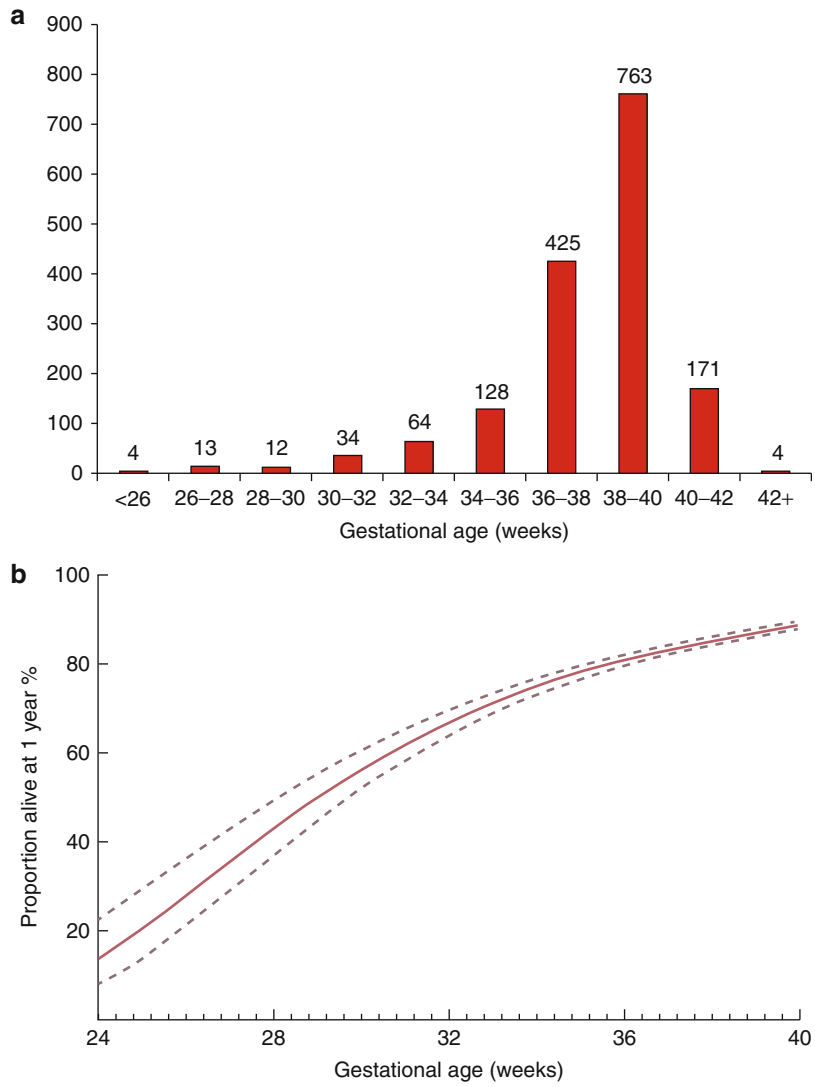

Fig. 8.2 Relationship between gestational age and survival. (**a**) Histogram depicting the distribution of gestational ages in all 1,618 study patients. Term is considered 37–40 weeks; 1,320 infants (82 %) were born at term, and 294 (18 %) were premature (only four infants were born after term). Of the premature children, 197 were born at less than 36 weeks, 49 at less than 32 weeks, and 13 at less than 28 weeks. (**b**) Nomogram illustrating the nonlinear relationship between gestational age and survival in the 1,557 actively managed children. This relationship held true (and was more pronounced) if all 1,618 children were analyzed (including those 61 who received comfort care only) (Hickey et al. [37])

medical records. These categories included usual and delayed surgical intervention, observation (early intervention not necessary), noncardiovascular (higher priority non cardiovascular conditions dictating care), and withdrawal (comfort cares instigated owing to unfavorable prognosis). Time-related survival was compared in the usual versus delayed population. Univariate and multivariable risk adjustment analysis revealed no significant impact of a usual versus delayed strategy. Important determinants of death in the delayed cohort included antenatal diagnosis and the cardiovascular diagnoses of total anomalous pulmonary venous connection, pulmonary atresia with intact ventricular septum, or truncus arteriosus.

Limitations of the study included a small sample size and heterogeneity of studied CHD

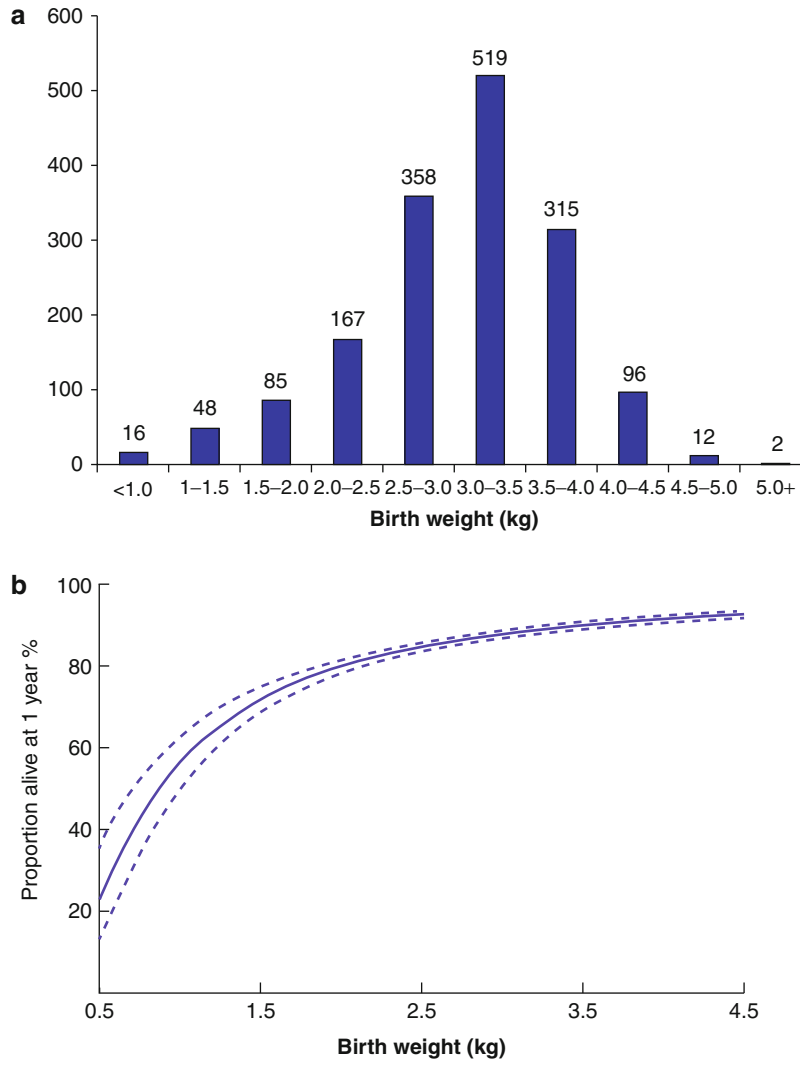

Fig. 8.3 Relationship between low birth weight and survival. (**a**) Histogram depicting the distribution of weights for all 1,618 study patients. Normal birth weight is generally considered to be 3.0–4.5 kg; 928 (57 %) infants were born with normal birth weight. Among the 652 born under 3.0 kg: 301 weighed less than 2.5 kg (low birth weight), 149 weighed less than 2.0 kg, 61 weighed less than 1.5 kg (very low birth weight), and 16 weighed less than 1.0 kg (extremely low birth weight). (**b**) Nomogram illustrating the nonlinear relationship between birth weight and survival in the 1,557 actively managed children. This relationship held true (and was more pronounced) if all 1,618 children were analyzed (including those 61 who received comfort care only) (Hickey et al. [37])

diagnoses and comorbidities, and the focus is primarily upon death rather than more long-term neurologic and other developmental sequelae. Despite these limitations, the data seemed to indicate a lack of consensus regarding an early or delayed approach; however the realization that a delayed approach did have a greater total complication burden.

Regardless of timing and the overall understanding of increased risk and mortality, advances in surgical techniques and the conduct of cardiopulmonary bypass have resulted in improved survival in both premature and LBW infants. The acceptance that early complete repair rather than a staged palliative approach has also lent to the philosophy that operative intervention on premature and LBW infants is warranted [38]. Although there lacks a prospective trial to evaluate the impact of prematurity or LBW upon surgical outcomes, there exist a significant number of studies looking at individual programmatic surgical

Table 8.4 Risk factors for death in all 1,557 of the 1,618 study children who were actively managed Hickey et al. [37]

	PE	*P* value	Reliability (%)
Early risk factors			
Atrioventricular septal defect	1.16	<.0001	98
Total anomalous PV connection	1.35	<.0001	98
Pulmonary atresia, IVS	1.19	.0002	84
Syndromic	1.02	.0007	78
Cardiac arrest at time of diagnosis	2.35	<.0001	78
Antenatal diagnosis	0.50	.0024	74
Birth weight (kg)	−0.49	**<.0001**	73
LV hypoplasia	1.63	<.0001	65
Interrupted aortic arch	1.18	.0097	59
Apgar score at 1 min	−0.15	<.0001	51
Gestational age	–	***.57***	–
Late risk factors			
Congenital CNS defect	3.11	<.0001	50

Gestational age was not a significant independent risk factor; when forced into the model, its level of significance was.57. The only risk factor with acceptable reliability associated with increased risk of late phase death was presence of a congenital CNS malformation. Similar analysis of all 1,618 study children (including those 61 who received comfort care only) revealed precisely the same risk factors listed, with the addition of: presence of trisomy 13 (PE, 2.92; P <.0001), presence of trisomy 18 (PE, 2.14; P <.0001), and presence of Turner syndrome (PE, 1.72; P =.018). *PE* Parameter estimate, *PV* Pulmonary vein, *IVS* intact ventricular septum, *LV* left ventricular, *CNS* central nervous system

results [39–44]. Overall survival rates for infants undergoing corrective or palliative reconstruction for CHD in these studies were 80–87 % [22]. These rates were indeed lower than for infants of normal weight with similar cardiac lesions. In addition, although most studies also confirmed an increased rate of morbidity for surgery in the LBW infant population; the combined effect of prolonged attempts at growth on more chronic forms of morbidity strengthened the argument for early primary repair.

The evaluation and management of the premature infant poses several challenges. The importance of addressing other congenital anomalies and genetic abnormalities is well recognized. A multidisciplinary team is required to address multi-organ issues, challenges regarding diagnosis and monitoring, and finally an overall comprehensive approach to peri- and postoperative management. It is clear that these infants pose higher risks for both morbidity and mortality. However, current medical and surgical strategies have allowed for absolute survival rates that are quite acceptable.

Abstract

Accurate knowledge of embryology is essential for interpretation of congenital cardiac malformations. Recent advances made in the understanding of cardiac development now make it possible to appreciate the morphology of not only the normal heart but also many congenital cardiac malformations. This is true not only for the molecular mechanisms that might lead to the malformations but also for the structure of the normal and abnormally developing heart. In this chapter, we discuss the progress made in demonstrating the structure of the developing heart, along with knowledge of the changes that occur in the expression of the genes and their products, which control the formation and differentiation of its various components.

Introduction

It is intuitive to believe that congenital cardiac malformations can be understood on the basis of disturbed cardiac development. The first person to propose a classification for the congenitally malformed heart, Maude Abbott, firmly believed that knowledge of embryology was essential for interpretation of congenital cardiac malformations [1]. Until recently, however, the necessary facts regarding the formation of the heart have been relatively deficient, often being based on retrospective interpretations of the morphology of the lesions themselves. The situation has changed markedly over the past two decades. Current knowledge of cardiac development is now sufficient to underscore the understanding of the morphology of not only the normal heart but also many congenital cardiac malformations. This is true not only for the molecular mechanisms leading to the malformations but also for the structure of the normal and abnormally developing heart. The advances in understanding morphology have, to great extent, been made possible by techniques that now permit imaging the developing heart in three dimensions. In this chapter, we combine this progress made in demonstrating the structure of the developing heart with knowledge of the changes that occur in the expression of the genes and their products that control the formation and differentiation of its various components.

Formation of the Embryo and the Role of the Heart-Forming Area

The cardiac primordium, usually described as the heart tube, is first seen as an endothelial structure during the process of embryonic folding. Subsequent to folding of the embryo, the embryo is disc-shaped, with endodermal, ectodermal, and mesodermal germ layers. At the margins of the disc, these layers are continuous with the walls of the amnion and the yolk sac, respectively (Fig. 9.1). Already at the stage when the embryo is a disc, it is possible to recognize its right and left sides caudally due to the presence of the primitive streak, which has the node at its cranial end. The cells destined to form the heart migrate bilaterally through the anterior part of the primitive streak during the process of gastrulation, entering the developing mesodermal region to give rise to the right- and left-sided heart-forming regions [2–4]. These two areas then fuse across the midline to create the cardiac crescent (Fig. 9.2). The embryo then grows rapidly relative to the surrounding extraembryonic tissues. As a consequence, and in conjunction with embryonic folding, the original junction between the embryo and the extraembryonic tissues becomes no more than the eventual navel (Fig. 9.3). The folding, which involves all layers of the original trilaminar disc, results in those parts of the disc initially positioned peripherally becoming transferred into a ventral location. Hence, the endodermal layer becomes rolled-up to form the gut, with the developing mouth initially being closed by the stomatopharyngeal membrane, itself flanked caudally and centrally by future pharyngeal mesoderm. This pharyngeal area, in turn, is bordered peripherally by the cardiogenic mesoderm, derived from the initial cardiac crescent. The overall cardiac area is contiguous with the mesoderm of the transverse septum, in which the liver will develop.

Along with the folding of the embryo, the heart-forming regions also fold, producing a trough, which begins to close in the middle to create the primary heart tube. In the past, this

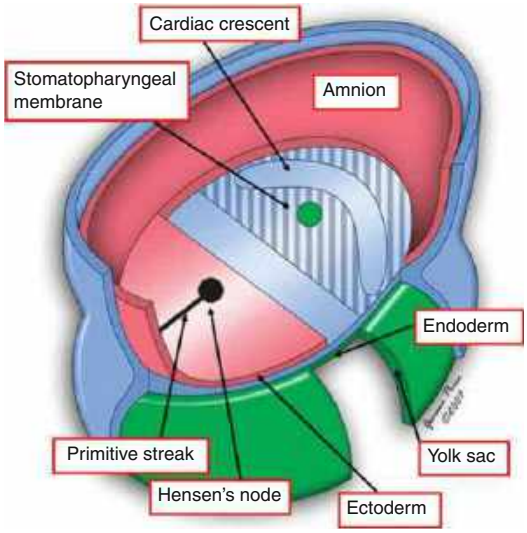

Fig. 9.1 The embryonic disc is a trilaminar structure, with a mesodermal layer sandwiched between endodermal and ectodermal layers. At the margins of the disc, the layers are continuous with the extraembryonic structures. The ectoderm has been removed in the cranial part of the so as to visualize the mesodermal structures. The figure was initially prepared for Chap. 3 of the third edition of "Paediatric Cardiology," written by Moorman, Brown, and Anderson and published in 2010 by Churchill Livingstone (Copyright in the figure is retained by the current authors)

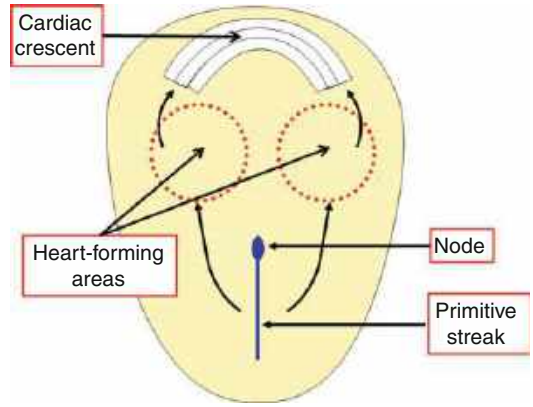

Fig. 9.2 Cells migrate from the primitive streak bilaterally to form the heart-forming areas and then the cardiac crescent. Subsequent migrations of the heart-forming cells from the cardiac crescent produce the heart tube. It has become conventional to designate two of these migrations as the first and second heart-forming regions, or heart fields. It remains moot as to whether these areas are discrete morphologically, as opposed to being temporal events. The figure was initially prepared for Chap. 3 of the third edition of "Paediatric Cardiology," written by Moorman, Brown, and Anderson and published in 2010 by Churchill Livingstone (Copyright in the figure is retained by the current authors)

so-called primary heart tube was believed to contain all the components of the definitive heart, which then achieved their definitive positions subsequent to looping and partitioning. We now know this not to be the case. The cardiomyocytes forming the initial tube give rise to little more than the left ventricular apex and the muscular ventricular septum [5]. With ongoing development, cells are added to form the other cardiac components, the trough closing in both cranial and caudal directions. Embryonic folding also changes the relations of the cardiac crescent to the developing body. The part initially located centrally comes to occupy a medial and dorsal position within the newly formed body of the embryo, while the initial peripheral margin of the crescent is the ventrocaudal part of the definitive heart tube. The component of the heart-forming area located medially, and added later to the forming heart tube, is now often considered to be discrete from the larger part of the cardiac crescent. Initially called the anterior heart field [6–8], this area is now more usually described as the second heart field, with this part itself now further divided into cranial and caudal components [9, 10]. As we will discuss, however, it is questionable whether this entire cardiogenic area should be considered as true distinct embryonic "fields."

Irrespective of such niceties concerning description, the component of the heart-forming area, lying centrally within the body of the developing embryo, is able to add material to both ends of the initial heart tube. It is also able to contribute to the heart tube via its connections with the pharyngeal mesenchyme. This portal, while it exists, is known as the dorsal mesocardium. Genetic lineage analyses have confirmed that new myocardium is added at both ends of the tube, which can be distinguished at its cranial or arterial, and caudal or venous, poles [10, 11]. The developmental program revealed by these analyses is directly comparable to that observed for

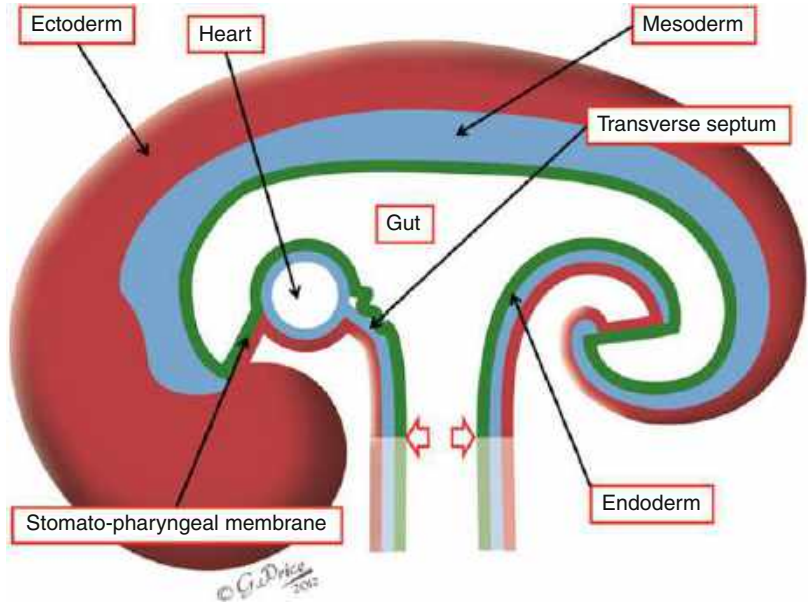

Fig. 9.3 Subsequent to folding of the embryonic disc, its margins are no more than the surrounds of the navel (*arrows*). At the completion of folding, the heart is located in the developing cervical region, with the transverse septum at its caudal end

differentiation of the initial heart tube from the primary heart field, with involvement of the transcription factors Nkx2-5, Gata4, Tbx5, and Mef2c, as well as fibroblast growth factors and bone morphogenetic proteins [12]. Although emphasis has been placed on the addition of myocardial structures at the arterial pole [8], non-myocardial tissues are also added through this portal, while the suggestion has been made that malformations involving the two poles are a common phenomenon [13]. Morphological boundaries, however, change markedly during growth of the cardiac components. The suggestion of morphologically discrete "fields," therefore, could reflect no more than temporal differences in the movement of tissues from the initial heart-forming area into the developing heart. In the chicken, for example, the cells initially present within the heart-forming areas, depending on their position, can form all parts of the definitive heart [14]. This observation is in keeping with current views on cellular diversity, with differences in the concentration of diffusing morphogens being known to create a number of different fates for a given cell, and hence promoting diversity within an initially homogeneous field.

Formation and Looping of the Heart Tube

When describing the development of the human heart, it is customary to use the gradations established subsequent to examination of the series of embryos collected and studied in the Carnegie Institute in the United States of America. These stages extend from 1 through 23, although the heart in man continues to show marked morphological changes subsequent to stage 23, which is equivalent to no more than about 8 weeks of development. The first signs of the heart in the developing human embryo are seen at stage 9, equivalent to about 20 days of development [15]. At this stage, the myocardial part of the heart is a mere strip, positioned ventrally relative to paired vascular channels, themselves having been formed ventral to the developing foregut, with endocardial jelly interposed between the myocardial and endothelial layers (Fig. 9.4A). By Carnegie stage 10, concomitant with formation of the trough as described above, the myocardial strip has folded itself around the vascular elements, which themselves have fused to produce a solitary lumen.

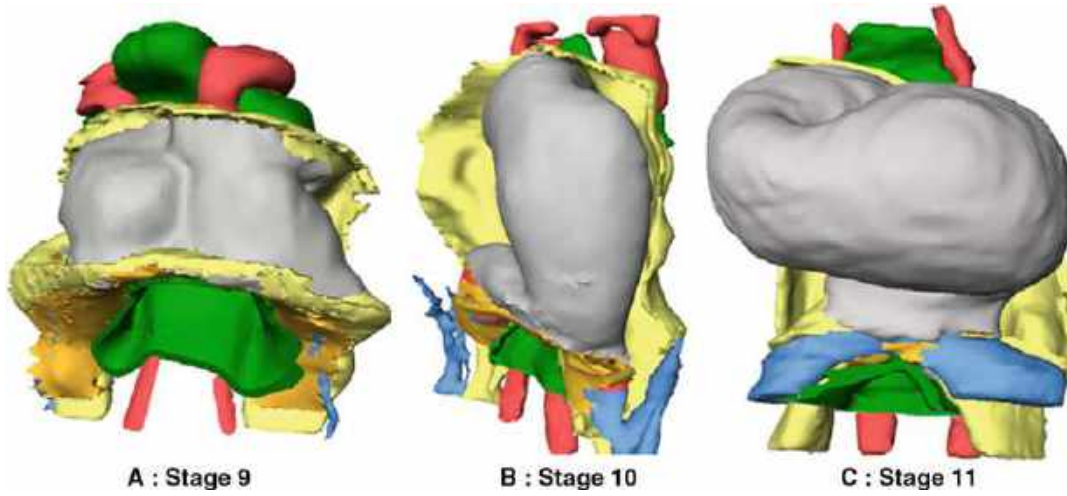

Fig. 9.4 The reconstructions, modified from the work of Sizarov and colleagues, show the changes taking place during formation of the heart tube through Carnegie stages 9 through 11 in the human heart. The myocardium is shown in *gray*, the margins of the pericardial cavity in *yellow*, and the epithelium of the developing foregut in *green*. The developing arterial channels are shown in *red* and the venous tributaries in *blue*. The figure was initially published in the second edition of "Hemodynamics and Cardiology: Neonatology Questions and Controversies," edited by Kleinman and Seri (The copyright is retained by the current authors)

The tube thus formed is enclosed within the pericardial part of the intraembryonic coelom, which at this stage is located within the cervical region of the developing embryo (Fig. 9.4B). Once formed, the connections of the lumen with the developing embryonic circulatory systems permit recognition of the arterial and venous poles. At the arterial pole, which is positioned cranially, the vascular elements extend symmetrically through the developing pharyngeal mesenchyme as the first aortic arches. At the venous pole of the tube, positioned caudally, the systemic venous tributaries are also initially symmetrical. They widen as they enter the pericardial cavity, joining together to drain into the primordium of the developing atrial component of the heart tube. By stage 11, equivalent to about 25 days of development, the tube becomes S-shaped, now possessing a ventricular loop, along with a discrete atrioventricular canal positioned between the atrial component and the inlet of the loop (Figs. 9.4C and 9.5). The process of looping was initially considered to reflect more rapid growth of the tube relative to its containing pericardial covering [16]. Looping, however, occurs even when the tube is separated from its arterial and venous attachments and continues in the absence of beating, thus excluding potential hemodynamic morphogenetic factors [17, 18]. Looping, therefore, is probably an intrinsic feature of cardiac development. One possible cause could reflect the known presence of Tbx2 in the inner curvature. This transcription factor is known to inhibit cellular proliferation. If the inner curve was proliferating less than the remainder of the tube, which is also known to be proliferating at the outer curve to produce the chamber myocardium, then these combinations could underscore looping. At all events, as a consequence of looping, the tube usually curves to the right. Such rightward turning, part of the breaking of embryonic symmetry, is independent of morphologically rightness or leftness within the heart. This is because the apical components of the right and left ventricles form in series from the outlet and inlet parts of the loop, respectively, while the atrial appendages grow in parallel from the initial atrial component of the heart tube. In the setting of isomerism, therefore,

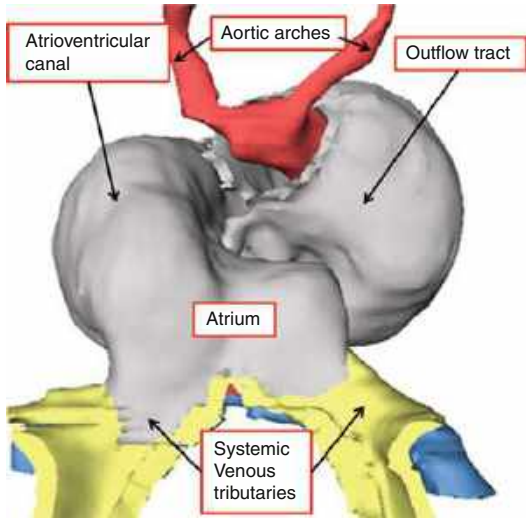

Fig. 9.5 The reconstruction of the stage 11 human heart prepared by Sizarov and colleagues, and shown as Fig. 9.4(**C**), is shown here as seen from behind. It shows the systemic venous tributaries opening in relatively symmetrical fashion to the atrial component of the heart tube. An atrioventricular canal is now formed in left-sided position, with the ventricular component having looped to the right, with the outflow tract seen arising from its cranial and right-sided end. The figure was initially published in the second edition of "Hemodynamics and Cardiology: Neonatology Questions and Controversies," edited by Kleinman and Seri (The copyright is retained by the current authors)

it is only the atrial chambers that are symmetrical, and then only their appendages [19]. The left atrial appendage is derived from the left half of the initial atrial component of the tube and the right appendage from the right half. This is not the case for the ventricles, since the apical part of each ventricle develops from a part of the tube containing both the initial right and left sides. Thus, although it is frequent to find rightward looping described as the first morphological evidence of the breaking of cardiac symmetry, this is not necessarily true. It is certainly untrue when considered in the context of the so-called visceral heterotaxy [20]. Morphological asymmetry can be demonstrated ahead of looping on the basis of the initial position of the atrioventricular canal [21] and in terms of formation of the atrial component of the initial linear heart tube [15].

The Building Blocks of the Heart

The morphologic processes involved in the formation of the heart tube are similar throughout the vertebrate classes. A relatively normal electrocardiogram can be recorded in mammalian hearts shortly after the completion of looping as described above and long before it becomes possible to recognize any anatomic components of the so-called conduction system. In animals such as fish, with unseptated hearts, it is also possible to record an electrocardiogram, but in the absence of any well-defined conduction system. The potential paradox is explained from knowledge of how the cardiac components develop from their building blocks. The initial heart tube is short and linear (Fig. 9.4A), being formed subsequent to the initial migration of cardiomyocytes from the heart-forming areas. Subsequent migrations from the heart-forming area then produce the atrial component of the linear tube, along with the right ventricle and the outflow tract. As these new parts are added, so the tube bends as described above (Fig. 9.4B, C). Once the tube has looped, it is possible to recognize the developing cardiac chambers as definitive entities, with the appearance of the atrial appendages permitting distinction at the atrial level and formation of the apical components distinguishing between the developing right and left ventricles. All these newly appearing components balloon from the initial linear heart tube [22]. Prior to the process of ballooning, the cardiomyocytes forming the walls of the linear tube are negative for connexin 40 and atrial natriuretic protein. The cardiomyocytes that form the walls of the atrial appendages, and the apical ventricular components, in contrast, are positive for both these proteins. This permits distinction of the walls of the initial tube as being composed of primary myocardium, with the walls of the ballooning components being made up of secondary, or chamber, myocardium (Fig. 9.6). The persisting interposition of segments of the primary tube between the chamber components then underscores the generation of a definitive electrocardiogram, since the areas of primary myocardium conduct slowly,

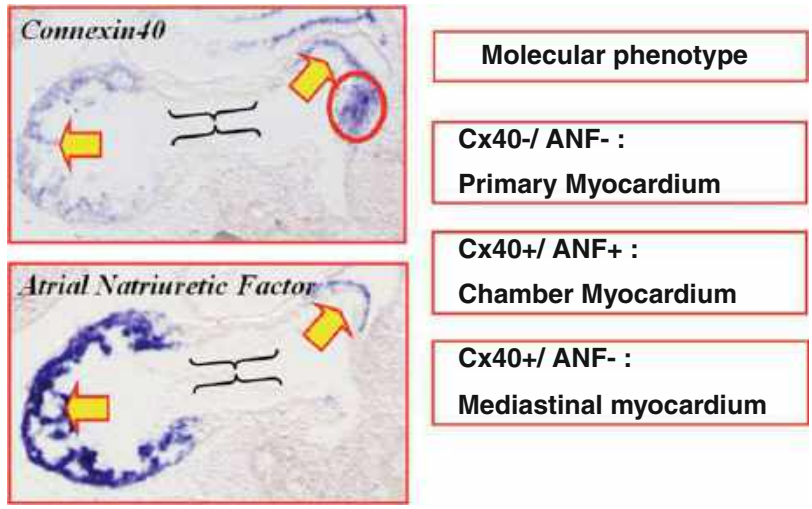

Fig. 9.6 The adjacent sections from a mouse embryo at about 9.5 days of development, equivalent to about 4 weeks of human development, have been processed to show expression of either connexin40 or atrial natriuretic factor. The locations of the proteins show how it is possible to distinguish three specific myocardial phenotypes. The primary myocardium of the initial heart tube, here forming the atrioventricular canal and shown by the *brackets*, is negative for both proteins, while the chamber myocardium, shown by the *arrows*, is positive for both. The mediastinal myocardium, shown in the *red* oval, is positive for connexin40, but negative for atrial natriuretic factor development. The figure was initially prepared for Chap. 3 of the third edition of "Paediatric Cardiology," written by Moorman, Brown, and Anderson and published in 2010 by Churchill Livingstone (Copyright in the figure is retained by the current authors)

while the cardiomyocytes of the chamber myocardium conduct rapidly. The persistence of the initial linear tube in the inner heart curvature also permits remodelling of the pathways for flow, so that the atrial cavities can eventually become connected directly to their respective ventricles and the arterial trunks brought into alignment with their appropriate ventricles. Such remodelling is essential since, when first formed, the atrioventricular canal is supported through virtually all its circumference by the developing left ventricle, while the outlet component is supported almost exclusively by the developing right ventricle. It is the realignment of the various components within the inner curvature that permits, eventually, the systemic venous return to be directed to the pulmonary trunk, and the pulmonary venous return to the aorta. Development of the pulmonary venous return, however, requires the involvement of yet another myocardial population. These cardiomyocytes enter the heart through the persisting dorsal mesocardial connection, being positive for connexin 40, but negative for atrial natriuretic factor (Fig. 9.6). This third population of cardiomyocytes, therefore, produces the mediastinal myocardium, which in turn gives rise to the dorsal wall of the left atrium, as well as providing the focus for formation of the primary atrial septum [23].

Formation and Separation of the Atrial Chambers

Subsequent to the process of rightward looping, the intrapericardial atrial component of the heart tube at the venous pole receives the systemic venous tributaries, while the arteries extending through the developing pharyngeal arches arise from the outflow tract at the arterial pole (Fig. 9.5). This situation is established by Carnegie stage 11 in the human heart and is equivalent to embryonic day 9.5 in the mouse. At this stage, the most caudal part of the atrial component retains its attachments to the pharyngeal mesenchyme through the dorsal mesocardium, the

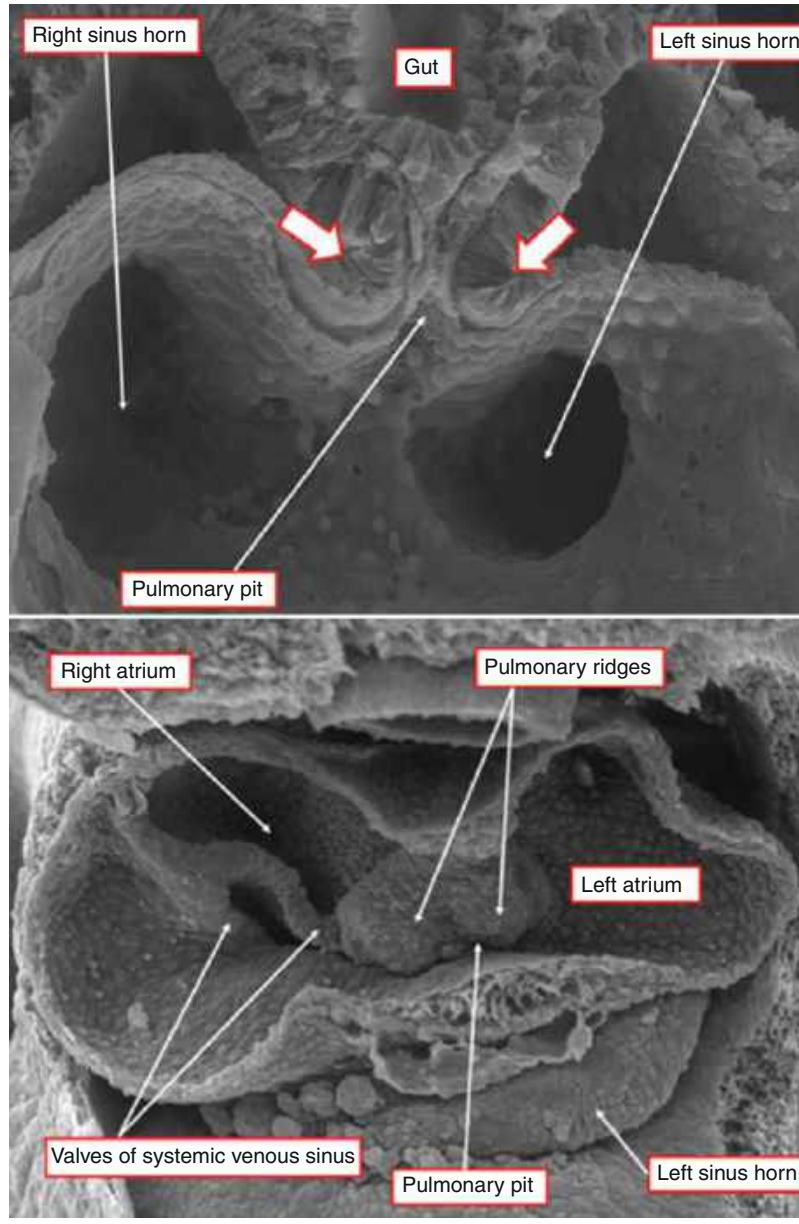

Fig. 9.7 The scanning electron micrographs show the developing mouse heart during embryonic day 9.5 (*upper panel*) and day 10.5 (*lower panel*). The *upper* panel shows a short axis cut across the dorsal mesocardium. The reflections of the atrial wall into the pharyngeal mesenchyme (*arrow*) form two ridges that flank the eventual site of opening of the pulmonary vein. The *lower* panel shows how these reflections become the pulmonary ridges, the left sinus horn by this stage having been incorporated into the left atrioventricular groove, its opening now enclosed within the valves of the systemic venous sinus (The copyright in the illustrations is retained by the authors)

systemic venous tributaries draining to the atrial component in relatively symmetrical fashion to either side of this area of attachment (Fig. 9.7, upper panel). As already explained, the entirety of the initial atrial component of the primary tube, along with the myocardial walls of the systemic venous tributaries, has a molecular phenotype, which is distinct from the walls of the developing atrial appendages (Fig. 9.6). And, already in the region of the persisting dorsal mesocardium, again as already explained, it is possible to recognize those walls of the developing atriums which contain the cardiomyocytes derived from the mediastinal mesenchyme. At this stage, however, there has yet to be formation of the lungs, which only subsequently bud forward from the tracheobronchial groove. When viewed from the aspect of the developing atrial cavity, nonetheless, the reflections from the pharyngeal mesenchyme of the walls to the right and

left sides of the dorsal mesocardium can be recognized as the right and left pulmonary ridges, enclosing a blind-ending, but midline, pulmonary pit (Fig. 9.7, upper panel).

With growth of the lungs from the tracheobronchial groove within the pharyngeal mesenchyme dorsal to the developing heart, there is marked realignment of the systemic venous tributaries, along with expansion of those walls of the developing atrial chambers derived from the mediastinal myocardium. The orifices of the systemic venous tributaries are initially relatively symmetrical as they open to the common atrial chamber, but the left-sided tributary soon decreases in size relative to its right-sided counterpart. Concomitant with this change, which occurs during embryonic day 10.5 in the mouse (Fig. 9.7, lower panel), the distal part of the left-sided tributary becomes incorporated into the developing left atrioventricular groove. As the tributary becomes incorporated within the groove, it retains its discrete wall, but its orifice comes to open to the right side of the developing atrial component (Fig. 9.8). At the same time, folds become recognizable at the junction between the right-sided atrial component of the heart tube and the orifices of all the systemic venous tributaries. Only subsequent to the appearance of these folds, which are known as the venous valves, is it possible to recognize the terminations of the systemic veins as an anatomical entity discrete from the right atrium, namely, the systemic venous sinus or sinus venosus (Fig. 9.7, lower panel, Fig. 9.8). The orifices within the confines of the venous valves now drain the blood from the right and left superior caval veins, along with the inferior caval vein, to the right atrium (Fig. 9.8). While these changes have been taking place, veins have also appeared within the developing lung buds that course towards the heart. These venous channels join together within the pharyngeal mesocardium, with canalization of a previous midline strand then providing an opening to the left side of the atrial cavity through the floor of the pulmonary pit. This connection of the pulmonary vein to the developing left atrium, initially as a solitary channel in both man and mouse, heralds the increase

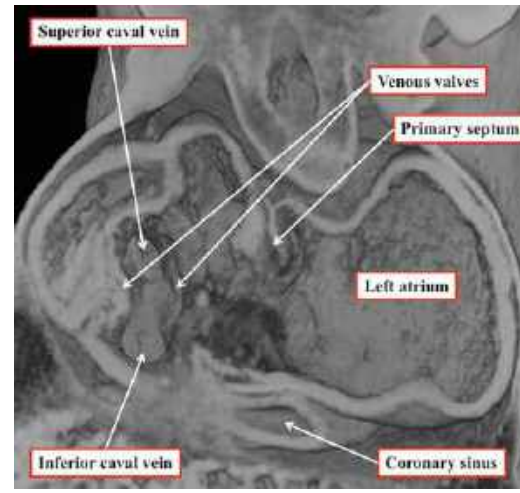

Fig. 9.8 The image is from an episcopic dataset prepared from a human embryo at Carnegie stage 14. It is a frontal section through the developing atriums, with the primary atrial septum seen in the atrial roof separating the developing right and left chambers. By this stage, the systemic venous tributaries have rotated at their entrance to the heart so as to open to the right atrium within the confines of the systemic venous sinus, the boundary with the atrium now marked by the venous valves. The orifices of the superior and inferior caval veins (SCV, ICV), along with the opening of the left sinus horn, are now within the confines of the venous sinus (The copyright in the illustration is retained by the authors)

in the size of the atrial walls formed from the mediastinal myocardium. Another of the signs of growth of the mediastinal myocardium is an increase in the size of the right pulmonary ridge. In addition, another ridge is formed at the atrial roof, again made up of mediastinal myocardium. This ridge is the primary atrial septum, or septum primum (Fig. 9.8). Because of the rightward shift of the orifices of the systemic venous tributaries, the primary septum, as it grows from the atrial roof towards the atrioventricular canal, is able to separate the systemic venous sinus from the orifice of the newly formed pulmonary vein. At the same time, the endocardial jelly that initially lined the entirety of the heart tube has changed within the atrioventricular canal, by a process known as endothelial-to-mesenchymal transformation, to become the superior and inferior atrioventricular cushions. These cushions themselves then increase in size, approaching each other

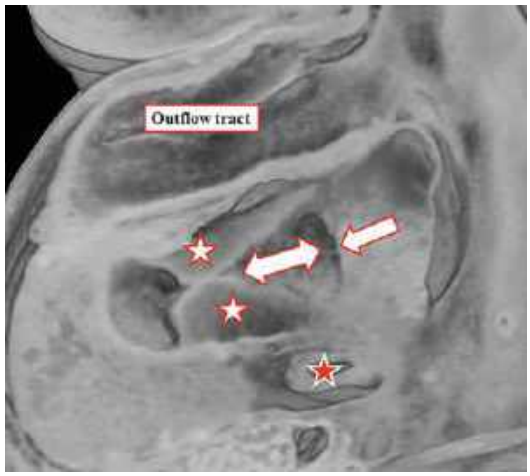

Fig. 9.9 The image is from an episcopic dataset prepared from a human embryo at Carnegie stage 15. It shows a long-axis section in parasternal equivalent through the atrioventricular canal. Endocardial cushions (*white stars with red borders*) are opposing each other within the canal, while the primary septum (*single-headed arrow*) is growing from the atrial roof towards the cushions. The space between the leading edge of the septum and the cushions (*double-headed arrow*) is the primary atrial foramen, or "ostium primum." Note that the left sinus horn is now incorporated within the left atrioventricular groove, possessing its own discrete walls (*red star with white borders*) (The copyright in the illustration is retained by the authors)

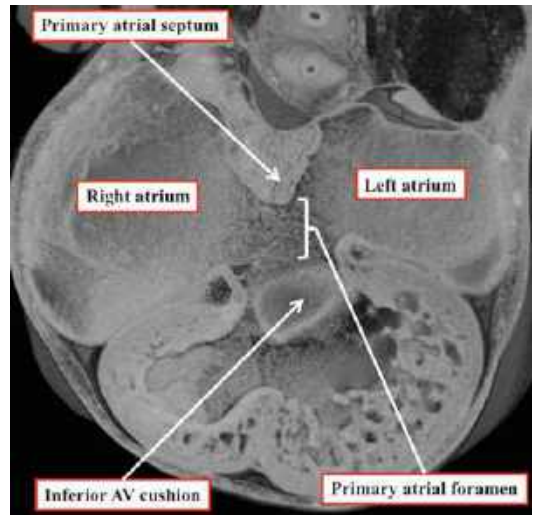

Fig. 9.10 The image, now of four-chamber long-axis plane, is from the same dataset as shown in Fig. 9.9, from a human embryo at Carnegie stage 15. The cut is through the inferior atrioventricular cushion. At this stage, the primary atrial septum has not broken away from the atrial roof (The copyright in the illustration is retained by the authors)

so (Fig. 9.9) as to divide the canal into right-sided and left-sided channels (Fig. 9.10). The primary atrial septum then grows towards these cushions, carrying on its leading edge a mesenchymal cap, which is continuous ventrally and dorsally with the superior and inferior atrioventricular cushions. The space between the mesenchymal cap, the right pulmonary ridge, and the cranial edges of the atrioventricular cushions is the primary atrial foramen, or ostium primum. Ongoing growth of the primary septum reduces progressively the size of the primary foramen, with the upper margin of the septum then breaking away from the atrial roof to produce the secondary atrial foramen, or foramen secundum (Fig. 9.11). Such a secondary foramen is needed so that, with eventual closure of the primary foramen, the richly oxygenated blood entering the heart from the placenta through the systemic venous sinus remains able to reach the left side of the developing heart. Closure of the primary atrial foramen is achieved by fusion of the mesenchymal cap of the primary septum with the atrioventricular endocardial cushions, the cushions by now also having fused with each other (Fig. 9.12). This process is further reinforced by ongoing growth of the right pulmonary ridge, with intrapericardial migration through the ridge of further tissues derived from the heart-forming areas. The tissue entering the heart is initially mesenchymal. Its expression of Islet1 reveals its origin from the second heart field [24, 25]. The ventral growth into the heart of this extracardiac tissue also carries forward the caudal ends of the valves of the systemic venous sinus, anchoring them to the right side of the fused endocardial cushions. The mesenchymal tissues derived from the right pulmonary ridge, along with the mesenchymal cap, then muscularize to form the anteroinferior buttress of the definitive atrial septum, thus forming the anchor for the persisting part of the primary atrial septum, which becomes the flap valve of the oval foramen (Fig. 9.13). These initial processes of atrial septation are comparable for

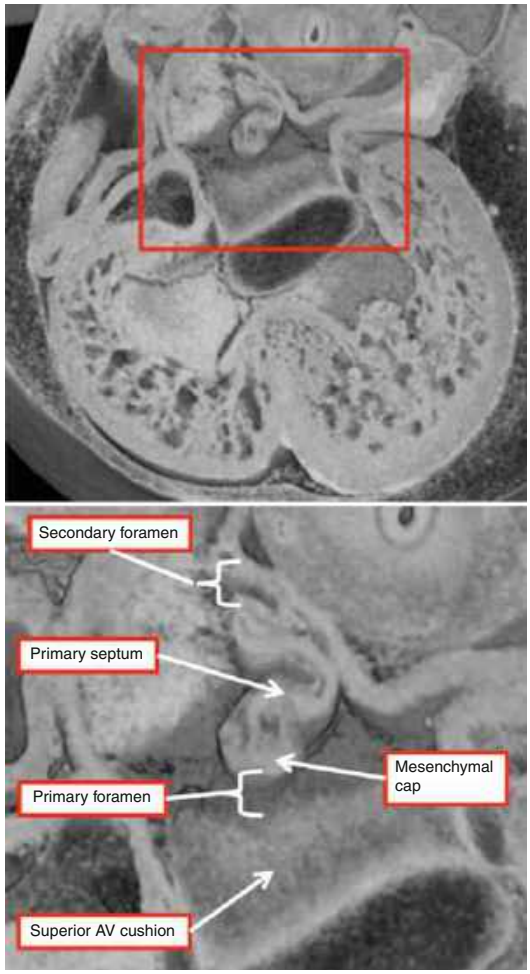

Fig. 9.11 The images are from an episcopic dataset prepared from a human embryo at Carnegie stage 16. They show a long-axis section in four-chamber plane through the developing atrioventricular junctions. The *lower panel* is a close-up of the area shown by the box in the *upper panel*. The primary atrial septum has now broken away from the atrial roof to produce the secondary atrial foramen (foramen secundum). The primary septum itself, with its mesenchymal cap, is approaching the atrioventricular cushions, diminishing the size of the primary foramen (The copyright in the illustration is retained by the authors)

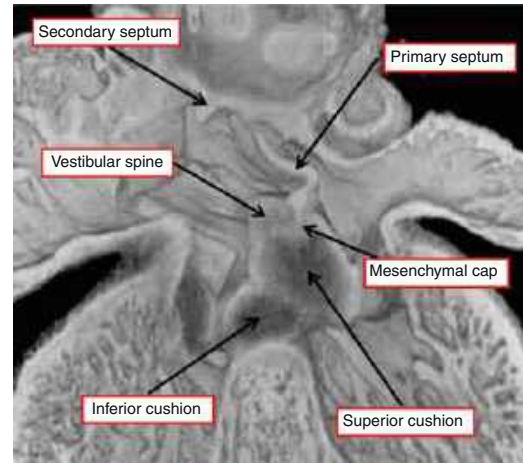

Fig. 9.12 The image is a four-chamber section from an episcopic dataset prepared from a mouse embryo at embryonic day 13.5. It shows the structures that have grown together to close the primary atrial foramen (ostium primum). The inferior atrioventricular cushion is also adherent to the developing ventricular septum. Note the formation of a second muscular atrial septum in the atrial roof (The copyright in the illustration is retained by the authors)

man and mouse (Figs. 9.12 and 9.13), but significant differences are then seen in the mechanisms required for postnatal closure of the oval foramen in man when compared with the arrangements in the mouse.

In the definitive heart of the mouse, the veins bringing the oxygenated pulmonary blood to the left atrium enter through a solitary orifice. In the human heart, in contrast, although initially a solitary pulmonary venous orifice is formed adjacent to the left atrioventricular junction, subsequent growth moves the site of pulmonary venous return to the atrial roof, initially through two (Fig. 9.14), and eventually through four orifices at the margins of the definitive left atrium. This migration of the pulmonary veins to the atrial roof is not complete until well after the completion of ventricular septation at the eighth week of gestation. Only after the right pulmonary veins have achieved their position in the atrial roof is the deep infolding created between their connections to the left atrium and the connection of the superior caval vein to the right atrium. It is this superior interatrial fold that forms the "septum secundum" in the human heart, with the flap valve derived from the primary atrial septum abutting against this structure after birth so as to close the oval foramen (Fig. 9.14). Full anatomic fusion between the flap valve and the rims of the foramen takes place in only three-quarters to two-thirds of the overall population. Those individuals in which anatomic fusion does not occur

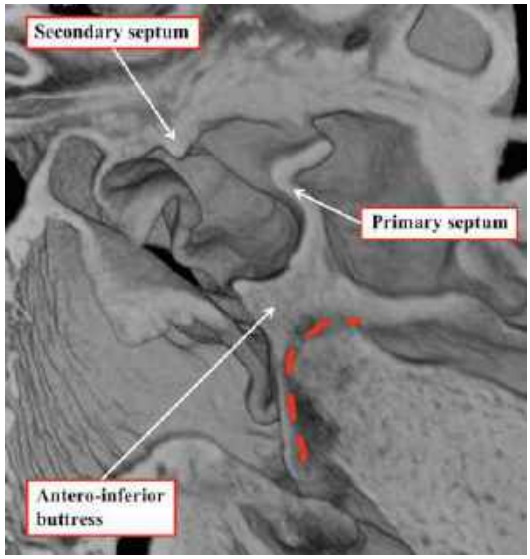

Fig. 9.13 The image is a comparable four-chamber section to the one shown in Fig. 9.12, but this time from a mouse embryo at embryonic day 16.5. The vestibular spine and mesenchymal cap have muscularized to form the antero-inferior buttress of the atrial septum, while the primary atrial septum itself forms the flap valve of the oval foramen (foramen ovale). Note that, in the mouse, there is formation of a secondary muscular septum at the atrial roof. In the human heart, this septal structure is replaced by the superior interatrial fold (see Fig. 9.14). The atrioventricular cushions have formed the insulating plane between the atrial and ventricular septal structures (*red dotted line*) (The copyright in the illustration is retained by the authors)

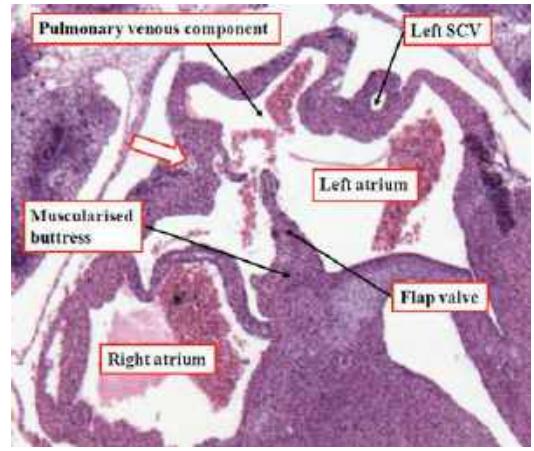

Fig. 9.14 The histological section, stained with the trichrome technique, is from a human embryo at 10 weeks' gestation. It shows how, subsequent to migration of the pulmonary veins to the atrial roof, there is formation of the deep superior interatrial fold (*arrow*). It is this fold that produces the so-called septum secundum, which in the mouse is a true muscular septum, since the pulmonary veins retain their position adjacent to the atrioventricular junction in the mouse, opening through a solitary orifice. In man as in mouse, nonetheless, the vestibular spine and mesenchymal cap muscularize to form the antero-inferior buttress of the atrial septum (The copyright in the illustration is retained by the authors)

have persistent patency of the oval foramen. In the mouse heart, in contrast, there is growth of a true second muscular ridge from the atrial roof (Fig. 9.13), although the ridge becomes continuous dorsally with a fold between the solitary pulmonary vein and the right atrial wall.

An integral part of atrial septation, therefore, is incorporation of the left superior caval vein into the left atrioventricular groove so that the entire systemic venous sinus opens to the right side of the initially common atrial part of the heart tube. At all times, the left-sided caval vein possesses its own walls, which are discrete from the walls of the left atrium. In the mouse, the left superior caval vein persists as a systemic venous channel, bringing the blood from the left side of the body directly back to the right atrium. In man, in contrast, the cranial part of the left-sided channel regresses, persisting only as the oblique vein of the left atrium, or the vein of Marshall. The caudal part of the channel then becomes the coronary sinus, which serves to drain most of the venous blood from the heart itself back to the right atrium. Should the intrapericardial part of the left-sided channel not regress in man, then it persists as the left superior caval vein. This venous channel has a characteristic intrapericardial course, passing between the orifices of the left pulmonary veins and the mouth of the left atrial appendage to enter the left atrioventricular groove and thence to open into the right atrium via the mouth of the coronary sinus.

The temporal sequence of development of the atrial septum serves to clarify the morphogenesis of the different types of interatrial communications. It is often stated that the sinus venosus defect exists because of absence of a wall common to the right atrium and the pulmonary veins,

hence forming a true septum between the right pulmonary veins and the superior caval vein [26]. In reality, however, there is no common wall between these venous structures. Each possesses its own wall. Instead, the sinus venosus defect is the consequence of abnormal connection of one or more of the right pulmonary veins to either the superior or inferior caval vein, the abnormal pulmonary vein, or veins retaining its or their left atrial connection. The defect is no more than a bridge between the venous channels, positioned outside the rims of the oval fossa [27]. The coronary sinus defect is also explained most conveniently on the basis of fenestration of an alleged common wall that separates the cavities of the left-sided systemic venous tributary and the left atrium. This again cannot be the case, since the left superior caval vein, derived from the left sinus horn, always possesses its own walls and is also discrete in terms of its lineage. The known spectrum of malformations extending from fenestration of the coronary sinus to its complete unroofing, leaving the orifice of the sinus to function as an interatrial communication, suggests erosion of both walls as the likely mechanism [28]. The morphogenesis of the ostium primum defect is now well established, since this lesion is an atrioventricular rather than an atrial septal defect. Shunting across the defect occurs at atrial level simply because the bridging leaflets of the common atrioventricular valve, derived from the atrioventricular cushions, are not only fused to each other, thus producing separate right and left valvar orifices within the common atrioventricular junction, but also to the crest of the deficient ventricular septum [29]. The presence of the common atrioventricular junction itself was long considered to be due to failure of fusion of the atrioventricular cushions, hence the old title of endocardial cushion defect. It is certainly the case that, in the setting of a common atrioventricular valve, the cushions have failed to fuse. In the ostium primum defect, in contrast, the presence of the connecting tongue suggests that the cushions have fused together, yet in the setting of a common atrioventricular junction. Some evidence now suggests that the commonality of the atrioventricular junction itself reflects failure of formation of the vestibular spine [30]. It is then failure of fusion of the vestibular spine itself with the mesenchymal cap that probably accounts for the rarest form of atrial septal defect, namely, the vestibular defect [31].

To summarize the steps involved in formation and septation of the atrial chambers, the initial atrial component of the linear heart tube is a common structure, with walls having a primary molecular phenotype. A dorsal corridor of primary myocardium is part and parcel of this atrial body, becoming committed to the definitive morphologically right atrium subsequent to the rightward shift of the systemic venous sinus [32]. This rightward shift also ensures that the entirety of the systemic venous sinus drains to the right atrium, with the junction between the sinus and the atrial body marked by the venous valves [33]. Remnants of these valves can be seen in the definitive right atrial chamber as the Eustachian and Thebesian valves, while undue persistence of the valves can produce subdivision of the right atrium, also known as cor triatriatum dexter [34]. As we will describe in our next section, it is the rightward half of the atrioventricular canal musculature that becomes sequestrated on the atrial side of the plane of atrioventricular insulation as the vestibule of the tricuspid valve. The right atrial appendage, which has the molecular phenotype of chamber myocardium, balloons ventrally from the rightward half of the initial atrial component of the linear heart tube. The body of the left atrium is derived, along with the pulmonary myocardium, from the mediastinal myocardium, which also gives rise to the primary atrial septum. It is relatively late in development, however, that the pulmonary venous component migrates to achieve its position at the atrial roof, with the secondary atrial septum, in reality the superior interatrial fold, only appearing subsequent to this migration [35]. The musculature of the pulmonary veins, known to be the focal source of many episodes of atrial fibrillation in elderly patients, has never possessed a primary myocardial phenotype nor have the pulmonary veins ever been related to the systemic venous myocardium [36]. The walls of the pulmonary venous component of the left atrium, along with

the primary atrial septum, are made up of mediastinal myocardium. As with the right-sided vestibule, it is the left half of the atrioventricular canal, initially with a primary phenotype, which becomes the vestibule of the mitral valve. The left atrial appendage, made of chamber myocardium, balloons from the leftward and ventral side of the atrial body and hence has a different morphological identity relative to the right appendage. This explains why only the appendages are truly isomeric in the setting of the so-called visceral heterotaxy [19].

The Formation and Septation of the Atrioventricular Canal

Subsequent to formation of the ventricular loop, and the initiation of ballooning of the apical components of the developing ventricles, it is possible to recognize part of the myocardium of the initial linear heart tube as a discrete atrioventricular canal (Fig. 9.15). At this stage, virtually the entirety of the circumference of the canal, except at the inner curvature, is supported by the myocardium of the part of the ventricular loop that is ballooning to produce the apical component of the developing left ventricle. Within the inner curvature, nonetheless, the right-sided wall of the canal already has a direct connection with the wall of the developing right ventricle (Fig. 9.16). As already described, atrioventricular cushions have formed within the canal, dividing it into right-sided and left-sided channels (Fig. 9.11). With ballooning of the apical trabecular components of the ventricles in series from the linear heart tube, it also becomes possible to recognize the developing muscular ventricular septum, with the primary interventricular foramen then bounded by the crest of the muscular septum and the inner heart curvature (Fig. 9.16). This foramen is never closed. Instead, it is remodelled so that the right half of the atrioventricular canal is placed in communication with that half of the outflow tract feeding the pulmonary arteries, and the left half of the canal remaining in communication with the part of the

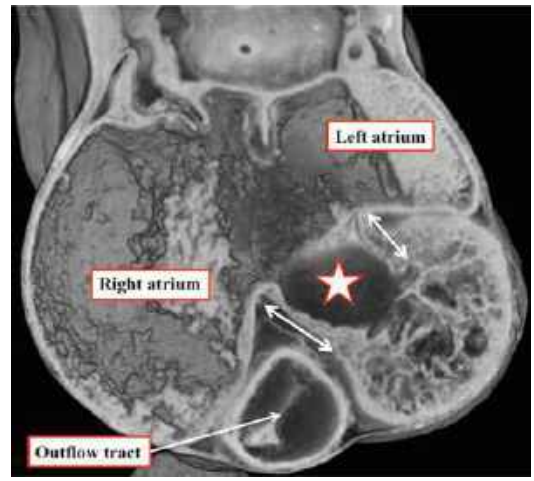

Fig. 9.15 The image is a section in four-chamber plane from an episcopic dataset prepared from a human embryo at Carnegie stage 14. The discrete musculature of the atrioventricular canal can be recognized at this stage (*double-headed arrows*), surrounding the atrioventricular cushions (*star*) (The copyright in the illustration is retained by the authors)

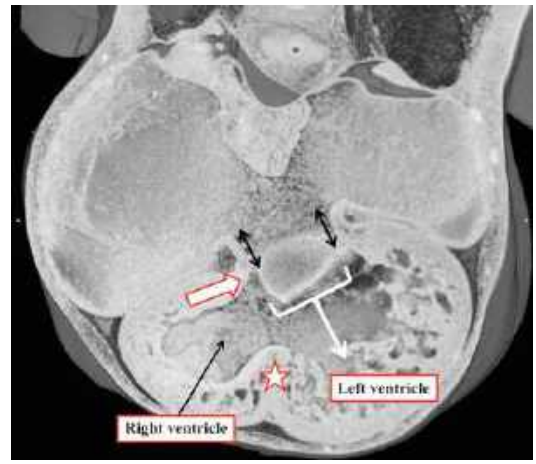

Fig. 9.16 The image, prepared from an episcopic dataset from a human embryo at Carnegie stage 15, shows how the atrioventricular canal musculature is still recognizable (*double-headed arrows*), but at this stage the larger part of the circumference of the canal is supported by the developing left ventricle. Already, however, the right atrial wall is in direct continuity with the wall of the developing right ventricle in the inner heart curvature (*white arrow with red borders*). The primary interventricular foramen, at this stage, is bounded by the inner curvature and the crest of the developing muscular interventricular septum (*star*) (The copyright in the illustration is retained by the authors)

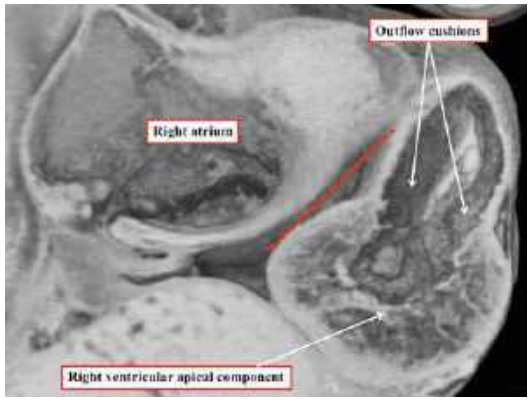

Fig. 9.17 The image is from an episcopic dataset prepared from a human embryo at Carnegie stage 13. It shows how, at this stage, the developing right ventricle has begun to acquire its apical trabecular component by ballooning and supported the entirety of the outflow tract, which is already populated by the paired outflow cushions. There is no direct communication, however, with the cavity of the right atrium (*red dotted line*), the blood entering the developing right ventricle through the primary interventricular foramen (The copyright in the illustration is retained by the authors)

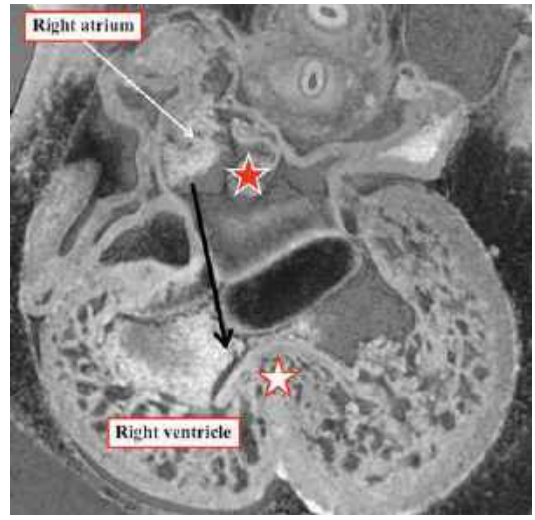

Fig. 9.18 The image, from an episcopic dataset prepared from a human embryo at Carnegie stage 16, shows how expansion of the atrioventricular canal has brought the cavity of the right atrium into direct continuity with the cavity of the right ventricle (*arrow*) and produced alignment between the developing atrial (*red star with white borders*) and ventricular (*white star with red borders*) septal components (The copyright in the illustration is retained by the authors)

outflow tract that feeds the developing aorta and the systemic arteries.

Prior to remodelling of the foramen, there is an extensive right-sided atrioventricular groove interposed between the cavities of the developing right atrium and right ventricle (Fig. 9.17), even though the walls of the developing chambers are in direct continuity through the right side of the atrioventricular canal. The right-sided groove becomes less deep subsequent to rightward expansion of the canal, along with continuing growth of the right ventricle. The consequence of this remodelling of the right side of the canal was well demonstrated by observing the fate of a ring of cells marked in the human heart by an antibody to the nodose ganglion of the chick [37]. The antibody initially marked the boundaries of the primary interventricular foramen. After remodelling of the inner heart curvature, the marked tissues surrounded the newly formed right atrioventricular junction. The process of remodelling also brought the dorsal end of the muscular interventricular septum in line with the underside of the fused atrioventricular cushions, the right channel of the atrioventricular canal thus becoming the inlet of the newly formed right ventricle (Fig. 9.18), albeit with sequestration of the initial musculature of the canal on the atrial aspect of the atrioventricular junction as the vestibule of the developing tricuspid valvar orifice. Since the canal was initially supported almost exclusively by the developing left ventricle, the left-sided channel of the atrioventricular canal was already positioned so as to function as the inlet to the left ventricle. With ongoing development, additional lateral cushions are formed in both newly created ventricular inlets, setting the scene for development of the leaflets of the atrioventricular valves (Fig. 9.19). Expansion caudally of the right-sided channel produces the eventual D-shaped orifice of the tricuspid valve, with the lateral cushion forming the primordiums of the antero-superior and inferior, or mural, leaflets and the conjoined atrioventricular cushions providing the substance for formation of the septal leaflet (Fig. 9.20). On the left side, the appearance of the lateral cushion initially produces a trifoliate configuration of the cushions relative to the

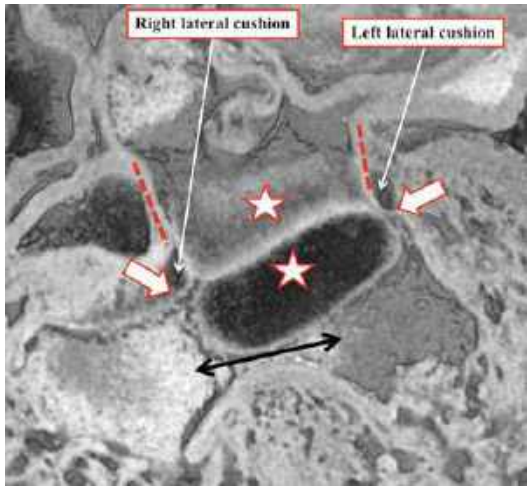

Fig. 9.19 Enlarging the area of the developing atrioventricular junctions as shown in Fig. 9.18 reveals the presence of right and left lateral atrioventricular cushions, in addition to the superior and inferior cushions (*stars*). The atrioventricular canal musculature (*red dotted lines*) is becoming sequestrated on the atrial aspect of the developing junctions, the potential plane of formation of the insulating plane shown by the *white arrows with red borders*. Note the interventricular communication between the inferior cushion and the crest of the muscular ventricular septum (*double-headed arrow*) (The copyright in the illustration is retained by the authors)

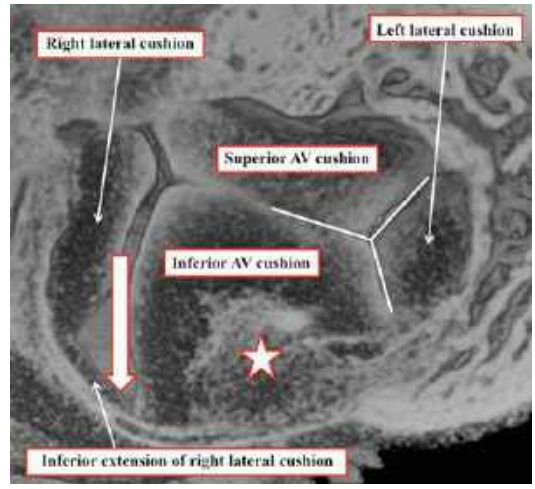

Fig. 9.20 The image is from an episcopic dataset from a mouse embryo at embryonic day 13.5. The right atrioventricular junction is expanding inferiorly (*arrow*) relative to the muscular ventricular septum (*star*), providing the primordiums for formation of the antero-superior and inferior leaflets of the tricuspid valve. The septal leaflet will be derived from the rightward components of the fused superior and inferior atrioventricular (AV) cushions. Note that, at this stage, the developing mitral valve has a distinct trifoliate appearance. The bifoliate configuration is not developed until the aorta is transferred to the left ventricle (The copyright in the illustration is retained by the authors)

developing mitral valvar orifice. Only after subsequent transfer of the aorta to the left ventricle (see below) do the superior and inferior cushions combine to form the aortic leaflet of the mitral valve, with caudal expansion of the left junction then permitting the lateral cushion to become the mural leaflet (Fig. 9.21). In both ventricular inlets, the trabecular layers of the myocardium condense to form the papillary muscles supporting the valvar leaflets, with delamination from the parietal ventricular walls producing the septal and inferior leaflets of the tricuspid valve, and the mural leaflet of the mitral valve [38], albeit that the cardiomyocytes subsequently disappear, presumably by apoptosis, since the valvar leaflets have an endocardial rather than a myocardial lineage [39]. Abnormal persistence of the myocardial components, nonetheless, accounts for the malformations known as the arcade lesion, in which the leading edge of the valvar leaflets remains myocardial. Failure of delamination of the leaflets from the myocardium of the ventricular inlets, along with expansion of the right ventricular wall, accounts well for the appearance of Ebstein's malformation. This lesion typically involves the tricuspid valve, with failure of delamination of the septal and inferior leaflets [38], but can rarely afflict the mitral valve, involving then the mural leaflet [40].

Formation of the Ventricles

It is ballooning in series from the ventricular component of the initial linear heart tube that produces the apical ventricular components. And, as described above, it is movement rightwards and subsequent expansion of the atrioventricular canal that brings the right atrioventricular valvar orifice into direct continuity with the

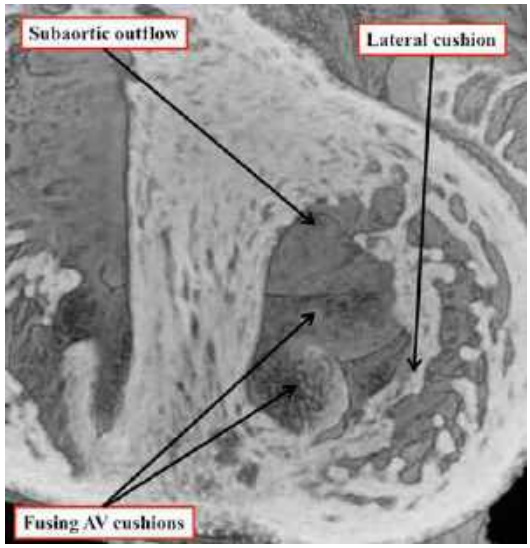

Fig. 9.21 The image is from an episcopic dataset prepared from a later stage of embryonic day 13.5 in the mouse. The aorta has now been transferred to the left ventricle. The left ventricular components of the atrioventricular cushions are now fusing to form the aortic leaflet of the mitral valve, while the lateral cushion is expanding to form the mural leaflet, thus conferring the postnatal bifoliate configuration of the valve (The copyright in the illustration is retained by the authors)

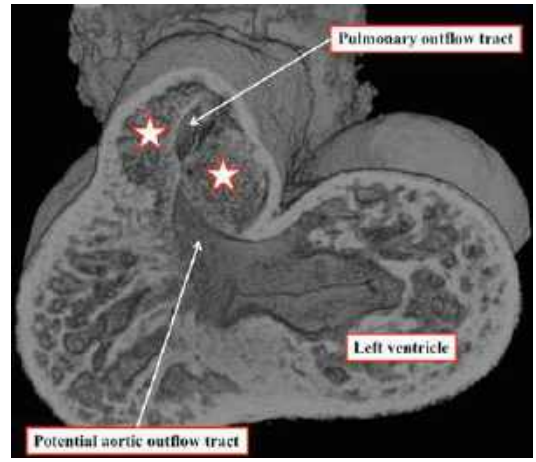

Fig. 9.22 The image is from an episcopic dataset of a mouse at embryonic day 11.5. At this stage, the outflow tract is still supported exclusively by the right ventricle. Within the proximal part of the outflow tract, the major outflow cushions (*stars*) are coming together to separate the pulmonary outflow tract, which will become the subpulmonary infundibulum, from the aortic vestibule, at this stage a right ventricular structure (The copyright in the illustration is retained by the authors)

apical component of the developing right ventricle (Fig. 9.18). The arrangement prior to expansion of the atrioventricular canal, however, is reminiscent of the situation found in malformed hearts with incomplete right ventricles, as seen in double inlet left ventricle or tricuspid atresia, with the developing right ventricle initially possessing only apical and outlet components [41]. At this initial stage, the developing right ventricle supports the entirety of the developing outflow tract (Fig. 9.17). Completion of ventricular formation, therefore, requires transfer of half of the outflow tract to the developing left ventricle. This is achieved by further remodelling within the initial cavity of the linear heart tube. Already by the time of this remodelling, the outflow tract itself has potentially been divided into pulmonary and aortic components by formation of cushions throughout its length. When first formed, these cushions have a spiralling relationship. As we will describe, the distal parts of these cushions initially fuse but then separate transversely to produce the proximal adjacent walls of the intrapericardial arterial trunks. The intermediate components of the cushions fuse, excavate, and separate to form the adjacent leaflets and sinuses of the arterial valves. It is the proximal parts of the outflow cushions that contribute to formation of the ventricular outflow tracts, specifically producing the infundibulum of the right ventricle. To achieve this, the cushions, packed with cells derived from the neural crest, initially come together edge to edge, thus separating the potential subpulmonary infundibulum from the aortic vestibule (Fig. 9.22). Once the cushions have fused, the newly separated aortic root is then transferred to the left ventricle by remolding of the leftward side of the primary interventricular foramen, this process bringing the proximal margin of the muscularized outflow cushions in line with the crest of the muscular ventricular septum (Fig. 9.23). The surface of the newly fused cushions then muscularizes [42], while the core of the fused cushion mass is eroded

Fig. 9.23 The image is from an episcopic dataset from a mouse of embryonic day 13.5. The aorta has now been transferred into the left ventricle, bringing the proximal edges of the outflow cushions in line with the ventricular septum and reducing in size the interventricular communication (IVC). The leftward part of the original foramen is now remolded to form the outflow from the left ventricle to the aortic root (*white arrow*) (The copyright in the illustration is retained by the authors)

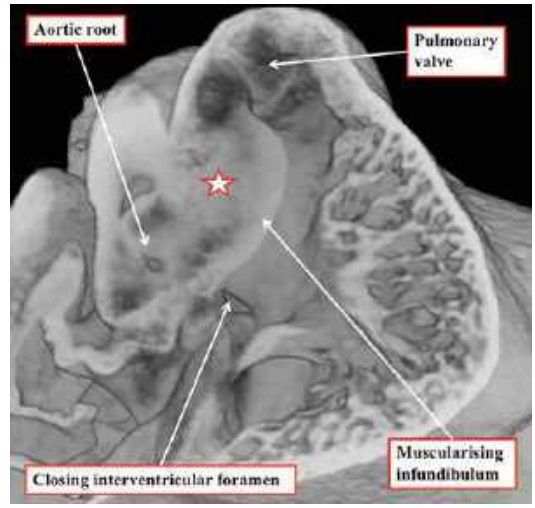

Fig. 9.24 The image, again from an episcopic dataset prepared from a mouse at embryonic day 13.5, shows the right ventricular aspect of the closing margins of the interventricular foramen. The cut across the inner heart curve shows how the surface of the outflow cushions is muscularizing to form the subpulmonary infundibulum. The central core of the cushions (*star*) will disappear by a process of apoptosis, thus producing the tissue plane between the free-standing infundibulum and the aortic root (The copyright in the illustration is retained by the authors)

by apoptosis, becoming the tissue plane that separates the subpulmonary infundibulum from the aortic root [43]. Subsequent to remodelling of the peripheral parts of the embryonic interventricular foramen to form, respectively, the right ventricular inlet and the left ventricular outlet, its central part is closed by apposition of the rightward edges of the superior and inferior atrioventricular cushions with each other, and with the muscularized outflow cushions (Fig. 9.24). This process was well described in the early twentieth century, accounting as it does for formation of the membranous part of the ventricular septum [44]. Only after delamination of the septal leaflet of the tricuspid valve, however, is the membranous septum itself divided into its interventricular and atrioventricular components [45].

Failure of proper division of the embryonic interventricular foramen accounts well for the production of perimembranous ventricular septal defects, while failure of muscularization of the outflow cushions provides a good explanation for the doubly committed and juxta-arterial defects [46]. Muscular defects are then explained by failure of compaction of the muscular septum, the so-called Swiss cheese defect being a frequent additional finding in the setting of the so-called ventricular non-compaction. This latter lesion, however, almost certainly reflects the failure of remodelling of the initially extensive trabecular component of the ventricular walls. At early stages of ventricular formation, the trabecular part of the walls is appreciably thicker than the compact layer (Fig. 9.18). The trabecular meshwork compacts to form the papillary muscles of the atrioventricular valves and also gives rise to the subendocardial ventricular conduction pathways. It is most unlikely, however, that the trabecules themselves condense to form the compact parts of the ventricular walls. Instead, it is likely that the growth of the compact wall outstrips that of the trabecular layer, which becomes increasingly insignificant. It is abnormal continued growth of the trabecular layer to keep pace with growth of the compact layer that accounts for the appearance of the congenital malformation now typically described as ventricular non-compaction [47].

Formation and Septation of the Aortic and Pulmonary Pathways

Subsequent to looping, the ventricular outflow tract is essentially supported exclusively above the cavity of the developing apical component of the right ventricle (Fig. 9.17). At this stage of development, the outflow component extends from the right ventricle to the margins of the pericardial cavity, where its lumen becomes continuous with the cavity of the aortic sac [48, 49]. At this early stage, the extrapericardial component known as the aortic sac is little more than a manifold feeding the bilaterally symmetrical arteries of the developing pharyngeal arches. There are five such arches, numbered one through four and six, although these arteries extending through the arches are never seen arising from the sac at the same time. By the time the fourth and sixth arches have appeared, the arteries coursing through the first two arches have lost their original connection with the aortic sac. The arteries of the fourth arches then feed the third arch arteries, which in turn feed the arteries of the first and second arches. It is during this stage of development, by the same process of endothelial-to-mesenchymal transformation that produced the atrioventricular cushions, that the endocardial jelly lining the outflow tract is invaded by cells to form the spiralling outflow cushions. Subsequent to their formation, the distal ends of the cushions are positioned cranially and caudally within the lumen of the distal outflow tract. At this stage, the fourth and sixth arch arteries arise symmetrically from the dorsal wall of the aortic sac, with the dorsal pharyngeal mesenchyme hence representing the presumptive aortopulmonary septum, separating as it does the cranial fourth arch arteries, which will eventually supply the systemic arteries, from the arteries of the sixth arches, which will give rise to the right and left pulmonary arteries (Fig. 9.25). Fusion of the distal cushions within the outflow tract then divides the initially common lumen into right-sided aortic and left-sided pulmonary pathways. The connection of these channels in the distal outflow tract with the developing extrapericardial

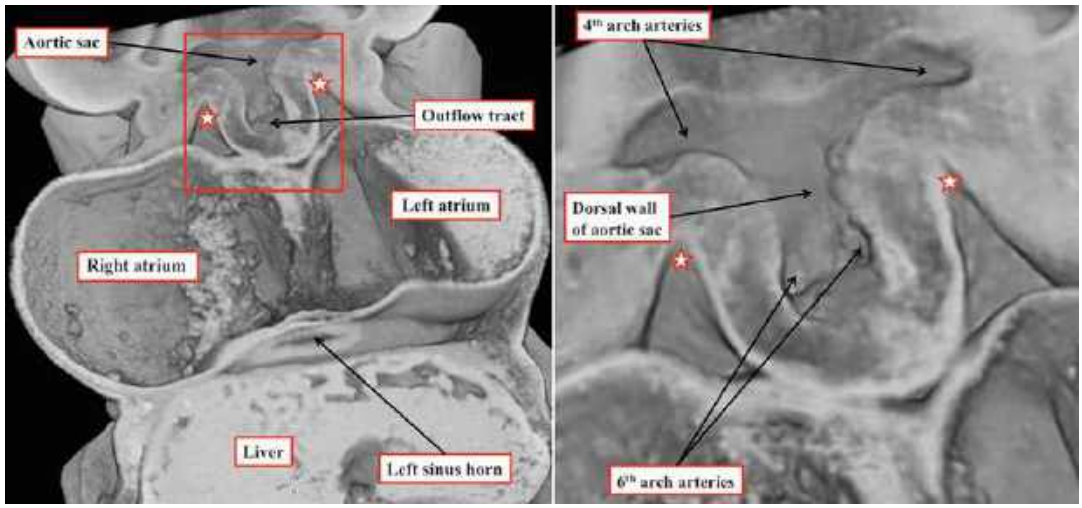

Fig. 9.25 The images are from an episcopic dataset prepared from a human embryo at Carnegie stage 13. The left-hand panel shows the overall frontal cut through the dataset, which demonstrates the union between the outflow tract and the pharyngeal mesenchyme, the *stars* showing the reflections of the fibrous pericardium. The *boxed area* is shown at higher magnification in the right-hand panel and demonstrates how the cavity of the outflow tract is continuous with the aortic sac at the level of the pericardial reflections. Arising from the aortic sac are the arteries running through the fourth and sixth pharyngeal arches. The fourth arch arteries will become the systemic channels, while the sixth arch arteries will supply the developing pulmonary arteries, so at this stage the dorsal wall of the sac is the putative aortopulmonary septum (The copyright in the illustration is retained by the authors)

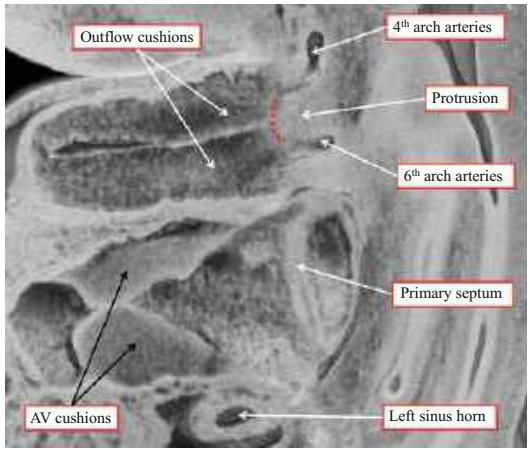

Fig. 9.26 The image is a sagittal section through a dataset prepared from a human embryo at Carnegie stage 15, replicating the parasternal long-axis echocardiographic cut. It shows how the protrusion from the dorsal wall of the aortic sac has extended intrapericardially, fusing with the distal end of the outflow cushions to connect the intrapericardial aortic channel with the fourth arch arteries and the pulmonary channel with the sixth arch arteries. See also Fig. 9.27. Note that the primary atrial septum has itself been sectioned, separating the primary and secondary interatrial communications. Note also the left sinus horn in the developing left atrioventricular junction (The copyright in the illustration is retained by the authors)

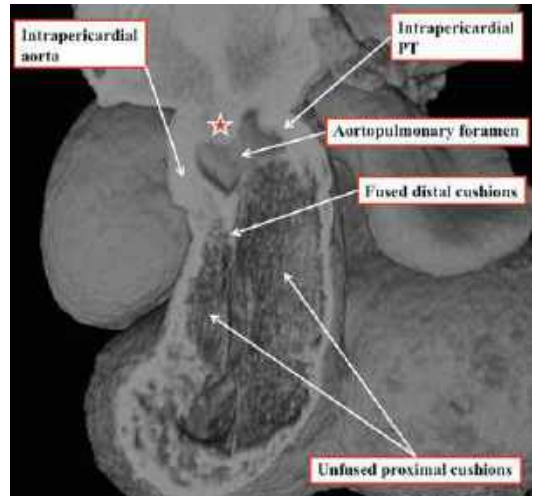

Fig. 9.27 The image is taken from an episcopic dataset prepared from a mouse embryo of embryonic day 11.5. It shows the stage just prior to fusion of the ventral protrusion from the dorsal wall of the aortic sac (*red star with white border*) and the distal ends of the outflow cushions, themselves already fused distally, although unfused proximally. Until the protrusion fuses with the cushions, there is a transient embryonic aortopulmonary foramen (The copyright in the illustration is retained by the authors)

systemic and pulmonary arterial pathways requires additional migration of cells from extracardiac sources into the outflow tract itself. These migrations populate both the walls of the outflow tract and the cushions that have formed within them [48, 49]. Migrations from the heart-forming fields enter the distal walls of the outflow tract to produce non-myocardial tongues. These new areas are initially positioned cranially and caudally but rapidly rotate to insinuate themselves between the myocardial walls overlying the distal ends of the cushions [48, 49]. The non-myocardial migrations will form the parietal walls of the intrapericardial arterial trunks. Formation of the adjacent walls of the aorta and the pulmonary trunk, in contrast, involves intrapericardial protrusion of the dorsal wall of the aortic sac so as to fuse with the distal margins of the cushions (Fig. 9.26), in the process obliterating a transient aortopulmonary foramen (Fig. 9.27). The protrusion itself has a core derived from the heart-forming areas, but a covering produced by cells derived from the neural crest. Further migrations of cells from the neural crest have filled the cushions themselves, the cells extending through the full extent of the cushions [50]. As the cushions fuse with each other, thus dividing the outflow tract into aortic and pulmonary pathways, they also fuse with the dorsal wall of the aortic sac (Fig. 9.26). Disappearance of the right-sided arteries percolating through the pharyngeal arches then means that right-sided aortic channel at the distal extent of the outflow tract feeds only the cranial part of the aortic sac, which feeds the persistent fourth aortic arch, destined to become the aorta. The left-sided pulmonary channel fills the caudal component of the aortic sac, which subsequent to the obliteration of the right sixth arch supplies both pulmonary arteries, with the left sixth arch then persisting as the arterial duct (Fig. 9.28).

Subsequent to this remodelling of the distal outflow tract and aortic sac into the intra- and extrapericardial parts of the systemic and

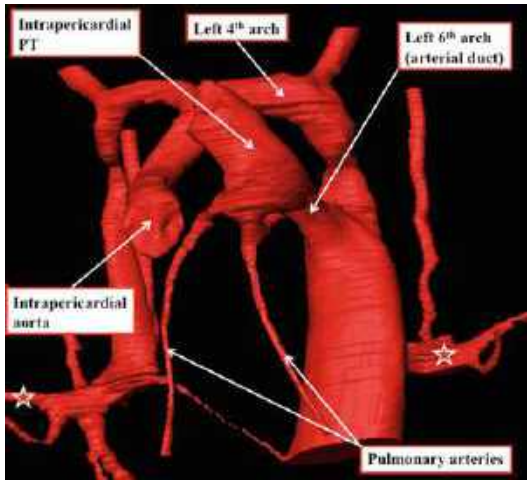

Fig. 9.28 The image is a reconstruction made from an episcopic dataset prepared from a mouse at embryonic day 12.5. It shows how the initially bilaterally symmetrical arteries coursing through the pharyngeal pouches have been transformed into the arch of the aorta and the arterial duct. The right-sided distal arches have already disappeared. The seventh intersegmental arteries (*stars*), however, have still to migrate cranially to become the subclavian arteries (The copyright in the illustration is retained by the authors)

pulmonary arteries, respectively, the proximal part of the outflow tract remains enclosed in a muscular turret [51]. This intermediate part of the outflow tract, in its muscular sleeve, is separated into two halves by fusion of the outflow cushions. The lateral margins of the cushions, however, do not fuse. Instead, cavities appear within the cushions that form the adjacent sinuses and leaflets of the aortic and pulmonary valves. The luminal components of the cavitated regions form the leaflets, while the abluminal components form the arterial valvar sinuses. At the same time, intercalated cushions [52] appear in the newly separated halves, with comparable cavitation forming the third, nonadjacent, leaflet and sinus of both arterial valves (Fig. 9.29). The central, fused, part of the ridges then disappears, thus creating the space between the newly formed aortic and pulmonary roots.

Failure of fusion of these cushions occupying the intermediate part of the outflow tract is the essence of common arterial trunk [53], with the separation of the intrapericardial parts of the common trunk depending on formation or absence of the ventral protrusion from the pharyngeal mesenchyme. Aortopulmonary window, in contrast, requires normal fusion of the cushions in the middle third of the outflow tract, hence the presence of separate aortic and pulmonary roots but failure of closure of the transient aortopulmonary foramen [49]. Bifoliate, or bicuspid, arterial valves are then well explained on the basis of excessive fusion of the edges of the cushions, or else formation of one of the facing cushions in continuity with the aortic intercalated cushion, these differences accounting well for the different phenotypes of bicuspid valves [54].

Development of the Cardiac Conduction System

As we have already intimated, although a well-defined conduction system is to be found only in mammalian hearts, an electrocardiogram of remarkably similar pattern can be recorded from animals as diverse as fish and man. This shows that the electrical connections between the cardiac components have been conserved during vertebrate evolution. Indeed, as we have already discussed, the development of the conduction system of the heart is inextricably associated with the formation of the basic cardiac building blocks. In the postnatal heart, the conduction system is made up of the sinus node, which creates the sinus impulse, the atrioventricular node which slows the impulse at the atrioventricular junctions, and the axis of conduction cells which disseminates the impulse to the ventricular myocardium. It is customary to describe these components as the "conduction system," but this nomenclature does not imply that the working cardiomyocyte fails to conduct. Rather, the cells of the various parts of the so-called conduction system are specialized to generate the impulse, delay it, and then disseminate it rapidly to the ventricular myocardium. The working cardiomyocytes themselves, so as to produce powerful synchronous contractions, also conduct rapidly, whereas the cells functioning as the

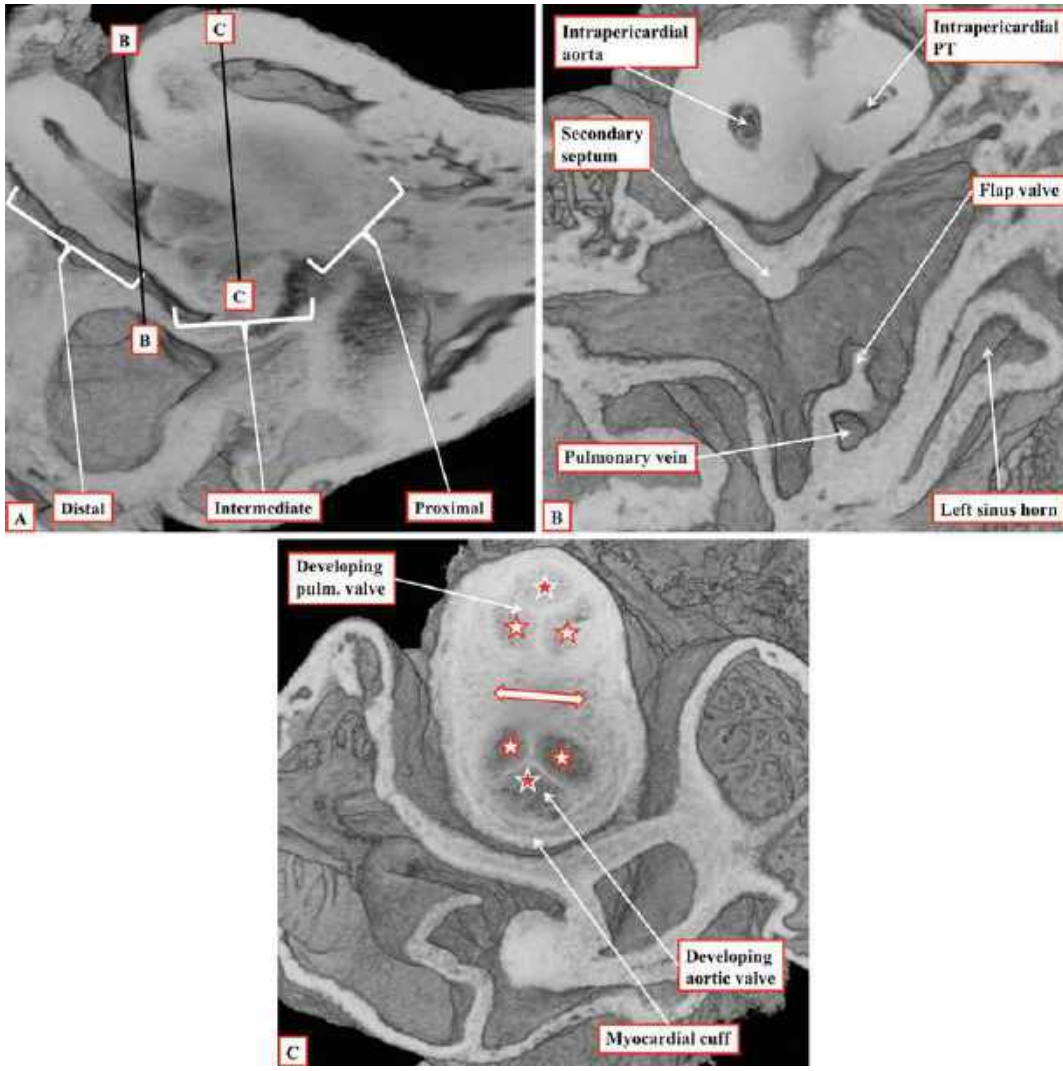

Fig. 9.29 The images come from an episcopic dataset prepared from a mouse at embryonic day 13.5. *Panel A* shows a long-axis cut through the heart viewed from the right side. It demonstrates the distal, intermediate, and proximal components of the developing intrapericardial outflow tract. The distal component has already separated into the intrapericardial aorta and pulmonary trunk, each channel now possessing its own discrete walls, as shown by the cross section at level *B* illustrated in the *middle panel*. The outflow cushions have fused in the intermediate part of the outflow tract, as shown in the cross section at level *C*, illustrated in the right-hand panel. The *double-headed arrow* shows the zone of fusion between the two major outflow cushions, which remain encased within a cuff of myocardium. The margins of the cushions, however, remain unfused, as shown by the *white stars with red borders*. These components, together with the intercalated cushions, shown by the *red stars with white borders*, now provide the primordiums for formation of the arterial valvar leaflets and their supporting sinuses. The cushions in the proximal part of the outflow tract have also fused. These cushions produce the muscular subpulmonary infundibulum, as shown in Fig. 9.24 (The copyright in the illustration is retained by the authors)

pacemaker and the atrioventricular node are poorly coupled and hence conduct slowly.

Since all the cardiomyocytes within the heart are coupled electrically, it is those with the highest pacemaking activity that take the lead in generating the impulse. In the normal individual, this leading pacemaker is always within the sinus node. During development, and prior to formation

of a discrete sinus node, the leading pacemaker is always found at the venous pole. All the cardiomyocytes forming the walls of the initial heart tube, nonetheless, are poorly coupled and also display intrinsic automaticity. This permits slow propagation of the depolarizing impulses along the cardiac tube and produces matching peristaltic waves of contraction, which push the blood in antegrade direction.

As part of the basic building plan, we also explained how the process of ballooning resulted in formation of the apical components of the ventricles and the atrial appendages and how this situation permitted recording of an adult type of electrocardiogram, with rapid atrial depolarization, a period of atrioventricular delay, and rapid ventricular depolarization. The electrocardiographic pattern reflects the development of the fast-conducting components interposed between the persisting slowly conducting segments of primary myocardium within the heart tube, the newly developed chamber myocardium expressing atrial natriuretic factor, along with the gap junctional proteins connexin 40 and 43, which permit fast conduction.

At this early stage, when flow is peristaltic, valves are not a prerequisite for forward flow. The slowly conducting atrioventricular canal and the outflow tract positioned between the ventricle and the great arteries, containing as they do the cushions produced by the endothelial-to-mesenchymal transformation, are able to function as sphincteric valves, due to their prolonged duration of contraction [55, 56]. These components retain their valvar function until the definitive valves have been sculpted at the atrioventricular and ventriculo-arterial junctions. Indeed, the primary myocardium of the outflow tract does not regress until after the arterial valves have been formed and does not disappear in its entirety until around the 12th week of human development. The primary myocardium of the atrioventricular canal is eventually incorporated into the atrial vestibules, becoming sequestrated on the atrial side of the atrioventricular junctions between 6 and 12 weeks of development. Part of the primary myocardium of the atrioventricular canal, nonetheless, persists as the slowly conducting atrioventricular node.

We now have a far better understanding of how the various myocardial components are formed during cardiac development. Thus, we now know that the combined action of the transcription factors Tbx5 and Nkx2-5 is required for the formation of the chamber myocardium of the atriums and ventricles. When we examine the levels of expression of Tbx5, we find a gradient over the heart tube, decreasing from caudally to cranially. This pattern may be sufficient to impose positional information, but it cannot explain the localized formation of the chambers and the conduction system. This requires the action of the transcriptional repressors Tbx2 and Tbx3, which are localized in the inflow tract, the floor of the atrium, the atrioventricular canal, the inner curvature of the ventricular region, and the outflow tract. It is in these regions that the repressors prevent the differentiation of primary into chamber myocardium, thus permitting the formation of the definitive conduction system. At earlier stages, Tbx3 is also expressed in the atrioventricular canal, the floor of the atrium, and around the orifices of the systemic venous tributaries. It is not found, however, in the dorsal mesocardium surrounding the entrance of the pulmonary vein. With ongoing development, Tbx3 is expressed more widely, extending from the atrioventricular canal to form a crescent on the crest of the ventricular septum. The presence of Tbx3 in these regions permits formation of the atrioventricular bundle and its branches. The ventricular conducting system originates in part from the ring of tissue delineated by the antibody to the nodose ganglion of the chick [37], with parts of this ring also persisting in the vestibule of the tricuspid valve as the so-called atrioventricular ring tissue [57]. Additional parts of the ring are found within the aortic root [58], where they form the so-called dead-end tract [59]. The presence of these remnants in normal hearts provides a solid base for understanding the disposition of the conducting system in a number of congenital malformations. The concept accounts particularly well for the morphology and disposition of the atrioventricular node and bundle in hearts

with straddling tricuspid valves [60], double inlet left ventricles [61], and in congenitally corrected transposition [62].

Development of the Coronary Circulation

The coronary arteries, which supply blood to the various tissues within the walls of the heart, and the coronary veins, which return the deoxygenated blood, are derived from the epicardium. This, in turn, is derived from the pro-epicardial organ, which in mammals is located within the inferior atrioventricular groove adjacent to the transverse septum [63]. Cells derived from this organ grow over the entire epicardial surface of the heart as far as the distal outflow tract. Under the influence of Wt1 and Raldh2 genes, they undergo epicardial-to-mesenchymal transformation [64]. Having become mesenchymal, the cells derived from the epicardial organ then penetrate the developing myocardial walls, forming the fibrous matrix of the compact myocardium, and give rise to the smooth muscular walls of the coronary arteries and veins. It is also suggested that, having penetrated to reach the endocardial surface of the ventricle, the epicardially derived cells also influence the formation of the ventricular conduction pathways, these being derived from the trabecular layer of the ventricular walls [65]. Although it was initially believed that the coronary arteries themselves achieved their aortic connection subsequent to the budding out from the aortic sinuses of the proximal coronary arteries, it is now well established that, in reality, the proximal coronary arteries grow into the aortic root [66]. When the arterial trunks have separated into their aortic and pulmonary components, the major coronary arteries almost without exception take origin from the aortic sinuses adjacent to the pulmonary trunk. This arrangement, coupled with the fact that there is no obvious pattern to sinusal origin in the setting of common arterial trunk [67], suggests that the process of separation of the roots by fusion of the intermediate components of the outflow cushions guides the epicardial coronary arteries to their appropriate aortic origin. Failure of this process would explain anomalous origin of a major coronary artery from the pulmonary trunk. It cannot be coincidental that this lesion is seen with some frequency in the setting of aortopulmonary window, itself associated with defective partitioning of the distal part of the outflow tract (see above). It is well established that the cardiac circulatory system is derived initially from the walls of the systemic venous sinus, only subsequently being converted into arterial and venous channels after formation of the capillaries in the compact layer of the myocardium [68].

Development During the Fetal and Neonatal Periods

Marked changes continue to occur in the structure of the developing heart subsequent to the establishment of the four-chambered organ, and after closure of the embryonic interventricular communication. Ventricular septation is complete at the end of the eighth week of development. At this stage, however, the pulmonary vein has still to migrate to the roof of the left atrium, the septal leaflet of the tricuspid valve has still to delaminate from the atrial septum, and the superior interatrial fold, the so-called septum secundum, has still to appear. These changes take place in the third month of gestation. In the six months that continue until term, although the heart has by now achieved its postnatal structure, differences are still evident when compared to the postnatal organ. The lie of the heart is different prior to birth, with the long axis much more horizontal. The absence of air in the lungs, however, makes it much easier for the fetal echocardiographer to display cardiac structure and to identify congenital malformations throughout gestation.

After birth, the intra-atrial pressures are equalized, and the flap valve of the atrial septum is kept in contact with the left side of the rims of the oval fossa, thus promoting subsequent anatomic fusion. In up to one-third of all normal individuals, nonetheless, the foramen remains probe patent. At birth, when calculated as the weight

of the right ventricle relative to that of the left ventricle and the septum, the left ventricle weighs about one-quarter more than the right. The right ventricle, however, has been working against the systemic pressure in the fetus, the pulmonary circulation not yet being active, and there is a preponderance of right ventricular function in the first 2 or 3 months after birth. With the establishment of the pulmonary circulation, the work of the right side of the heart decreases, and the left side of the heart, particularly the ventricle, grows rapidly to meet the demands of the active neonate. By the end of the third month, the left ventricle has already become thicker than the right. It becomes twice as thick by the second year and three times as thick by puberty. The other change required to convert the fetal into the postnatal circulation is closure of the arterial duct. This normally occurs on the first day of life, with the muscular walls of the duct becoming converted into the arterial ligament over the ensuing weeks.

Transition from Fetal to Neonatal Circulation

10

Bettina Cuneo

Abstract

This chapter will review the transition from the fetal to the neonatal circulation. First, it will describe the prenatal hemodynamics throughout gestation in the developing fetus with a normal heart. Second, it will compare hemodynamics of the normal fetus with the flow patterns and distribution of cardiac output in the fetus with structural cardiac defects, concentrating on severe and ductal-dependent cardiac anomalies. Third, it will describe the postnatal hemodynamics with implications for neonatal management of the infant with structural cardiac defects.

Keywords

Ductus venosus • Ebstein's anomaly • Fetus • Patent ductus arteriosus • Patent foramen ovale • Tetralogy of Fallot • Transition • Transposition of the great arteries

Introduction

The majority of current knowledge of the fetal circulation, including patterns of blood flow, distribution of cardiac output, and function of the myocardium comes from fetal sheep data accrued over the last 40 years by Abraham M. Rudolph and his colleagues at the Cardiovascular Research Institute in San Francisco, California. With the advances in fetal imaging techniques, including ultrasound and MRI, it is now possible to examine the circulation in the human fetus. In particular, Doppler evaluation of the fetal heart and the systemic and pulmonary circulations as early as 10 weeks of gestation have improved the understanding of cardiac development in the normal fetus and the fetus with cardiovascular abnormalities. Identifying the earliest alterations in fetal hemodynamics in the setting of structural or functional cardiac defects will not only advance the understanding of the natural history of these defects, but may provide an opportunity for in utero intervention, or at the very least, an opportunity to optimize postnatal care for improved outcome.

The Normal Fetal Circulation

The fetal circulation operates in parallel, rather than in series. This means that the relative-contributions of each chamber can change without affecting the total cardiac output. The parallel circulation is possible because of the two fetal shunts that equalize pressures between the atria and the great vessels: the foramen ovale and the ductus arteriosus. Despite equalization of pressure and the ability to maintain a constant combined cardiac output (CCO), the distribution of the cardiac output differs based on preload and afterload. The left ventricle faces a higher afterload than the right ventricle because it ejects into a high resistance/poor compliance circuit: the coronary arteries, the upper body, and the fetal head. In contrast, the right ventricle ejects into a low resistance/high compliance circuit: the fetal body and the placenta.

Oxygenation and Blood Flow

Blood is oxygenated in the placenta and returns to the fetus through the umbilical veins (Fig. 10.1). Flow volume in the umbilical vein increases linearly with fetal weight, but remains fairly constant throughout gestation, ranging from 140 to 180 ml/kg/min in the second trimester to 110–170 ml/kg/min at term [1, 2]. In the first trimester, umbilical venous flow is pulsatile, but by 13 weeks it is continuous [3]. Umbilical venous blood is well saturated with a PO2 of 30–35 mmHg (saturation 80 %). In the liver, the umbilical vein divides into the ductus venosus (DV), a slender structure which connects the intraabdominal umbilical vein to the proximal inferior vena cava (IVC), and a right branch which joins the portal vein to supply the right lobe of the liver. In the human fetus, about 70 % of umbilical venous blood passes through the liver, while 20–30 % is diverted through the DV.

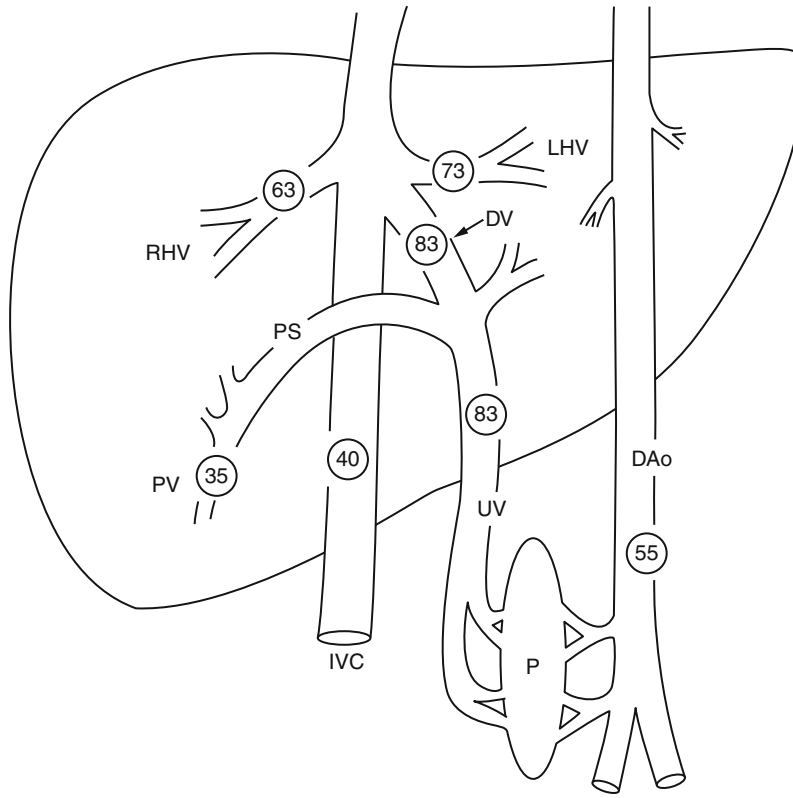

Fig. 10.1 Oxygen saturations in vessels near the liver in the fetal lamb. Oxygen saturations in the respective vessels are shown (*circles*). *Dao* descending aorta; *DV* ductus venosus; *IVC* inferior vena cava; *L* and *RHV* left and right hepatic veins; *P* placenta; *PS* portal sinus; *PV* portal vein; *UV* umbilical vein

Later in pregnancy, flow to the DV decreases to about 20 % [4, 5]. Shunting across the DV preferentially increases in response to hypoxemia, nitric oxide, and prostaglandins [6–8]. Because of a portocaval pressure gradient, as blood enters the DV from the umbilical vein, flow velocity increases from 10 to 22 cm/s in the umbilical vein to 60–85 cm/s in the DV. Flow velocity in the DV increases linearly with advancing gestation [9]. Doppler indices, in the DV, the IVC as well as the hepatic veins decrease with advancing gestation, probably reflecting improved diastolic filling and ventricular compliance [3].

Blood from the DV and the left hepatic vein enters the left side of the IVC at a higher velocity than blood from the distal IVC and the right hepatic vein. Due to the differential speed of the IVC/DV blood, there is a streaming effect separating the more highly oxygenated DV blood on the left from the less oxygenated IVC blood on the right [5, 10].

The circulation in the normal fetus is shown in Fig. 10.2. When IVC blood enters the heart, separation of the two streams is maintained by the crista dividens, which deflects the highly oxygenated blood across the foramen ovale to the left atrium (LA) [11, 12]. In the LA, oxygenated blood mixes with the small volume of blood returning from the pulmonary veins, and continues through the left ventricle to the ascending aorta. Less oxygenated blood from the distal IVC and right hepatic vein and all but 2–3 % of superior vena cava (SVC) blood pass through the tricuspid valve into the right ventricle. Thus, blood with the highest oxygen content, about 25 mmHg and oxygen saturation about 65 %, is delivered to the coronary circulation and the fetal brain. A small portion (about 10 %) traverses the aortic isthmus. Less oxygenated blood, with PO2s 17–20 mmHg and oxygen saturation 55 %, passes through the pulmonary valve to the patent ductus arteriosus and, to a much lesser extent, the fetal lungs. From the ductus arteriosus, blood flow travels to the descending aorta and to the lower half of the fetal body and the placenta. Because the ductus arteriosus is as large as

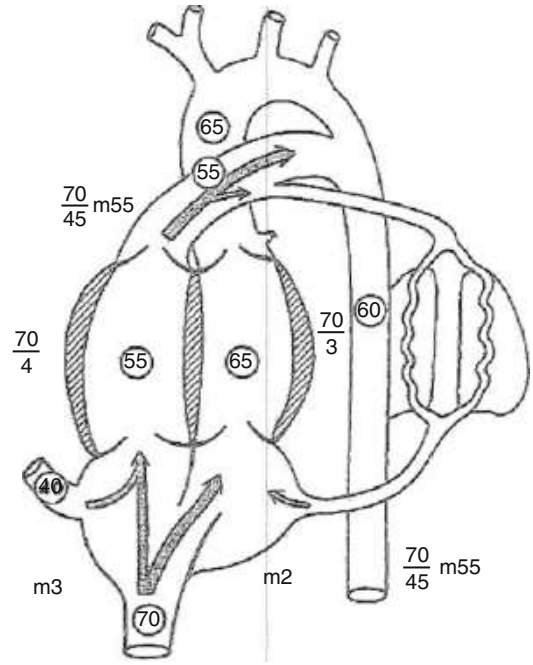

Fig. 10.2 Circulation in the normal fetus. Oxygen saturations in the respective chambers are shown in *circles*

the descending aorta, there is equalization of pressure between the aorta (AO) and the pulmonary artery (PA) and between the right and left ventricles. Thus, the distribution of blood flow distal to the ductus arteriosus will depend on differences in the vascular resistances between the placenta and the fetal body. Since placental vascular resistance is much lower than the resistance of the fetal body, the placenta receives the majority of flow from the descending aorta, or about 40–45 % of the combined cardiac output.

The Pulmonary Circulation

The course of blood flow ejected from the right ventricle depends on the downstream lung and placental resistances. The resistance in the fetal lungs is very high because of a small cross-sectional area, poor arborization (especially

before 20 weeks), and prominent muscular components of the intrapulmonary arteries [13, 14]. In comparison to the placenta, the pulmonary vascular resistance is so high that early in gestation only 4 % of the combined ventricular output enters the pulmonary vascular bed. By the end of gestation, the flow to the lungs has increased only to 7 % of the combined cardiac output [14]. The percent of combined cardiac output through the lungs almost doubles from early in gestation to term, probably related to decreased vascular impedance and increased cross-sectional area of vessels in the pulmonary vascular bed [15, 16]. The high resistance and low-flow state of the pulmonary bed throughout gestation explains the typical Doppler wave form in the branch pulmonary arteries in the human fetus: a sharp early systolic flow acceleration, a rapid flow deceleration in mid systole, and low diastolic forward flow [15].

Investigation of the pulmonary circulation in the human fetus has demonstrated a fall in the pulsatility index between 20 and 34 weeks of gestation, suggesting that pulmonary vascular resistance falls during this period [15, 17]. After this period, lung growth continues, but vascular impedance either does not change or increases.

In addition to gestational age–related changes in vascular resistance, the response to hypoxia, hyperoxia, and vasoreactive substances in the lamb fetus varies by gestational age [83]. This was shown in an elegant study by Rasanen and colleagues, who demonstrated that maternal hyperoxia decreased human fetal pulmonary vascular impedance and increased pulmonary blood flow between 31 and 36 weeks of gestation. This vasoreactivity did not occur before 20–26 weeks of gestation [18]. This "hyperoxia test" has been used in the late gestation fetus at risk for pulmonary hypoplasia or hypoplastic left heart syndrome and highly restrictive or intact atrial septum to predict the need for intervention or postnatal survival. A nonreactive test predicted mortality in 79 % of fetuses at risk for pulmonary hypoplasia, and the immediate need for catheter intervention in newborns with hypoplastic left ventricle and restrictive atrial septum [19, 20].

Doppler Investigation of Fetal Blood Flow

Tricuspid and Mitral Valves

Flow velocity wave forms reflect the maturation changes of the fetal myocardium and changes in loading conditions imposed by increasing demands of the fetal cardiovascular system. The flow patterns and the peak velocity across the atrioventricular valves are determined by the ventricular diastolic function, the relaxation velocity, ventricular compliance, and preload and afterload. At 8 weeks of gestation, the AV valve filling pattern becomes biphasic [21] with a dominant "a" wave, indicating the greater contribution of atrial contraction to ventricular filling in late diastole. Peak "a" and "e" waves increase as gestation progresses; however, peak "e" wave velocity of both AV valves increases to a greater extent, reflecting improved myocardial relaxation and decreased afterload [22]. The volume of blood flow across the AV valves increases in a linear relationship relative to fetal crown rump length [82]. Reflecting the right ventricle's greater contribution to the combined ventricular output, trans-tricuspid blood volume is greater than transmitral blood volume from the first trimester to term [23].

Pulmonary Artery and Aorta

In contrast to peak flow velocities across the AV valves which are based on diastolic indices, peak flow velocities across the semilunar valves are determined by contractility and afterload. As early as 10 weeks, examination of the human fetus demonstrates higher peak flow velocities across the aortic valve compared to the pulmonic valve [24]. Due to myocardial mechanics, fetal systolic function increases from 13 weeks to term. Flow velocities increase from 30 cm/s at 13 weeks to 50–110 cm/s across the pulmonary valve and 60–120 cm/s across the aortic valve at term [3]. Although the peak flow velocity is higher across the aorta, the diameter of the

pulmonary artery is larger (about 1.5:1); thus, the stroke volume of the RV is higher (by about 28 %) than the LV during the second and third trimesters. These observations support the suggestion of RV dominance in fetal hemodynamics.

The Patent Ductus Arteriosus

Right ventricular afterload and systolic pressure are primarily related to resistance in the ductus arteriosus. The presence of a ductus arteriosus equalizes pressures in the aorta and the pulmonary artery, even in the presence of semilunar valve stenosis. In early gestation, flow in the ductus arteriosus is systolic, but by about 14 weeks and definitely 17 weeks, end-diastolic flow can be readily visualized [25]. Peak flow velocity increases from 50 cm/s to 130–160 cm/s between 15 and 39 weeks of gestation [25, 26]. The hallmark of ductal constriction, commonly caused by prostaglandin inhibitors, such as indomethacin, is an increase in diastolic flow velocity and a pulsatility index (peak systolic velocity – minimum diastolic velocity/mean velocity) <1.9 [27].

Middle Cerebral Artery

The pulsatility index, which reflects downstream flow resistance and filling pressure in the middle cerebral artery, does not change from 11 to 13 weeks, when diastolic velocities are first measurable, to 20 weeks [28]. In most studies, the pulsatility index rises until 26 weeks, and then decreases [84], suggesting that in late gestation, the decrease in cerebral vascular resistance is greater than the concomitant increase in cerebral blood volume.

Aortic Isthmus

Similar to the ductus venosus and the foramen ovale, the aortic isthmus is one of the watershed areas in the fetal circulation, and may be the only true arterial shunt in the fetal circulation [29]. The patent foramen ovale (PFO) equalizes pressures between the right and left atrium, and the ductus equalizes pressures between the PA and Ao, but the isthmus is only connection between the two circulations.

The Fetal Myocardium and Cardiac Function

Contraction of the heart is a finely orchestrated event involving the contractile unit of the heart (sarcomere and the contractile proteins myosin, troponin, and tropomyosin) and the sarcoplasmic reticulum, which regulates calcium uptake and release. Contractility depends on the number of sarcomeres, contractile protein isoforms and the number of calcium binding sites, the functionality of the sarcoplasmic reticulum and T-tubules, and the density of beta-adrenergic receptors and sympathetic nerve endings.

In the fetal heart, these elements are structurally and functionally immature. The fetal cardiac contractile units are both immature and decreased in number. In addition, the T-tubular system in the sarcoplasmic reticulum is poorly developed, with the result that calcium uptake is impaired [30]. In addition to underdeveloped contractile units, the fetal heart has a paucity of sympathetic innervation and beta-adrenergic receptors [31, 32]. These inherent properties of the immature myocardium result in heart rate, rather than stroke volume being the primary mechanism to increase cardiac output. The limited ability of the fetal heart to increase stroke volume is seen in the following examples. First, at the same muscle length, the fetal myocardium develops less active tension and generates less force, thus contractility is reduced [33]. Second, the Frank-Starling mechanism is operational in the fetus, that is, cardiac output is augmented by small changes in preload, but beyond 19 weeks of gestation, the fetal heart is operating near the top of the Frank-Starling curve [34]. Both ventricles have a diminished capacity to increase stroke volume from increased preload, but perhaps due to histological differences the RV has

less ability to tolerate increased diastolic filling pressures [34, 35]. This may be one of the reasons that hydrops develops with extracardiac vascular malformations. Third, the fetal myocardium has impaired relaxation characteristics, probably related to a high percentage (60 %) of noncontractile elements and lesser numbers of sarcomeres [33] and contractile proteins [36]. The uncoupling of calcium from troponin, essential for muscle relaxation, occurred much more slowly in fetal myocardium [37]. Noncompliance of the chest wall, pericardium, and lungs may mechanically limit diastolic filling [38]. Clinically, the stiffness in the myocardium manifests as decreased passive filling during diastole (Reed et al. 1986). Finally, the fetal heart tolerates even small increases in afterload very poorly [39].

As gestation progresses, contractility increases. Myocardial adrenergic receptor density increases and the sarcoplasmic reticulum matures and becomes more efficient in distributing calcium to troponin-binding sites [30]. Velocity of sarcomere shortening increases [40]. Calcium-activated myosin ATPase activity increases due to a higher concentration of adult myosin isoforms [41] and myofibrillar number increases [42]. Thyroid hormone is a known mediator in the maturation of fetal cardiac contractility and regulation of cardiomyocyte growth in utero by suppressing proliferation of myocytes late in gestation during the transition from cardiac hyperplasia to cardiac hypertrophy [43].

Cardiac Output in the Fetus

The fetal circulation is in parallel, meaning the cardiac output of each ventricle is not equal, but "combined." The percentage of combined ventricular output that each ventricle contributes is determined by the different afterloads faced by the right and left ventricles. The parallel circulation is possible only because of the aortic isthmus, which effectively separates the left ventricular cardiac output to the high resistance fetal brain and upper body from the right ventricular output to the low resistance placenta and lower body. Only the afterload faced by each ventricle differs significantly. There is a contradiction between those two sentences: on the one hand, preload is mentioned to be similar for both ventricles, and on the other hand, it is written that right ventricle receives a greater proportion of the venous return.

Of the venous return to the fetal heart, about 70 % is supplied by the IVC and 20 % by the SVC. Approximately 50 % of the combined ventricular output is ejected into the pulmonary artery, the majority of which enters the descending aorta. Less than 10 % passes into the fetal lungs because they have a high vascular resistance for two reasons: First, they are unexpanded and filled with fluid. Second, the lower PO2 content constricts the smooth muscle of the pulmonary arterioles [44]. Thus, approximately 42 % of the combined ventricular output passes through the ductus arteriosus to the descending aorta, which also receives about half of the cardiac output from the LV, the other half (21 %) having been distributed to the upper body, brain, and coronary circulation. Flow in the descending aorta is thus 67 % of the combined ventricular output. Right and left ventricular stroke volumes and the combined cardiac output in the human fetus increase as gestation progresses, from 40 ml/min at 15 weeks [45] to 1,470–1,900 ml/min near term [17, 45]. Right ventricular stroke volume exceeds left ventricular stroke volume by about 28 % throughout gestation [46].

Distribution of Fetal Cardiac Output

The distribution of cardiac output changes with gestational age and is different in the human fetus than in other mammals. In the human fetus, the RV contributes 55–60 % of the combined cardiac output. In the majority of studies, right-sided dominance of the fetal circulation persists throughout gestation in both sheep and humans, but the right heart/left heart ratio varies from 1.2–1.5/1 in humans to >1.5/1 in sheep [17, 45]. The lower ratio of

Table 10.1 Distribution of blood flow expressed as percent of combined (biventricular) cardiac output

	Near-term fetal lambs	Human fetuses, present study (13–41 weeks)	Human fetuses (19–39 weeks)	Human fetuses (18–37 weeks)	Human fetuses (age unknown)
Right cardiac output, %	60	59	53–60		
Left cardiac output, %	40	41	47–40		
Ductus arteriosus blood flow, %	54	46	32–40		
Pulmonary blood flow, %	6	11	13–25	22	6
Foramen ovale blood flow, %	34	33	34–18	17–31	36
Biventricular output, $\mathbf{mL \cdot min^{-1} \cdot kg^{-1}}$	462	425	470–503		

right-to-left flow in the human fetus compared to the sheep fetus may be due to increased left ventricular output to the larger human brain. Fetal hypoxia and acidosis result in further decrease in the right heart/left heart ratio due to a lower cerebral vascular resistance promoting "brain sparing" and increased fetal systemic resistance and RV afterload. The LV ejects about 33 % of the combined output, of which 21 % goes to the cerebral and coronary circulations, and less than 10 % crosses the aortic isthmus.

Flow in the ductus arteriosus increases exponentially as gestation progresses. Ductal flow receives 78 % of the right-sided cardiac output and 46 % of the combined cardiac output. In contrast, 90 % of right cardiac output goes to ductus arteriosus; the difference in pulmonary blood flow between the two species account for the differences. In the lamb fetus, the ductus arteriosus receives 90 % of the right cardiac output.

Intuitively, it would be expected that pulmonary blood flow increases as gestation progresses due to changes in the vascular resistance of the pulmonary vasculature (see above). However, pulmonary blood flow results vary in different studies (Table 10.1). Pulmonary blood flow does not increase in most studies, and expressed as percentage of combined cardiac output and right ventricular cardiac output, varied from 6.4 % and 11 % [47], to 11 % and 22 % [45], and to 22 % and 48 % [48]. Rasanen and colleagues found that PBF as percentage of combined cardiac output increased from 13 % to 15 % between 20 and 30 weeks [17]. In all but one study, pulmonary blood flow in the fetal lamb varied with gestation and as percentage of cardiac output was lower than in the human fetus [49].

Flow through the patent foramen ovale (PFO) varies between studies. Mielke found that 33 % of combined cardiac output traversed the PFO independent of gestational age [45]. Both St. John-Sutton and Rasanen found that PFO flow varied inversely with gestational age from 31 % to 34 % at mid-gestation to 18 % in later (>30 weeks) gestation [17, 48].

As there are differences in fetal blood flow to the brain between the lamb and the human fetus, there are also differences in the amount of flow through the ductus venosus. In the lamb, about 50 % of the umbilical venous flow traverses the ductus venosus. In the normal physiological state, a maximum of 28–32 % of umbilical venous blood is shunted to the DV at 18–20 weeks in the human fetus: The amount of shunting decreases as gestation progresses [5].

The percent of cardiac output that is sent to the placenta increases from 17 % at 10 weeks to 33 % at mid-gestation. Blood flow then decreases to 20 % of the CCO beyond 32 weeks [17]. Impedance in the placenta decreases throughout gestation because of increased growth of the placenta and the cross-sectional area of the placental vasculature. Vasoactive substances

can affect placental vascular resistance: enothelin and prosanoid cause vasoconstriction and nitric oxide causes vasodilation [50, 51].

Fetal Circulation in the Abnormal Heart

Structural and functional fetal cardiac anomalies result in abnormal flow patterns within the fetal circulation [52]. However, with the exception of myocardial dysfunction, prolonged arrhythmias, or valvar insufficiency, most structural cardiac defects are well tolerated in utero because of the unique parallel fetal circulation. Fetal shunts, including the foramen ovale and ductus arteriosus, and watershed areas, such as the aortic isthmus and DV, allow redistribution of blood flow from the abnormal ventricle or great vessel to the unaffected cardiac chamber. With the redistribution of blood flow, oxygen delivery to various organs changes. For example, complete admixture of venous return which occurs by necessity in all single ventricles, results in a higher PO2 content in the main pulmonary artery and a lower PO2 content in the ascending aorta. These physiological changes have both in utero and postnatal consequences, including the high proportion of growth restriction in fetuses with CHD [53].

Left Heart Abnormalities

Left ventricular outflow lesions in the fetus range from mild aortic valve stenosis or coarctation of the aorta, which cause little or no significant changes in cardiac output or oxygen delivery, to critical aortic stenosis or mitral and aortic valve atresia with hypoplastic left ventricle (HLHS), which result in profound alterations of blood flow and oxygen delivery. The response of the ventricle to aortic valve obstruction depends on the severity of the obstruction and the rapidity with which it developed. If obstruction is mild or develops gradually, the LV can maintain cardiac output by hypertrophy. However, increased LV mass is at the expense of ventricular compliance and increased end-diastolic filling pressures. If the obstruction is severe or occurs rapidly, the LV cannot compensate, and stroke volume decreases. Thus, although the anatomy and pathology of a hypoplastic left ventricle and a severely dilated and dysfunctional left ventricle associated with critical aortic stenosis are different, in both cases the LV stroke volume is reduced, end-diastolic pressure is increased, and cardiac output of the LV falls. Thus, the alterations in the fetal circulation are similar. If there is no mitral or aortic insufficiency, left-sided obstructive lesions are well tolerated in utero.

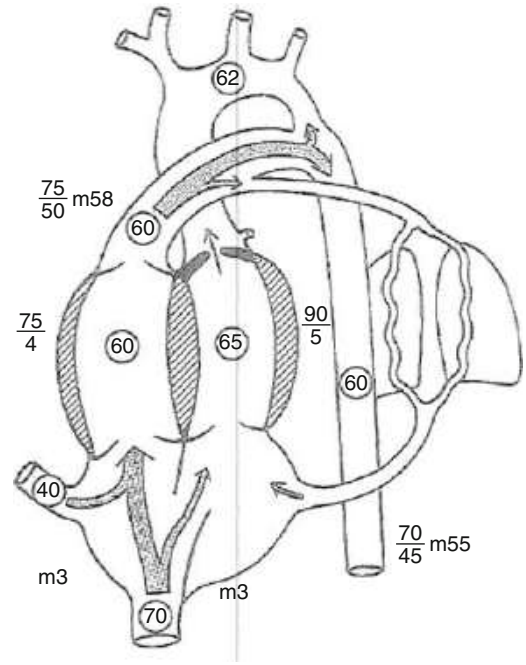

Fig. 10.3 Circulation, oxygen saturations, and pressures in the fetus with mitral and aortic atresia (hypoplastic left heart syndrome)

The course of the circulation in the fetus with severe LV dysfunction or hypoplasia is shown in Fig. 10.3. The combined fetal cardiac output is maintained by the right ventricle; thus, there is increased volume through the pulmonary artery and the ductus arteriosus and less through the transverse aortic arch and isthmus. Another reason for reduced blood flow through the transverse aortic arch is the increased impedance of the hypoplastic isthmus compared to the low

impedance of the fetal descending aorta (and placenta). However, with anatomic or functional aortic atresia, the entire cerebral circulation depends on retrograde ductal flow.

Oxygen delivery in the fetus with left outflow obstruction is affected as follows. With mitral atresia or high LA pressure from elevated LV end-diastolic pressure impairing transmitral flow, the normal right-to-left shunt across the PFO reverses. Less blood flow crossing from RA to LA may further slow growth of the left heart. In addition, preferential streaming of oxygenated blood across the foramen ovale to the left heart, coronary and cerebral circulation does not occur because of the reverse shunt at the foramen: Oxygenated blood from the IVC mixes with less oxygenated blood from the SVC and pulmonary veins in the right atrium. The oxygen saturation of blood entering the right ventricle, pulmonary artery, and ductus arteriosus is higher than normal, and oxygen delivery to the cerebral circulation is lower. Thus, oxygen delivery to the fetal brain is diminished because of less blood flow and a lower oxygen content of blood. This has been one explanation for the decreased head circumference found in newborns with HLHS [54].

To compensate for the lower oxygen delivery to the cerebral circulation, autoregulatory mechanisms in the fetus act to compensate for hypoxia by decreasing cerebral vascular resistance, increasing résistance in the umbilical artery [55, 56], and increasing flow in the ductus venosus, which delivers a greater proportion of more highly oxygenated blood to the heart [49]. Therefore, in response to the lower oxygen content and diminished blood flow volume, cerebral vascular resistance decreases in fetuses with functional or anatomical aortic atresia [57–59]. If there is limited antegrade flow across the left ventricular outflow tract, cerebral vascular resistance is intermediate between the normal fetus and the fetus with aortic atresia [58, 59].

The fetus with interrupted aortic arch type B usually has subaortic obstruction and a large ventricular septal defect (VSD) caused by posterior misalignment of the infundibular septum. Increased resistance across the subaortic obstruction results in a left-to-right shunt and increased oxygenation of blood to the pulmonary arteries, which may increase pulmonary artery pressure.

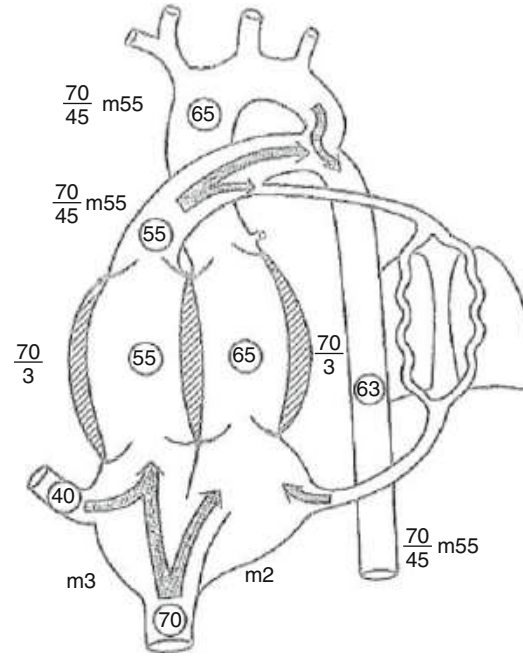

Fig. 10.4 The course of the circulation, oxygen saturations, and pressures in the fetus with ductal-dependent ("critical") coarctation of the aorta

Although mild coarctation of the aorta in the absence of VSD is not thought to disrupt in utero flow patterns, coarctation associated with hypoplasia of the transverse arch (so-called neonatal coarctation) is marked by decreased blood flow from the left ventricle to the aorta (Fig. 10.4). Echocardiographically, neonatal or ductal-dependent coarctation of the aorta is usually recognized by exaggerated size disproportion between the pulmonary artery and the aorta, and sometimes between the right and left ventricles. Also seen in coarctation is bidirectional shunting or, occasionally, left-to-right shunting across the foramen ovale. This suggests that there is increased blood flow volume and ventricular output across the right heart, pulmonary artery, and ductus arteriosus. In the presence of a VSD (and a bidirectional shunt), oxygenation in the

pulmonary artery and ascending aorta might be somewhat higher and lower, respectively, than normal. Cerebral vascular resistance in fetuses with coarctation is either normal or somewhat less than normal [58, 59], but in contrast to fetuses with aortic atresia, the head circumferences of fetuses with coarctation are normal [54].

Flow patterns in utero can anticipate the cardiovascular response to birth. For example, the flow pattern across the aortic isthmus can predict the postnatal hemodynamics in fetuses with left-sided obstructive lesions. Reverse isthmic flow, which occurs in systole, signifies decreased LV output and predicts a ductal-dependent postnatal circulation [29]. On the other hand, antegrade flow across the isthmus suggests the left ventricle is capable of sustaining the postnatal circulation. Critical obstruction at the level of the foramen can be detected by characteristic pulmonary venous flow patterns in utero [60] predicting the need for immediate postnatal creation of a patent foramen ovale [61].

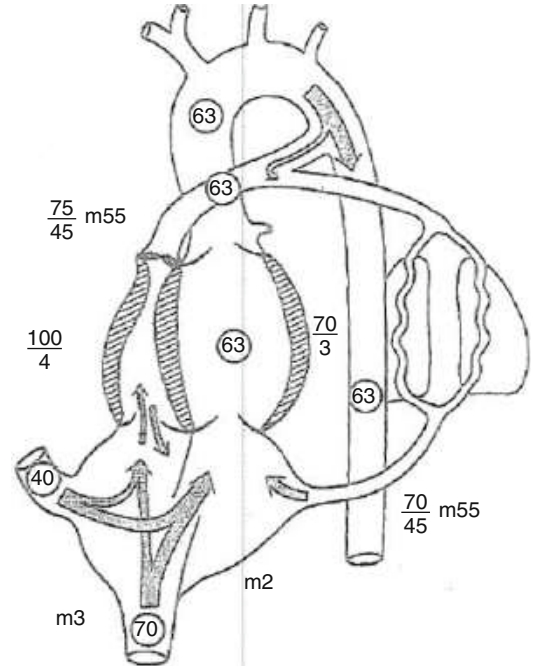

Fig. 10.5 The course of the circulation, pressures, and oxygen saturations in the fetus with pulmonary atresia and/or tricuspid atresia with intact ventricular septum

Right-Sided Obstructive Lesions

The spectrum of right-sided obstructive lesions, which reduce pulmonary blood flow, ranges from mild isolated valvar pulmonary stenosis to pulmonary and tricuspid atresia with hypoplastic right ventricle. Obstruction can be anatomic due to hypoplasia of the pulmonary outflow tract (usually the right ventricle) or pulmonary valve, or functional, as in the case of Ebstein's anomaly of the tricuspid valve or severe tricuspid valve dysplasia. In the latter cases, if there is severe insufficiency from the abnormal tricuspid valve, the RV is unable to generate sufficient pressure to overcome pulmonary artery pressure and open the pulmonary valve. As with left-sided obstructive lesions, if pulmonary outflow tract stenosis is mild to moderate and develops gradually, hypertrophy of the RV can maintain cardiac output until ventricular compliance decreases and filling pressures increase and the balance of the cardiac output is shifted to the LV and the combined cardiac output is maintained. Thus, because of the parallel circulation even with RV dysfunction or hypoplasia, most right-sided obstructive lesions are well tolerated in fetal life. The exceptions are those right-sided defects with severe tricuspid or pulmonary insufficiency as is seen with Ebstein's anomaly or tricuspid valve dysplasia, or tetralogy of Fallot with absent pulmonary valve or dysplastic pulmonary valve. The incidence of cardiac failure and in utero demise is increased with severe tricuspid or pulmonary valve insufficiency.

The fetal blood flow patterns in right-sided obstructive lesions depend upon the degree of and site of obstruction: The more proximal the obstruction (tricuspid valve vs. pulmonary valve), the more abnormal the flow pattern. The course of the circulation in the fetus with pulmonary atresia and/or tricuspid atresia with intact ventricular septum is shown in Fig. 10.5. Almost all of the systemic venous blood preferentially crosses the foramen ovale to the left heart, because resistance to flow into the RV is high due to the decreased compliance and increased filling pressures from the hypertrophied and

hypoplastic RV. Thus, the right atrium is decompressed through the foramen ovale, and as long as the foramen is large enough to accommodate the increased flow, heart failure should not develop. Because of the increased flow volume across the foramen ovale, RV stroke volume decreases and LV stroke volume increases. While in the normal heart, most of the cardiac output traverses the ductus arteriosus to the fetal body, in this case the ductus arteriosus carries only about 8 % of the combined cardiac output, which is reflected in its small size relative to the much larger aortic isthmus that carries 75 % of the combined cardiac output. When pulmonary obstruction develops early in gestation, and especially when flow is left-to-right through the ductus arteriosus (pulmonary atresia), the inferior angle at which the ductus arteriosus joins the descending aorta is much more acute than the normal oblique angle.

In the presence of a VSD, the blood flow patterns of the fetus with tricuspid atresia/pulmonary atresia will be somewhat different. The size of the VSD and the degree of right ventricular outflow tract (RVOT) obstruction will determine whether pulmonary blood flow is relatively normal or diminished. If the VSD is large and obstruction mild to moderate, a left-to-right shunt across the VSD increases pulmonary blood flow and the size of the pulmonary arteries. If the VSD is restrictive or the RVOT obstruction severe, pulmonary blood flow will be retrograde through the ductus arteriosus. These flow patterns can change with advancing gestation; for example, pulmonary atresia can develop from pulmonary stenosis.

The alterations in oxygen delivery in the fetus with pulmonary/tricuspid valve atresia and hypoplastic right ventricle depend on the presence or absence of a VSD. As there is complete admixture of the IVC, SVC, and pulmonary venous blood in the left atrium, the PO2 in the pulmonary blood flow will be higher than normal and the PO2 in the cerebral circulation will be lower than normal (Fig. 10.6). Higher oxygen content in the pulmonary circulation may decrease arteriolar vasoconstriction and the development of vascular smooth muscle, and affect the transaction of the

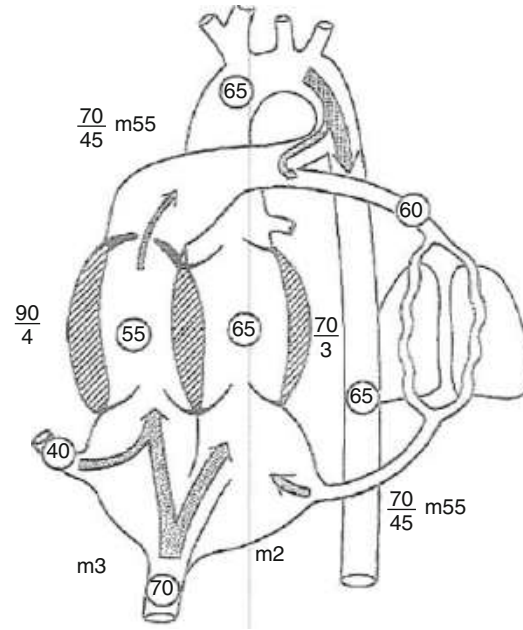

Fig. 10.6 The course of the circulation, oxygen saturations, and pressures in a fetus with tricuspid atresia and ventricular septal defect

pulmonary vascular bed from fetal to neonatal life. The effect of lower oxygen delivery on cerebral vascular resistance does not appear to be as straightforward as it is in the fetus with HLHS: In some studies, CVR was not different than normal [57, 59]; in other studies, CVR was decreased but not to the same extent as in fetuses with HLHS [58]. It may be that lower oxygen saturation is compensated by increased cerebral blood flow volume. Head circumferences in fetuses with right outflow obstructive lesions are either normal or minimally smaller than normal.

Similar to right heart obstructive lesions with a functional or anatomic single ventricle, the hemodynamic changes in the fetus with a normal right ventricle and varying degrees of pulmonary stenosis will depend on the degree of RVOT obstruction and the presence of a VSD. The extent of abnormalities in flow and oxygenation, however, are much less severe (Fig. 10.7). Flow across the foramen ovale and tricuspid valve is normal; the degree of obstruction in the pulmonary artery determines the flow pattern distal to the tricuspid valve. Because of the VSD,

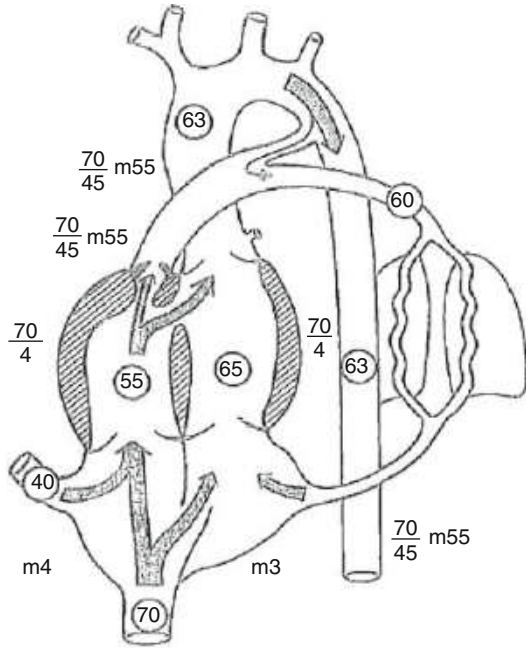

Fig. 10.7 The course of the circulation, pressures, and oxygen saturations in the fetus with pulmonary stenosis and ventricular septal defect

some of the flow will bypass the obstructed RVOT and pass to the LV and ascending aorta: With pulmonary atresia, all of the combined ventricular output will enter the ascending aorta. Thus, the PO2 of the cerebral circulation will be lower than normal. In this situation, pulmonary blood flow will be supplied retrograde to the pulmonary arteries from the ductus arteriosus. If, on the other hand, the obstruction across the RVOT is mild to moderate, very little RV blood flow will traverse the VSD, pulmonary blood flow and PO2 will be normal, and shunting through the duct will be from the pulmonary circulation to the systemic circulation.

Ebstein's Anomaly or Tricuspid Valve Dysplasia

Although anatomically different, blood flow patterns and oxygenation of the fetus with severe tricuspid insufficiency from either Ebstein's anomaly or tricuspid valve dysplasia is essentially the same. Antegrade flow across the pulmonary valve decreases because of preferential flow to the right atrium, which has a lower pressure and higher capacitance. The result is a dilated RA, increased flow to the LA across the foramen ovale, and decreased flow into the pulmonary artery and ductus arteriosus. If the foramen ovale is small, pressure in the already volume overloaded RA and RV will increase, and heart failure will rapidly develop. The dilated RV may compress the LV, restricting LV filling; thus, the LV cannot compensate for the decreased stroke volume of the RV, and the combined cardiac output decreases. If the tricuspid insufficiency is severe and occurs early in gestation, there are two consequences: First, the considerable enlargement of the RA and RV may also compromise growth of the fetal lungs. Second, the RV mass does not increase normally because of the high regurgitant volume, and the RV may not be able to generate sufficient pressure during systole to open the pulmonary valve. This results in functional pulmonary atresia, and just as in anatomic pulmonary atresia, pulmonary blood flow is completely dependent on the ductus arteriosus. In the most severe cases, not only is there functional pulmonary atresia, but concomitant pulmonary insufficiency. This causes a "circular shunt" which further exacerbates the volume overloaded right ventricle as the ductus arteriosus flow enters the RV during diastole. Low cardiac output may reduce placental blood flow, and so both oxygen and nutrient delivery to the fetus are impaired. Mixing of relatively desaturated right atrial and right ventricular blood with pulmonary venous blood in the left atrium reduces the PO2 of the cerebral circulation.

It is no wonder that there is a high incidence of demise in these fetuses; in fact the mortality in fetal Ebstein's anomaly/tricuspid valve dysplasia has not changed between 1991 and 2005 from 38 % to 48 % [60, 62–64]. Although many hemodynamic variables have been suggested as prognostic indicators, a CT ratio of >66 %, functional pulmonary atresia, and decreased LV function (compression or increased Tei index) all point to a poor prognosis for fetal or neonatal survival [65–67].

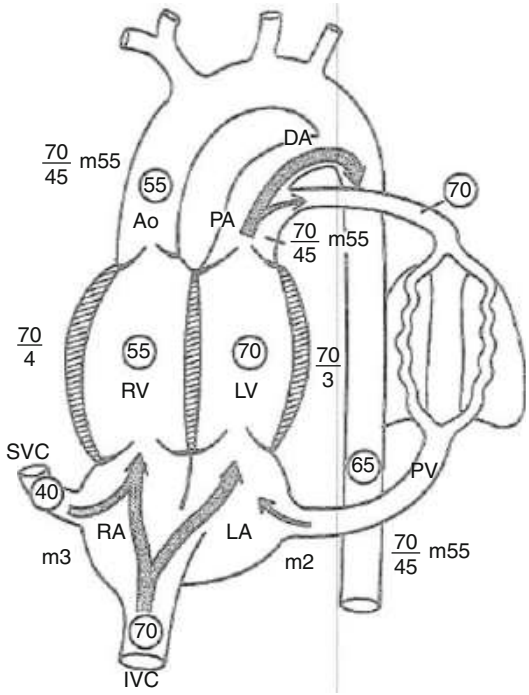

Fig. 10.8 Hemodynamics in the fetus with D-transposition of the great vessels and intact ventricular septum

Transposition of the Great Arteries

Patterns of blood flow in transposition of the great arteries (TGA) have been examined in detail. Since there is atrioventricular concordance, the preferential streaming of oxygenated blood through the ductus venosus and the foramen ovale to the left ventricle, as previously described, continues to occur. However, rather than entering the ascending aorta, oxygenated blood instead traverses the main pulmonary artery, and thence the ductus arteriosus and lungs (Fig. 10.8). Hence, oxygen saturation in the ascending aorta is about 20 % lower than in the normal fetus, while saturation in the pulmonary artery is higher (75 % vs. 50 %). The decreased oxygen content of the ascending aorta results in cerebral vasodilation and a "brain-sparing" effect similar to what occurs in fetuses with HLHS [57, 58, 68]. This is one of the speculations that head circumferences of fetuses and neonates with TGA are smaller than normal.

The increased oxygen content of the pulmonary arterial blood results in pulmonary vasodilation and increased blood flow with a higher oxygen concentration to the lungs. This has two consequences: First, increased flow volume and higher oxygen saturation early in pregnancy can result in premature maturation of the arteriolar muscles and pulmonary hypertension. Second, the increased pulmonary blood flow is at the expense of flow to the ductus arteriosus: Normally 85 % of RV output enters the ductus arteriosus, but in transposition the combination of pulmonary vasodilation and higher ductal impendence change the balance. In addition, the ductus is known to constrict in the presence of increased oxygen [69], with a progressive constrictive response at later gestational ages [70]. Restricted flow and higher oxygen content of the circulation to the ductus arteriosus may predispose to ductal constriction, as seen by reverse (aorta to pulmonary artery) flow during fetal life. Constriction of the ductus arteriosus can also contribute to the development of pulmonary hypertension in the fetus with TGA. It is not known why not all fetuses with TGA develop pulmonary hypertension; one hypothesis is that the ductus venosus may constrict and divert less volume of oxygenated blood to the left heart [71].

The altered hemodynamics of TGA also affect the size of the foramen ovale. Because of increased pulmonary blood flow, there is increased pulmonary venous return which raises left atrial pressure. Increased left atrial pressure can restrict the foramen ovale and promotes premature constriction or even closure, which theoretically can make it restrictive. The oxygen saturation in the pulmonary veins is also higher than normal because the lungs extract little if any oxygen.

Changes in the Circulation After Birth

The Postnatal Circulation in the Normal Fetus

There are four major cardiovascular adaptations after birth [72]. The first is loss of the placenta as the primary respiratory organ. With the clamping

of the umbilical cord, the systemic venous return to the IVC decreases from 40 % to 20 %. With less flow, the ductus venosus constricts and in hours to days closes. With removal of the low resistance placenta from the circulation, the systemic resistance promptly increases.

The second major adaptation occurs with the infant's first breath. The third adaptation pattern is change in the circulation from in parallel to in series, and the fourth concerns the changes in myocardial performance. Expansion of the lungs and breathing room air is associated with resorption of alveolar fluid and increased alveolar PO2 by stimulating pulmonary stretch receptors and relaxing vasodilation of pulmonary vasculature. Pulmonary vascular impedance plummets, and with the combination of increased surface area and decreased impedance, pulmonary blood flow increases. In the fetal lamb, pulmonary blood flow increases from 35 to 160–200 ml/kg/min [44]. Ventilation with oxygen further decreases pulmonary vascular impedance by decreasing the vasoconstriction of the medial smooth muscle and increases pulmonary blood flow. The combination of ventilation and oxygenation maximizes pulmonary blood flow.

Vasoreactive substances also influence the pulmonary blood flow in the newborn. Both prostaglandin and nitric oxide are known pulmonary vasodilators and their effects are inhibited by indomethancin and N-w-nitro. Treatment with either of these inhibitors prior to ventilation and oxygenation of newborn lambs will limit the fall in pulmonary vascular impedance and increase in pulmonary blood flow [44].

After the initial dramatic fall in pulmonary vascular impedance, pulmonary artery pressures continue to fall in the first weeks of life, probably related to regression of the muscular layer of the preacinar pulmonary arterioles. In the human infant, the nadir of pulmonary vascular impedance is 6–8 weeks [44]. The mechanism of regression of the muscular layer of the pulmonary arteries is unknown: speculations include apoptosis of the cells or precursors of the medial arteriolar layer or inhibition of further cell growth [44].

Within minutes to hours after birth, the increased pulmonary blood flow brings about a concomitant increase in pulmonary venous flow: from 8 % to 31 %. Because of the combination of increased pulmonary venous return and decreased flow to the right atrium from the IVC, the atrial pressures equalize, promoting closure of the foramen ovale [73]. Additionally, with the abrupt drop in pulmonary vascular resistance and increase in systemic vascular resistance, very little blood flow enters the ductus. As PO2 in the blood increases, endogenous production of PGE decreases, promoting ductal constriction and closure. With the constriction and closure of the ductus venous, the foramen ovale, and the ductus arteriosus, the parallel circulation of the fetus is transformed to the circulation in series of the infant. This means that the cardiac output is now defined as the volume of blood ejected by each ventricle, and unlike the circulation in parallel, that volume of blood is equal between the right and left ventricles [74].

With the circulation now in series and increased thermoregulatory and respiratory requirements (oxygen consumption in the newborn lamb increases from 7 to 18 ml/min/kg) [75, 76], the output of the ventricles increases substantially. When compared to fetal cardiac output, LV output increases threefold and RV output 1.5 times [77]. Augmented preload, specifically increased pulmonary venous return, is one mechanism whereby the LV increases cardiac output. Decreased afterload, due to decreased afterload from the low resistance pulmonary vascular bed, is another mechanism that can increase cardiac output in the RV. However, the increase in cardiac output is not entirely accounted for by changes in preload and afterload, suggesting other mechanisms. One such mechanism relates to the high pericardial pressure in utero which limit diastolic filling of the ventricles. After delivery and ventilation, the drop in intrapleural pressure allows improved filling and ventricular compliance allowing the ventricles to expand [38].

In addition to mechanical changes described above, histological changes in the myocardium promote increased cardiac output through increased contractility. The fetal heart grows by

hyperplasia of small myocytes with large nuclei. Thus, the DNA/protein ratio in fetal lamb myocardial cells is high and falls after birth, as myocytes become larger, and the heart size increases by hypertrophy. Cortisol is one of the stimuli for the maturation of the myocardium: Fetal cortisol levels rise just prior to birth [78].

Other hormones are influential in aiding the increased postnatal cardiac output. Responsiveness to beta-adrenergic receptors increases during labor and delivery, and together with higher catecholamine levels during the physiological stresses of birth, augment both myocardial contractility and heart rate. Thyroid hormone may be another key element in increased myocardial performance in the newborn, but its effects may not be immediate. Thyroid hormone deficiency in adult animals reduces cardiac output by limiting the number and responsiveness of beta-adrenergic receptors. Thyroid hormone appears to be important in utero as well: Fetal lambs undergoing thyroidectomy had a decreased number of beta-adrenergic receptors and a depressed response to catecholamine infusion after birth [31].

Postnatal Circulation in the Infant with Obstructed Systemic Blood Flow

The clinical presentation of the infant with left outflow obstruction will depend on the severity of obstruction, whether the defect is dependent on postnatal patency of the ductus arteriosus and the size of the foramen. After birth, obstruction from a stenotic aortic valve can be expected to increase because of increased LV output from 179 to 240 ml/min/kg and increased systemic afterload, obstruction from a stenotic aortic valve can be expected to increase. As long as flow across the aortic arch has been antegrade, left ventricular cardiac output should be adequate to sustain postnatal circulation in series. However, if the LV end-diastolic pressure is elevated due to cardiac dysfunction or decreased compliance from endocardial fibroelastosis, or a hypoplastic/stenotic mitral valve, left atrial pressures will rise and pulmonary venous congestion will ensue. This will happen shortly after birth if the foramen is small, which is common in left outflow obstruction. If retrograde flow in the transverse arch was noted in utero, PGE can be started to maintain ductal patency until balloon valvuloplasty or surgery can relieve the valve obstruction.

With aortic atresia, continued patency of the ductus arteriosus is essential for postnatal survival until surgery can be done. Flow across the ductus arteriosus decreases after birth because the placenta is removed from the circulation. Increasing pulmonary vascular resistances by respiratory therapy with nitrogen or CO_2 can increase the percentage of right-to-left shunt through the ductus arteriosus and improve systemic output. Flow across the foramen increases immediately after birth and continues to increase as pulmonary vascular resistance falls. With mitral atresia, the entire cardiac output must pass through the foramen ovale, so restriction to the left-to-right shunt across the latter results in pulmonary edema and cyanosis. If there is severe restriction or an intact atrial septum, an immediate balloon septostomy or laser creation of an atrial communication can be lifesaving.

Postnatal Circulation with Obstructed Pulmonary Blood Flow

Defects in this category include tricuspid atresia and VSD with normally related great vessels, pulmonary atresia and intact ventricular septum, Ebstein's anomaly of the tricuspid valve with functional pulmonary atresia, and tetralogy of Fallot with severe pulmonary stenosis or atresia, or absent pulmonary valve.

Tricuspid Atresia and Pulmonary Atresia with Intact Ventricular Septum

When the ventricular septum is intact, the postnatal blood flow patterns do not differ substantially from fetal blood flow patterns. If the pulmonary valve is atretic, the postnatal hemodynamics depend on the degree of RV hypoplasia and the tricuspid valve function. The RV is frequently suprasystemic. If there is some

patency of the tricuspid valve but pulmonary atresia, there is usually a tiny RV and tricuspid insufficiency. If the tricuspid valve is large, there is a greater amount of tricuspid valve insufficiency. The pulmonary blood flow depends on the size of the ductus arteriosus. As the ductus arteriosus constricts after birth, pulmonary blood flow decreases resulting in hypoxemia and acidemia. The foramen ovale usually remains patent because it is larger than normal due to the increased RA to LA shunt in utero, and because the flap of the foramen does not close the defect due to low left atrial pressures from decreased pulmonary blood flow. In the presence of a VSD, the size of the VSD and the degree of pulmonary outflow obstruction determines postnatal hemodynamics. If the VSD is large, the pulmonary arteries are usually not obstructed because of left-to-right shunting through the VSD in utero. After birth, the pathophysiology is like that of a large VSD: pulmonary blood flow, left atrial pressure and ventricular end-diastolic pressures all increase, and there will be pulmonary venous congestion. Systemic vascular congestion can also occur if the LA pressure is high enough to close the foramen ovale. If the VSD is small, the postnatal hemodynamics are similar to those of patients with pulmonary atresia with intact ventricular septum.

An important determinant of LV function in infants with pulmonary/tricuspid atresia and intact ventricular septum is sinusoids connecting the coronary arteries and the RV cavity. The blood flow to the embryonic ventricle is through a series of sinusoids. Coronary arteries develop later, connect with the aorta, and the sinusoids obliterate. It is believed that when pulmonary atresia develops very early and the RV is suprasystemic, the high pressure in the RV prevents regression of the sinusoids and maintains sinusoid to coronary artery flow. During diastole, the pressures in the RV decrease, and flow is from the coronary arteries to the sinusoids in the RV, rather than to the coronary arteries in the LV. Thus, any stimulus that would decrease diastolic pressure in the RV would promote "coronary steal" from the LV myocardium. A second concern is the high number of coronary abnormalities in this situation. Sometimes the coronary arteries do not even connect with the aorta, and perfusion of myocardium supplied by that coronary is dependent on the diastolic RV pressure. Frequently, there are areas of stenosis at the coronary artery-sinusoid junction further predisposing the myocardium to ischemia and fibrosis.

Tetralogy of Fallot

The postnatal hemodynamics of the newborn with tetralogy of Fallot depend upon the degree of outflow tract obstruction, the size of the ductus arteriosus and/or multiple aorto pulmonary collaterals (MAPCAs), and the relationship of pulmonary to systemic resistance. Both MAPCAs and a ductal-dependent pulmonary circulation can be detected by fetal echocardiography. If MAPCAs are the source of pulmonary blood flow, the flow will increase as pulmonary vascular resistance falls and as systemic arterial pressure increases. The volume of flow throughout the MAPCAs can be high and even result in pulmonary venous congestion and heart failure. On the other hand, if there are no MAPCAs and pulmonary blood flow is through the ductus arteriosus, the amount of flow will depend on the size of the ductus arteriosus. Due to the large VSD, pressures in the right and left ventricles will be equal, and the net direction of blood flow will depend on the differences in RV and LV afterload, or between systemic blood pressure and RVOT obstruction.

Ebstein's Anomaly/Tricuspid Valve Dysplasia

The timing of delivery and management of the newborn with severe tricuspid valve disease is one of the most challenging areas of perinatal/neonatal cardiology. Delaying delivery until fetal lung maturity is assured often results in hydrops and possibly intrauterine demise. While decreased pulmonary vascular resistance after birth may promote antegrade flow across the RVOT, the RV stroke volume remains low because of the large regurgitant flow, atrialization of the RV or

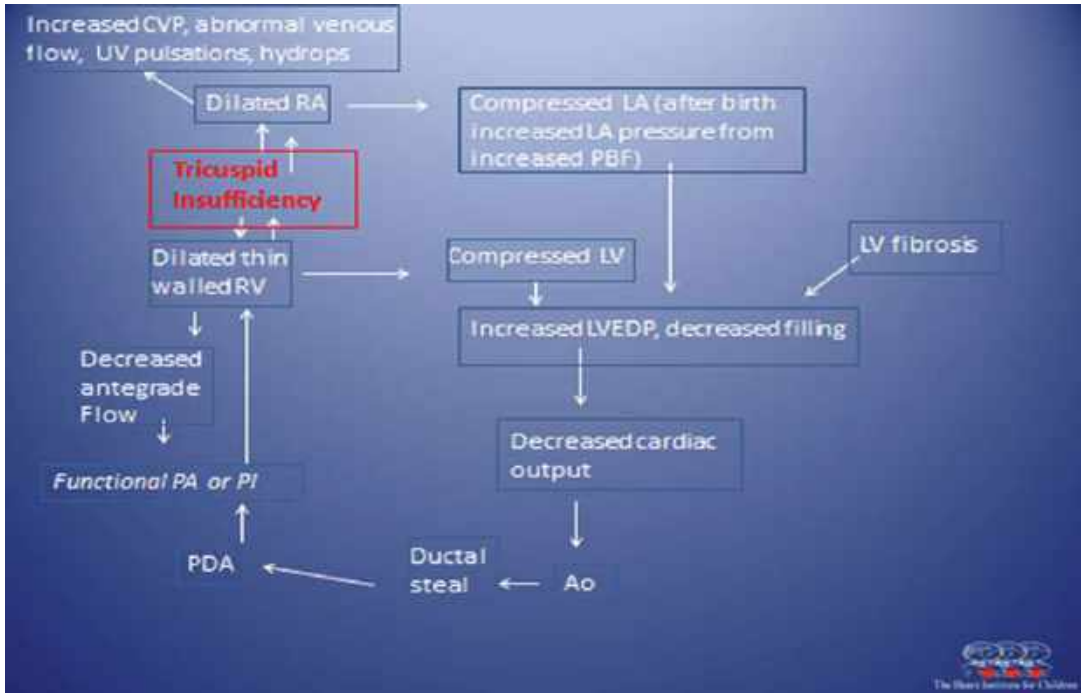

Fig. 10.9 The hemodynamic effects of the so-called circular shunt seen in the fetus with severe tricuspid insufficiency due to tricuspid valve dysplasia or Ebstein's anomaly and pulmonary insufficiency

a paper-thin RV which cannot generate sufficient pressure to provide pulmonary blood flow, and often, pulmonary insufficiency which results in a "circular shunt" (Fig. 10.9). There is hypoxemia for many reasons: high right atrial pressures promote a right-to-left atrial shunt throughout the foramen, inadequate pulmonary blood flow from decreased RV stroke volume, and if the ductus is patent, increased pulmonary artery pressure and vascular resistance. Heralding a poor neonatal outcome are a CT ratio of >90 % (66 % in the fetus), functional pulmonary atresia with pulmonary insufficiency, and LV dysfunction. Of those who survive to be born alive, those who die during the neonatal period have a high incidence of pulmonary hypoplasia (due to severe and long-standing cardiomegaly), hydrops, and functional pulmonary atresia/pulmonary insufficiency. Atrial arrhythmias, including atrial flutter, can cause even greater compromise of cardiac output and oxygenation [79].

Successful management of the newborn with severe Ebstein's anomaly/tricuspid valve dysplasia depends on an understanding of the pathophysiology, especially with regard to the ductus arteriosus. If there is a fixed anatomical obstruction to the RVOT, continued patency of the ductus arteriosus to augment pulmonary blood flow combined with pulmonary vasodilators can improve hypoxia. But if there is functional atresia, especially with pulmonary insufficiency, there will be increased systemic steal to the systemic circulations from the pulmonary arteries. Pulmonary artery pressures will increase and the RV will have to pump against systemic pressure. This will exacerbate the circular shunt and poor RV and LV output. On the other hand, ligating the ductus arteriosus and dropping the pulmonary vascular resistance can promote antegrade pulmonary artery flow. Using this approach in select cases reduced mortality to only 7 % in one study [67].

Transposition of the Great Arteries

A successful transition to postnatal life in the fetus with D-TGA and intact ventricular septum is possible only with a widely patent ductus arteriosus or foramen ovale. Without persistence of these fetal channels, there can be no mixing of oxygenated and deoxygenated blood (Fig. 10.10), and the newborn will develop several cyanosis and acidemia. The adequacy of the foramen ovale and ductus arteriosus for immediate newborn survival can be difficult to determine before birth, but the findings of a hypermobile intraatrial septum that passes from the LA to the RA, and reverse (Ao to PA) shunting in the ductus arteriosus have been found to be predictive of the need for immediate postnatal balloon atrial septostomy [80]. Other clues seen on fetal echocardiography are a ductus arteriosus diameter of <3 mm, continuous flow in the ductus arteriosus suggesting obstruction or and the flap of the foramen ovale bulging greater than 50 % into the left atrium [81]. Urgent balloon atrial septostomy is necessary in 10–50 % of newborns with D-TGA and intact ventricular septum.

Following delivery, systemic vascular resistance increases and afterload on the systemic RV increases. However, afterload on the LV decreases and the pulmonary vascular resistance falls. Pulmonary blood flow increases as does LA pressure, which promotes apposition of the flap of the foramen ovale and restriction or even closure. If the foramen ovale is large, either following balloon septostomy or de novo, the increase in LA pressure will promote a left-to-right shunt and improve mixing and oxygenation of the infant. There can also be bidirectional shunting across the ductus arteriosus to improve mixing. The volume of the ductus arteriosus shunt will depend on the size of the ductus arteriosus and the ratio between systemic and pulmonary vascular resistance. Because the pulmonary circulation has been exposed to higher oxygen levels in utero, the pulmonary vascular resistance may fall more quickly after birth.

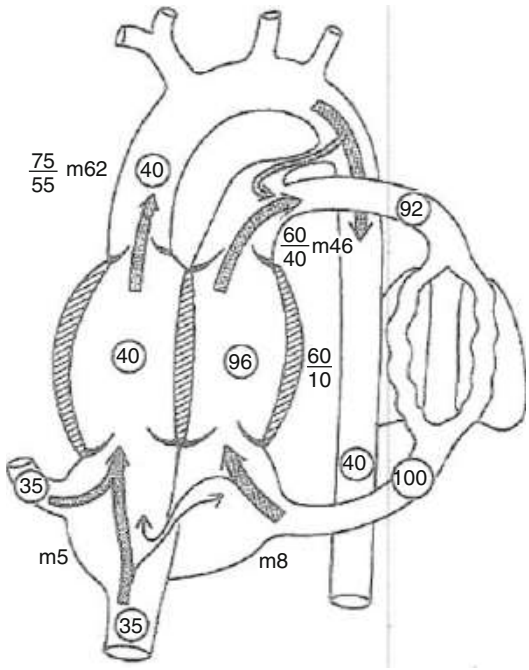

Fig. 10.10 The postnatal hemodynamics in the newborn with D-transposition of the great vessels, intact ventricular septum, and no semilunar valve abnormalities

Structural Heart Disease in the Fetus

11

John M. Simpson and Caroline B. Jones

Abstract

Congenital heart defects can be diagnosed by ultrasound during fetal life with a high degree of diagnostic accuracy at specialist centers. Cardiac defects characterized by an abnormal four-chamber view of the heart have higher detection rates than those lesions which depend on views of the outflow tracts for their detection. Prenatal detection allows appropriate preparation for delivery and for the prenatal identification of associated anomalies. Prediction of babies who will require emergency postnatal intervention means that planning the site of delivery and emergency management is facilitated. There is evidence that postnatal outcome may be improved by prenatal diagnosis of some cardiac lesions including hypoplastic left heart syndrome, transposition of the great arteries, and coarctation of the aorta.

Introduction

Prenatal diagnosis of congenital heart disease has evolved dramatically over the past 30 years since the earliest reports of accurate fetal diagnosis. Virtually all forms of structural cardiac defect have now been described during fetal life and large series of thousands of cases have been reported [1]. However, there are significant challenges which remain which include risk stratification for purposes of prognostication, the role of intervention to alter the natural history of congenital heart disease, and optimal perinatal management of affected fetuses. The optimal screening policy for congenital heart defects is in a state of flux with the introduction of screening tests such as nuchal translucency scanning which may identify fetuses at high risk for congenital heart disease [2, 3] in addition to traditional historic or fetal risk factors.

For pediatric cardiologists, neonatologists, intensive care specialists, and other healthcare professionals involved in the immediate care of affected infants, there is a crucial role for the fetal cardiologist to indicate potential perinatal clinical problems so that adequate preparation for delivery is made. This chapter aims to address several of the practical aspects around screening and perinatal care in addition to description of the structural lesions themselves.

Screening for Congenital Heart Disease

The "Low-Risk" Population

In the absence of specific risk factors, views of the fetal heart are simply incorporated into the obstetric anomaly scan which is widely performed in many countries. The most common view of the fetal heart which is obtained is the four-chamber view (Fig. 11.1, Video 11.1). This view has the advantage that there are external reference points to indicate that the sonographer is in the appropriate cut, namely, that a single rib is visualized around the fetal thorax. The key features of this view are shown in Fig. 11.1. If the sonographer scans in a plane just below the fetal heart, then the stomach can be visualized to the left and the relationship of the aorta and

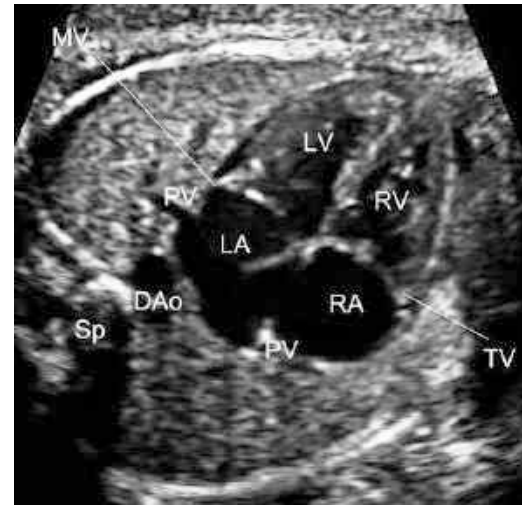

Fig. 11.1 4CH: Cross section through the fetal chest demonstrating a normal four-chamber view. The following structures are visualized: right and left atria (*RA, LA*), right and left ventricles (*RV, LV*), and mitral (*MV*) and tricuspid valves (*TV*). Pulmonary veins (*PV*) can be seen entering the LA from the left and right sides. The descending aorta (*DAo*) lies in front of the fetal spine (*Sp*)

Video 11.1 Transverse view through the fetal chest demonstrating a normal four-chamber view with good systolic function. Left and right ventricular chambers are of equal size. Normal differential insertion and movement of the mitral and tricuspid valves is seen. The flap valve of the foramen ovale can be seen moving from right to left. Pulmonary veins can be seen entering either side of the left atrium

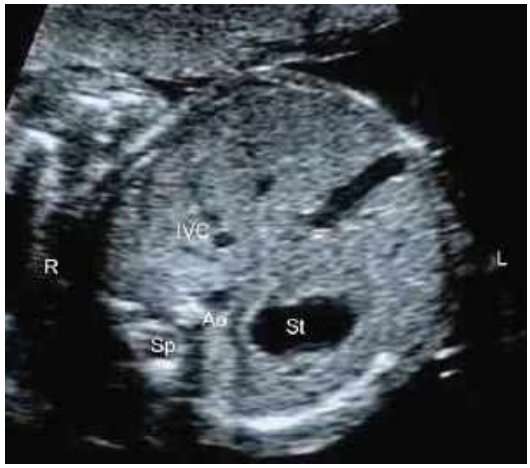

Fig. 11.2 Situs: Normal arrangement of abdominal vessels seen in cross section through the upper fetal abdomen. The descending aorta (*Ao*) and fetal stomach (*St*) are visualized on the fetal left (*L*). The inferior vena cava (*IVC*) lies to the right (*R*) of the fetal spine (*Sp*) and anterior to the Ao

Video 11.2 Transverse view through the upper fetal abdomen. The stomach and pulsatile descending aorta can be seen on the fetal left. The inferior vena cava lies to the right of the fetal spine and is anterior to the aorta

inferior vena cava can be observed to infer that there is usual atrial arrangement (normal cardiac situs) (Fig. 11.2, Video 11.2).

There is regional variation about whether additional views are obtained as part of routine anomaly scans. Extended views of the heart which can be obtained include those of the left ventricular outflow tract, right ventricular outflow tract, and

Fig. 11.3 LVOT: Cross section through the fetal chest demonstrating a normal left ventricular outflow tract. The aortic valve (*AoV*) can be seen arising normally from the left ventricle (*LV*). The interventricular septum (*IVS*) is seen dividing the left and right ventricles (*RV*). Note the continuity between the septum and anterior wall of the aorta. The left atrium (*LA*) is connected to the LV by the mitral valve

the "three-vessel" view in the upper mediastinum (Figs. 11.3, 11.4, and 11.5 and Videos 11.3, 11.4, 11.5, and 11.6). Such views can be obtained by a sweep cranially from the views of abdominal situs through the four-chamber view to the outflow tracts [4, 5]. Some cardiac lesions, for example, hypoplastic left heart or tricuspid atresia, will be associated with an abnormal four-chamber view of the heart. However, other cardiac lesions affecting the outflow tracts such as transposition of the great arteries, tetralogy of Fallot, or common arterial trunk (truncus arteriosus) will depend on extended views of the outflow tracts for their detection, because the four-chamber view is typically normal or near normal. Although pregnancies may be subdivided into those perceived to be at high or low risk for congenital heart disease, most cases of congenital heart disease occur in the low-risk population. Thus, detection of affected fetuses depends on the skills and training of sonographers providing the screening examination. Ensuring a high uniform standard of training represents a major challenge [6].

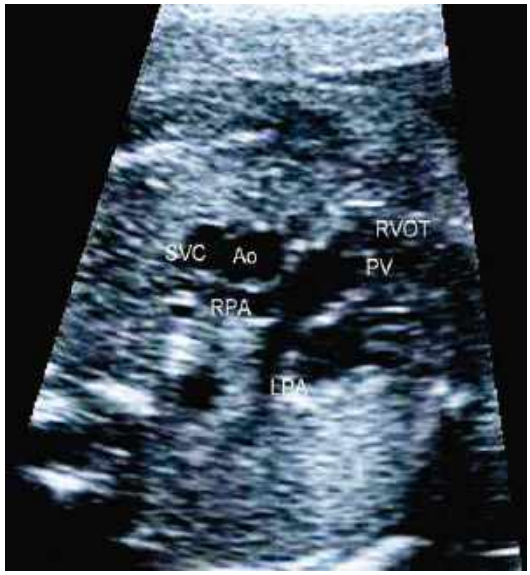

Fig. 11.4 RVOT: Cross section through the fetal chest demonstrating a normal view of the right ventricular outflow tract. The pulmonary valve (*PV*) and main pulmonary artery is demonstrated arising from the right ventricular outflow tract (*RVOT*) and branching into the left and right pulmonary arteries (*LPA, RPA*). The aorta (*Ao*) and superior vena cava (*SVC*) are visualized to the fetal right

Fig. 11.5 3VV: Cross section through the upper fetal chest demonstrating a normal three-vessel view. The ductus arteriosus (*DA*) and right (*R*) superior vena cava (*SVC*) are seen. The aorta is seen passing in front and to the left (*L*) of the trachea (*Tr*) confirming a left aortic arch. The thymus (*Thy*) is seen in front of the three vessels

The "High-Risk" Population

For some pregnancies, the risk of congenital heart disease is sufficiently elevated that detailed fetal echocardiography is indicated. Such assessments will be performed by operators who have had specific training in the diagnosis and management of congenital heart disease. These fetal echocardiograms will include a comprehensive assessment of all cardiac connections, with the use of color-flow and pulsed-wave Doppler to assess flow into and out of the heart [7, 8]. Fetal cardiologists are integral to these assessments and will provide explanation and guidance to expectant parents with regard to the associations, prognosis, and approach to management of the congenital heart lesion.

Traditional risk factors for referral for detailed fetal echocardiography include a family history of congenital heart disease in a first-degree relative and fetal factors known to be associated with congenital heart defects including extracardiac anomalies or fetal hydrops [7–9]. Nuchal translucency (NT) thickness has an association with congenital heart disease which is independent of the fetal karyotype and for which the strength of the association increases with the value of NT [10]. There is debate about the threshold of NT which should prompt referral, but most workers favor the 99th percentile as a threshold [11] for detailed fetal echocardiography. Recent work has addressed whether interrogation of ductus venosus flow will improve targeting of fetal echocardiography [12]. Table 11.1 includes referral indications for detailed fetal echocardiography according to the recommendations of different groups who have published in this field [7–9].

Impact of Prenatal Diagnosis of Congenital Heart Disease on Prenatal Management

The initial priority of the fetal cardiologist is to confirm congenital heart disease in the fetus or provide reassurance of normality. In some situations, for example, suspicion of fetal

Video 11.3 Cross section through the fetal chest demonstrating a normal left ventricular outflow tract. The interventricular septum is intact and seen dividing the left and right ventricles. The left atrium is connected to the left ventricle by the mitral valve. Scanning up towards the fetal head the main pulmonary artery can be seen crossing the aorta

Video 11.4 Cross section through the fetal chest demonstrating the anteroposterior course of the normal right ventricular outflow tract. The pulmonary valve (*PV*) and main pulmonary artery are demonstrated arising from the right ventricular outflow tract (*RVOT*). This can be seen branching into the left and right pulmonary arteries and the ductus arteriosus that passes towards the fetal spine to join the descending aorta. The aorta and superior vena cava are visualized to the right of the main pulmonary artery

coarctation of the aorta, it may not be possible to reach a clear definitive diagnosis. For other lesions, notably aortic valve and pulmonary valve stenosis, there may be progression of severity with advancing gestational age, necessitating sequential studies to try to provide fuller information. A full cardiological diagnosis is essential so that parents can be advised with respect to the cardiac prognosis and potential associations. Prenatal diagnosis affords the parents time to consider the treatment options and potentially to meet with cardiac surgeons or interventional cardiologists who may be involved after birth [6].

Video 11.5 Cross section through the upper fetal chest demonstrating a normal three-vessel view. The ductus arteriosus and right-sided superior vena cava are seen on either side of the aorta. The aorta is seen passing in front and to the left of the trachea confirming a left aortic arch. The thymus can be seen in front of the three vessels

Aside from the cardiac findings, investigation for potential associated abnormalities, including karyotypic abnormalities and extracardiac structural anomalies, is important. As a minimum, a detailed anomaly scan is undertaken to check the fetus for other structural abnormalities and any other markers of karyotypic abnormality. Amniocentesis or chorionic villus sampling to check the fetal karyotype is typically discussed. The strength of the association between the cardiac lesion and chromosomal abnormalities depends on the cardiac lesion as well as other sonographic findings. Some cardiac lesions such as simple transposition of the great arteries, aortic valve stenosis, and laterality disturbances are rarely associated with major karyotypic abnormalities, whereas other lesions such as atrioventricular septal defect and ventricular septal defects are much more commonly associated with chromosomal abnormalities. Abnormalities of the outflow tracts, for example, tetralogy of Fallot and common arterial trunk (truncus arteriosus), may be associated with specific genetic findings, notably chromosomal 22q11 deletions. If fetal karyotyping is performed, then analysis for 22q11 deletions needs to be specifically requested because standard techniques will not detect such deletions. Thus, the overall prognosis which is conveyed to parents will take account not only of the cardiac findings but also the associated findings as far as these can be determined during fetal life.

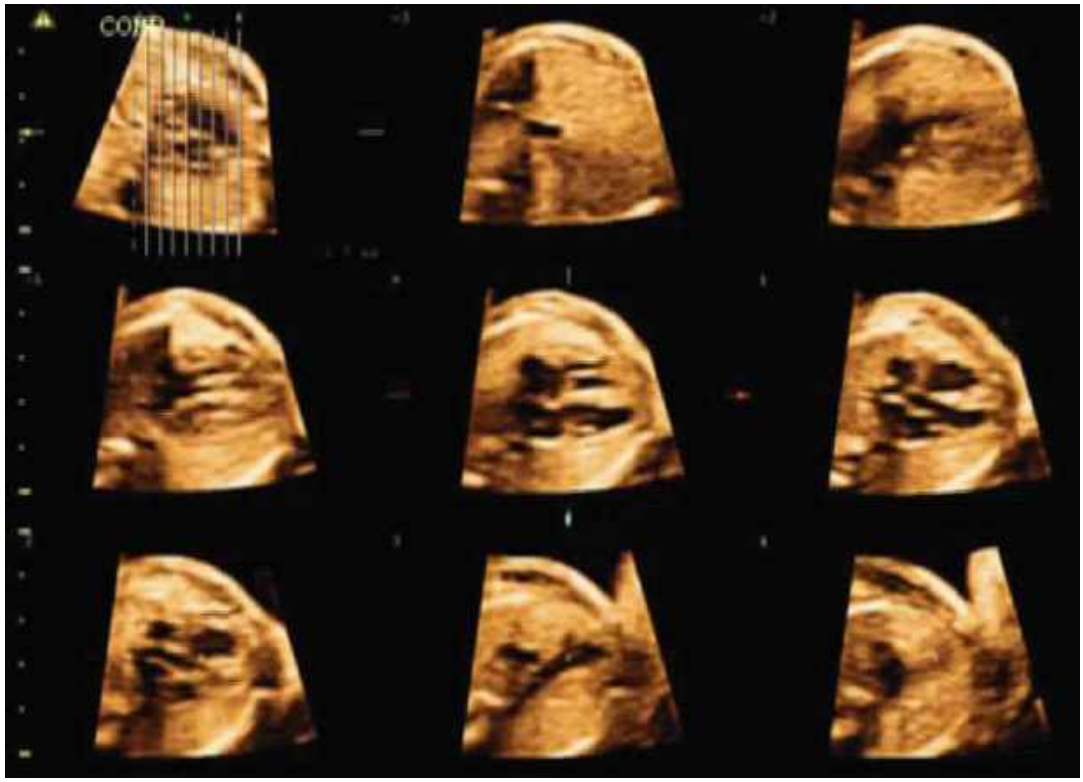
Spectrum of Congenital Heart Defects Diagnosed During Fetal Life

For practical purposes, the lesions described in this section have been subdivided into those which can be detected on the four-chamber view of the fetal heart and those which are primarily of the outflow tracts. Those lesions which present a particular difficulty in terms of prenatal diagnosis are described in the third section. These lesions are summarized in Table 11.2 [13].

Four-Chamber View Abnormalities

Hypoplastic Left Heart Syndrome

This lesion is characterized by severe underdevelopment of left heart structures including the mitral valve, left ventricle, and aorta. "Classical" forms of hypoplastic left heart syndrome are characterized by mitral and/or aortic atresia, but a subgroup of fetuses who fall into this spectrum may have had critical aortic stenosis with a dilated left ventricle earlier in gestation [14]. This is the group for whom balloon perforation of the aortic valve has been undertaken with the aim of promoting growth and development of left heart structures [15]. In hypoplastic left heart syndrome during fetal life, the circulation is supported by the right ventricle which pumps systemic arterial blood antegrade across the arterial duct. The blood supply to the brain is achieved by retrograde flow in the aortic arch. This group of lesions is invariably duct dependent postnatally, necessitating prompt commencement of prostaglandin E. Restriction of blood flow at the level of the foramen ovale is



Video 11.6 Nine panel TUI display illustrating parallel transverse views of the normal heart through the fetal chest

a particular prenatal consideration [16] both for immediate postnatal management and with regard to longer-term prognosis. If the foramen ovale is highly restrictive, this may result in secondary pulmonary vascular damage which may preclude completion of a total cavopulmonary circulation after birth [17]. The reported results for this patient group are worse than those fetuses without restriction [17]. In view of the poor prognosis which has been observed in this subgroup of fetuses with hypoplastic left heart syndrome, prenatal intervention has been undertaken with the aim of improving the perinatal condition and prognosis [18] (Fig. 11.6, Videos 11.7a and 11.7b).

Critical Aortic Stenosis

Critical aortic stenosis is a relatively rare lesion during fetal life. The severity of aortic stenosis is variable, but most affected fetuses have reduced contraction of the left ventricle (Fig. 11.7). The size of the left ventricle is variable ranging from dilated to severe hypoplasia of the left heart structures. Critical aortic stenosis may progress during gestation with subnormal growth and development of the mitral valve, left ventricle, and aorta [14]. There is a variable degree of mitral valve disease and left ventricular endocardial fibroelastosis. Prenatal balloon aortic valvuloplasty has been advocated to improve growth of the left heart and left ventricular function [14, 15]. This is set against the risk of the interventional procedure and the guarded results to date (Videos 11.8a, 11.8b, and 11.8c).

Coarctation of the Aorta

Fetuses with coarctation of the aorta will usually show an abnormality of the four-chamber view, with dominance of the right ventricle compared to the left. This is accompanied by a discrepancy in the size of the great arteries, particularly the

Table 11.1 Summary of risk factors which should prompt detailed cardiac evaluation

Fetal factors
Suspected cardiac abnormality on screening ultrasound
Increased nuchal translucency thickness
Fetal hydrops
Fetal abnormality with known association with congenital heart disease, e.g., exomphalos, diaphragmatic hernia
Fetal arrhythmia
Abnormal fetal karyotype, e.g., trisomy 21
Abnormal ductus venosus flow patterns (ISUOG guidelines)
Multiple pregnancies, e.g., monozygotic twin pregnancies, twin-twin transfusion (ASE guidelines)
Maternal and familial risk factors
Family history of congenital heart disease (CHD) in a first-degree relative
Diabetes mellitus – mothers who are established diabetics on treatment
Mothers with a tendency to diabetes which is solely related to pregnancy are not judged candidates for fetal echocardiography
Mothers taking known teratogenic drugs, e.g., anticonvulsants, lithium
Maternal anti-Ro or anti-La antibodies
Mothers who have anti-Ro and/or anti-La antibodies are candidates for fetal cardiology assessment in view of the risk of developing fetal heart block. The mother with autoimmune disease who does not have anti-Ro or anti-La antibodies is not a candidate for fetal echocardiography
Maternal infections, e.g., parvovirus, Coxsackie
Maternal ingestion of prostaglandin synthetase inhibitors, e.g., ibuprofen
In vitro fertilization (ASE guidelines)

Table 11.2 Ease of detection of different congenital heart lesions according to the sonographic views required (Reproduced with permission [13])

Examples of major lesions evident on "four-chamber views" of the fetal heart
Hypoplastic left heart syndrome
Severe coarctation of the aorta
Critical aortic stenosis
Tricuspid atresia
Pulmonary atresia with intact ventricular septum
Atrioventricular septal defect
Double-inlet ventricles
Examples of major lesions where the four-chamber view of the heart is typically normal/near normal and for which views of the outflow tracts are required
Transposition of the great arteries
Tetralogy of Fallot +/− pulmonary atresia
Common arterial trunk
Some forms of coarctation of the aorta
Examples of lesions which are difficult to detect even in experienced hands
Total anomalous pulmonary venous drainage
Coarctation of the aorta (milder forms)
Some types of ventricular septal defect
Milder forms of aortic and pulmonary valve stenosis
Lesions which cannot be predicted from prenatal cardiac imaging
Patent arterial duct
Secundum atrial septal defects

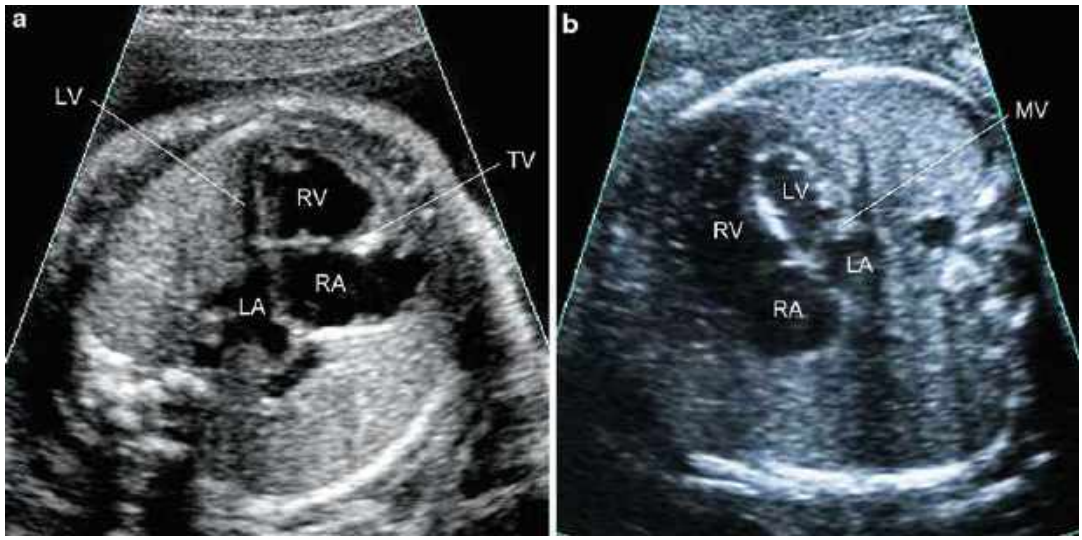


Fig. 11.6 (**a**) Four-chamber view in a fetus with mitral atresia. There is a bright band of tissue seen separating the small left atrium (*LA*) from a slit-like left ventricle (*LV*). The right atrium (*RA*) and right ventricle (*RV*) are the dominant structures separated by the tricuspid valve (*TV*). (**b**) Four-chamber view of a fetus with aortic atresia. The left atrium (*LA*) is small and the left ventricle (*LV*) and mitral valve (*MV*) are bright and severely hypoplastic. The right atrium (*RA*) and tricuspid valve (*TV*) appear normal and the right ventricle (*RV*) forms the cardiac apex

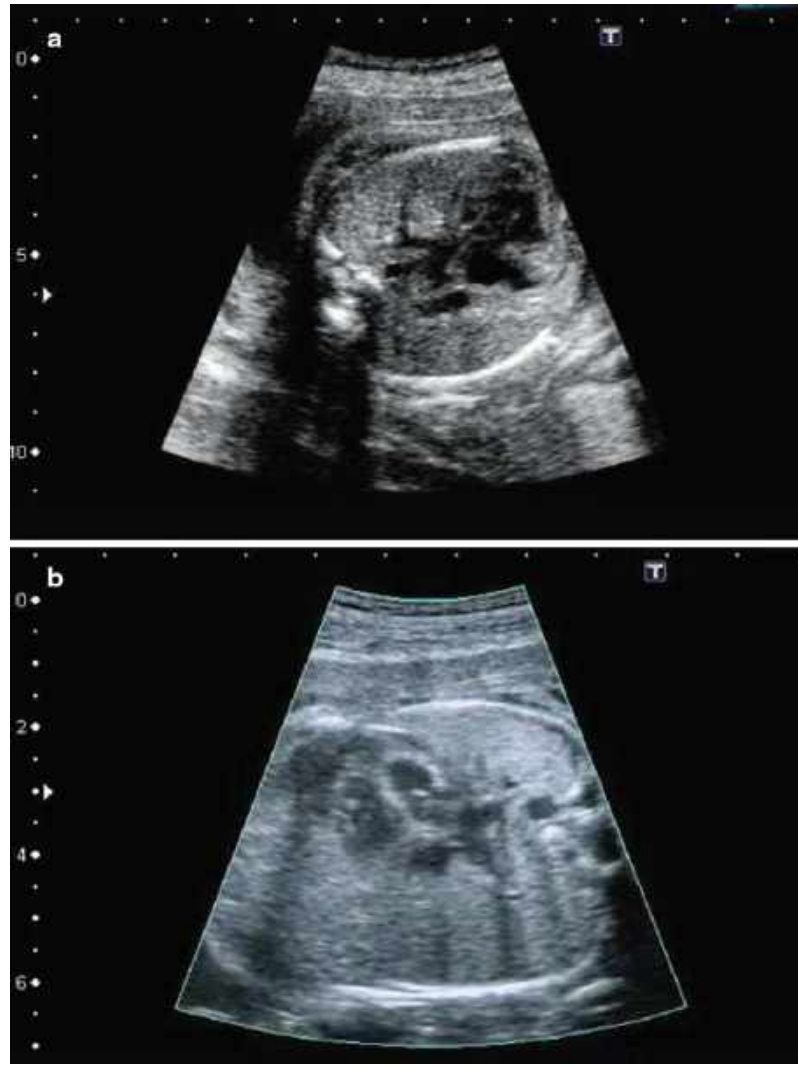
distal aortic arch (Fig. 11.8). In the fetal circulation, the arterial duct is patent with antegrade flow from the right ventricle to the descending aorta. Thus, loss of pulsatility of the descending aorta is not a prenatal feature of juxtaductal coarctation of the aorta. Making a definitive diagnosis of coarctation of the aorta during fetal life is difficult and some fetuses with cardiac asymmetry may be entirely normal [19, 20]. The use of gestation-specific z-scores to gauge the size of the ductal and aortic arches may improve diagnostic accuracy [21]. Postnatally, initial echocardiography may be definitive, but in many cases it is necessary to permit the arterial duct to close to assess whether arch obstruction develops as the duct constricts. Even after ductal closure, some infants may continue to present later and most units will follow sequentially [22]. At the other end of the spectrum, fetuses with the most severe underdevelopment of left heart structures may have to undergo single-ventricle palliation postnatally if the left heart is not judged adequate to support the systemic arterial circulation [22] (Videos 11.9a and 11.9b).

Tricuspid Atresia

The four-chamber view in this lesion is invariably abnormal (Fig. 11.9). Typically, there is a complete absence of the right atrioventricular connection rather than an imperforate tricuspid valve. The coexistence of a ventricular septal defect is universal; although the size of the defect is variable, restriction of blood flow at the level of the ventricular septal defect is a postnatal consideration. In most cases there is usual arrangement of the great arteries [23], although stenosis/atresia of the pulmonary valve may occur. In a minority of cases, the great arteries are transposed which is frequently associated with hypoplasia of the aortic arch [23] (Videos 11.10a and 11.10b).

Pulmonary Atresia with Intact Ventricular Septum

This lesion represents a spectrum of abnormalities, with a variable size of the right ventricle, development of the pulmonary arteries, and coexistence of right ventricular to coronary communications (Fig. 11.10). Most cases have hypoplasia of the tricuspid valve and



Video 11.7 (**a**) Four-chamber view in a fetus with mitral atresia. The left ventricle is thin and slit-like and in the position of the mitral valve is a bright band of tissue. The right atrium and right ventricle are dominant separated by the tricuspid valve. (**b**) Transverse views of a fetus with aortic atresia and hypoplastic left heart syndrome. The left ventricle is non-apex forming, hypoplastic, and echogenic consistent with endocardial fibroelastosis. There is very little movement of the mitral valve and there is poor left ventricular contractility

a diminished right ventricular cavity. In some there is muscular atresia, i.e., there is muscle interposing between the cavity of the right ventricle and the pulmonary arteries, whereas in other cases the right ventricle is tripartite and there is "membranous" atresia with only an imperforate pulmonary valve interposing between the right ventricular cavity and the pulmonary arteries. Prenatal sonographic features, particularly the size of the tricuspid valve, can assist in prognostication with regard to postnatal outcome [24, 25] (Videos 11.11a and 11.11b).

Ebstein's Anomaly of the Tricuspid Valve

Ebstein's anomaly of the tricuspid valve is characterized by apical displacement and rotation of the tricuspid valve (Fig. 11.11). The hemodynamics associated with this lesion are a spectrum and frequently quite complex. At the mild end of the spectrum, despite displacement of the tricuspid valve, tricuspid valve function is good and there is normal antegrade flow into the right ventricular outflow tract, branch pulmonary arteries, and arterial duct. These findings are associated with normal heart size and relatively normal growth of the pulmonary artery and its

Fig. 11.7 Four-chamber view in a fetus with critical aortic stenosis. The left ventricle (*LV*) is dilated with a globular appearance. The mitral valve (*MV*) apparatus and endocardium appear bright consistent with a degree of endocardial fibroelastosis. No abnormalities are seen in the right heart; *RA* right atrium, *RV* right ventricle, *TV* tricuspid valve

branches. At the severe end of the spectrum, tricuspid valve regurgitation may be very severe, leading to right atrial dilatation and poor (or absent) antegrade flow into the branch pulmonary arteries. The enlarged right heart structures can compress the left heart leading to impaired biventricular performance. Echocardiographically, the heart may become massively enlarged with compression or true hypoplasia of the surrounding lung tissue. Hydrops may develop and is an adverse prognostic sign. Scoring systems, related to the echocardiographic findings, have been designed in an attempt to grade severity and likely postnatal outcome [26] (Videos 11.12a, 11.12b, and 11.12c).

Abnormalities of the Outflow Tracts

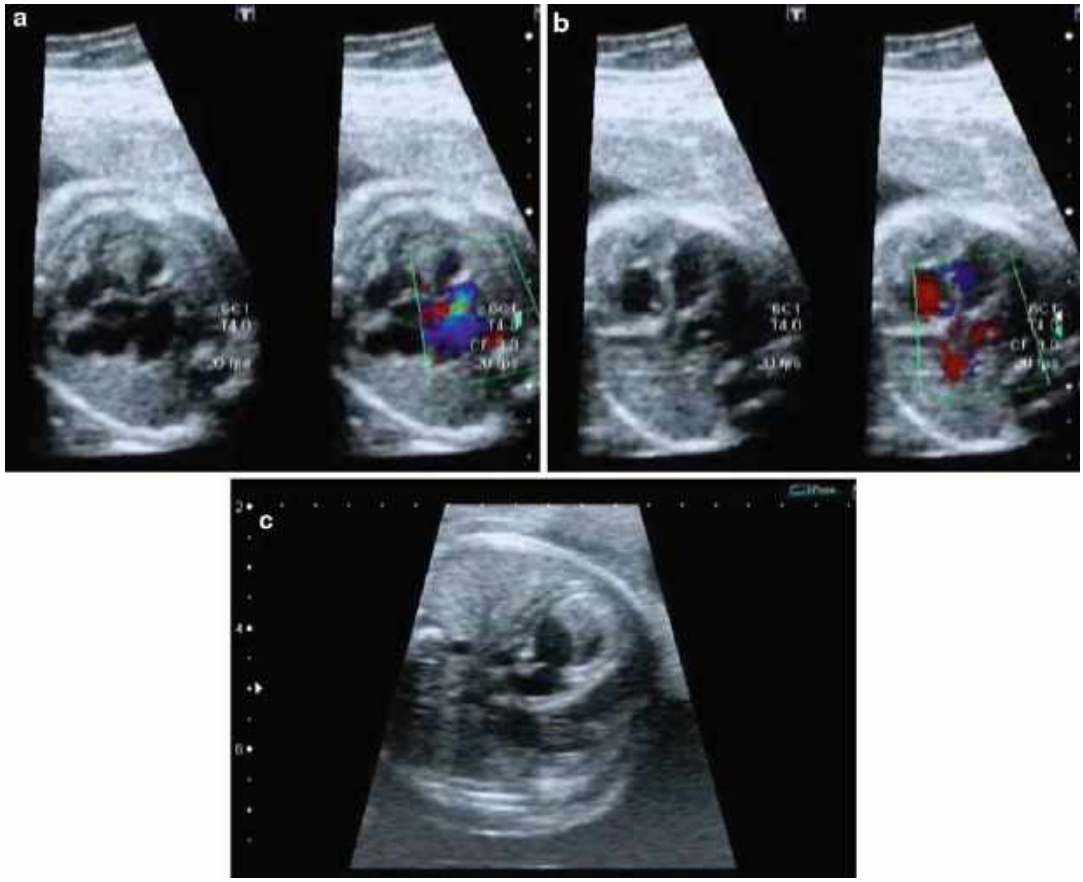
Some cardiac abnormalities may be relatively confined to the outflow tracts so that the appearances of the four-chamber view of the heart are normal or near normal. Such lesions include transposition of the great arteries, common arterial trunk (truncus arteriosus), and tetralogy of Fallot (and its variants). Examples of the commoner or classical forms of these abnormalities will be discussed in more detail.

Transposition of the Great Arteries

Transposition of the great arteries is a lesion for which the detection rates during fetal life are frequently low [27]. The reason for this is that the abnormality may be difficult for the nonspecialist sonographer to detect on the anomaly scan. Furthermore, infants with simple transposition rarely have extracardiac or chromosomal abnormalities so there is a lack of other sonographic abnormalities or soft markers to prompt detailed fetal echocardiography [28]. In simple transposition, the four-chamber view is usually normal. On the sonographic sweep towards the outflow tracts, the first artery to arise is the pulmonary artery which hooks posteriorly towards the spine (Fig. 11.12). On scanning more superiorly, the aorta is seen to arise from the right ventricle. The great arteries assume a more parallel orientation than normal and the three-vessel view is abnormal. With respect to immediate postnatal care, important factors include the size of the arterial duct and the foramen ovale. Prostaglandin E is commenced postnatally to promote mixing of blood across the duct. A minority of fetuses may be profoundly hypoxic and acidotic in the immediate postnatal period due to restriction of blood flow at the level of duct and foramen ovale [29]. In this situation prompt balloon atrial septostomy is lifesaving. Unfortunately, accurate prediction of which fetuses will develop severely restricted flow at the level of the duct and foramen ovale is difficult from fetal echocardiography [30] (Video 11.13).

Common Arterial Trunk (Truncus Arteriosus)

In fetuses with common arterial trunk, there is a single artery which arises from the heart, typically astride a ventricular septal defect (Fig. 11.13). The pulmonary arteries arise from the trunk either as a single pulmonary artery which then divides (type 1) or with separate origins of the pulmonary arteries (types 2 and 3).



Video 11.8 (**a**) 2D four-chamber view and color Doppler in fetus with critical aortic stenosis. The left ventricle is bright and has poor systolic function. The mitral valve is abnormal with restricted movement causing severe mitral regurgitation. (**b**) 2D view and color Doppler of the left ventricular outflow tract in fetus with critical aortic stenosis. The aortic valve and ascending aorta are small with preserved antegrade flow. (**c**) Four-chamber view in a fetus with critical aortic stenosis. There is cardiomegaly with a dilated and poorly functioning left ventricle. The left ventricle is thickened and bright consistent with a degree of endocardial fibroelastosis. The mitral valve has restricted movement. The right heart function appears relatively well preserved though there is abnormal motion of the interventricular septum suggesting high pressures in the left ventricular cavity

Echocardiographically, visualization of the origin is crucial to differentiate this lesion from tetralogy of Fallot with pulmonary atresia [31, 32]. There is a variable degree of truncal valve stenosis and regurgitation which is an important prognostic factor for postnatal management. Important associations include chromosome 22q11 deletions for which imaging of the thymus may assist in prediction of affected fetuses [33]. Postnatally, the vast majority of affected fetuses do not require immediate surgery unless the degree of truncal valve stenosis or regurgitation is particularly severe (Video 11.14).

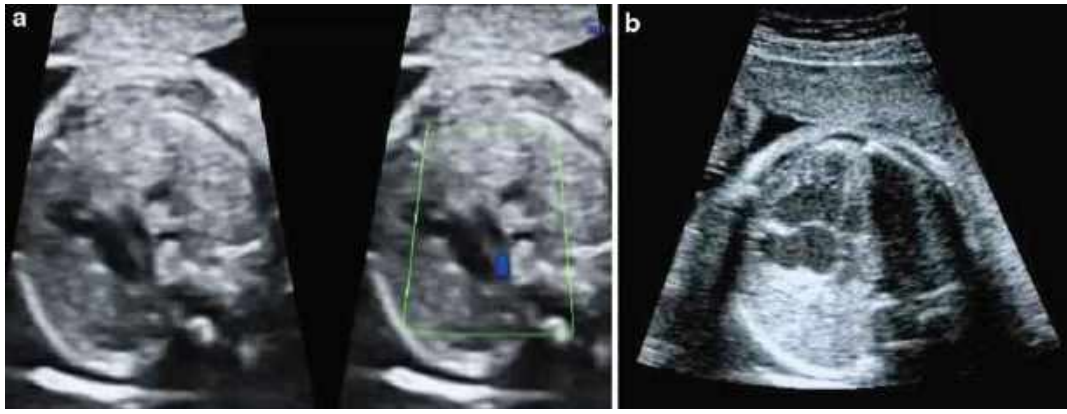
Tetralogy of Fallot

Tetralogy of Fallot is characterized by a normal or near-normal four-chamber view of the fetal heart, overriding of the aorta above a ventricular septal defect and a variable degree of hypoplasia of the pulmonary arteries which arise normally from the right ventricle [34]. There is a high

Fig. 11.8 (**a**) Three-vessel view in a fetus with coarctation of the aorta and a hypoplastic transverse aortic arch. There is disproportion in the size of the ductus arteriosus (*DA*) and aorta (*Ao*) as they pass in front of the trachea (*Tr*). The aorta tapers down further towards the aortic isthmus suggesting coarctation. A single right-sided superior vena cava (*SVC*) is seen. (**b**) Sagittal view of through the thorax of a fetus with a hypoplastic aortic arch. There is hypoplasia of the transverse arch between the left common carotid artery (*LCCA*) and left subclavian artery (*LSCA*). Narrowing is seen in the region of the aortic isthmus (*AoI*) just distal to the left subclavian artery (*LSCA*) consistent with coarctation of the aorta. *AAo* ascending aorta, *DAo* descending aorta. (**c**) Four-chamber view of a fetus with coarctation of the aorta. There is marked size discrepancy between the left (*LA* left atrium, *LV* left ventricle, *MV* mitral valve) and right heart structures (*RA* right atrium, *RV* right ventricle, *TV* tricuspid valve). The left ventricle is apex forming

incidence of right-sided aortic arch [35]. Given that both right and left ventricles pump at systemic arterial pressure during fetal life, hypertrophy of the right ventricle is not a typical feature of tetralogy of Fallot during fetal life (Fig. 11.14). Important associations during fetal life include extracardiac abnormalities and chromosomal abnormalities notably trisomy 21 and chromosome 22q11 deletions [34] (Video 11.15).

The hemodynamic assessment of tetralogy of Fallot during fetal life is important, particularly to predict whether the pulmonary circulation will be duct dependent in the early postnatal period. The Doppler velocity of blood flow across the pulmonary valve is less helpful during fetal than postnatal life because of the systemic pressure downstream as opposed to the low pulmonary vascular resistance after birth. Factors which have been shown to predict the need for early surgery or intervention to improve pulmonary blood flow include failure of growth of the pulmonary arteries during sequential assessment and



Video 11.9 (**a**) 2D and color Doppler three-vessel view in a fetus with coarctation of the aorta and a hypoplastic transverse arch. There is disproportion in the size of the ductus arteriosus and aorta as they pass in front of the trachea. The aorta tapers down further towards the aortic isthmus suggesting coarctation. A single right-sided superior vena cava is seen. Color Doppler confirms that antegrade flow through the aortic arch is preserved. (**b**) Four-chamber view of a fetus with coarctation of the aorta. There is marked disproportion between left and right heart structures with right ventricular dominance. The left ventricle has good systolic function and forms the cardiac apex. There is normal excursion of the mitral valve. Note a complete rib is seen on either side of the fetal chest confirming a true transverse view is demonstrated

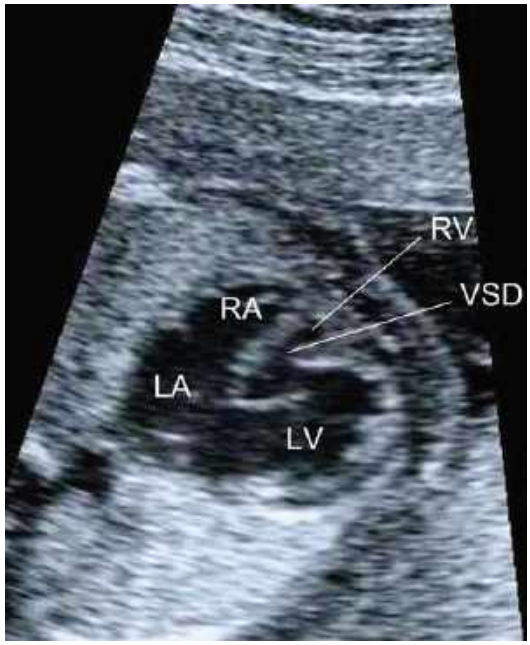


Fig. 11.9 Transverse cut through the thorax in a fetus with tricuspid atresia. There is a bright band of tissue and no communication between the right atrium (*RA*) and hypoplastic anterior right ventricle (*RV*). Blood flows through the foramen to left atrium (*LA*) and left ventricle (*LV*) through a ventricular septal defect (*VSD*) into the RV to supply the pulmonary circulation

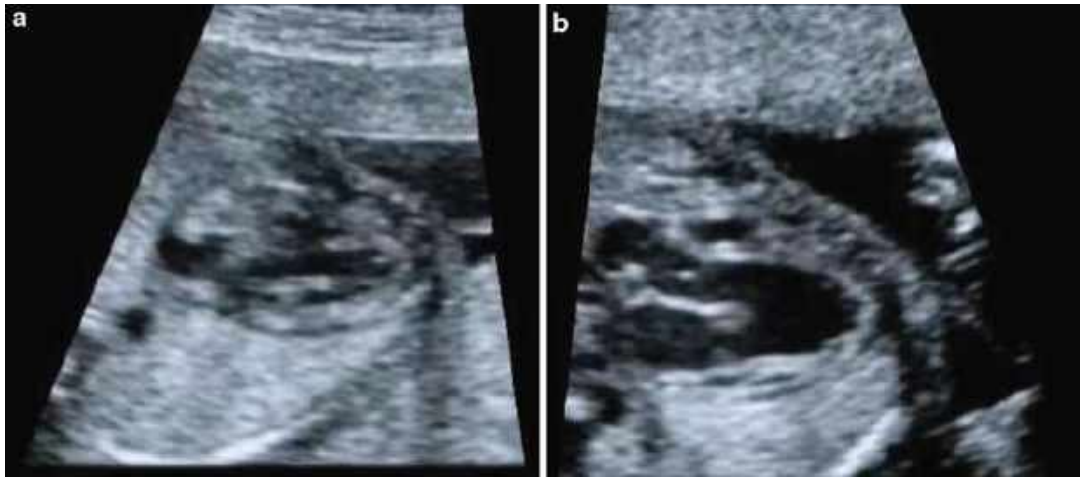
reversal of flow in the arterial duct, i.e., flow from the aorta to the pulmonary arteries [34].

Tetralogy of Fallot with Pulmonary Atresia

Tetralogy of Fallot with pulmonary atresia (also termed pulmonary atresia with ventricular septal defect) needs to be considered separately from classical tetralogy of Fallot in terms of its management. In this situation, there is no antegrade flow from the right ventricle into the pulmonary arteries. Blood flow to the pulmonary arteries is highly variable. In some fetuses there is a single source of pulmonary blood flow via the arterial duct and in others there are multiple aortopulmonary collateral arteries. The development of the pulmonary vascular bed is also variable ranging from good sized, confluent pulmonary arteries through to severely hypoplastic or absent pulmonary arteries fed by major aortopulmonary collateral arteries. During fetal life, due to the high pulmonary vascular resistance and the tortuous course of collateral arteries, it may be impossible to define the precise anatomy of the pulmonary vascular bed and its arterial supply [36] (Fig. 11.15, Video 11.16).



Video 11.10 (**a**) Four-chamber view of a fetus with tricuspid atresia. There is a bright band of tissue and no communication between the right atrium and right ventricle. There is normal excursion of the mitral valve and good left ventricular function. The hypoplastic right ventricle is seen anterior to the left ventricle. A ventricular septal defect is seen in the inlet view that supplies blood to the right ventricle and pulmonary circulation. (**b**) Parallel sweep through the thorax of a fetus with tricuspid atresia. The aorta is seen arising from the left ventricle. The pulmonary artery is somewhat hypoplastic and arises from the right ventricle. The main pulmonary artery continues in an anteroposterior direction and crosses the ascending aorta confirming normal arrangement of the great arteries

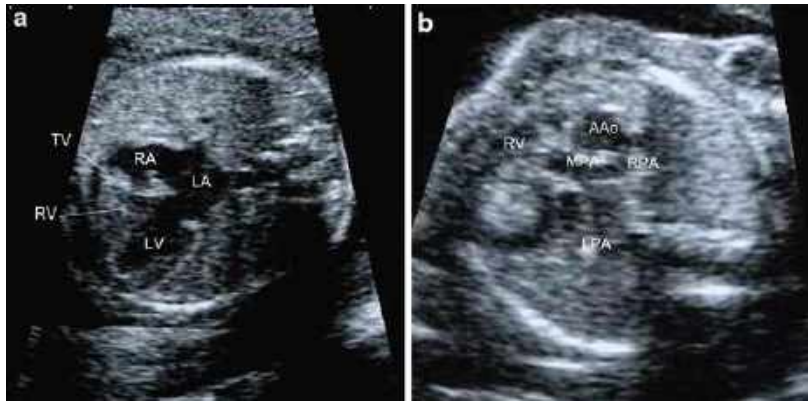


Fig. 11.10 (**a**) Four-chamber view of the heart in a fetus with pulmonary atresia with intact ventricular septum. The right ventricle (*RV*) is densely hypertrophied and muscle bound and it is difficult to see the ventricular cavity. In this image captured in diastole, the tricuspid valve (*TV*) is not seen to open freely. *RA* right atrium, *LA* left atrium, *LV* left ventricle. (**b**) View of the right ventricular outflow tract in a fetus with pulmonary atresia with intact ventricular septum. There is no continuity between the right ventricle (*RV*) and main pulmonary artery (*MPA*). The branch pulmonary arteries are confluent but hypoplastic. *AAo* ascending aorta

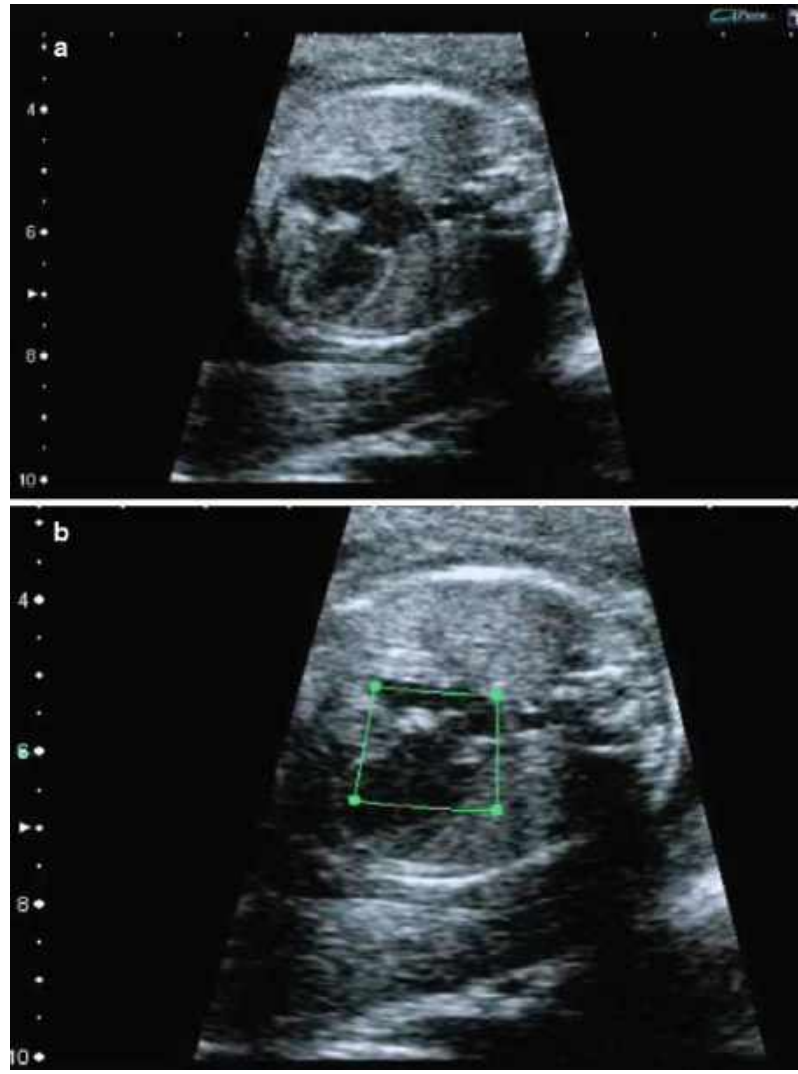
Tetralogy of Fallot with Absent Pulmonary Valve

In this variant of tetralogy of Fallot, there are a number of echocardiographic features which differ from more classical forms of tetralogy of Fallot [37]. Firstly, the branch pulmonary arteries are dilated rather than hypoplastic; secondly, the arterial duct is absent in most



Video 11.11 (**a**) Four-chamber view of the heart in a fetus with pulmonary atresia with intact ventricular septum. The right ventricle is densely hypertrophied and muscle bound with poor contractility. There is severely restricted movement of the tricuspid valve. Left ventricular function appears preserved. (**b**) Color Doppler four-chamber view of the heart in a fetus with pulmonary atresia with intact ventricular septum. There is poor right ventricular function and severely restricted movement of the tricuspid valve. Left ventricular function is good with normal color flow seen through the mitral valve. There is limited movement of the tricuspid valve and no color flow seen entering the muscle bound right ventricular cavity

cases; and thirdly, there is a rudimentary valve ring rather than a fully developed pulmonary valve (Fig. 11.16). There is a very strong association with chromosome 22q11 deletions. With respect to postnatal management, tracheobronchomalacia is a frequent accompaniment, potentially related to external compression of the airways by the dilated pulmonary arteries and also to intrinsic maldevelopment of the airways themselves. In any event, early respiratory compromise is well recognized which may necessitate positive-pressure ventilation. Ventilation itself has difficulties due to air trapping leading to overexpansion of the lungs. The prognosis for affected infants who require respiratory support is guarded. Respiratory difficulties can continue despite surgical plication of the pulmonary arteries (Videos 11.17a and 11.17b).

Diagnoses Which Are Difficult to Make During Fetal Life

1. Isolated Total Anomalous Pulmonary Venous Drainage

   Isolated total anomalous pulmonary venous drainage is a difficult diagnosis to make during

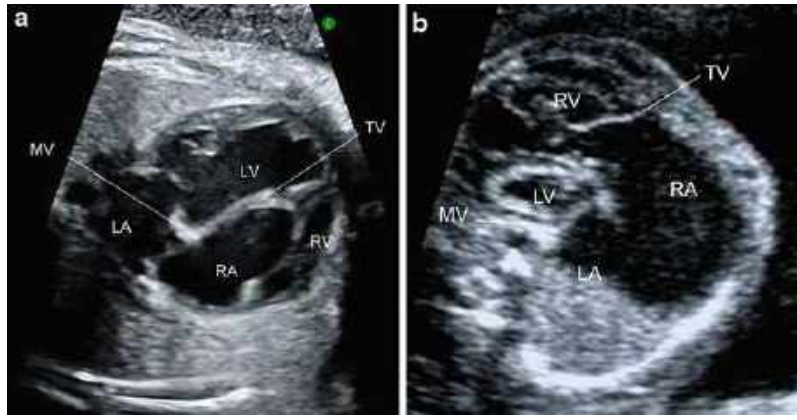


Fig. 11.11 (**a**) Four-chamber view of a fetus with Ebstein's anomaly of the tricuspid valve. The left heart structures appear normal (*LA* left atrium, *LV* left ventricle, *MV* mitral valve). Note the marked displacement of the tricuspid valve (*TV*) annulus into the right ventricular cavity. The right ventricle (*RV*) is small and seen at the cardiac apex, and there is a large "atrialized" portion resulting in a large right atrium (*RA*). (**b**) Transverse view through the fetal thorax demonstrating a "wall to wall" heart in a fetus with Ebstein's anomaly of the tricuspid valve. There is massive cardiomegaly with the cardiac apex displaced towards the left axilla. The left atrium (*LA*) is connected to the left ventricle (*LV*) by a normal mitral valve (*MV*). There is a marked displacement of the tricuspid valve (*TV*) into the right ventricle (*RV*) creating a grossly dilated right atrium (*RA*)

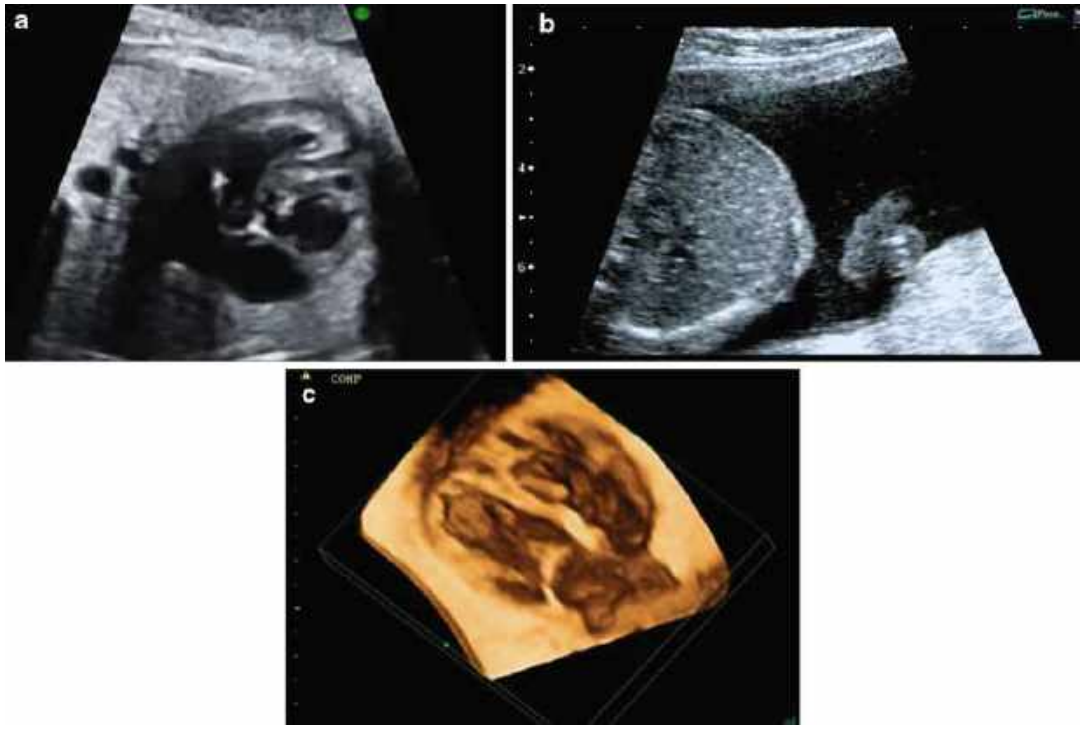
fetal life [38]. On the fetal anomaly scan at screening level, the four-chamber view may be normal and the outflow tracts are normal. Due to the relatively low pulmonary blood flow during fetal life, visualization of a pulmonary venous confluence behind the left atrium is difficult. In later gestation, right heart dominance may be observed to arouse the suspicion of this condition as a differential diagnosis.

2. Coarctation of the Aorta
   Although coarctation of the aorta may be observed as a "four-chamber" abnormality with asymmetry of the left and right heart, in some cases the four-chamber view is completely symmetrical and the diagnosis may only be suspected by asymmetry on the three-vessel view or longitudinal view of the aortic arch [21]. Furthermore, patency of the arterial duct means that false-positive and false-negative diagnoses are made [19, 20].
3. Small-/Moderate-Sized Ventricular Septal Defects
   During intrauterine life, the left and right ventricular systolic pressures are equal so there will not be the same flow pattern across the defect as there is in postnatal life. The membranous septum is very thin making it possible to suspect a ventricular septal defect when, in reality, none exists (false-positive diagnosis). Conversely, "dropout" of the ultrasound image, particularly in the membranous septum, may be regarded as a normal variant, in the presence of a true ventricular septal defect (false negative). In practice, multiple views of the ventricular septum, coupled with color-flow Doppler, are required to confirm the diagnosis.
4. Mild to Moderate Stenosis of the Pulmonary or Aortic Valves
   Mild to moderate pulmonary valve stenosis or aortic valve stenosis is compatible with a normal four-chamber view of the heart with good ventricular function. Unless color-flow Doppler or pulsed Doppler interrogation of the valves is undertaken, there may be no suspicion of these lesions on screening level ultrasound scans. These lesions are well known to progress with advancing gestational age.



Video 11.12 (**a**) Four-chamber view of a fetus with Ebstein's anomaly of the tricuspid valve. The left heart structures appear normal with good left ventricular function. There is marked displacement of the tricuspid valve annulus into the right ventricular cavity. As we scan towards the fetal head, the tricuspid valve can be "en face" consistent with rotation of the valve orifice into the right ventricular outflow tract. (**b**) Four-chamber rendered image demonstrating Ebstein's anomaly of the tricuspid valve. The IVC is seen entering the floor of the right atrium. The ridge of atrioventricular groove is clearly seen; however, the tricuspid valve attachments are significantly displaced into the right ventricular cavity. A rudimentary septal leaflet of the tricuspid valve is seen moving in and out of plane. (**c**) Transverse view through the fetal thorax demonstrating a "wall to wall" heart in a fetus with Ebstein's anomaly of the tricuspid valve. There is massive cardiomegaly with the cardiac apex displaced towards the left axilla. There is significant displacement of the tricuspid valve annulus in to the right ventricular cavity. The left heart structures appear normal; however, left ventricular function is significantly impaired

Thus, in some cases it is possible that midtrimester scans are normal or near normal even when a severe abnormality becomes evident by term.

Management of Congenital Heart Disease Following Prenatal Diagnosis

Prenatal diagnosis of congenital heart disease allows expectant parents to be informed about the nature of the congenital heart lesions, potential associations, and how to plan perinatal care. Prenatal investigations may include detailed anomaly scanning to exclude extracardiac abnormalities. Fetal karyotyping is also normally discussed. The strength of the association with karyotypic abnormalities will depend on the cardiac lesion and other sonographic findings. Some cardiac lesions, such as atrioventricular septal defects with normal cardiac situs, are strongly associated with major trisomies, whereas others, such as simple transposition of the great arteries, are rarely associated with karyotypic abnormalities. Fetal karyotyping may include targeted analysis for specific chromosomes such as 22q11 deletions in addition to standard analyses.

Following prenatal diagnosis of congenital heart disease, detailed perinatal planning is required. For many cardiac lesions, prenatal diagnosis makes little impact on initial neonatal cardiac management. Examples include isolated ventricular septal defect and atrioventricular septal defect, i.e., those cases without evidence of left or right heart obstruction who would not be expected to present until the pulmonary vascular resistance falls postnatally. For these cases, there is no cardiac indication to alter delivery plans, provided that the need for nonurgent cardiac assessment in the neonatal period is understood.

Fig. 11.12 Sagittal view through the thorax of a fetus with transposition of the great arteries with intact ventricular septum. The great arteries arise in parallel. The aorta (*Ao*) arises from the anterior right ventricle (*RV*) and gives rise to the head and neck vessels. The artery arising from the left ventricle (*LV*) is the main pulmonary artery (*MPA*)

Location of Delivery

For fetuses who have duct-dependent lesions or where there is a potential need for early neonatal surgery or intervention, then delivery at or near a cardiac center may be preferable so that prompt postnatal investigations can be planned without the need for transfer of the infant. Importantly, this also ensures that parents are available for explanation and consent for early neonatal procedures. Ensuring delivery at the cardiac center may involve induction of labor at term, but most infants can be delivered by a normal vaginal delivery rather than Caesarian section. Some parents may favor delivery at or near a cardiac center, even if the cardiac findings are not suggestive of the need for very early intervention.

Video 11.13 Sagittal view through the thorax in a fetus with transposition of the great arteries with intact ventricular septum. The great arteries arise in parallel. The aorta arises from the anterior right ventricle and gives rise to the head and neck vessels. The main pulmonary artery is posterior to the aorta and arises from the left ventricle; it can be seen branching. The ventricular septum appears intact in this view

This largely reflects local facilities and parental concerns about separation from their newborn infant if assessment at a geographically remote cardiac center (even if nonurgent) has been recommended.

Fig. 11.13 View through the fetal thorax in a case of common arterial trunk. There is a single outlet from the heart that gives rise to a small main pulmonary artery (*MPA*) that subsequently bifurcates. The ascending aorta (*AAo*) becomes the aortic arch and can be seen giving rise to the head and neck vessels. *RV* right ventricle, *LV* left ventricle

Impact on Mode of Delivery

For most cardiac lesions, given prenatal circulatory physiology, a normal vaginal delivery is attainable. Caesarian delivery is reserved for a minority of cases and may be considered for a number of reasons. Firstly, some fetuses with structural abnormalities may have associated arrhythmias such as complete heart block or tachycardias which may make it impossible to assess fetal well-being by conventional cardiotocographic monitoring. For this reason, Caesarian section may be preferred. Secondly, there may be a potential need for immediate postnatal intervention where it is necessary to have a team immediately available for the resuscitation and immediate cardiac management of the affected fetus. This has included infants with TGA with both a restrictive atrial septum and restrictive arterial duct, fetuses with hypoplastic left heart with restrictive/intact atrial septum, and hydropic fetuses where immediate fluid drainage from body cavities such as the pleural space may be indicated urgently. Without a predictable time of delivery, it may be logistically difficult to maintain such a team and so Caesarian delivery may be preferred. In practice, there is an individualized discussion

Video 11.14 View through the fetal thorax demonstrating the features of common arterial trunk. There are balanced ventricles and a single outlet arising from the heart above a ventricular septal defect. The small main pulmonary artery arises from the ascending aorta and can be seen branching into small confluent pulmonary arteries. The ascending aorta continues as the aortic arch and gives rise to the head and neck vessels

Fig. 11.14 View through the fetal thorax in a case of tetralogy of Fallot. The aorta (*Ao*) overrides a ventricular septal defect (*VSD*) and receives blood from both the right (*RV*) and left ventricle (*LV*)

Video 11.15 Views illustrating the features of tetralogy of Fallot in the fetus. The ventricles are balanced and there is a ventricular septal defect, and the aorta overrides this defect. The pulmonary artery is smaller than the aorta suggesting some limitation to flow

between all relevant subspecialities to reach decisions about the optimal mode of delivery in such cases. Table 11.3 includes the commoner situations where immediate postnatal cardiac intervention is likely to be required.

Impact of Prenatal Diagnosis on Postnatal Outcome

For some lesions, there is published evidence of an improved postnatal outcome associated with prenatal diagnosis. These lesions include hypoplastic left heart syndrome, transposition of the great arteries, coarctation of the aorta, and pulmonary atresia.

Hypoplastic Left Heart Syndrome

Tworetzky et al. [39] reported zero mortality among 14 prenatally diagnosed infants with HLHS versus a mortality of 13 of 38 infants who were diagnosed postnatally. Prenatal diagnosis was also associated with a reduced requirement for inotropes, better ventricular function, and less tricuspid valve regurgitation compared to the group of infants who were diagnosed postnatally. Another series has confirmed better condition at presentation for infants who were diagnosed prenatally which did not translate into reduced operative mortality [40]. Abnormal neurological outcome is a particular concern for infants with HLHS due to their duct-dependent systemic arterial circulation, with the risk of cardiovascular collapse if the lesion is not detected before birth. A reduced incidence of abnormal neurological events has been reported in infants with prenatal diagnosis of HLHS [41].

Transposition of the Great Arteries

Transposition of the great arteries has the potential to cause early postnatal deterioration due to failure of mixing of oxygenated and deoxygenated blood at the level of the atrial septum and/or the arterial duct. Prenatal diagnosis might be expected to improve postnatal condition due to the early administration of prostaglandin E to maintain ductal patency or balloon atrial septostomy to improve mixing of blood at atrial level. The largest series examining the impact of

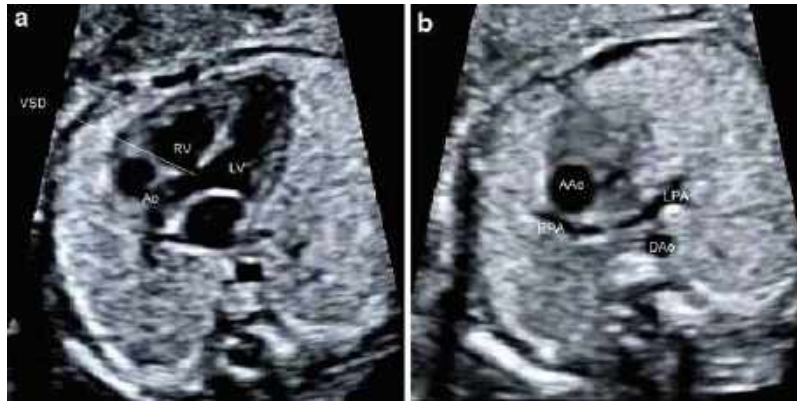


Fig. 11.15 (**a**) Left ventricular outflow tract view in a fetus with pulmonary atresia and ventricular septal defect (*VSD*). The aorta (*Ao*) is the single outlet from the heart and overrides the *VSD*; it receives all blood ejected from the right (*RV*) and left ventricles (*LV*). (**b**) View of the branch pulmonary arteries. There is no main pulmonary artery identified; the left (*LPA*) and right pulmonary arteries (*RPA*) are confluent but significantly hypoplastic. *AAo* ascending aorta, *DAo* descending aorta

Video 11.16 Transverse views through the chest of a fetus with pulmonary atresia and ventricular septal defect (*VSD*). The four-chamber view is relatively normal. The aorta overrides the VSD and there is no main pulmonary artery. There are hypoplastic confluent pulmonary arteries that are supplied by a vessel originating from the underside of the aortic arch

prenatal diagnosis on the outcome of transposition of the great arteries (TGA) is from France [29]. Their data included 68 infants who were prenatally diagnosed and 250 who were not. There was zero preoperative mortality in the prenatal group versus 6 % in the postnatally diagnosed group. Postoperative mortality was also significantly better for infants who were diagnosed during fetal life. Another study, however, did not observe an impact of prenatal diagnosis on condition at presentation or outcome [40].

Coarctation of the Aorta

Coarctation of the aorta does not typically cause cardiovascular compromise during fetal life due to ductal patency which permits the right ventricle to support the systemic arterial circulation via the arterial duct. Furthermore, in susceptible infants, ductal constriction after birth has been described to create a "sling" around the distal aortic arch thereby causing constriction of the aortic isthmus. The impact of prenatal diagnosis of coarctation of the aorta on postnatal outcome appears positive [42] in terms of preoperative morbidity and mortality as well as ventricular function at presentation. The reported data [42] had the advantage of access to pathological data so that infants who died prior to presentation to hospital were included. Available data in this regard suggests that there is still a significant minority of infants who may succumb prior to diagnosis [43].

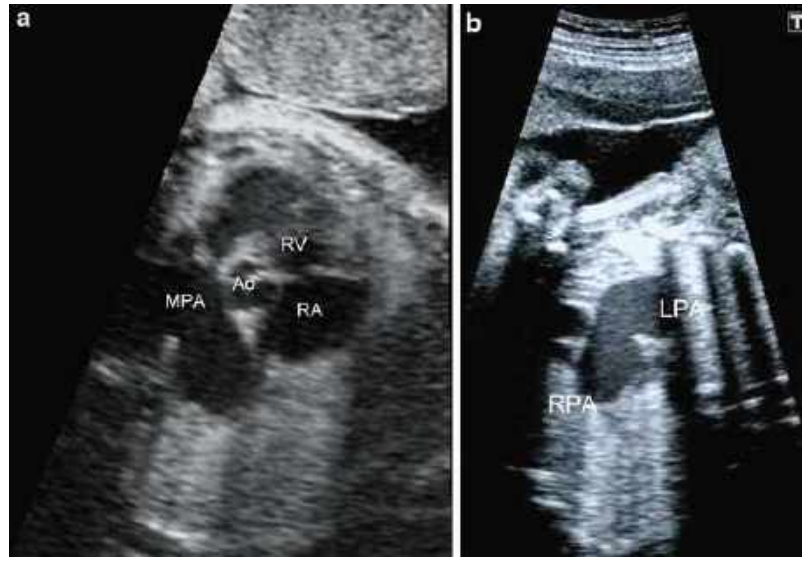

Fig. 11.16 (**a**) Short-axis view of a fetal heart with absent pulmonary valve. There is no recognizable pulmonary valve and there is a narrowing in this region. The main pulmonary artery (*MPA*) then bifurcates into its branches that are grossly dilated. *RA* right atrium, *RV* right ventricle. (**b**) Sagittal view through the fetal chest illustrating the gross dilatation of the branch pulmonary arteries. *RPA* right pulmonary artery, *LPA* left pulmonary artery

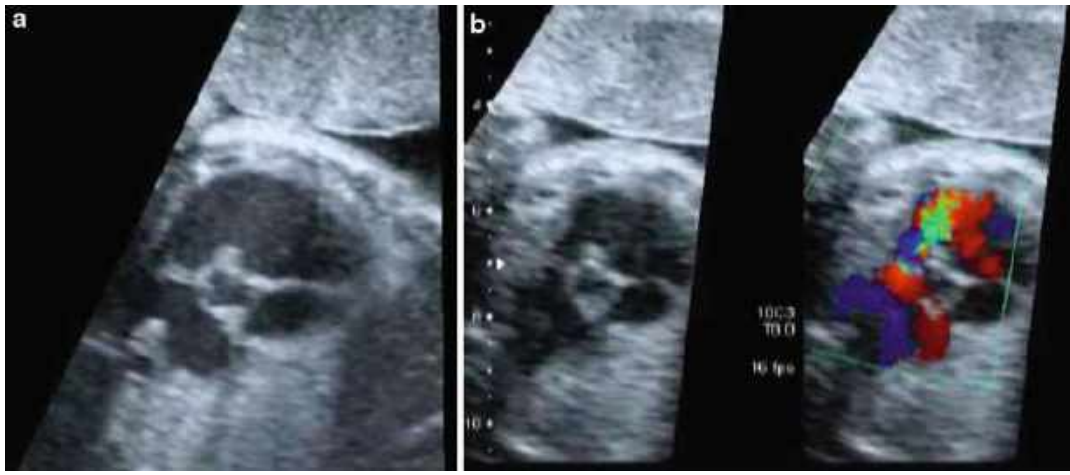

Video 11.17 (**a**) Short-axis view of the fetal heart in a case with tetralogy of Fallot and absent pulmonary valve. The trileaflet aortic valve is seen centrally. There is some tissue in the pulmonary position but no true pulmonary valve; this area appears narrowed. The main pulmonary artery is short and gives rise to the branch pulmonary arteries that are grossly dilated. (**b**) Color Doppler short-axis view of the fetal heart with tetralogy of Fallot and absent pulmonary valve. To and fro flow is seen in the pulmonary artery with both stenosis and severe pulmonary incompetence. The aortic valve is seen centrally and flow through the ventricular septal defect is demonstrated

Pulmonary Atresia

Infants with duct-dependent pulmonary blood flow are at risk of significant hypoxic insult postnatally if their condition remains unrecognized once the arterial duct begins to constrict. Data is available on the impact of prenatal diagnosis on the outcome of infants with duct-dependent pulmonary blood flow [44]. The prenatally diagnosed infants had better oxygen saturations at presentation than those diagnosed postnatally, but this did not translate into better short-term mortality or morbidity.

Table 11.3 Cardiac lesions and clinical situations for which immediate perinatal attention is required

Cardiac lesion	Potential complication	Specific potential interventions
HLHS or critical aortic stenosis with intact/severely restrictive atrial septum	Severe hypoxemia	Balloon atrial septostomy/surgical septectomy
	Metabolic acidosis	
Simple TGA with restrictive atrial septum and arterial duct	Severe hypoxemia	Balloon atrial septostomy
	Metabolic acidosis	
Absent pulmonary valve syndrome	Airway compression	Positive-pressure ventilation
	Respiratory failure/air trapping	Plication of pulmonary arteries
Severe Ebstein's anomaly	Pulmonary hypoplasia	Positive-pressure ventilation
	Ventilatory failure	High inspired oxygen
	Severe hypoxemia	Nitric oxide
	Management of hydrops	Drainage of pleural effusions/ ascites
Complete heart block +/− congenital heart disease	Cardiac failure	Chronotropic agents
	Hydrops	Temporary pacing
		Drainage of pleural effusions/ ascites
Suspected obstructed TAPVD	Hypoxemia	Early surgical repair
	Metabolic acidosis	

HLHS hypoplastic left heart syndrome, *TGA* transposition of the great arteries, *TAPVD* total anomalous pulmonary venous drainage

Evaluation of Fetal Cardiovascular Physiology in Cardiac and Non-cardiac Disease

12

Anita Szwast and Jack Rychik

Abstract

Detailed assessment and management of abnormalities of the human condition is possible prior to birth. With the advent of prenatal ultrasound, it is now known that many congenital, developmental, and acquired disorders of early life have an onset and extensive natural history prior to birth. Knowledge of this prenatal natural history, a course that is specific to each condition within the unique setting of fetal physiology, can contribute to a better understanding of the postnatal state. Complex conditions of the neonate, infant, and child are best cared for and managed if understood within the context of their origins.

This chapter will provide a review of the tools available for assessing the prenatal cardiovascular physiology of a variety of forms of structural congenital heart disease, as well as the impact of a number of extracardiac anomalies and disorders upon the fetal cardiovascular system.

Introduction

Detailed assessment and management of abnormalities of the human condition is possible prior to birth. With the advent of prenatal ultrasound, it is now known that many congenital, developmental, and acquired disorders of early life have an onset and extensive natural history prior to birth. Knowledge of this prenatal natural history, a course that is specific to each condition within the unique setting of fetal physiology, can contribute to a better understanding of the postnatal state. Complex conditions of the neonate, infant, and child are best cared for and managed if understood within the context of their origins.

This chapter will review the tools available for assessing the prenatal cardiovascular physiology of a variety of forms of structural congenital heart disease, as well as the impact of a number of extracardiac anomalies and disorders upon the fetal cardiovascular system.

Table 12.1 Indications for performance of fetal echocardiography

Maternal indications
• History of CHD
• Maternal diabetes
• Maternal genetic or metabolic disorders (e.g., Marfan syndrome, phenylketonuria)
• Teratogen exposure (e.g., lithium)
• Rubella infection
• Maternal autoimmune disease (e.g., Sjögren disease, systemic lupus erythematosus)
• Exposure to prostaglandin synthetase inhibitors (e.g., indomethacin, aspirin)
• In vitro fertilization (in particular, intracytoplasmic sperm injection)
Fetal indications
• Chromosomal abnormality
• Extracardiac abnormality
• Fetal heart beat irregularity
• Fetal hydrops
• Increased 1st trimester nuchal translucency
• Multiple pregnancy with suspicion of twin-twin transfusion syndrome
• Abnormal obstetrical ultrasound screen

Tools Used to Evaluate Fetal Cardiovascular Physiology: Doppler Echocardiography

Ultrasound technologies are able to provide great detail concerning the fetal cardiovascular system through the application of fetal echocardiography. Two-dimensional imaging provides information on structure and Doppler imaging provides data on blood flow characteristics. Conventional timing for fetal echocardiography is typically at 18–24 weeks gestation and is usually pursued after routine obstetrical ultrasound reveals some element for concern or if there is a direct indication (Table 12.1). Early fetal echocardiography is technically feasible at 13–14 weeks gestation and can be utilized for high-risk mothers.

Throughout gestation, expected Doppler flow patterns for the umbilical artery, umbilical vein, middle cerebral artery, and ductus venosus have been well described in the literature. In fetuses with underlying congenital heart disease as well as extracardiac conditions known to impact the cardiovascular system, Doppler echocardiography enables practitioners to sort out complex physiologic processes and may uncover evidence of cardiovascular compromise that may not otherwise be evident with 2D and color Doppler techniques alone.

Arterial Flow Patterns

Umbilical Artery

As a vital structure linking the fetus to the placenta, resistance within the umbilical artery is normally quite low in order to promote blood flow to the placenta so that nutrients and gases may be effectively exchanged. Doppler interrogation of the umbilical cord can be performed in a free loop during fetal apnea. Values of umbilical artery Doppler measurements used for assessing placental vascular resistances are constantly higher at the fetal compared to the placental extremity of the umbilical cord. For valid comparisons of repeated measurements either on the same fetus or between subjects, it is crucial that

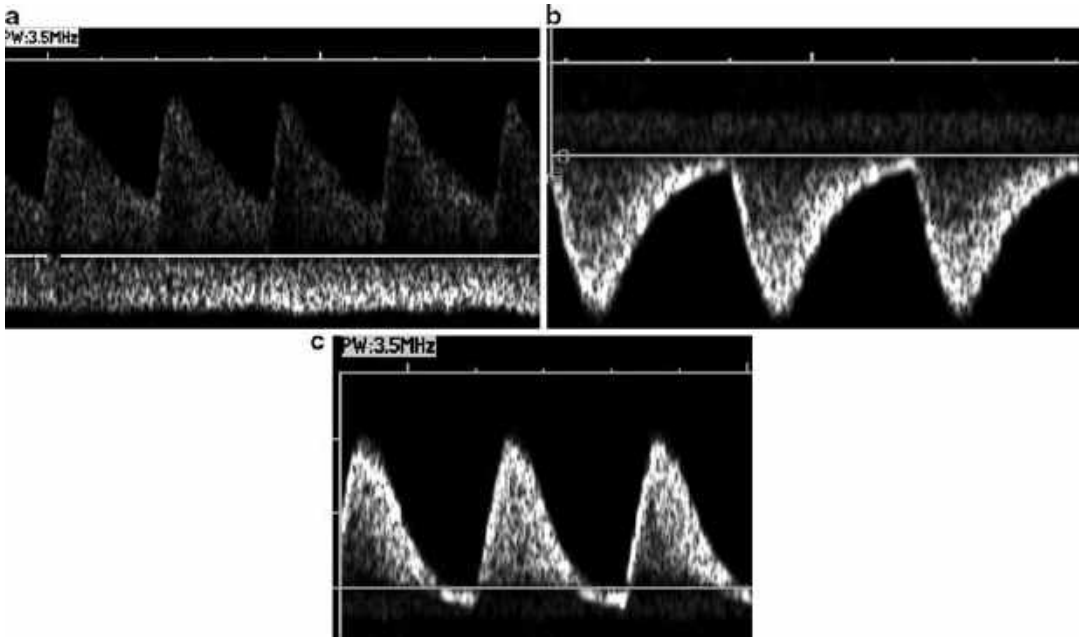

Fig. 12.1 Umbilical artery Doppler flow patterns. (**a**) Normal tracing. (**b**) Decreased diastolic flow reflecting some degree of elevated placental vascular resistance. (**c**) Diastolic flow reversal indicating severely elevated placental vascular resistance, or a vascular "steal" phenomenon

the recordings be made always at the same point (fetal or placental extremity) on the umbilical cord [3, 4]. Reference values for umbilical artery Doppler waveforms over the course of gestation are available [1–6]. Measurements devised to assess resistance within the vessel include (1) the S/D ratio, defined as the peak systolic velocity/end-diastolic velocity ratio; (2) the pulsatility index (PI), defined as the peak systolic velocity-end-diastolic velocity/time-averaged maximal velocity; and (3) the resistance index (RI), defined as the peak systolic velocity-end-diastolic velocity/end-diastolic velocity. As shown in Fig. 12.1, the normal Doppler flow pattern within the umbilical artery is characterized by continuous forward flow in both systole and diastole. Although absent end-diastolic flow within the first trimester is normal, absent or reversed diastolic flow within the second or third trimester is abnormal and is consistent with elevated placental vascular resistance, such as in intrauterine growth restriction. Studies have demonstrated poor neonatal outcomes and increased risk of intrauterine fetal demise in fetuses with absent or reversed end-diastolic flow within the umbilical artery [7–10]. Early delivery may be indicated to improve outcomes after 28 weeks gestation [11]. In various forms of congenital heart disease, the umbilical artery resistance may be elevated [12–14], although it rarely exceeds the 95 % confidence interval for gestational age [13].

Middle Cerebral Artery

Doppler interrogation of the middle cerebral artery provides key information regarding overall fetal well-being through the measure of cerebrovascular resistance. Figure 12.2 demonstrates the normal Doppler flow pattern within the middle cerebral artery. Most of the flow within the vessel occurs during systole with only a small amount of flow in diastole. Reference values over the course of gestation have also been established for the middle cerebral artery Doppler waveforms [2, 5, 6, 15–17]. Although cutoff points vary between studies, an elevated peak systolic velocity of the

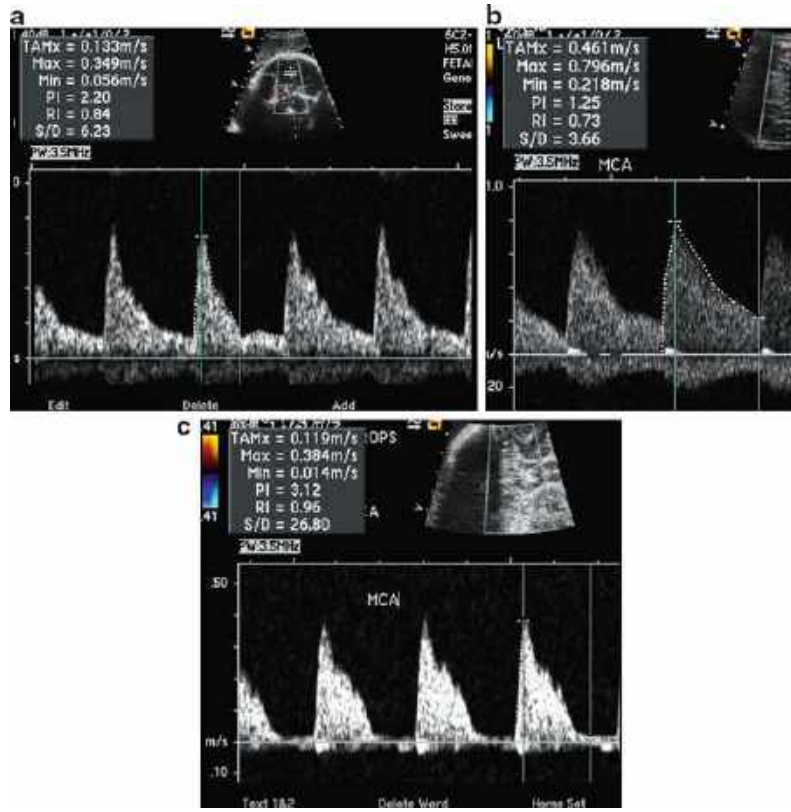

Fig. 12.2 Middle cerebral artery Doppler flow patterns. (**a**) Normal tracing. Note PI value of 2.20. (**b**) Increased diastolic flow suggesting diminished cerebrovascular resistance. The PI = 1.25, lower than normal. (**c**) Absent diastolic flow indicating elevated cerebrovascular resistance. PI = 3.12

middle cerebral artery Doppler waveform has proven to be a sensitive marker for fetal anemia [18–23]. In addition, a high middle cerebral artery peak systolic velocity may be predictive of perinatal mortality in fetuses with intrauterine growth restriction [24].

Investigators have identified altered blood flow patterns to the brain in fetuses with underlying congenital heart disease [12, 25–27]. Delivery of blood flow to the brain in utero can be variable and depend upon the type of CHD present [12, 26, 27]. In left-sided obstructive lesions, such as hypoplastic left heart syndrome (HLHS), anatomical constraints limit aortic blood flow with retrograde perfusion of the brain from the ductus arteriosus. Utilizing Doppler techniques, studies have demonstrated decreased cerebrovascular resistance in HLHS fetuses compared to normals [12, 14, 25–27]. A lower cerebrovascular resistance likely reflects an autoregulatory attempt to increase cerebral blood flow, under conditions where blood flow delivery is inherently diminished, a phenomenon known as "brain sparing." Whether this abnormal flow pattern impacts fetal brain development is an ongoing area of investigation, although abnormalities of the brain have been described in fetuses and neonates with congenital heart disease even prior to any surgical palliation [28–31]. Conversely, in fetuses with increased flow to the brain secondary to right-sided obstructive lesions, the middle cerebral artery pulsatility index is increased compared to normal fetuses, as the cerebral vasculature vasoconstricts in an attempt to limit cerebral blood flow [12]. Intriguingly, single-ventricle physiology alone does not determine cerebrovascular resistance. Fetuses with single-ventricle physiology with unobstructed aortic flow, yet decreased pulmonary flow, have normal or elevated cerebrovascular resistance, while fetuses with single-ventricle physiology and obstructed aortic flow, such as hypoplastic left heart syndrome, have reduced cerebrovascular resistance compared to normal controls [32].

In fetuses with normal cardiovascular physiology, the resistance within the cerebral vasculature should be greater than the placental resistance. In other words, the cerebro-placental resistance (CPR) ratio, which is a ratio of the pulsatility indices of the middle cerebral artery to the umbilical artery, should be >1.08 [33]. However, in fetuses with chronic hypoxia or inadequate cardiac output, there may be "cephalization of flow," characterized by lower resistance in the brain compared to the placenta. This phenomenon is otherwise known as the "brain-sparing effect." In fetuses with intrauterine growth restriction, a CPR ratio <1.08 is associated with adverse perinatal outcomes [33, 34]. Fetuses with congenital heart disease, such as hypoplastic left heart syndrome, have lower CPR compared to controls [25–27]. However, whether an abnormal CPR ratio is associated with adverse perinatal outcome has not been established yet for fetuses with underlying congenital heart disease.

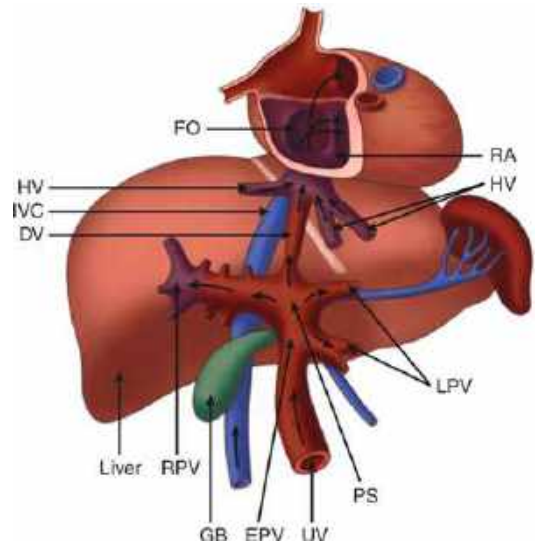

Fig. 12.3 Subdiaphragmatic venous system in the fetus. Umbilical venous return enters into the portal sinus and can either traverse the ductus venosus into the right atrium or enter the right and left portal veins and flow into the hepatic parenchyma. Note the constriction of the ductus venosus which acts to (1) control the amount of blood entry into the heart and into the liver and (2) creates a streaming effect directing oxygen-rich blood preferentially across the foramen ovale to the left atrium. In this manner, the most richly oxygenated blood returning from the placenta is directed to the left side of the heart, coronary arteries, and cerebrovasculature. *DV* ductus venosus, *EPV* extrahepatic portal vein, *GB* gall bladder, *FO* foramen ovale, *HV* hepatic vein, *IVC* inferior vena cava, *LPV* left portal vein, *PS* portal sinus, *RA* right atrium, *RPV* right portal vein, *UV* umbilical vein (From Mavrides et al. [35])

Venous Flow Patterns

Ductus Venosus

The ductus venosus is a key site of shunting within the fetal cardiovascular system, enabling oxygenated blood within the umbilical vein to bypass most of the hepatic circulation in order to return to the heart via the inferior vena cava (Fig. 12.3). Of note, the fraction of umbilical venous return traversing the ductus venosus decreases with gestation, with a greater proportion of umbilical venous return flowing into the portal venous system and through the liver parenchyma in late gestation. The normal Doppler flow pattern, comprised of *s*, *d*, and *a* waves, is shown in Fig. 12.4. The *s* wave corresponds to ventricular systole, the *d* wave to ventricular diastole, and the *a* wave corresponds to the nadir during atrial contraction in late diastole. Reference ranges over the course of gestation are published [36–38]. Resistance in the ductus venosus gradually declines over the course of gestation [38]. Given its proximity to the heart, flow abnormalities, secondary to elevated central venous pressure, are seen in the ductus venosus prior to the umbilical vein. Within the ductus venosus, as central venous pressure increases, the *a* wave velocity progressively declines to baseline and ultimately becomes reversed. Reversal with atrial contraction in the ductus venosus can be seen in many pathologic states: (1) severe tricuspid regurgitation, as in Ebstein's anomaly or in the recipient twin of the twin-twin transfusion syndrome (see below); (2) severe right ventricular hypoplasia and hypertrophy, as in pulmonary atresia with an intact ventricular septum; (3) complete heart block, wherein the atrium is contracting against a closed tricuspid valve; (4) intrauterine growth restriction; and (5) reentrant SVT with short

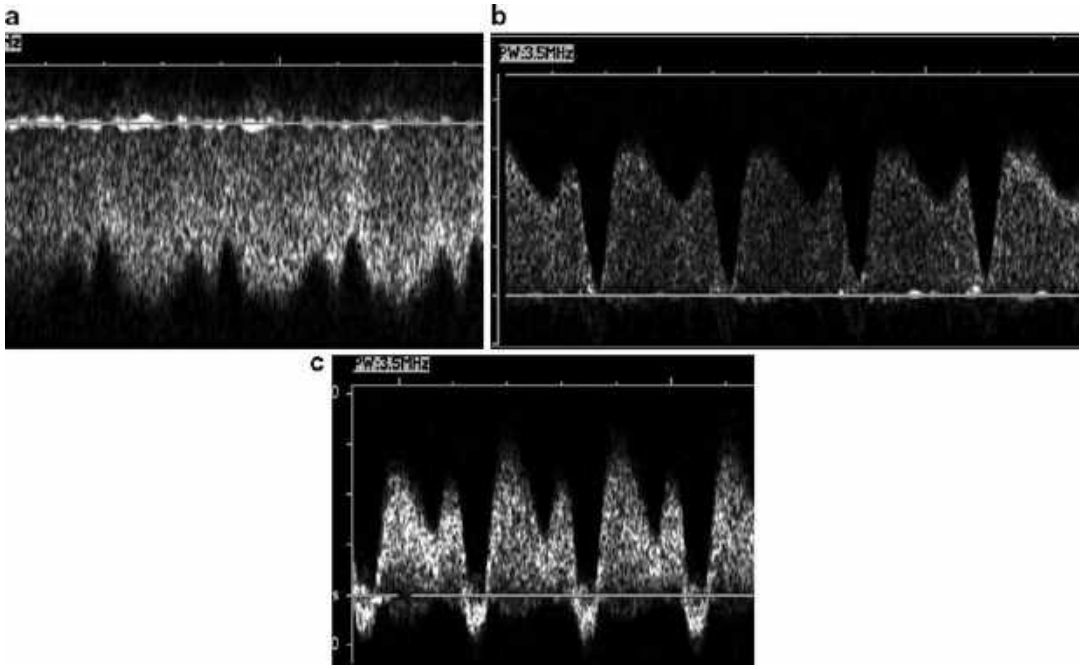

Fig. 12.4 Ductus venosus flow patterns. (**a**) Normal tracing. (**b**) Decreased flow with atrial contraction indicating right atrial or right ventricular altered compliance. (**c**) Reversal of flow with atrial contraction

ventriculoatrial interval where giant retrograde *a* waves are constantly observed [39]. All of these conditions are associated with elevated central venous pressure.

Absence of the ductus venosus may be seen in association with congenital heart disease as well as underlying chromosomal anomalies [40–44]. Hydrops fetalis can occur with absent ductus venosus if the umbilical vein inserts directly into the inferior vena caval/right atrial junction as the resistance to massive umbilical venous return is eliminated, leading to massive cardiomegaly and high-output congestive heart failure [40, 42–44].

Umbilical Vein

The normal Doppler flow pattern within the umbilical vein is described as low velocity, non-pulsatile flow, although venous pulsations may be observed in the first trimester [45]. Tracings should be acquired during fetal apnea since respiratory variation in the Doppler tracing may be seen in second- and third-trimester fetuses. Reference ranges for umbilical venous flow are published [46, 47]. Within the umbilical vein, as central venous pressure rises, notching is seen first at end diastole. In cases of severe compromise, such as in hydrops fetalis, complete atrioventricular block, or severe heart failure in the recipient twin with twin-twin transfusion syndrome, and venous pulsations, consisting of *s*, *d*, and *a* waves, may be seen. Figure 12.5 illustrates the umbilical venous Doppler flow pattern in a normal fetus and in a fetus with heart failure and venous pulsations.

Atrioventricular Valve Inflow Pattern

The Doppler flow pattern across the atrioventricular valve reflects the impedance to ventricular filling and ventricular compliance. The normal Doppler flow pattern consists of a smaller *e* wave, representing active relaxation rather than passive filling during early diastole [48], and a dominant *a* wave, representing active atrial contraction. Figure 12.6 demonstrates the normal

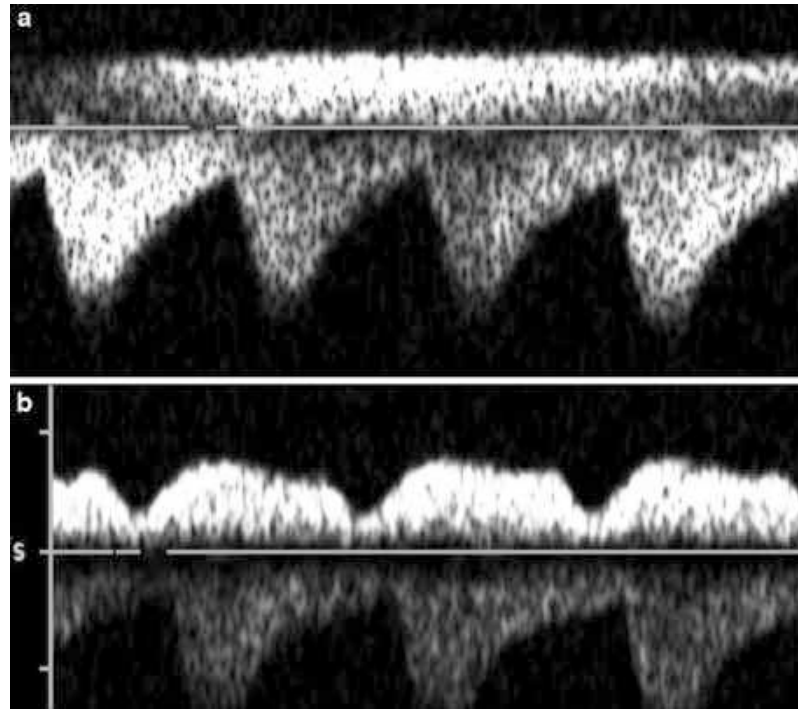

Fig. 12.5 Umbilical venous Doppler flow. (**a**) Normal continuous, non-phasic low velocity flow. (**b**) Pulsations in the umbilical vein, an abnormal finding typically seen in association with abnormal flow in the ductus venosus. This indicates very abnormal right-sided heart compliance

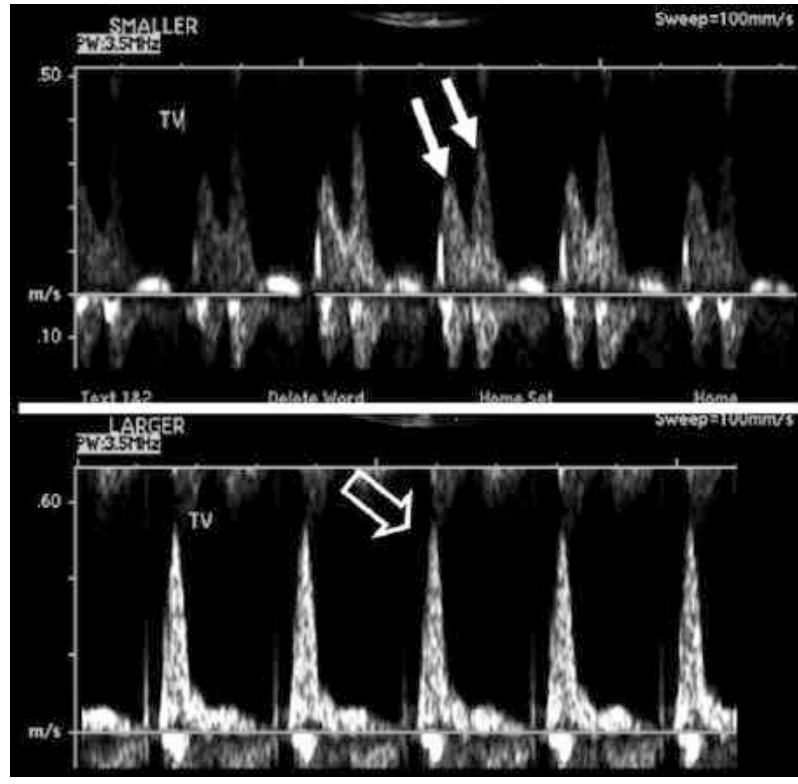

Fig. 12.6 Atrioventricular valve inflow patterns. *Top panel* illustrates the normal biphasic flow pattern with dominant second waveform peak (A wave, with atrial contraction). *Bottom panel* illustrates monophasic fused waveform, indicating poor right ventricle compliance

fetal inflow pattern. The ratio of the *e* wave to *a* wave increases progressively over the course of gestation as the relaxation properties of the fetal myocardium gradually improve [49, 50]. In contrast to the mature adult myocardium, the fetal myocardium has inherent diastolic dysfunction secondary to a greater percentage of noncontractile elements [51]. The immaturity of the fetal myocardium is present both in systole and diastole. Early in diastole, the "suction effect" caused by the active relaxation of the immature myocardium is less efficient, draining less blood into the ventricular cavities. The fetal *a* wave is dominant because there is more blood left in the atrial cavities after the first diastolic phase. With maturation, myocardial relaxation becomes stronger and a progressive increase of the *e* wave is observed [50]. It is interesting to note that in the mature myocardium, the *e* wave is dominant and the *a* wave is significantly smaller. This explains, in part, why fetuses with complete heart block are at high risk for the development of hydrops fetalis. During the second and third trimesters, observation of fetuses with complete AV block (CAVB) and heart rates >60 bpm without hydrops fetalis is the rule. Yet, all share the absence of contribution of active atrial contraction. Obviously, the active phase of early relaxation is crucial for an adequate cardiac output. The importance of heart rate must also be taken into account. Finally, in immune-related CAVB, the inflammatory process can also involve the myocardial fibers and partly explains the hydrops.

Without the contribution of active atrial contraction, preload may become compromised, leading to an overall reduced cardiac output. Examples of fetuses with altered ventricular compliance secondary to hypertrophy, or secondary to endocardial fibroelastosis, include critical aortic stenosis or hypoplastic left heart syndrome with mitral stenosis and aortic atresia or pulmonary atresia with an intact ventricular septum on the right side. In these, the normal biphasic inflow pattern may fuse into a single monophasic peak, as shown in Fig. 12.5.

Pulmonary Circulation

Ductus Arteriosus

The ductus arteriosus plays a key role in utero, allowing the majority of deoxygenated blood which exits the right ventricle to bypass the lungs in order to return to the placenta via the descending aorta. In utero, only 13 % of the combined cardiac output reaches the lungs at 20 weeks gestation, although the percentage increases to close to 25 % near term [52]. Flow within the ductus arteriosus should normally be all antegrade and laminar, with the majority of flow occurring during systole and a smaller amount of flow occurring during diastole. The ductus arteriosus is normally large and unrestrictive to avoid passage through the fetal lungs, which are under high pressure in fetal life, since the placenta is the site of oxygenation and ventilation.

At birth, exposure to oxygen leads to a cascade of events resulting in luminal constriction and ultimately disappearance of the ductus arteriosus. Abnormal constriction or narrowing of the ductus arteriosus is possible before birth. Utilizing Doppler echocardiography, operators may characterize the alterations in flow pattern as a consequence of narrowing by measuring the pulsatility index, as a reflection of arterial wave dampening (the lower the pulsatility index, the greater the waveform dampening and degree of ductal narrowing). Mild ductal constriction is defined as a pulsatility index between 1.5 and 1.9, moderate ductal constriction as a pulsatility index between 1 and 1.5, and severe ductal constriction as a pulsatility index <1.0 [53]. Figure 12.7 demonstrates the Doppler flow pattern in a normal fetus and in a fetus with ductal constriction. In contrast to the normal Doppler flow pattern, when there is significant ductal constriction, there is increased runoff in diastole. Numerous medications have been associated with the development of ductal constriction. These include corticosteroids, high-dose aspirin, and prostaglandin synthetase inhibitors [54–59]. Recently, some investigators have suggested that maternal ingestion of herbal teas [60] or foods rich in polyphenols [61] may also cause ductal constriction.

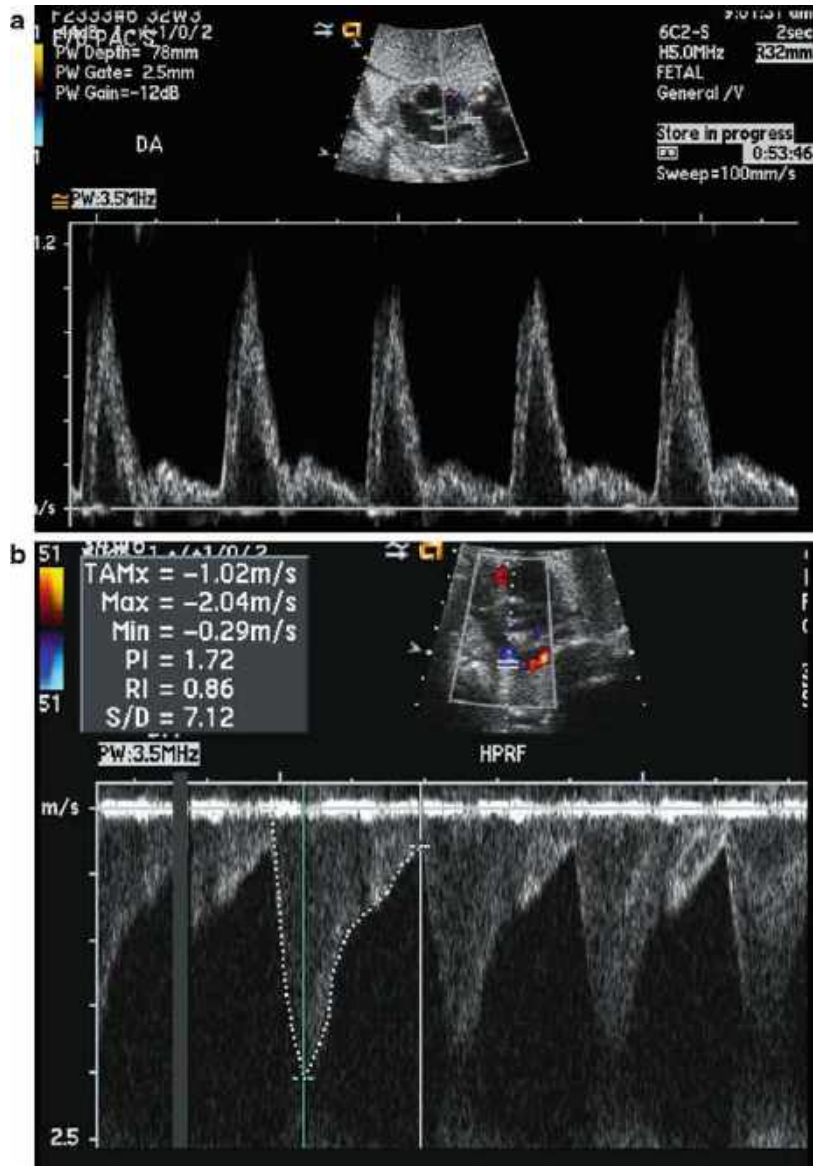

Fig. 12.7 Ductus arteriosus Doppler flow patterns. (**a**) Normal widely patent ductus arteriosus flow pattern. (**b**) Ductal constriction with increased diastolic flow. This is a result of incomplete passage of systolic stroke volume through the narrowing with persistent flow into diastole. Note the pulsatility index (PI) = 1.72

Constriction of the ductus arteriosus can lead to increased afterload on the right ventricle [53]. Ventricular hypertrophy may occur first [62]. However, with more significant constriction, the right ventricle may begin to show signs of failure, evidenced by tricuspid regurgitation, pulmonary insufficiency, and decreased right ventricular function [63]. Severe right ventricular compromise may result in intrauterine fetal demise [64]. When following fetuses with severe ductal constriction and evidence for right ventricular failure, the offending agent must be identified and removed or caregivers may wish to consider early delivery to avoid an intrauterine fetal demise [63–65].

Branch Pulmonary Artery

In many different types of congenital heart disease, cardiopulmonary interactions play a critical role in the pathophysiology of the disorder.

There are a number of congenital heart lesions at risk for pulmonary vascular maldevelopment and/or critical lung hypoplasia. In hypoplastic left heart syndrome with a restrictive atrial communication, impeded egress from the left atrium leads to pulmonary venous hypertension and development of pulmonary vasculopathy. In tetralogy of Fallot with pulmonary atresia or diminutive branch pulmonary arteries, there may be development of aortopulmonary collaterals, with abnormal pulmonary vasculature. In severe Ebstein's anomaly with massive cardiomegaly, cardiac structures can compress the lung leading to impaired pulmonary growth and lung hypoplasia. Doppler interrogation of branch pulmonary arteries and veins can provide important information regarding the health of the pulmonary vasculature prenatally. Figure 12.8 illustrates the typical Doppler flow pattern within the branch pulmonary artery. Normal values for the branch pulmonary arteries over the course of gestation are published for the proximal, mid, and distal branch pulmonary artery [66–69]. In lesions known to cause lung hypoplasia, such as a congenital diaphragmatic hernia, multicystic or dysplastic kidney, or chronic premature rupture of membranes, an increased pulsatility index within the branch pulmonary artery is a reliable predictor for lethal lung hypoplasia postnatally [70].

More recently, investigators have studied the response of the pulmonary vasculature to maternal hyperoxygenation testing to predict lethal lung hypoplasia postnatally. In normal fetuses, the pulmonary vasculature should vasodilate in response to maternal hyperoxygenation after 31 weeks gestation with a 20 % decline in the branch pulmonary artery pulsatility index [71]. Indeed, in fetuses at risk for lung hypoplasia, an abnormal response to maternal hyperoxygenation testing accurately predicted lethal pulmonary hypoplasia with a sensitivity of 92 %, a specificity of 82 %, a positive predictive value 79 %, and a negative predictive value 93 % [72].

In hypoplastic left heart syndrome, restriction at the atrial septum leads to maladaptive changes within the pulmonary vasculature, characterized by "arteriolization" of the pulmonary veins and dilation of the lymphatics [73, 74]. Maternal hyperoxygenation testing may be of benefit in identifying fetuses which require immediate intervention on the atrial septum to prevent lethal hypoxemia at the time of birth. An abnormal response to maternal hyperoxygenation testing, defined as a <10 % decline in the branch pulmonary artery pulsatility index, correctly identified HLHS fetuses which needed immediate intervention on the atrial septum at birth with a sensitivity of 100 %, a specificity of 94 %, a positive predictive value of 71 %, and a negative predictive value of 100 % [75]. Figure 12.9 demonstrates maternal hyperoxygenation testing for a fetus with an open septum and with a restrictive septum.

Pulmonary Vein

Doppler interrogation of the pulmonary veins provides tremendous insight into the degree of atrial level restriction in fetuses with left-sided obstructive lesions. Flow within the pulmonary veins should normally be all antegrade, although some normal fetuses may have a small proportion of retrograde flow with atrial contraction [76]. Figure 12.10 illustrates the pulmonary venous Doppler flow pattern, which is comprised of *s*, *d*, and *a* waves. Over the course of gestation, the *s*, *d*, and *a* wave velocities increase [76–78]. In contrast, as left atrial and left ventricular compliance improve during the second half of pregnancy, the pulsatility index for pulmonary veins decreases [77].

In hypoplastic left heart syndrome, investigators have shown increased flow reversal with atrial contraction in the pulmonary veins of HLHS fetuses with a restrictive atrial septum [74, 79–83]. Figure 12.10 illustrates the pulmonary venous Doppler flow pattern in a fetus with a restrictive atrial septum. Quantitative measures of the amount of forward flow compared to the amount of retrograde flow in the pulmonary veins of HLHS fetuses are possible [81]. A forward-to-reverse ratio of flow <5 within the pulmonary veins was the strongest predictor for the need for

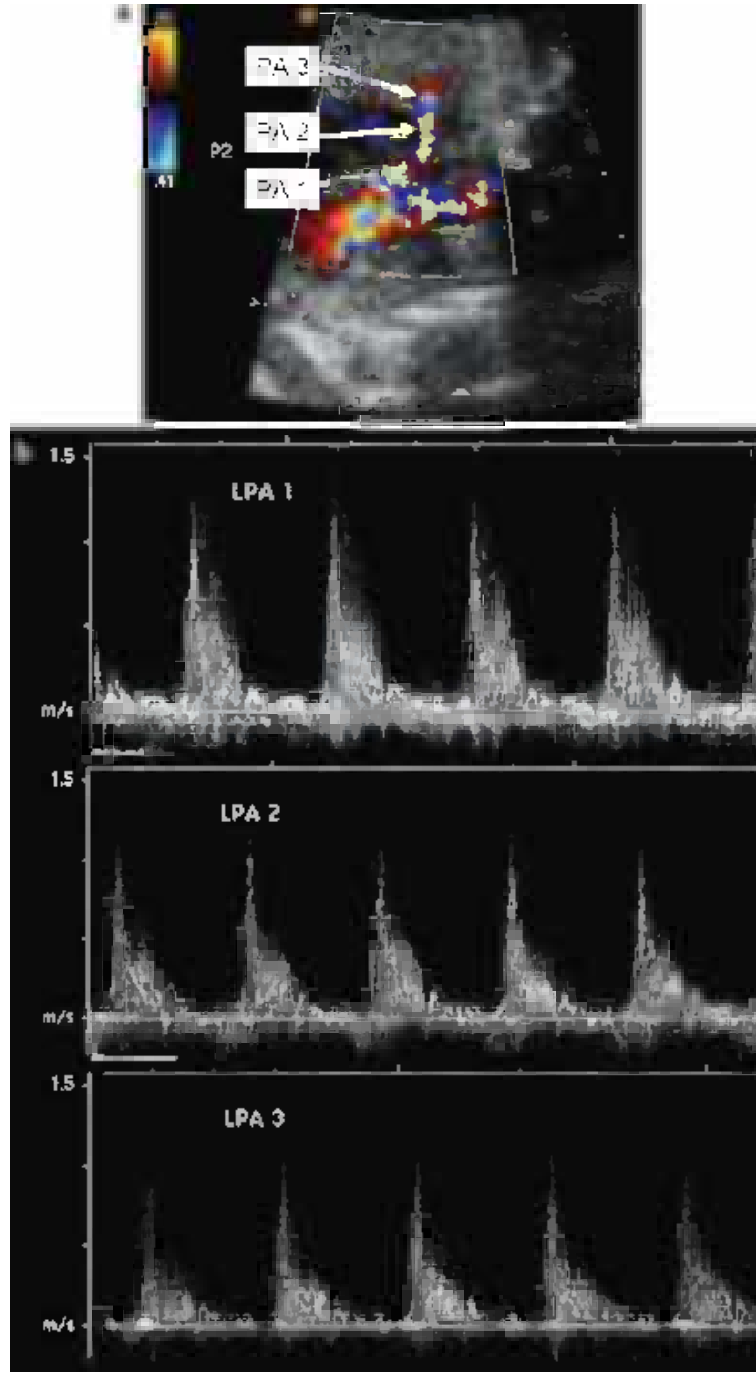

Fig. 12.8 Doppler sampling in the branch pulmonary artery. (**a**) Color-flow imaging demonstrates the 3 sites proximal (PA1), mid (PA2), and distal (PA3), which can be sampled and tracings obtained. (**b**) Note the variability in appearance of tracings based on site of sampling

urgent intervention on the interatrial septum at birth with a sensitivity of 88 % and a specificity of 97 % [81]. In a subsequent study, lowering the threshold of forward-to-reverse flow within the pulmonary veins to 3:1 optimized specificity and lowered the false-positive rate for predicting the need for urgent intervention on the interatrial septum at birth [79].

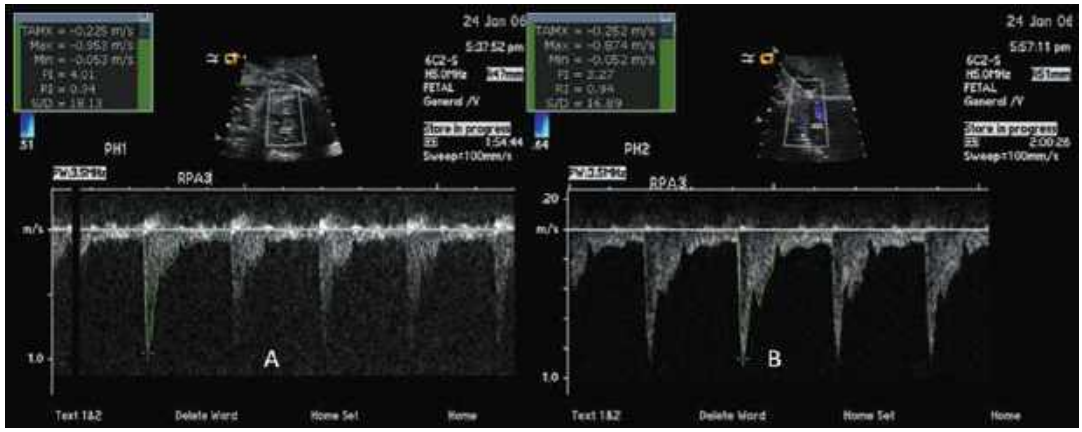

Fig. 12.9 Maternal hyperoxygenation testing for a fetus with HLHS and an open atrial septum. (**A**) The branch pulmonary artery Doppler flow pattern at the 1st branching point within the lung during room air. (**B**) The flow pattern at the same point during hyperoxygenation testing. Note the higher secondary peak in systole and the increased flow in diastolic illustrating pulmonary vasoreactivity with relaxation in response to oxygenation. With hyperoxygenation, the fetal pulmonary artery pulsatility index decreased from 4.01 to 3.27

Fetal Echocardiographic Findings Predictive of Postnatal Physiology in Congenital Heart Disease

Left-Sided Obstructive Lesions

In fetal life, the normal flow pattern across the atrial septum should be all right to left and flow across the aortic arch should be all antegrade. However, left-to-right flow at the patent foramen ovale and retrograde flow in transverse arch have been cited as prenatal markers for inadequacy of the left ventricle [84, 85]. In a small subset of hypoplastic left heart syndrome, some fetuses present with aortic stenosis and a dilated dysfunctional left ventricle and over time exhibit absence of left ventricle growth with evolution toward HLHS. In evolving HLHS, key echocardiographic parameters that accurately predict progression from critical aortic stenosis to HLHS include (1) retrograde flow in the transverse aortic arch, (2) left-to-right flow at the patent foramen ovale, (3) monophasic mitral valve inflow pattern, and (4) significant LV dysfunction [84]. In contrast, fetuses with right ventricle/left ventricle disproportion who are diagnosed with coarctation of the aorta postnatally demonstrate predominantly antegrade flow across the transverse arch yet bidirectional or left-to-right flow at the interatrial communication [86, 87]. Therefore, any fetus with hypoplastic left-sided structures and bidirectional or left-to-right flow at the interatrial communication should have prostaglandin infusion initiated in order to maintain ductal patency at birth pending a full postnatal assessment of the adequacy of the left-sided structures to support systemic perfusion.

Right-Sided Obstructive Lesions

In right-sided obstructive lesions, such as critical pulmonary stenosis, tetralogy of Fallot, or tricuspid atresia with a ventricular septal defect and pulmonary stenosis, reversal of flow within the ductus arteriosus is a marker of inadequate pulmonary blood flow postnatally [85, 88]. Therefore, prostaglandin infusion should be initiated at birth and parents counseled toward the need for a neonatal intervention to augment pulmonary blood flow. In fetuses with pulmonary atresia with an intact ventricular septum, a tricuspid annular Z score <-3, a tricuspid valve/mitral valve ratio <0.56, or the presence of right ventricular-dependent coronary-cameral

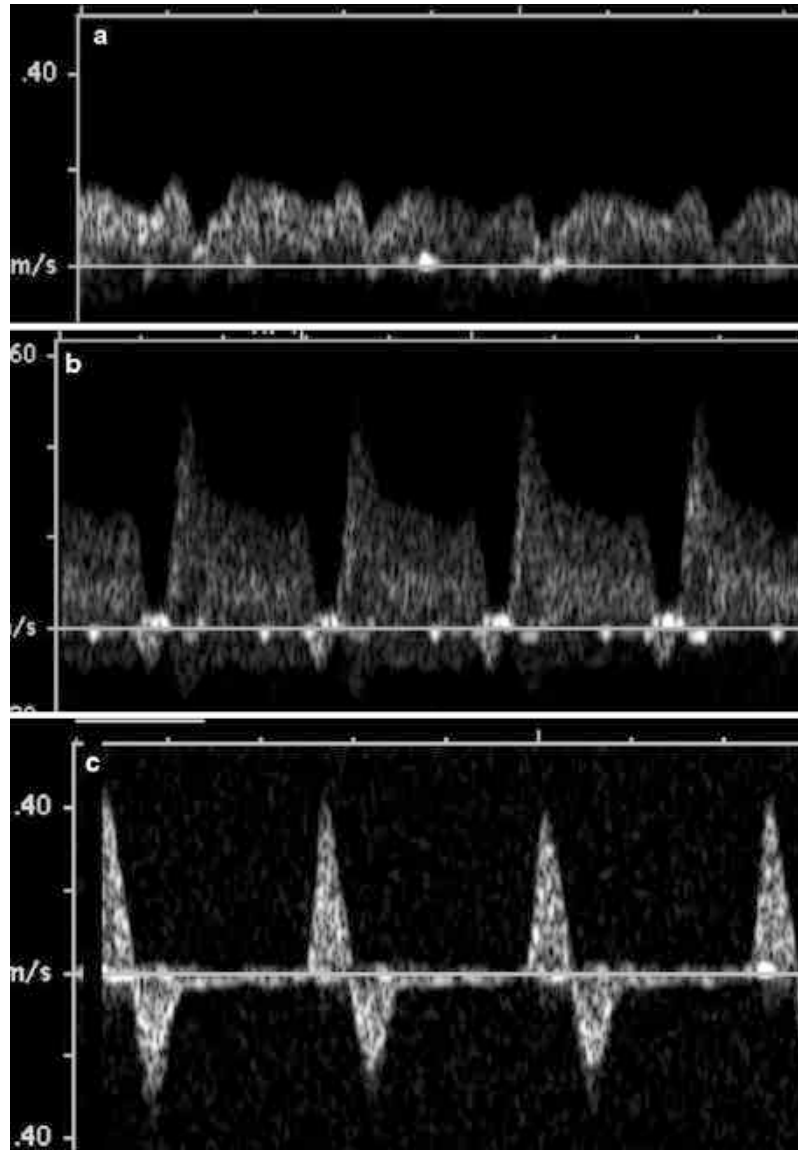

Fig. 12.10 Pulmonary venous Doppler flow patterns. (**a**) Normal flow pattern as seen in the sampling of a pulmonary vein from a fetus with a structurally normal heart. (**b**) Pulmonary vein sample from a fetus with HLHS but open atrial septum. Note the small degree of reversal of flow with atrial contraction. (**c**) Pulmonary vein sample from a fetus with HLHS and intact atrial septum. There is marked reversal of flow, with a nearly equal degree of forward and reversed flow suggesting severe impediment to left atrial egress

fistulae predicts the need for a single-ventricle palliation rather than a biventricular repair postnatally [89–91].

D-Transposition of the Great Arteries

In *d*-transposition of the great arteries (D-TGA) with an intact ventricular septum, lethal cyanosis may be present postnatally if there is inadequate mixing. Sites for potential mixing in the newborn with D-TGA are left to right at the atrial level and from aorta to pulmonary artery at the level of the ductus arteriosus. Such shunts are essentially important in order to maintain adequate oxygenation until a corrective arterial switch operation can be undertaken. Prenatal assessment of the interatrial communication to determine the need for urgent balloon atrial septostomy postnatally remains problematic. Fetuses with *d*-TGA at highest risk for hypoxia postnatally have an abnormal foramen ovale, defined as fixed in position, flat, and/or redundant septum primum, and/or a restrictive ductus arteriosus, defined as

Table 12.2 Delivery classification scale for fetal cardiovascular disease

	Definition	Examples	Action	Personnel
Class I	No hemodynamic instability	VSD, AV canal, truncus Arteriosus	Evaluation and monitoring	Neonatology
Class II	Ductal-dependent lesions, stable hemodynamics anticipated	Pulmonary atresia, critical coarctation or AS, HLHS	Vascular access, PGE infusion, +/− arterial line	Neonatology
Class III	Possibility or likelihood of hemodynamic instability	TGA, TAPVR	Vascular access, PGE infusion, arterial line	Neonatology + cardiology
Impact (*Immediate postpartum access to cardiac therapy*)	Hemodynamic instability is anticipated at separation from placental circulation	HLHS + IAS, Ebstein's, CHB, hydropic fetus	C-section in cardiac facility (operating room or cath lab) with neonatal resuscitation in adjacent cardiac room	Cardiac intensive care, catheterization laboratory, cardiac anesthesia, cardiac surgery, as necessary

AS aortic stenosis, *CHB* complete heart block, *HLHS* hypoplastic left heart syndrome, *IAS* intact atrial septum, *PGE* prostaglandin E infusion, *TAPVR* total anomalous pulmonary venous return, *TGA* transposition of the great arteries

a small ductus arteriosus, or a ductus arteriosus with continuous high-velocity flow or reversal of flow in diastole [92]. Other investigators evaluated the mobility of the septum primum flap and the flow pattern in the ductus arteriosus [93] and found that a hypermobile septum primum flap or reversed flow in diastole in the patent ductus arteriosus had a significant association with urgent balloon atrial septostomy. Despite these guides, significant restriction at the interatrial communication is not always recognized prenatally and many neonates continue to unexpectedly require an urgent balloon atrial septostomy at birth. Consequently, if D-TGA is identified prenatally, delivery at an institution where there is rapid access to performance of a lifesaving balloon atrial septostomy within minutes after birth is strongly recommended.

Delivery of the Fetus with Congenital Heart Disease

The transition from the safety of the supported environment of the maternal uterus to the independent postnatal state outside of the womb can be variably fraught with danger, depending upon the nature of the congenital heart disease at hand. Different forms of congenital heart disease require different strategies for management. At these authors' institution, a delivery classification system for fetal cardiovascular disease that takes into consideration the elements of potential instability at birth and the needs of the neonate was created (Table 12.2). This system is helpful in communicating to all members of the neonatal caretaker team as to what to expect at time of delivery.

Class I is designated for the fetus that will need no special care at birth with lesions such as a large ventricular septal defect or an atrioventricular canal defect. *Class II* is designated for fetuses with serious heart disease, but in whom stability is anticipated so long as ductal patency is maintained for either systemic or pulmonic perfusion. Examples include the fetus with HLHS or tetralogy of Fallot with pulmonary atresia. These fetuses may be cyanosed at birth but should remain stable during the delivery process. *Class III* is assigned to fetuses with the potential for instability at birth and who therefore require greater scrutiny and attention. Examples include D-TGA, or those in whom there is suspicion of anomalous pulmonary venous return that may be obstructed. *Class IV* is assigned to fetuses that are deemed to be at great risk for circulatory collapse or severe hypoxemia as soon as separated from placental circulation. Such fetuses can

be delivered via the "IMPACT" procedure (Immediate Postpartum Access to Cardiac Therapy). This is a strategy for scheduled Caesarian section delivery in a cardiac operating room or catheterization laboratory with a team ready to immediately intervene upon the newborn and perform whatever necessary measures required. Examples include the fetus with HLHS and intact atrial septum for which an immediate atrial septostomy or stenting procedure may be indicated or for the fetus with complete heart block that may require urgent postnatal pacing to maintain cardiac output.

Impact of Extracardiac Disorders on Fetal Cardiovascular Physiology

Twin-Twin Transfusion Syndrome

Multiple gestation pregnancy that is monochorionic (twins that share a placental plate) may have abnormal vascular connections between the partner fetuses, resulting in the development of "twin-twin transfusion syndrome" (TTTS). Inter-twin vascular connections may be arteriovenous, venovenous, or arterio-arterial. An inadequate number of arterio-arterial connections reduce the ability to equilibrate volume flow between the circulations when there is an abundance of arteriovenous connections in one direction. TTTS occurs in approximately 15 % of monochorionic twins, and if undetected or if left untreated, can result in significant cardiovascular morbidity, neurological insult, or death of one or both twins in nearly 80 %.

The precise pathophysiology of TTTS is still debated. One theory is as follows. Exchange of blood volume from a "donor" twin to a "recipient" twin can take place, with hypovolemia in the donor and volume loading in the recipient [94]. Hypovolemia in the donor then naturally leads to a release of vasoactive agents with activation of the renin-angiotensin system and vasoconstriction, this in order to preserve perfusion to vital organs. Unfortunately, these agents released by the donor follow the load to the recipient. Hence, the recipient is exposed to increased preload and a host of all the wrong vasoactive mediators leading to a progressive unique cardiomyopathy. An alternative theory states that increased levels of renin-angiotensin may be released by the placenta as a consequence of the vascular flow disturbance, with selective influence on the recipient [95].

There are classic cardiovascular findings noted in TTTS [96–99]. In the recipient, there is cardiomegaly, ventricular hypertrophy, and atrioventricular valve regurgitation. Doppler echocardiographic assessment indicates diminished right ventricular compliance as evidenced by changes in the ductus venosus (decreased flow with atrial contraction), umbilical venous pulsations, and fusion of early and late atrioventricular valve inflow waveforms into a single peak waveform. The right ventricle is affected first and to a greater degree than the left. Estimates of right ventricle pressure by interrogation of the tricuspid valve velocity indicate elevated pressure suggesting increased overall systemic vascular resistance. Approximately 15 % develop some change in the right-sided outflow tract ranging from a decrease in pulmonary artery to aorta size ratio (diminution in pulmonary artery size) to pulmonary valve stenosis to frank anatomical pulmonary atresia. "Functional" pulmonary valve atresia with a valve that is not seen opening with no antegrade flow but with pulmonary insufficiency is possible. In some recipients, the heart may appear no different than a case of pulmonary atresia with intact ventricular septum, as can be seen in the singleton with this form of congenital heart disease. In the donor, hyperdynamic systolic function related to hypovolemia can be seen and Doppler assessment of the umbilical artery reveals low diastolic flow reflective of elevated placental vascular resistance.

Quantitative characterizations of the cardiovascular manifestations of TTTS have been described. Measures of the myocardial performance index (MPI) have been found useful in grading severity of disease [100]. Fusion of early and late diastolic atrioventricular valve inflow waveforms will lead to reduction of inflow time and hence increase the MPI value. A semiquantitative method for scoring the

qualitative elements of the cardiovascular findings in TTTS the "CHOP TTTS cardiovascular score" was developed [98]. The score provides a means for monitoring the initial state of presentation, allows for a way to assess for either progression of findings or regression after treatment, and creates a metric that can be used to correlate to postnatal and long-term outcomes.

Laser photocoagulation of placental vascular connections is an effective therapy for TTTS, resulting in survival of most twins. A decrease in the burden of cardiovascular findings by reduction various scoring methods has been demonstrated following laser. As the number of survivors continues to increase, prospective screening for cardiovascular and neurological residua following laser treatment for TTTS will be of great interest.

Congenital Chest Anomalies: Congenital Cystic Adenomatoid Malformation and Congenital Diaphragmatic Hernia

Lung lesions in the fetus may secondarily affect cardiovascular function. Large congenital cystic adenomatoid malformations (CCAM) are abnormal growths of the terminal respiratory bronchiole. These masses can grow to giant size, compressing both normal lung tissue and the heart. Increased intrathoracic pressure leads to an alteration in Doppler-derived filling parameters of the heart and can cause tamponade [101, 102]. The physiological impact is seen on both right and left ventricles. In the most severe cases, the heart size is small and the diaphragm inverted concave toward the abdomen, with deviation in the course of the inferior vena cava as it pierces the diaphragm. Sudden relief of intrathoracic pressure as seen during fetal surgical resection of CCAM creates a phenomenon similar to sudden relief of a large pericardial effusion, resulting in impaired coronary perfusion and the potential for myocardial ischemia [103].

In congenital diaphragmatic hernia (CDH), abdominal contents are extruded into the chest cavity. However, in contrast to CCAM, increased intrathoracic pressure is not a factor, as pressure is equalized between the abdomen and chest cavities. Congenital heart disease is seen in up to 10 % of all fetuses with CDH [104], and chromosomal, genetic, or syndromic abnormalities are common. Pulmonary hypoplasia and pulmonary vascular abnormalities are typically present and may be associated with the most common cardiac finding in the fetus with CDH – that of relative left ventricle hypoplasia [105]. Upon fetal echocardiography, the left ventricle can appear slim and under-filled, with a small short-axis mid-ventricular dimension but with relatively normal mitral and aortic annulus measures. Decreased filling of the left ventricle may be due to a variety of factors, such as (1) selective compression by abdominal contents of the left heart as left-sided CDH is more common than right-sided CDH with decreased right-to-left shunting at the atrial level due to altered left ventricular compliance and (2) decreased pulmonary venous return and hence diminished left ventricular volume due to pulmonary hypoplasia. Decreased filling of the left side of the heart can result in impaired blood flow into the aorta, with reversal of flow in the aortic isthmus or transverse aorta. This can make it extremely difficult to distinguish between retrograde flow due to impaired ventricular filling or the actual presence of a coarctation of the aorta. Serial evaluation and postnatal assessment may be necessary to distinguish between these two possibilities.

Sacrococcygeal Teratoma and Arteriovenous Malformations

Sacrococcygeal teratoma (SCT) is a highly vascularized tumor of mixed tissue origin [106]. When large, the SCT can act as a giant arteriovenous malformation resulting in an increased volume load on the heart and a low-resistance vascular "sink" which may compete with the placenta and steal blood away. SCT leads to a massive volume load on the heart, which leads to cardiomegaly and induces atrioventricular valve regurgitation through annular dilation,

which further promotes cardiomegaly. Fetal hydrops due to high-output heart failure and fetal demise are common. Cerebral arteriovenous malformations (vein of Galen malformation) can also lead to massive volume load and hydrops.

Serial monitoring through Doppler echocardiography is important for prenatal management. Serial assessment of fetal combined cardiac output (right plus left ventricle) can help determine the timing for early delivery or for in utero treatment. Using Doppler echocardiography, cardiac output can be estimated as the product of the cross-sectional area of the site of assessment (aorta for left side, pulmonary artery for right side) times the velocity time integral of flow (area under the spectral Doppler curve) times the heart rate. The normal combined right and left ventricle cardiac output in the fetus is relatively stable at approximately 400–500 ml/kg/min throughout gestation [107]. Combined cardiac output in the fetus with SCT can double to values as high as 1,000 ml/kg/min. Progressive increase in combined cardiac output or identification of diastolic flow reversal in the umbilical artery heralds impending demise. Surgical resection of giant SCT is possible in the fetus and should be considered in such circumstances [103].

Summary

Through the application of fetal echocardiography, complex physiologies can be elucidated which offer insight in to a host of conditions. Doppler echocardiography provides the tools necessary to better understand the impact of various disorders and anomalies.

Fetal Myocardial Mechanics

13

Anita J. Moon-Grady and Lisa K. Hornberger

Abstract

Maturational and structural differences and external constraint on the fetal myocardium give rise to observed differences in cardiac function between fetal and postnatal life. Traditional M-Mode, gray-scale 2-dimensional, and Doppler blood flow techniques give indirect insight into myocardial function and its interactions with the vasculature. Over the past decade, several new indices derived from echocardiographic Doppler and tissue Doppler measurements have been proposed as noninvasive measures of systolic and diastolic dysfunction. One of the newest technologies enlisted in the evaluation of fetal and postnatal myocardial function has been measurement of myocardial strain and strain rate using algorithms to track individual regional myocardial mechanics. Tissue Doppler, 2D speckle, tissue and feature tracking are among the newer noninvasive ultrasound-based techniques which allow direct noninvasive assessment of myocardial motion and mechanics and may have a role in helping to unravel the intricacies of developmental maturational changes in myocardial mechanics. Additionally, understanding the strengths and limitations of these techniques may assist in future research to determine their role in clinical practice.

Introduction: Overview of Myocardial Development

The fetal myocardium shows significant structural differences from the mature heart [1]. The internal organization of the immature myocyte, including the central core of mitochondria, nucleus, and membranous material surrounded by thin layer of myofibrils, contributes to the reduced contractility of the fetal compared to the neonatal and adult myocyte [2]. A reduced cytosolic calcium gradient as a consequence of less developed sarcoplasmic reticulum, reduced number of calcium pumps, and functional changes in the handling of calcium in the sarcoplasmic reticulum contribute further to the diminished contractile capacity of the fetal myocardium and even its ability to actively relax. The giant protein titin (also called connectin), a principal contributor to passive tension in the myocardium, has been shown to exhibit species-specific isoform switching during development with corresponding functional changes during heart development, and cardiac troponin I also exhibits isoform switching during development [3–5].

Although clinical measures of cardiac systolic performance including fractional shortening and ejection fraction do not change appreciably during fetal and with the transition to postnatal life [6–8], at the myocyte level, the late-gestation fetus produces less contractile force than the adult, though, in fact, evidence from modeling suggests that active tension and force-generating ability of the myocardial tissue during fetal heart development increases throughout gestation [9]. Diastolic function of the fetal myocardium is also very different from the more mature myocardium after birth. Early animal investigations have suggested there is greater diastolic wall tension for a given radius at a whole heart level [10]. During gestation, blood flow velocities during diastolic ventricular filling gradually increase during early diastole, suggesting that there may be differences in both active early filling and in the compliance of the ventricular myocardium, the latter of which may be partially explained by the less organized nature of the myocardium, and differences in number of contractile elements as well as differences in the composition of the extracellular matrix [2]. However, at the sarcomere level there is no difference after correcting for percentage of contractile elements in fetal sheep myocytes (30 % in the fetus versus 60 % in the adult) [11]. Furthermore, in studies of early embryonic chick hearts, although the heart has been shown to undergo major changes in mass, morphology, and loading, peak circumferential and longitudinal strains relative to end diastole have been shown to be similar in magnitude and do not change significantly, and peak principal strains do not show significant changes, suggesting that wall strain is maintained within a relatively narrow range during primary cardiac morphogenesis [12].

Although both experimental animal and echocardiography-based clinical studies have provided insight into developmental changes in systolic and diastolic function in the mid- and third-trimester fetus, there is a paucity of data regarding early fetal contractile performance [13] and even less even on fiber architecture particularly in the developing human heart. Most of the current knowledge comes from work in animal models. The two-layered

myocardium of the early cardiac tube is an epithelium that contains actin microfilaments [14]. These filaments are arranged in polygonal arrays around the cell margins in the outer layer, while the inner layer contains circumferentially oriented filaments. Some authors have speculated that in the very early embryo, as the apical microfilaments contract to form each of the paired tubes, the latter may be drawn together by external loads. Additionally, there are mechanical effects associated with the looping process and longitudinal curvature due to looping alteration of the stress distribution in the primitive ventricle. In a straight tube, wall stresses are axisymmetric; however, the stress distribution in a curved tube will vary around the circumference of the tube. Lin and Taber [15] found that the peak systolic stress occurs in the outer myocardial layer along the inner curvature, when constructing models of the early ventricle as a thick-walled curved tube, and hypothesized that alterations in stresses may influence the expression of genes and other biochemical products [16]. Subsequent to looping, in very early fetal mice, progressive organization of myofibrils is thought to be crucial in the genesis of developmental increases in contractility [17]. Scanning electron micrographs suggest that randomly oriented sarcomeres align gradually during development, and several investigators have described circumferentially arranged actin filaments in the outer layer of the two-cell-thick myocardium as early as stage 10 [14, 18]. It is not clear, however, how the fibers become aligned to form the highly ordered pattern of the more mature myocardium and how the fetal myocardium comes to attain its mature adult form, a complex helical arrangement of fiber sheets which assumes a right-handed helical geometry in the subendocardial region, with gradual change to a left-handed geometry in the subepicardium. Net left ventricular torsion increases gradually from infancy to adulthood in humans [19]. Fiber architecture in the mature human myocardium is quite complex, exhibits regional variation, and differs substantially in the right versus left ventricle. In the left ventricle, for instance, longitudinal fibers predominate in the subendocardium, while subepicardial fibers exhibit a longitudinal arrangement on the oblique margin of the left ventricle, but a circumferential arrangement on the acute margin [20], while the right ventricular free wall has a predominance of longitudinal and oblique fibers. Longitudinal fibers are nearly absent from the interventricular septum. Furthermore, myocyte arrangement in the mature human myocardium has been described as a continuum of two helical fiber geometries, with right-handed helical arrangement in the subendocardium and left-handed in the subepicardium [21]. This mature pattern produces a wringing motion throughout the cardiac cycle; however, it has been suggested that the relative orientation of the net helical twist (counterclockwise at the apex, clockwise at the base in systole) is not yet present in the immature heart [19]. This incredibly intricate interaction of the individual myocyte with the heart as a functioning organ is only beginning to be studied by noninvasive means, but both magnetic resonance and ultrasound techniques are showing promise in unraveling the complexity of myocardial mechanics in normal and abnormal states. Doppler methods have been applied for assessment of tissue velocities, and both Doppler and non-Doppler feature-tracking methods are being applied to echocardiographic images to provide velocity and displacement information and permit quantification of myocardial strain and deformation in the developing human heart. This chapter will briefly discuss the concepts involved in the current understanding and the application to both normal and disease states in the fetus.

Basic Properties and Definitions

Basic Properties of the Myocardium: Definitions

Displacement – the distance that a certain feature moves between two time points

Velocity – displacement per unit time. Velocity is expressed in centimeters or meters per second and is abbreviated "v".

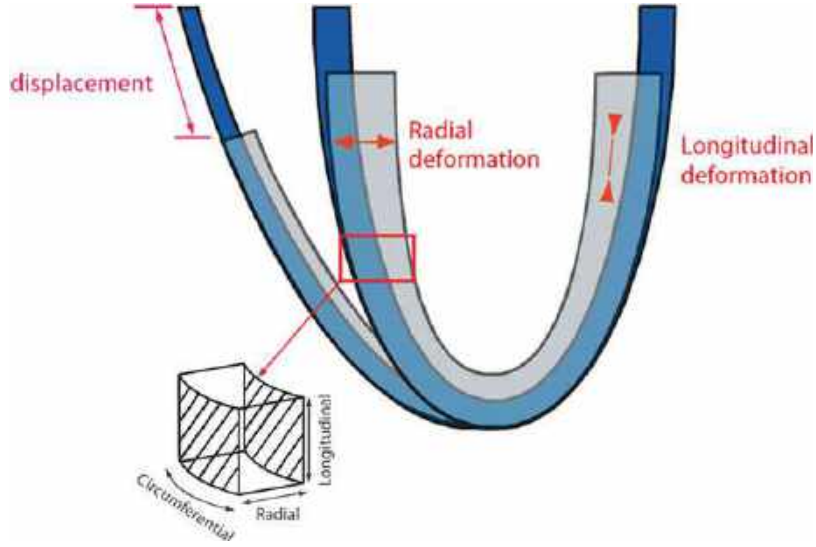

Fig. 13.1 Motion and deformation components as applied to the study of myocardial mechanics

Strain – the deformation of tissue, normalized to its initial size or shape. Strain is unit-less, usually expressed as a percentage. By convention, lengthening will be represented by a positive strain value, shortening (contraction) as a negative value. Strain is abbreviated as "S" or epsilon (ε).

Strain rate – the rate at which tissue deformation occurs, usually expressed as 1/s

Rotation – displacement, expressed in degrees, around the long axis of the ventricle

Twist – absolute base-to-apex difference in rotation

Torsion – base-to-apex gradient in the rotation angle along the long axis of the ventricle, expressed in degrees per centimeter

Regional or segmental strain – strain measured in a local region

Global strain – approximated by averaging of multiple segmental strain components from individual myocardial segments

When the spatial coordinates of an object are known during the deformation process, additional definition may apply. These include natural and Lagrangian strains and strain rates:

Natural strain – instantaneous deformation expressed relative to segment length at a previous time instance

Lagrangian strain – instantaneous deformation expressed relative to the original coordinates

It has been shown that the Lagrangian strain and the natural strain have a fixed (nonlinear) relationship, $\varepsilon(\text{natural}) = \ln(1 + \varepsilon(\text{Lagrangian}))$ where "ln" represents natural log. Importantly, this relationship only holds when the rate of deformation is constant as a function of time. Lagrangian and natural strain values are approximately equal at small values of strain (<10 %), but for most cardiac mechanics applications the difference will be significant. For this reason, it is important to define which type of strain is measured when studying the heart [22].

Displacement and velocity are vectors and as such have direction. When applied to cardiac mechanics, the orientation of the vectors can be described in terms of orientation to the axis of the heart for any given cardiac segment (Fig. 13.1). Note that local coordinate systems will necessarily differ from a global Cartesian coordinate system in which the *x*, *y*, and *z* planes are determined by the heart or ventricle in its entirety (with *x* representing the long axis, *y* toward a line running down the center of the chamber, and *z* perpendicular to both). Within a given segment of the myocardial wall, local coordinate system component vectors become longitudinal (from apex to base, tangent to the epicardium), radial (from epicardium to

endocardium), and circumferential (perpendicular to the radial vector and the longitudinal vectors).

Methods Available for Assessing Myocardial Mechanics

PW and color tissue Doppler velocities
Color Doppler strain, strain rate analysis
2D speckle-tracking velocity, strain, strain rate analysis

Traditionally used echocardiographic assessments of ventricular systolic function are based on either linear methods (M-mode assessment of fractional shortening) or are based on geometric assumptions that may be invalid in the fetus (i.e., that the systemic ventricle assumes the shape of a prolate ellipsoid). Displacement and long-axis function in the fetus can be studied by M-mode [23]. Global assessment of myocardial function has been attempted by applying the myocardial performance index (isovolumic time divided by ejection time, determined by pulsed-wave Doppler of inflow and outflow blood pool velocities [24]), but this index is known to be preload and afterload dependent. Ideally, when assessing myocardial properties directly, velocity, strain, and strain rate are more direct measures than the indirect measures noted above. Pulsed-wave tissue Doppler imaging (PW-TDI) tissue velocities can be measured within the fetal myocardium [25] with a high temporal resolution and adequate feasibility; however, limitations exist in sensitivity for detection of disease in fetuses largely due to wide confidence intervals even in normal fetal measurement [26]. Echocardiographic measurements of tissue peak annular velocities in systole (S') and diastole (early, E', and with atrial contraction, A') theoretically assess systolic and diastolic function and are independent of geometry assumptions [27, 28] (Fig. 13.2). PW-TDI-derived velocity measurements have been studied extensively in the adult population and have been found to be easily obtainable and reproducible echocardiographic indices and sensitive indicators of systolic and diastolic dysfunction in general; in adults, decrease in peak S' correlates with heart failure symptoms and mortality, and decrease in mitral E' correlates with worsening time constant of ventricular relaxation (tau) and worsening dP/dtmin as does a decrease in Vp [29, 30]. The ratio of either E/E' or E/Vp correlates with pulmonary capillary wedge pressure and left ventricular end-diastolic pressure measured invasively [28, 31–33].

In the fetus, it has previously been shown that values for Vp and E/Vp are indicative of maturational changes in the myocardium simulating gradually improving diastolic function [34], and it has also been shown that both RV and LV E/E' ratios in normal fetuses remain constant through the second and third trimester of gestation [35] suggesting similar findings. PW-TDI derived isovolumic acceleration (IVA), in invasive animal studies, has been shown to be a relatively load-independent index of myocardial contractility correlating closely with invasive pressure-volume indices [36–38]. This index has been studied in fetal lambs and in human fetuses and seems to have a significant positive correlation with gestation, in keeping with gestational-age-related increase in myocardial contractility [39, 40]. Further, in a chronically instrumented fetal lamb model, induced metabolic acidosis was shown to significantly reduce both RV and LV IVA, suggesting this may be a useful parameter for detection of fetal compromise, though not yet thoroughly studied in human fetuses [41]. Reduction in peak left ventricular S' and E/E' ratio has been correlated with hydrops in a small study of fetuses [42]. Peak systolic velocities, however, have been shown to be preload and afterload dependent and therefore may have limited utility in evaluating fetuses in which these cannot be measured or controlled and are constantly changing with gestation; furthermore, tissue Doppler velocities are affected by tethering and translational motion of the heart and therefore cannot accurately reflect actual myocardial contraction velocity – nonviable myocardium may appear normal if adjacent to normal tissue, for instance, and small movements of the fetus during sampling may affect velocity measures. Moreover, PW-TDI does not allow for simultaneous

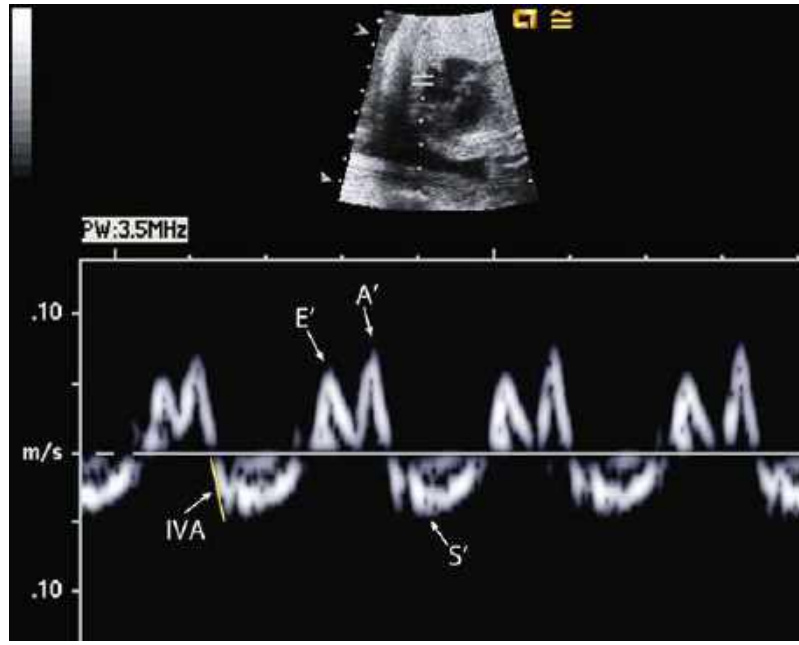

Fig. 13.2 Normal tissue Doppler spectra obtained from the lateral tricuspid annulus in a normal fetus at 30 weeks' gestation. Peak velocities in systole (S'), early diastole (E'), and late diastole (A') as well as the slope of the isovolumic contraction phase (IVA) can be measured

sampling in multiple areas of the myocardium, and the measurement of velocity of course is highly angle dependent, and in the fetus, where lie can be variable even during the course of a single examination, this may introduce significant variation in measurement.

Strain and strain rate assessment has the theoretical advantage over velocity in that they are not affected by translational motion or tethering to adjacent segments. Strain and strain rate are less load dependent than velocity [43]. At present, there are several methods for determining strain and strain rate noninvasively, including MRI and echocardiographic techniques. Because of the inapplicability of MRI to the fetal heart with the currently available technology, only echo-derived measurements will be discussed in this chapter.

The initial application of echocardiography to strain imaging utilized Doppler technology. Color tissue Doppler imaging (C-TDI) strain rate is calculated from the velocity gradient between two points of known distance apart (the sample volume length); strain is then calculated by integrating strain rate. It has an advantage over PW-TDI in that data can be post-processed and multiple areas of the myocardium can be simultaneously sampled. Velocity gradients and differing velocities in regions of the heart can thus be analyzed. C-TDI techniques have the additional advantage that from multiple velocity measurements over differing regions, the strain and strain rates can be calculated. C-TDI, however, as it relies on information obtained from a Doppler signal, remains angle dependent, and only motion toward or away from the probe can be quantified [44] (Fig. 13.3).

Analysis of the information contained in two-dimensional gray-scale B-mode images can circumvent the angle-related limitations of Doppler-based techniques. These "speckle-tracking" techniques, generally termed "2D speckle-tracking echocardiography" or "2D-STE" rely on identifying patterns of gray scale (the artifactual, but region-specific pattern generated by wave interference) within small regions and how their position varies through the cardiac cycle and are therefore angle

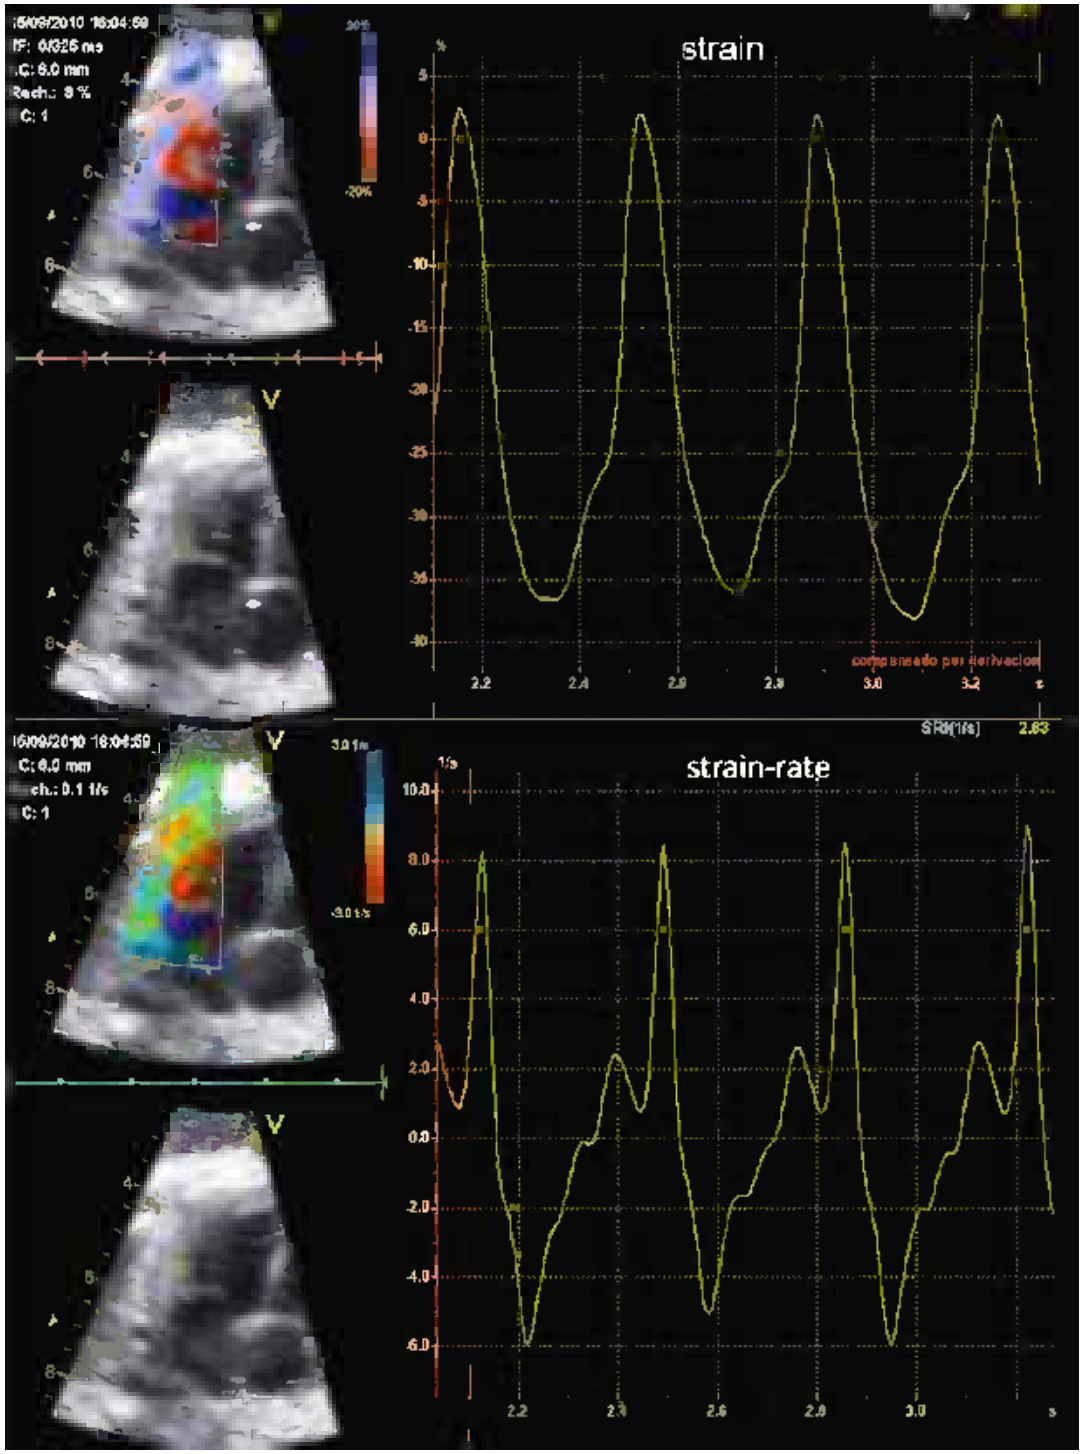

Fig. 13.3 Strain and strain rate curves obtained by color tissue Doppler imaging technique. Note the angle dependence inherent in this method, with a very small angle of insonation in the reference image (Courtesy of Drs. Fatima Crispi and Eduard Gratacós)

independent. Various speckle-tracking echocardiographic techniques are available that differ primarily in their tracking algorithms. Velocity vector imaging (VVI; Siemens Medical Solutions, Mountain View, CA) and automated function imaging (AFI; GE Medical Systems, Milwaukee, WI) are two commonly employed speckle-tracking echocardiographic techniques. AFI has been compared and validated against Doppler-based measurements [45] and cardiac magnetic resonance imaging [46]. The AFI or VVI software tracks echocardiographically generated speckles and factors annulus motion, periodicity, and border tracking to track the myocardium. The software uses mathematic modeling to track myocardial motion and then is able to calculate myocardial velocity, strain, and strain rate for these data (Fig. 13.4). When regions of myocardium move, they have a motion vector which can be separated into vectors of interest, i.e., radial and longitudinal motion. As for C-TDI, deformation or strain could be calculated from strain rate derived from the velocity vector gradient. However, speckle tracking also allows direct calculation of strain from changes in distance between tracked features rather than calculating based on velocity measurements. In both in vitro and in pig and canine models, good correlation is obtained between circumferential and longitudinal systolic strain by VVI and sonomicrometry [45, 47]. Global strains measured by 2DSE and tagged magnetic resonance imaging demonstrate close agreements in animals [48] and pediatric patients [49], best with frame rates of 60–90 frames/s. However, care must be taken when comparing results obtained with the commercially marketed software currently available, as the tracking algorithms are proprietary and have been shown to produce differing results when directly compared and validated against an MRI standard, tagged harmonic phase magnetic resonance imaging [50]. In adults with ischemic myocardial disease, AFI appears to be more accurate in comparison with MRI and has the best discriminative ability for the detection of regional myocardial dysfunction [50]; average values for adult patients at baseline for strain are slightly lower when obtained by VVI versus AFI [50].

Applications in the Normal Fetus

Velocity

Tissue velocities in general increase with gestation, likely due in part to somatic growth of the fetal heart and changing loading conditions; in addition, gradients in velocity are seen within the myocardium, with higher longitudinal velocities in the right ventricular free wall than the left (both of which are higher than the interventricular septum), likely due to differences in fiber orientation. Finally, velocities are higher in the base than in the apex for both the right and the left ventricle. Pulsed-wave Doppler techniques have been applied over a range of gestations in the human fetus, and both systolic and diastolic gestational-age-related changes have been reported using this method [25, 51]. PW-TDI allows for excellent temporal resolution, and thus early and late diastolic events can be separated, and early systolic isovolumic acceleration which precedes systolic contraction during ejection can be discerned. In studies of fetuses from the late first trimester to term, a positive correlation of myocardial velocities can be seen with gestational age, in systole and in early diastole. With gestation, a gradual increase in early diastolic tissue velocity is seen with no change in late diastolic velocity, leading to a gradual decrease in early/late diastolic velocity ratio that may correspond with improving diastolic function and decreased reliance on passive filling with more advanced gestation. Studies in disease states have thus far been limited, but in fetuses of mothers with pregestational diabetes, decreases in early diastolic velocities have been observed, and in placental insufficiency and in fetal heart failure, tissue velocities have been shown to be lower [26, 42]; in hydropic fetuses, similarly, both systolic and diastolic tissue velocities are lower than expected for gestational age. Tissue velocity measures by PW will be higher, due to detection of peak velocity, than those determined by color TDI which returns the mean velocity of tissue within the sample volume. The values therefore are not

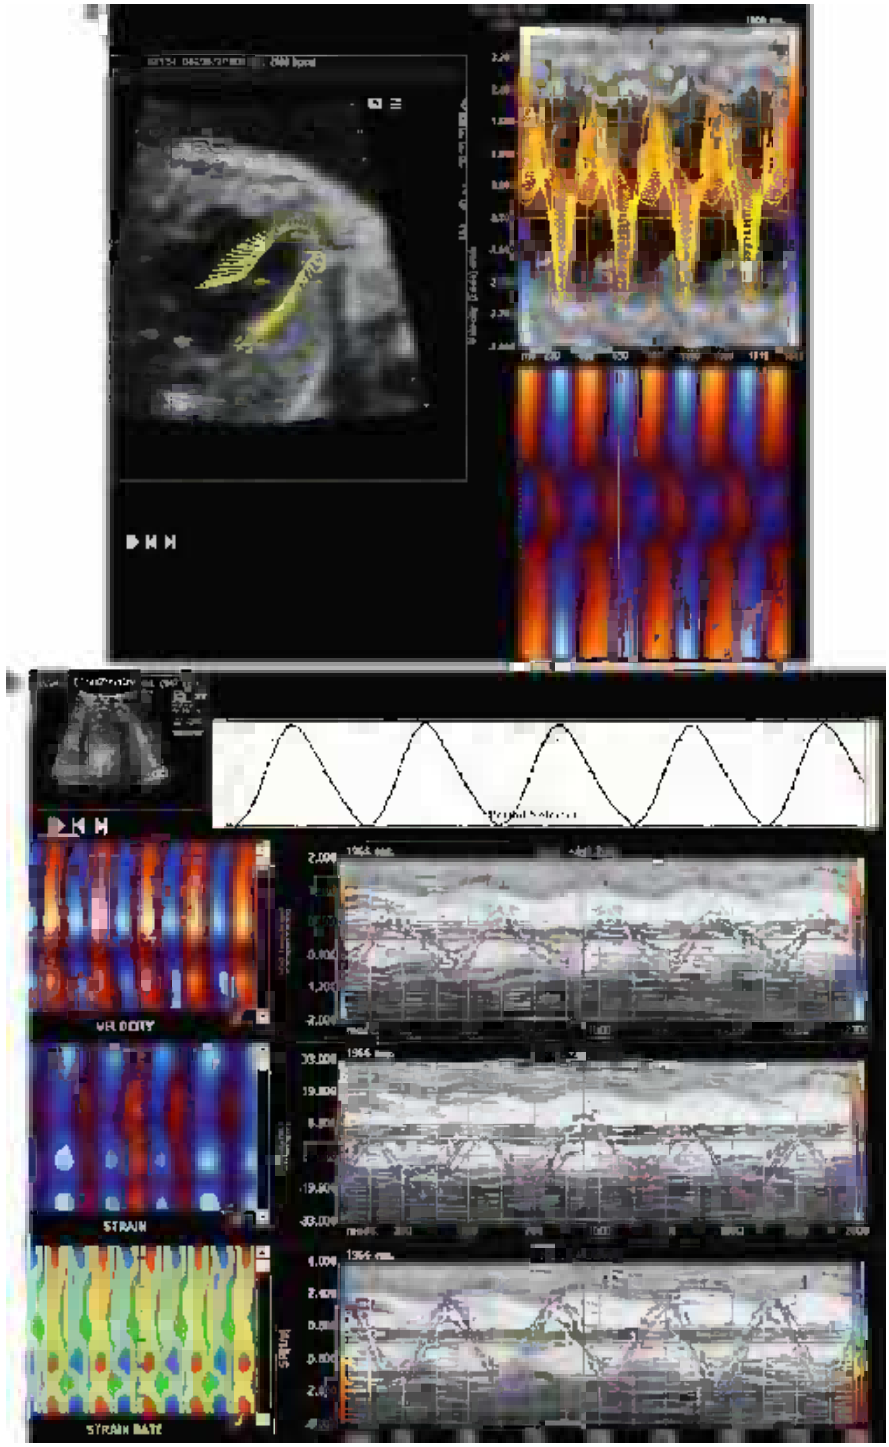

Fig. 13.4 Illustration of application of 2D speckle-tracking echocardiography in a normal fetus at 30 weeks' gestation. Endocardial borders are manually traced and the tracking algorithm applied to produce the resultant vectors for analysis. *Panel A* shows longitudinal assessment, *panel B* radial velocity, strain, and strain rate curves, both over five cardiac cycles

interchangeable. This said, similar trends as far as gestational-age-related changes have been recorded with color TDI [51, 52].

Strain and Strain Rate

In normal hearts there exists a region-specific strain gradient from the epicardium to endocardium [53]. There have been a few studies of strain and strain rate in fetuses utilizing color Doppler TDI at various gestations and in normal fetuses (Table 13.1). However, as noted above, the technique remains angle dependent. The advantages of 2D STE in applications to fetal myocardial mechanics include the ability to measure motion independent of the angle of image acquisition and the ability to measure motion in multiple directions (e.g., longitudinal and radial motion) from a single image, which make it ideal for assessment of the fetus, who may present in varying nonstandard positions during image acquisition. Several authors have applied 2D STE to the normal mid- to late-gestation fetus for assessment of longitudinal mechanics (Table 13.1), though only one study to date has also addressed circumferential strain [54]. In general, feasibility seems reasonable, though several studies report up to 20–30 % interobserver variability and there are problems with application to individual fetuses and to disease states given the very wide confidence intervals reported in these studies. As can be seen from the table, absolute measures of strain and strain rate differ, as expected, between AFI and VVI methods and between color TDI and 2D STE; despite these differences in absolute measurement, however, trends in changes during gestation should be similar. Interestingly, there are conflicting data from these early studies. Peak longitudinal strain for the right ventricle is higher than for the left in most studies (likely due to differences in fiber orientation discussed above), but there is disagreement regarding gestational-age-related change with most studies finding no trend but some reporting increase and some decrease through the second half of gestation. Though various explanations have been put forth, no clear trends are seen in this handful of reports. Looking only at VVI-based measurements, it would seem that gestational-age-related trends are only detected at higher frame rates; however, this does not explain the conflicting results using AFI and color TDI, where frame-rate limitations are not as much of a factor. Though most studies showing no change in gestation have utilized low frame rates, a lack of correlation has also been observed in some high frame-rate studies; similarly, strain rate study has shown conflicting conclusions in this respect. Technique variations (color TDI versus STE) cannot explain the differences either, as can be seen from the table. It is possible that variation in reporting of global versus regional or segmental values may introduce some of these conflicting conclusions, though in most studies segmental and global measurements have not seemed to be significantly different and there is a tendency to report global measurements [55–60]. Clearly more work in this area, with larger numbers of fetuses per study, is needed, and no definitive conclusions can be drawn based on the presently available data as relates to longitudinal mechanics. Significant limitations in temporal resolution have led to a lack of application of these methods to diastolic function in all patients (normal values for diastolic strain and strain rate in adults are yet to be published), with essentially no extant data in fetuses. There is also a paucity of data on the use of strain and strain rate imaging of the atria, though studies in adults have shown that left atrial strain imaging is feasible [61, 62] and that decreased peak left atrial strain during ventricular systole correlates with elevated left ventricular end-diastolic pressure elevation [63]. Vector velocity imaging has been used to begin to understand normal developmental changes in fetal right atrial function [64] as well as reservoir strain and strain rate [65]. Khoo et al. showed that emptying fraction, fractional area change, and filling and emptying rates normalized for atrial volume are constant from the midtrimester to term [64]. Atrial reservoir strain and contraction strain rate have been documented in the mid- and third trimester and appear to be independent of atrial volumes in the normal fetus, but inversely related to ventricular strain and strain rate [66].

Table 13.1 Published studies of myocardial mechanics in normal human fetuses utilizing several different techniques

Reference	Method	N	Median GA (range)	IOV	Peak longitudinal strain (%)		Peak longitudinal strain rate (1/s)		Gestational age-related change?		Global or regional	Frame rates

[b]Reported Lagrangian strain; there is an up to 20 % difference natural versus Lagrangian (Matsui)

Applications in the Abnormal Fetus: Maternal and Fetal Disease States

It has previously been demonstrated that maturational patterns of myocardial architecture and strain are altered in chick embryos, in models of hypoplastic left heart produced by ligation of the left atrium [67]. Chick embryos normally develop a dominance of RV circumferential over longitudinal contraction; however, in the model this develops significantly earlier in the more spherical right ventricle. The maturational course of myofiber architecture in chick embryos has also been altered following placement of a conotruncal band [65], by disruption of the left vitelline vein [68], further evidence of the link between altered hemodynamics, histological and morphological changes, and impetus for continued investigation into the area of myocardial mechanics in the human fetus.

Alterations in global ventricular function have been demonstrated (using the calculated myocardial performance index) in several fetal disease states including maternal pregestational diabetes, twin-twin transfusion syndrome, constriction of the ductus arteriosus, and cardiomyopathy, as well as in fetal structural disease including aortic stenosis and tricuspid valve diseases such as Ebstein's malformation of the tricuspid valve. Study of these diseases using newer and more specific measures of myocardial mechanics stands to provide further insight into the pathophysiology of fetal myocardial disease states and may help with prediction of prognosis as well as in guiding therapy [54, 69] (Fig. 13.5). They may indeed contribute critically to understanding of the evolution of normal and abnormal mechanics in the human heart and fetal cardiac adaptation to disease. Some authors have hypothesized that abnormal values obtained using new techniques including Doppler and STE will be associated with either impaired systolic or diastolic function as determined by traditional methods and may provide further insight into the mechanics involved by evaluating all parts of the cardiac cycle and regional myocardial forces rather than the traditional global function assessment. It has been shown in adults that abnormalities of ventriculo-ventricular interaction affect both absolute strain values and also the distribution of strain [53]. Myocardial velocity, strain, and strain rate analysis has been applied to disease states in adults and had been shown to be useful in assessment of myocardial viability [70–72], for detection of early dysfunction due to chemotherapy [73], and in studies of differences in right ventricular mechanics in patients with systemic right ventricles in the setting of prior atrial switch operation [74], in which decreased longitudinal global strain was associated with increased risk for adverse clinical events. What effect the fetal circulation and its resultant systemic right ventricle has on myocardial mechanics in the fetus that may bear important implications to the neonatal transition period is as yet unstudied. Differences in strain, displacement, and velocities in the fetus with congenital heart disease are only beginning to be studied [54, 69, 75]. In a study of 15 fetuses with heart disease, lower values of global strain were seen in fetuses with worse clinical status, but did not correlate with outcome [55]. In fetuses with severe tricuspid valve regurgitation, left ventricular function has been shown to be compromised, and there is an observed mid-septal strain decrease relative to that observed in normal fetuses, a finding also not correlated with clinical outcome [69]. In fetal hypoplastic left heart syndrome, right ventricular longitudinal strain and displacement have been shown to be reduced relative to the normal fetal right ventricle (Brooks JACC 2011 – accepted for publication in JASE). In contrast, radial displacement and circumferential to longitudinal displacement are increased relative to the normal right ventricle but comparable to the normal fetal left ventricle, suggesting that the right ventricle as a single ventricle may develop functional features more akin to the normal left ventricle even before birth. In contrast to the changes in function that occur in the single right ventricle associated with HLHS, the single left ventricle in critical right heart obstruction has been shown to have contraction velocities and deformation patterns comparable to the normal fetal left ventricle despite altered filling patterns suggesting less

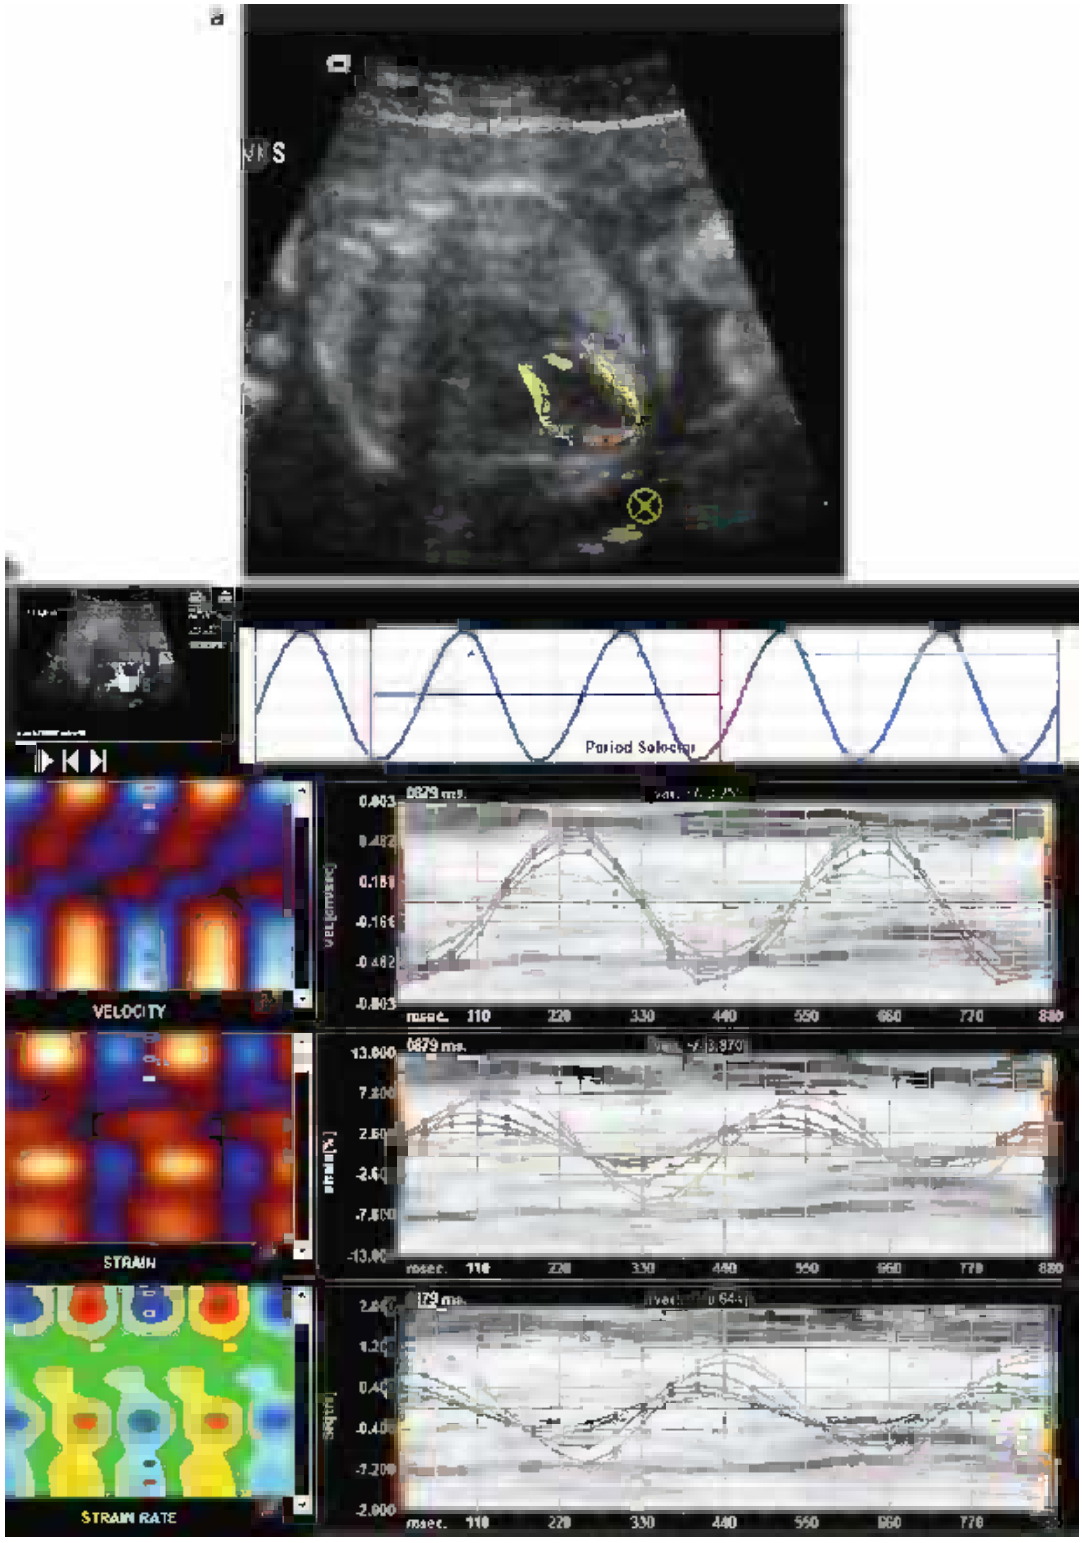

Fig. 13.5 (continued)

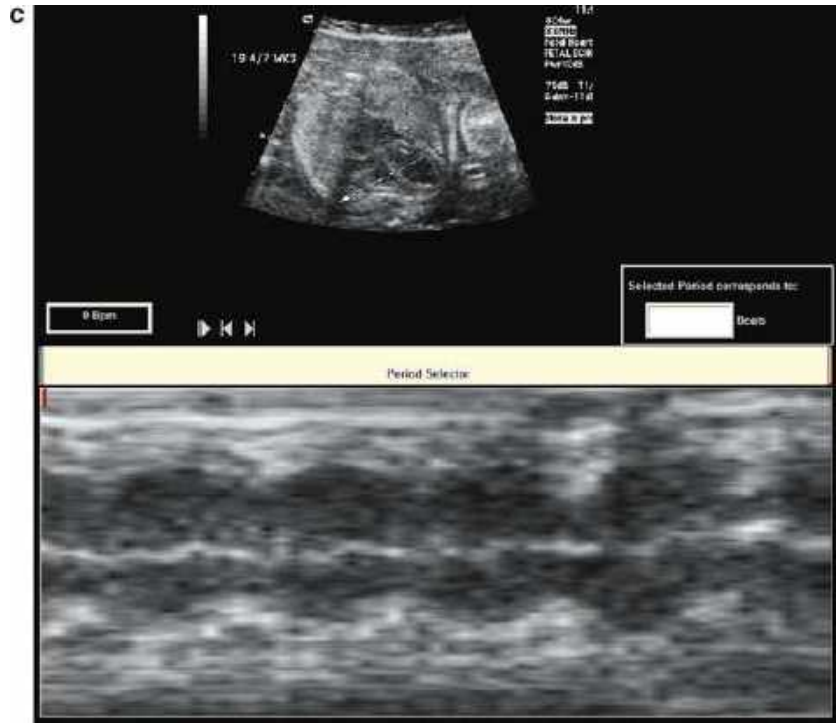

Fig. 13.5 Application of 2D speckle-tracking echocardiography in severe fetal aortic stenosis. The left ventricle is dilated and moderately dysfunctional, with monophasic mitral inflow Doppler patterns. The corresponding velocity, strain, and strain rate curves are shown, exhibiting reduction in all parameters versus published normal (see Table 13.1)

need for adaptation (Brooks JASE 2011). In the recipient twin in twin-twin transfusion syndrome where there is evolution of ventricular hypertrophy, diastolic and eventual systolic dysfunction, right and left ventricular strain have been shown to be decreased [76, 77], possibly related to alterations in afterload or due to myocardial hypertrophy (either of which may have the effect of decreasing tissue deformation) [78, 79].

Vector velocity imaging has also been only recently implemented to study the influence of fetal heart disease on atrial function (Fig. 13.6). In Ebstein's anomaly of the tricuspid valve, right atrial emptying fraction, fractional area change, and both filling and emptying rates have been found to be significantly reduced compared to those measured in the normal fetus and the fetus with critical right heart obstruction which may contribute to the high incidence of fetal cardiovascular compromise among the former [80]. Reduced right atrial tissue velocities, displacement, and deformation which progressively diverge from controls later in gestation have also been demonstrated in fetuses with hypoplastic left heart syndrome [81]. Unlike observations in controls, these progressive alterations in right atrial function have been shown to be inversely related to right atrial volumes. The clinical utility of these parameters of atrial function in predicting fetal outcomes has yet to be explored.

Future Directions

Despite its advantages over Doppler-derived techniques for assessing mechanics, major limitations of 2D STE still exist, in that using this method only speckles which remain within the imaging plane and can be tracked; features which pass through the plane of insonation during the

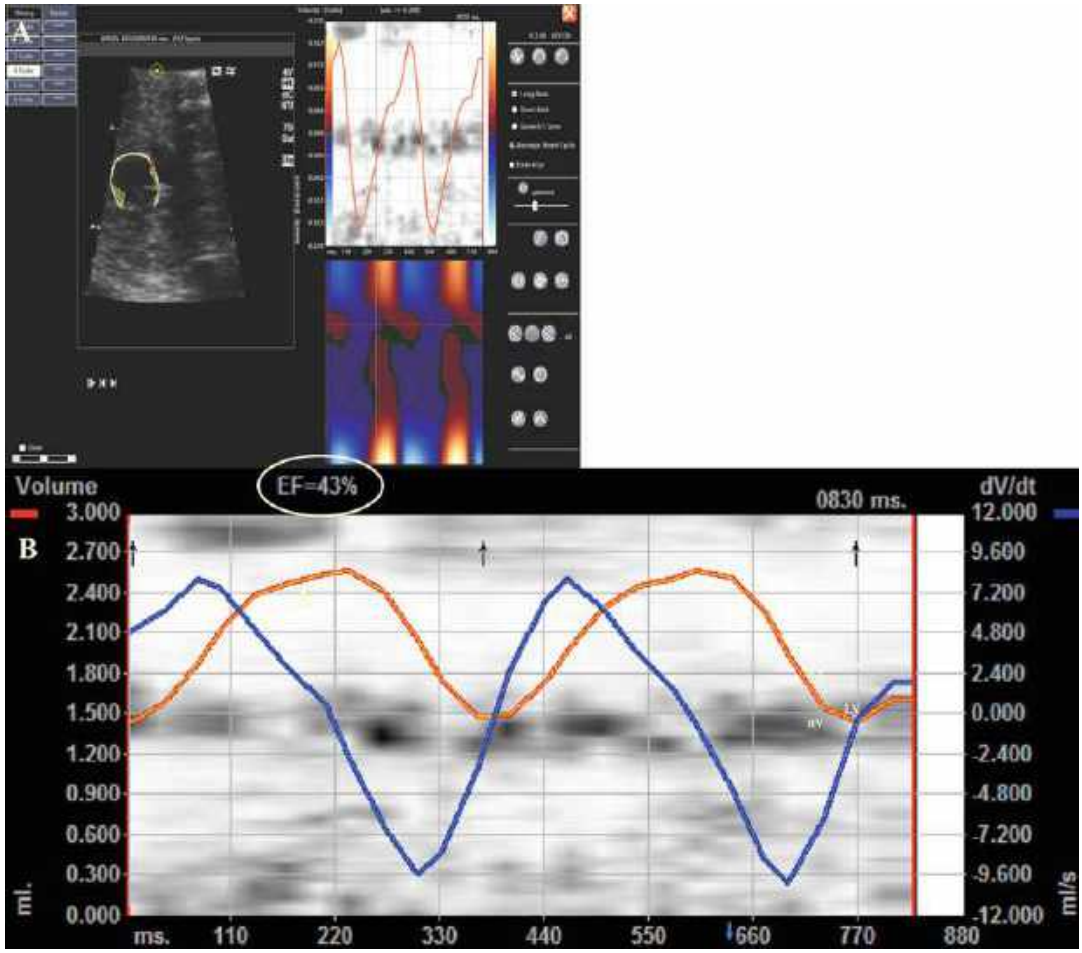

Fig. 13.6 Application of 2D speckle-tracking echocardiography to assessment of atrial function. (**A**) After two fetal cardiac cycles are selected using anatomical M-mode, the right atrial endocardial border is traced and the software algorithm tracks the border through cardiac cycle. (**B**) A graphical plot is then generated showing estimated maximum and minimum atrial volume (*red*), as well as filling and emptying rate (*blue*). A calculated right atrial emptying fraction is displayed (*circled*)

cardiac cycle are not included. Some 3D echocardiography systems provide the means with which to track speckles through the plane via acquisition of a 3D volumetric dataset [82, 83], but there are currently no published data from the fetus using this technique.

Despite the promise that these techniques hold, the clinical relevance of the information remains to be proven and several issues need to be kept in mind when considering their application in both research and clinical arenas. Some of the issues are technical, others are observer dependent, and still other limitations lie in interpretation. Currently, there are concerns regarding vendor-specific image acquisition, storage, and processing, resulting in limited cross-vendor applicability [84–88]. There are conflicting data regarding the effects of load dependency of the various indices. Further, standardization in reporting has still not been achieved, with some authors referring to natural strain, others Lagrangian strain, and regional versus global measure reporting is also as yet unstandardized. Peak velocity is used in some methods, while methods rely on calculations based on mean velocities; therefore care must

be taken when analyzing new data to make comparisons with prior reports that refer to the correct type of data. Color Doppler velocity data, for instance, cannot be directly compared with pulsed Doppler or speckle-tracking-derived velocity data, necessitating separate validation for each method, not simply for each index [86, 89]. Experience of the researcher or clinician will also likely be a factor not only in successful reproduction of measurements but also in processing times, until such time as the techniques can be successfully automated. Despite showing promise in the research arena as it relates to unraveling new dimensions in fetal cardiac mechanics, wide confidence intervals for normal human fetuses (Table 13.1) and extremely high inter- and intra-observer variability have been reported but down-played in the extant literature regarding application of these techniques to fetuses, making application in its current form to individual patients with disease states unlikely to provide useful clinical data [44]. Technical difficulties arise in both acquisition of raw data due to maternal and fetal movement during scanning and limitation of frame rates in many patients to below that even of standard 30 frames per second used in standard clinical DICOM storage. The issues of frame rate may well be overcome via a combination of new advances in the imaging equipment itself along with innovative solutions for storage of higher frame-rate captures in the fetus [90], but in general, frame rates are presently still a major hurdle, one which may result in a loss of temporal detail and dramatically increase the variability of measurement even within the same fetus [90]. Wide ranges of "normal" values for longitudinal strain and strain rate have been reported even in normal fetuses, in ranges which seem incompatible with what is presumably a lack of true physiologic perturbation of mechanics [91]. There have been no studies of radial mechanics and only one small report relating to circumferential mechanics in human fetuses (which also reported a very low success rate in tracking of the myocardium in the short-axis images) [54]. Refining of image acquisition, processing, analysis, and reporting with a goal of producing reproducible, reliable, and accurate measurements in normal populations of fetuses will be necessary prior to the adoption of these techniques on a true research basis for examining disease states and well before widespread application in clinical practice. Nevertheless, exciting information is on the horizon in this area.

Fetal Arrhythmias

14

Lisa Howley and Michelle Carr

Abstract

This chapter will review the diagnosis and management of cardiac arrhythmias that may occur during fetal life. Abnormalities of cardiac rhythm can be accurately diagnosed during the prenatal period. Clinical detection of fetal rhythm abnormalities is important as these arrhythmias may cause fetal hemodynamic compromise, increasing the risk of in utero or postnatal demise of the affected fetus. Fetal rhythm abnormalities, particularly tachyarrhythmias, often respond positively to prenatal drug therapy with improved prognosis. Thus, precise assessment of the mechanism of the fetal rhythm disturbance is essential in order to determine appropriate medical therapy.

Keywords

Arrhythmia • Atrial • Bradycardia • Doppler • Fetal • Flutter • Heart block • M-mode • Tachycardia • Therapy • Treatment • Ventricular

Introduction

Abnormalities of cardiac rhythm can be accurately diagnosed during the prenatal period [1–3]. Fetal cardiac arrhythmias occur in up to 1–3 % of all pregnancies and account for 10–20 % of referrals to fetal cardiologists [4]. The fetal heart rate naturally varies with changes in gestational age and fetal activity level [4]. The fetal cardiac rhythm is regular and during the second half of pregnancy, the heart rate normally ranges between 110 and 180 beats/min [5]. Fetal cardiac arrhythmias are therefore defined as heart rhythms that are irregular or heart rates that fall outside the normal range [6]. Fetal arrhythmias may be subdivided into three broad categories:

- *Irregular fetal heart rhythms*: those rhythms which are irregular due to beat-to-beat variability, but the average fetal heart rate is normal
- *Tachyarrhythmia*: rhythms which are faster than 180 beats/min and may be continuous or paroxysmal

- *Bradyarrhythmia*: rhythms which are persistently slower than 110 beats/min

Assessment of Fetal Heart Rhythm

Fetal arrhythmia assessment can be a challenging task. Currently, routine fetal rhythm assessment can be performed largely using M-mode and Doppler techniques. These two techniques provide information about the mechanical activity of the atria and ventricles which give indirect information regarding the electrophysiological events.

M-Mode Technique

Because obtainment of fetal cardiac electrical activity remains a challenge, it has become a common practice to analyze fetal atrial and ventricular activity using ultrasound technology. M-mode imaging was one of the first echocardiographic modalities used in assessing fetal arrhythmias (Fig. 14.1). Because of its high temporal resolution, it remains an important part of arrhythmia assessment. Electrical events are inferred from the motion of the cardiac chambers [6–11]. The M-mode cursor must be positioned so that atrial and ventricular activity can be recorded simultaneously. M-mode imaging is dependent on favorable fetal position and good image quality, and this modality may be limited by hypocontractile myocardium in the setting of a hydropic fetus or poor image resolution.

Pulsed Doppler Technique

The simultaneous display of atrial and ventricular mechanical activities is also possible using Doppler ultrasound [2, 12–14]. There are several sites where pulsed-wave Doppler (PWD) can be performed. Conventionally, PWD sampling has been performed in the left ventricular chamber between the mitral and aortic valves with evaluation of the relationship between the atrial

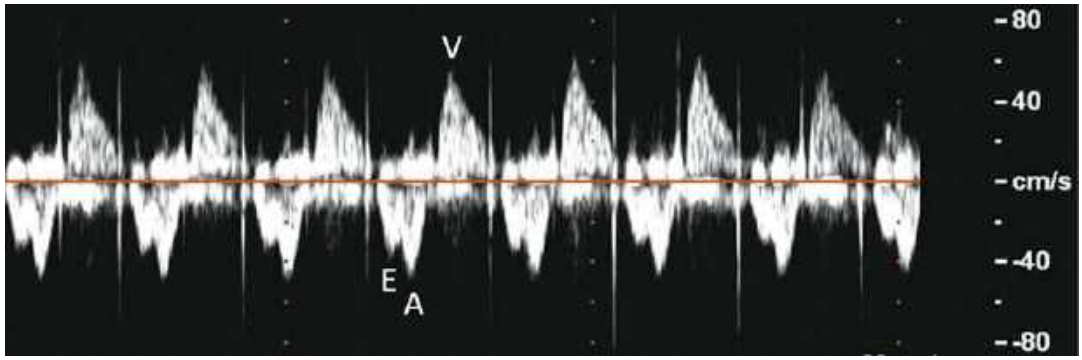

Fig. 14.2 Normal pulsed Doppler image obtained from an apical five-chamber view with the sample volume positioned in the left ventricle to obtain both ventricular inflow and outflow. The flow below the baseline is normal mitral inflow with an e-point (*E*) and a-point (*A*). The E represents passive diastolic inflow and the A represents atrial contraction. The flow above the *baseline* represents the left ventricular outflow through the aorta (*V*)

contraction and outflow Doppler signal. PWD interrogation must be parallel to both the left ventricular inflow and outflow in order to optimally display the flow signals reflecting atrial and ventricular activation (Fig. 14.2). Notably, PWD sampling in the left ventricular chamber is limited when atrial contraction occurs against a closed atrioventricular (AV) valve such as may occur in short VA reentrant SVT, atrial flutter, or AV block.

More recently, simultaneous PWD interrogation of venous and arterial flow in an adjacent vein and artery has also been incorporated into the evaluation of fetal arrhythmia. This technique demonstrates the relationship between atrial contraction (blood flow reversal in the vein) and ventricular contraction (forward flow in the artery). These sampling sites include the superior vena cava and adjacent ascending aorta [13] (Fig. 14.3), the pulmonary vein and branch pulmonary artery [14], or even the inferior vena cava and descending aorta. There are many advantages of using the SVC/Ao method over the PWD in the left ventricular chamber: first, the absence of an AV valve which, when closed, may interrupt flow from the atrium to the ventricle and therefore disrupt the atrial Doppler signal; furthermore, a normal increase of heart rate (>160 bpm) or a moderate increase in PR interval (first-degree AV block) will cause an overlap of E and A waves or, in the severe forms, the disappearance of the A wave which then occurs during ventricular systole [15].

Fetal Electrocardiography and Magnetocardiography

Analysis of cardiac rhythm is based on the ability to record atrial and ventricular activity simultaneously. In the postnatal period, cardiac rhythm is commonly analyzed through a recording of electrical activity of the heart, the electrocardiogram (ECG). The first studies of fetal arrhythmias utilized fetal ECG which was recorded from the maternal abdominal wall. By report, this technique is technically challenging and clear separation of atrial and ventricular electrical activity has been difficult [16]. Similarly, the use of fetal magnetocardiography has been proposed as a substitute for fetal ECG. This modality records the magnetic field created by the electrical activity of the fetal heart with generation of waveforms similar to those seen with fetal ECG [17]. However, due to limitations of equipment and lack of the technology at most centers, fetal magnetocardiography is currently not used for routine assessment of fetal cardiac rhythm.

Tissue Velocity Imaging (TVI)

TVI is the newest echocardiographic modality to be used in fetal rhythm assessment. It measures the motion of the myocardium and allows for

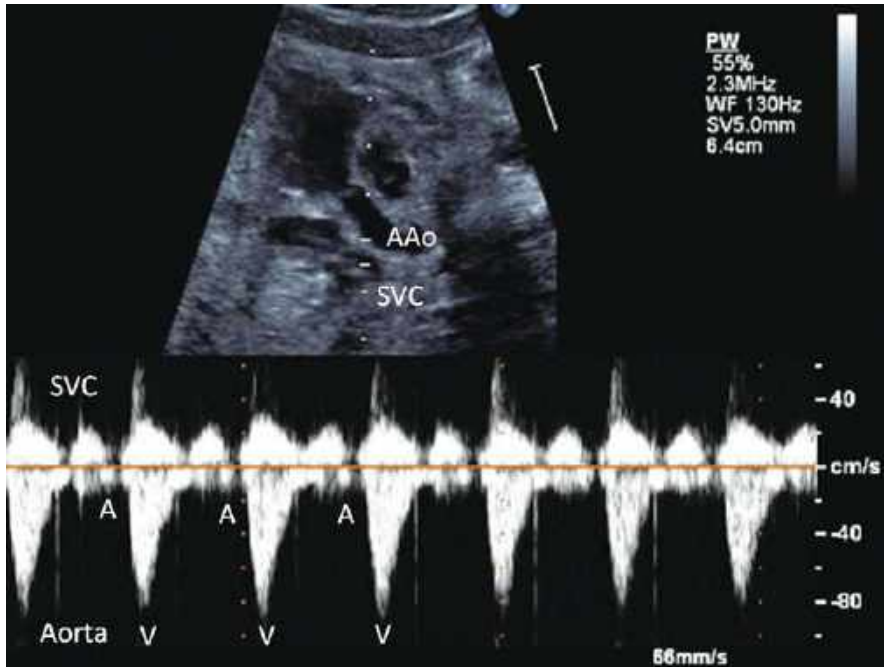

Fig. 14.3 Normal pulsed Doppler tracing obtained using the SVC/Ao method. The sample volume is placed to include both the SVC and ascending aorta flows. Aortic ejection is seen below the *baseline*, while antegrade venous flow in the SVC is demonstrated above the baseline. Atrial contraction in the SVC is noted by small reverse "a" waves prior to each aortic ejection. The interval between atrial contraction (*A*) and the beginning of aortic ejection (*V*) is the atrioventricular (*AV*) interval. The ventriculo-atrial (*VA*) interval is measured from the beginning of aortic ejection (*V*) to the "a" wave

precise timing of the atrial and ventricular events. TVI has the advantage of defining the mechanical relationship of atrial and ventricular wall motion [18] and has the capability to analyze the activity of several regions of the heart within the same cardiac cycle. Despite the fact that TVI is very effective at defining arrhythmias, unfortunately this echocardiographic modality is currently not universally available, and it is dependent upon good fetal image quality.

Irregular Fetal Heart Rhythms

Irregular fetal heart rhythms are generally detected during routine auscultation of the fetal heart, most commonly after 28 weeks' gestation, in otherwise uneventful pregnancies [7]. Premature atrial contractions (PACs) account for a majority of irregular fetal heart rhythms, presenting as occasional early or "skipped beats" during examination. PACs may be followed by a ventricular contraction and are then referred to as conducted PACs (Fig. 14.4).

Alternatively, if the PAC occurs quite early in diastole, during the ventricular electrical refractory period, the atrial signal may not conduct to the ventricle which results in a blocked PAC (Fig. 14.5). PACs are generally transient and benign [7].

Premature atrial beats become significant when they occur with such timing to initiate a sustained tachycardia. The risk of this occurring is around 2 % in fetuses with normal ventricular rates [4] but increases to as much as 10 % in fetuses with multiple blocked atrial ectopic beats which cause a low ventricular rate [4]. Progression of PACs to sustained tachycardia has been well described [7, 19]. Both atrial flutter and supraventricular tachycardia (SVT) rhythms have been described following initial fetal presentation with PACs [20]. While PACs are usually well tolerated in fetuses with normal

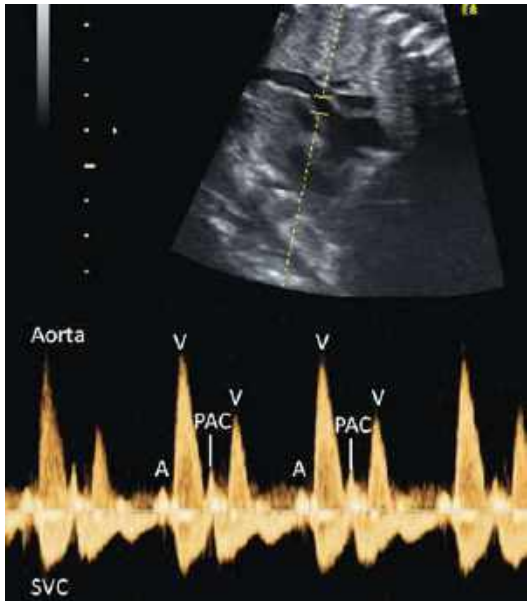

Fig. 14.4 Pulsed Doppler tracing obtained using the SVC/Ao method which demonstrates conducted PACs. The sample volume is placed to include both the SVC and ascending aorta flows. With each premature atrial beat (*PAC*), conduction to the ventricle occurs, resulting in a premature ventricular beat (*V*)

cardiac anatomy and function, they may not be well tolerated in the setting of significant structural or functional cardiac disease.

Less commonly, premature ventricular contractions (PVCs) also may cause an irregular heart rhythm. The ratio of occurrence of PACs to PVCs in utero is approximately 10:1 [21], and PVCs may be difficult to distinguish from PACs in utero. A premature ventricular beat not preceded by an atrial signal should be interpreted as a PVC.

Atrial or ventricular premature contractions are often benign and are not commonly associated with congenital heart disease. However in the setting of frequent ectopy, ultrasound evaluation of the fetal cardiac structure is warranted in order to exclude intracardiac tumors and underlying myocardial disease [22].

Fetal Tachycardia

Fetal tachycardia is defined as a sustained heart rate that exceeds 180 beats/min. Differentiation between various mechanisms of fetal tachycardia is important as accurate diagnosis can define the likely prognosis and response to medical treatment. When compared to neonates, the fetal myocardium is intrinsically more susceptible to sustained tachycardia than neonates due to the immature structure and function of the sarcoplasmic reticulum [23], the delayed development of the atrioventricular fibrous annulus and the presence of transient atrioventricular connections [24–27]. Aside from sinus tachycardia, the main etiologies of fetal tachycardia include supraventricular tachycardia (70–75 %) and atrial flutter (25–30 %) [28]. Ventricular tachycardia is very rare.

Sinus Tachycardia

Sinus tachycardia is characterized by heart rates ranging from 180 to 200 beats/min with normal 1:1 AV conduction and a long ventricular-atrial (VA) time interval consistent with normal AV conduction and repolarization (Fig. 14.6). Typically there is variability in the baseline heart rate. Sinus tachycardia is an appropriate response to a variety of fetal and maternal conditions which may include fetal infection, fetal distress, and maternal hyperthyroidism. The important goal of treatment in fetal sinus tachycardia is to recognize and address the underlying condition causing the increased fetal heart rate.

Supraventricular Tachycardia

Supraventricular tachycardia is a broad diagnosis containing tachyarrhythmias with a variety of mechanisms. These arrhythmias can be divided into those with a short VA interval, those with a long VA interval, those with superimposed V and A Doppler signals, and atrial reentrant tachycardias [7].

- *Short VA Tachycardia*. In fetal and early postnatal life, the most common mechanism of SVT is atrioventricular reentry tachycardia (AVRT) via an accessory pathway [25, 26] (Fig. 14.7). In AVRT, a cardiac impulse from

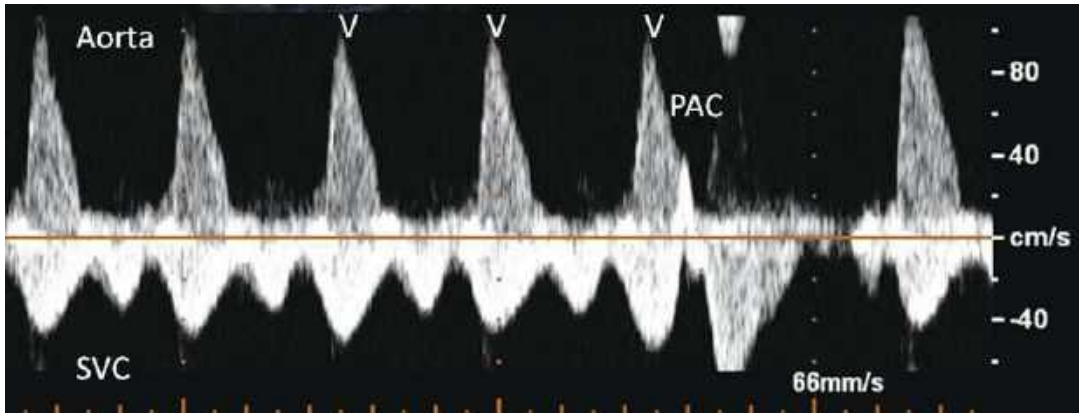

Fig. 14.5 Blocked PAC demonstrated using the SVC/Ao Doppler method. There is absence of ventricular ejection after the premature beat (*PAC*), causing an irregular ventricular rate (*V*). Sinus rhythm resumes with the following beat. *A* atrial contraction

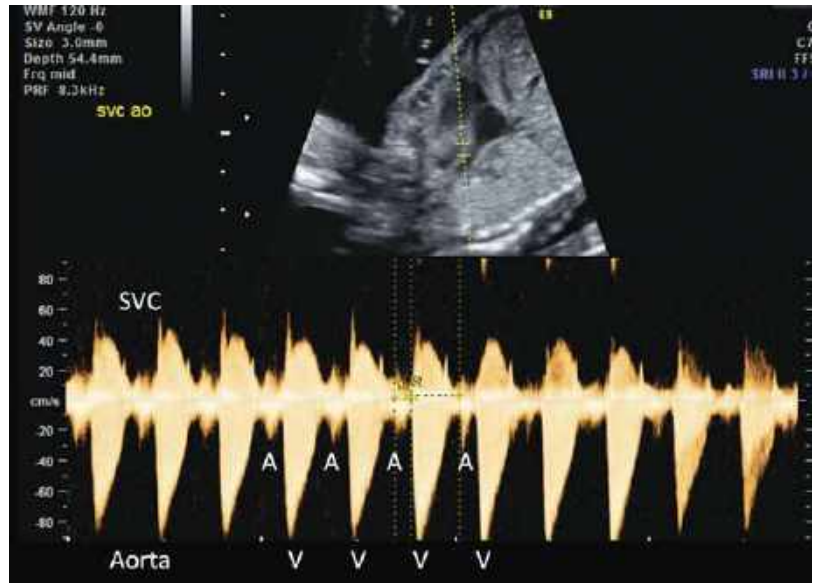

Fig. 14.6 Sinus tachycardia demonstrated using the SVC/Ao Doppler method. The fetal heart rate is 182 beats/min. There is normal mechanical atrioventricular conduction with a short AV interval and long VA interval. *A* atrial contraction, *V* ventricular contraction

the ventricle travels retrograde to the atrium via an accessory bypass tract, and then, this impulse is subsequently conducted antegrade from the atrium back to the ventricle via the atrioventricular node (AV node). This circuit is called orthodromic conduction, with rapid retrograde conduction via the accessory pathway (VA interval) and slow antegrade conduction through the AV node (AV interval). Characteristics of fetal AVRT include ventricular rates of 230–280 beats/min with minimal variability, 1:1 atrioventricular conduction with a shorter VA time interval relative to the AV interval, and abrupt onset and cessation of the arrhythmia. At birth, 10 % of affected fetuses have Wolff-Parkinson-White syndrome [26, 29].

- *Long VA Tachycardia*. Causes of long VA tachycardia with a shorter AV interval relative to the VA interval include sinus tachycardia, ectopic atrial tachycardia (EAT), and permanent junctional reciprocating tachycardia (PJRT). When a fetus is determined to have EAT, this is usually the result of enhanced

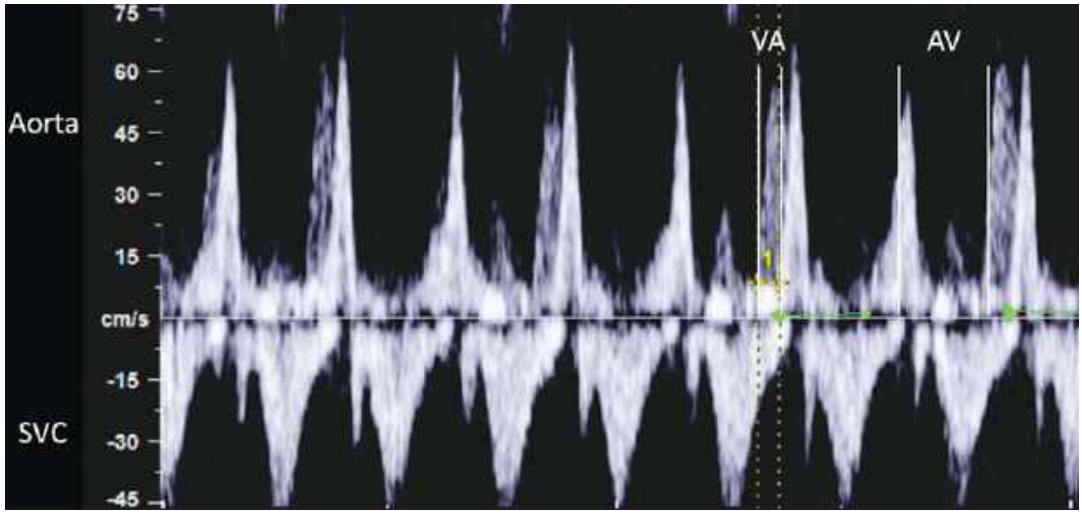

Fig. 14.7 Doppler tracing obtained with the SVC/Ao method in a fetus with tachycardia. The VA interval is significantly shorter than the AV interval, suggesting a short VA tachycardia. Tall (cannon) "a" waves are superimposed on the aortic ejection signal and are reflective of atrial contraction occurring against a closed atrioventricular valve

automaticity originating from a single atrial focus or a wandering atrial pacemaker with a rate that exceeds the normal sinus node. In EAT, there is a normal 1:1 AV relationship with ventricular rates of 200–250 beats/min, evidence of beat-to-beat variability, and gradual onset and offset [30] (Fig. 14.8).

PJRT is a reentrant tachycardia in which the conduction velocity via an accessory pathway from the ventricle to the atrium is slow, thus resulting in a long VA interval (Fig. 14.9). Fetal PJRT often starts and stops suddenly, has a lower ventricular rate than AVRT, usually 180–220 beats/min, and maintains a 1:1 AV relationship. Fetuses diagnosed with a long VA tachycardia are the least likely to develop hemodynamic compromise and hydrops fetalis [30].

- *Superimposed A and V Tachycardia*. Junctional ectopic tachycardia (JET) and atrioventricular nodal reentrant tachycardia (AVNRT) are very rarely encountered prenatally and are suspected when the A wave is superimposed on the V wave.
- *Fetal Atrial Flutter*. Atrial flutter is the second most common tachyarrhythmia and is the result of an intra-atrial reentrant circuit. In the fetus with atrial flutter, atrial rates range from 300 to 550 beats/min. The AV node, which is not part of the reentrant circuit, has a protective mechanism for the ventricles and variably blocks AV conduction, resulting in a substantially slower fixed or varying ventricular rate (2:1, 3:1, 4:1 block) (Fig. 14.10). Typically, atrial flutter is diagnosed later in gestation (range 30.7–34.4 weeks) than other tachyarrhythmias as a critical atrial mass is required to sustain an atrial reentrant circuit [27]. Studies have demonstrated that on average, fetal atrial flutter was diagnosed 4 weeks later in gestation than AVRT [30].

Ventricular Tachycardia

Ventricular tachycardia in the fetus is very rare, accounting for less than 5 % of fetal tachyarrhythmias [31]. The diagnosis of fetal ventricular tachycardia is made when the ventricular rate is in excess of the atrial rate, usually between 180 and 300 beats/min, and there is evidence of AV dissociation [7]. The majority of fetal ventricular tachycardia is believed to be due to an ectopic ventricular focus as seen in newborns. Long QT

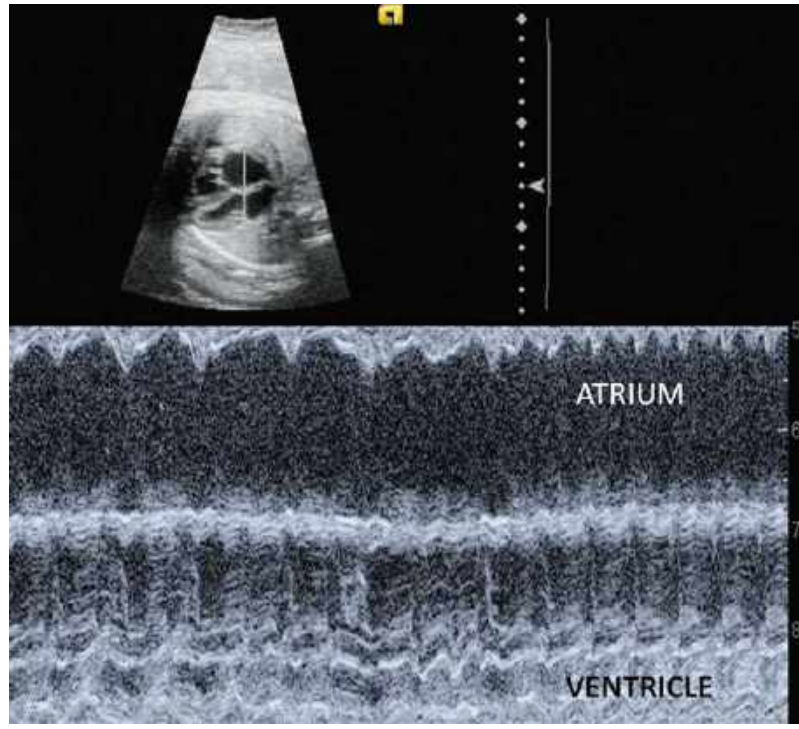

Fig. 14.8 M-mode tracing of ectopic atrial tachycardia. The atrial beats (A) appear irregular with evidence of a rapid increase in frequency

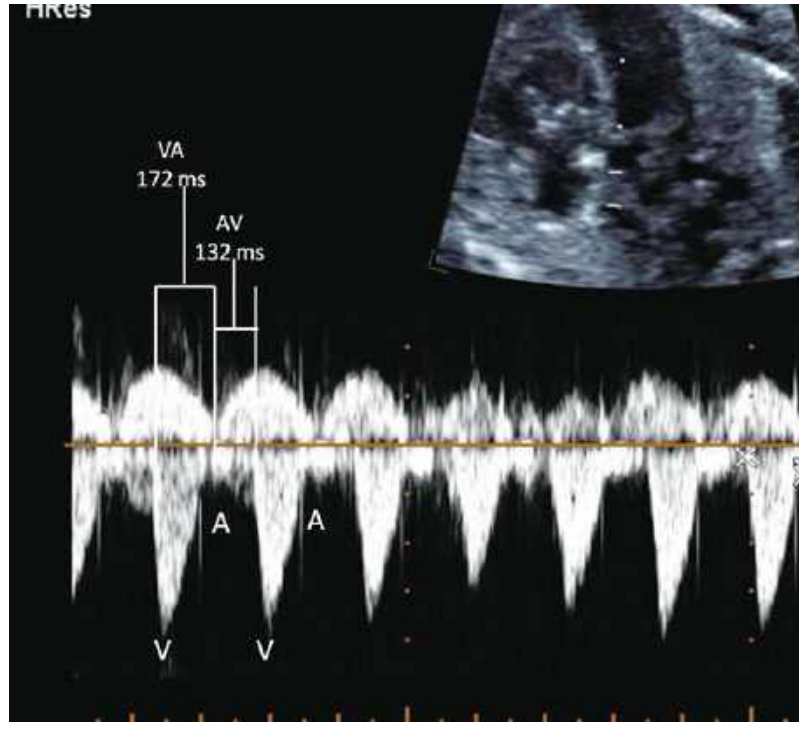

Fig. 14.9 Doppler tracing obtained with the SVC/Ao method in a fetus with tachycardia. The AV interval is significantly shorter than the VA interval, suggesting a long VA tachycardia. The "a" waves are of normal amplitude. *A* atrial contraction, *V* ventricular contraction

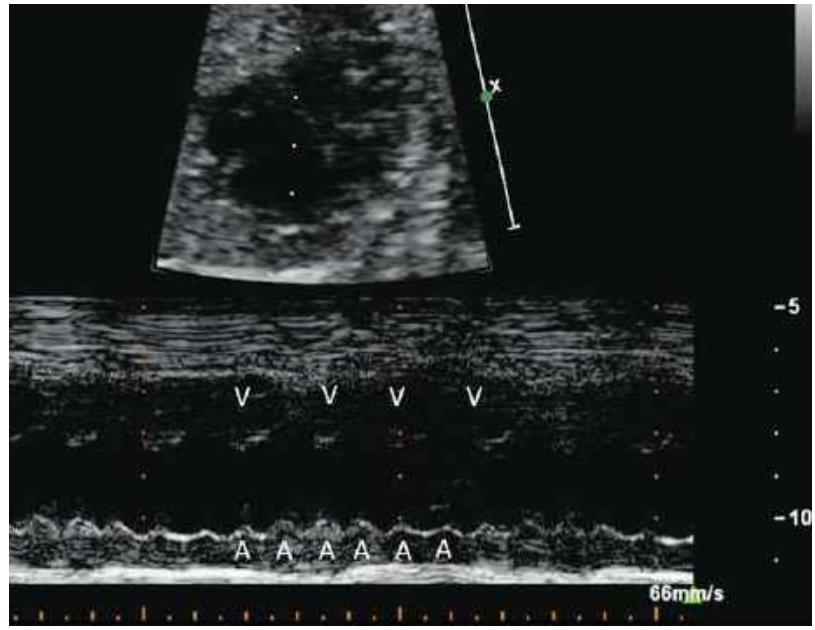

Fig. 14.10 M-mode tracing in a fetus with atrial flutter. There is 2:1 atrioventricular conduction. *A* atrial contraction, *V* ventricular contraction

syndrome should also be considered as a possible etiology in any fetus presenting with ventricular tachycardia and a history of either bradycardia or a combination of bradycardia and tachycardia [32]. Due to the rare incidence of fetal ventricular tachycardia, no large studies exist to provide specific prenatal treatment guidelines.

Pathophysiology of Fetal Tachyarrhythmia

Recognition of sustained tachycardia is very important when evaluating the fetus as a persistently elevated heart rate may have detrimental consequences. While in a sustained tachyarrhythmia, there is substantial shortening of the diastolic period of the cardiac cycle which collectively impedes adequate ventricular filling and reduces myocardial perfusion. This shortened ventricular filling time, combined with the relative stiffness of the immature fetal myocardium, results in increased atrial and systemic venous volume loads. Simultaneously, coronary artery perfusion which occurs predominantly in diastole is also reduced due to the shortened diastolic period. The combination of poor myocardial perfusion and inadequate oxygen delivery may cause worsening ventricular dysfunction and lead to tachycardia-induced cardiomyopathy. This can result in an elevated systemic venous pressure which can significantly reduce lymphatic flow and may progress to nonimmune hydrops fetalis, placental edema, and polyhydramnios [4].

Hydrops fetalis, a severe manifestation of fetal heart failure, is identified at presentation or evolves in 40–50 % of fetuses with SVT [11]. In cases of short VA reentrant SVT, hydrops fetalis may appear even in the absence of heart failure as a result of atrial contractions during ventricular ejection causing tall *A* waves in the vena cavae Doppler tracings and increased systemic venous congestion [3]. Fetuses with hydrops fetalis have an associated mortality rate as high as 35 % when compared with 0–4 % of non-hydropic fetuses [29]. If a constant sinus rhythm can be reestablished in the fetus, improvement and even resolution of ventricular dysfunction and hydrops fetalis can be achieved prior to birth.

Fetuses at highest risk for developing signs of heart failure are those with more incessant SVT, those with earlier onset of SVT (<32 weeks'

gestation), and those with structural heart disease [7]. While actual ventricular rates and tachycardia mechanisms have not been clearly identified as risk factors for the development of heart failure in human fetuses, research has demonstrated that fetal lambs with sustained heart rates above 210–220 bpm have pulsations in the umbilical venous flow pattern associated with considerable elevation of systemic venous pressure [33].

Treatment of Fetal Tachyarrhythmia

In utero treatment of fetal tachyarrhythmia with pharmacological therapy was first described by Eibschitz et al. [34] who treated fetal tachycardia with propranolol in 1975. Since this first report, there is now extensive experience in the pharmacological management of fetal AVRT and atrial flutter, whereas treatment of fetal ventricular tachycardia and long VA tachycardia remains limited. The rationale for treatment of fetal tachycardia is the increased risk of fetal cardiac failure with greater likelihood for intrauterine or neonatal death. Historically, fetuses prenatally diagnosed with tachycardia were quickly delivered, frequently preterm, often with poor outcome [23, 29]. Today the emphasis is on prenatal transplacental therapy with the aim of converting the tachycardic fetus to sinus rhythm and preventing or resolving signs of cardiac failure prior to delivery.

There are three management options available for the treatment of fetal tachyarrhythmia: (1) no treatment, (2) antiarrhythmic intrauterine pharmacological therapy, and (3) delivery of the fetus. The treatment decision should be based on the condition of the fetus, the characteristics of the arrhythmia (duration, heart rate, mechanism), the gestational age of the fetus, the health of the mother, and the willingness of the mother to undergo treatment. The decision to proceed with in utero antiarrhythmic treatment should only be made after a thorough risk-benefit analysis as well as detailed counseling of the parents.

In non-hydropic fetuses greater than 35 weeks' gestation with sustained or intermittent tachycardia, careful observation without antiarrhythmic treatment may be a safe management option. In this fetal population, hydrops will rarely develop presumably due to the improved intrinsic properties of the fetal heart in late gestation. However, if sustained tachycardia is left untreated, elective cesarean section is often the recommended mode of delivery as obstetric interpretation of fetal heart tracings is not possible during labor. For this reason, a trial of transplacental treatment with digoxin is often attempted in hopes of conversion to normal sinus rhythm which would then facilitate a vaginal delivery.

Prior to 35 weeks' gestation, the risks associated with preterm delivery often outweigh the potential hazards of pharmacological treatment to the mother and fetus. Irrespective of the mechanism of tachycardia and the fetal heart rate, it is known that fetuses at highest risk for developing heart failure are those with incessant SVT and of lower gestational age [7, 35]. Even preterm fetuses with intermittent tachyarrhythmia are recognized to have an increased risk of hydrops and death, and therefore, intrauterine pharmacological treatment is offered to the majority of preterm fetuses with either intermittent or incessant tachyarrhythmia, independent of signs of fetal cardiac compromise.

Maternal Surveillance During Transplacental Treatment

Prior to initiation of any antiarrhythmic medication, a thorough medical evaluation of the pregnant mother including a 12-lead ECG must be performed to rule out evidence of underlying maternal disease such as Wolff-Parkinson-White syndrome, long QT syndrome, or other cardiovascular contraindications. Initial maternal serum studies should be collected including a basic metabolic panel (sodium, potassium, chloride, bicarbonate, creatinine, blood urea nitrogen, calcium, and magnesium levels). Additional maternal thyroid function studies should be collected if amiodarone is the selected treatment drug. Because of the potentially life-threatening side effects of antiarrhythmic therapy, transplacental drug therapy should be initiated in a monitored inpatient setting.

Antiarrhythmic Medications

Most fetal tachyarrhythmias can be successfully treated through maternal/transplacental administration of antiarrhythmic medications. To date, no prospective standardized trials have been conducted to determine optimal treatment strategy for fetal tachycardia and therefore a wide variation exists in clinical practice. It is accepted that no single medication can safely and effectively convert all fetal tachyarrhythmias to a normal sinus rhythm. In the absence of controlled drug trials, antiarrhythmic drug selection is frequently based on caregiver experience and preference and therapeutic approaches may significantly differ among institutions. Currently, the most commonly used antiarrhythmics are digoxin, flecainide, sotalol, and amiodarone, but many other drugs have been used with less frequency. Table 14.1 illustrates the pharmacokinetics and risks of the medications commonly used to treat fetal tachyarrhythmias.

Digoxin is generally used as first-line therapy for fetal tachyarrhythmias, particularly if a short VA tachycardia mechanism is determined. The drug has two main effects: (1) it induces vagal slowing of the sinus and AV nodes and (2) it enhances myocardial contractility. In the absence of hydrops, the fetal serum levels are 70–100 % of maternal levels. However, in the setting of hydrops, the placental passage of digoxin is distinctly impaired and adequate digoxin concentration in the fetus is unable to be obtained [28]. For the treatment of fetal tachyarrhythmias, high maternal digoxin levels between 2.0 and 2.5 ng/mL should be achieved. Use of digoxin with successful conversion to normal sinus rhythm has been reported in 50–100 % of non-hydropic fetuses, but in only 0–20 % of patients with hydrops [13, 23, 29, 36, 37]. In the setting of hydrops, atrial flutter, and long VA tachycardia, digoxin is not preferred and alternative transplacental medications (flecainide, sotalol, and amiodarone) should be considered either alone or in combination with digoxin.

Flecainide, a class IC antiarrhythmic medication, is a frequently used medication that blocks slow sodium channels, causing prolongation of the cardiac action potential. This blocking effect on the cardiac sodium channels increases in concordance with increased fetal heart rate. Thus, flecainide is potentially more useful in fetal tachyarrhythmias with higher fetal heart rates [38, 39]. This drug readily crosses the placenta, even in the setting of hydrops, and therapeutic maternal levels are reached within 3 days of drug initiation. Flecainide has resulted in normal sinus rhythm in 58–100 % of fetuses without hydrops and 43–56 % of those with hydrops [13, 23, 29, 30, 36, 37]. However, flecainide is adversely known to depress cardiac performance, particularly in patients with compromised myocardial function. Paradoxical proarrhythmia effects increase in the presence of major structural cardiac disease, ventricular dysfunction or arrhythmia, and hypokalemia, and therefore, use of flecainide should be avoided in patients with these conditions.

Sotalol, a class III antiarrhythmic medication with nonselective β-blockade effects, is used to treat both fetal SVT and atrial flutter. Sotalol inhibits inward potassium channels, causing progressive prolongation of repolarization and slowing of the cardiac action potential. It has been demonstrated to exhibit a positive inotropic effect, particularly at a slower heart rate [39]. Placental transfer is excellent even in the setting of hydrops with adequate fetal levels between 70 % and 100 % of maternal levels within 2–3 days after drug initiation. Sotalol has been successful in conversion to normal sinus rhythm in 40–100 % of non-hydropic fetuses and 50 % of those with hydrops [40]. The most feared adverse effect of class III antiarrhythmic medications is the associated proarrhythmic risk, namely, the development of torsade de pointes in the mother. To minimize this maternal risk, long QT syndrome must be excluded prior to drug initiation, and routine evaluation of the maternal ECG throughout the duration of sotalol treatment must be performed. If maternal QT prolongation ($\geq$500 milliseconds) occurs, extreme caution should be used if the drug is continued, and sotalol should absolutely be discontinued if the QT interval extends $\geq$550 ms.

Table 14.1 Antiarrhythmic therapy for fetal tachyarrhythmia – the most commonly used antiarrhythmic agents (Data obtained from the following publications: Kleinman et al. [6], Hansmann et al. [42], Jaeggi et al. [30], Oudijk et al. [43], Fouron et al. [3], Jaeggi et al. [39])

Drug name (indication)	Dosage	Therapeutic maternal plasma concentration	F:M ratio	Side effect: maternal	Side effect: fetal
Digoxin (SVT, AF)	*Loading dose*: (over 2–3 days) 0.3–0.5 mg IV q 8 h or *Loading dose*: (over 2 days) 0.5 mg q 12 h PO *Maintenance dose*: 0.25–0.75 mg/day PO[a]	2.0–2.5 ng/mL	0.8–1.0[b]	Narrow therapeutic range: proarrhythmia nausea, anorexia, visual disturbances, fatigue C/I: VT, WPW, AV block	Proarrhythmia
Flecainide (SVT, AF)	*Loading dose*: none *Maintenance dose*: 100 mg q 8 h (q 6 h) PO	0.4–1 μg/mL	0.7–0.9	Proarrhythmia, vertigo, nausea, paresthesia, headache, negative inotrope	Proarrhythmia, negative inotrope
Sotalol (SVT, AF, VT)	*Loading dose*: none *Maintenance dose*: 80–160 mg q 12 h (q 8 h) PO[a]	1.5–2.5 μg/mL	0.7–2.9	Proarrhythmia, hypotension, bradycardia, vertigo, nausea	Proarrhythmia, bradycardia
Amiodarone (SVT,VT)	*Loading dose*: (over 5–7 days) 1,200 mg IV infusion over 24 h or *Loading dose*: (over 5–7 days) 200 mg q 4 h PO *Maintenance dose*: 600–800 mg/day PO *Direct therapy* (infusion into umbilical vein over 10 min): 2.5–5 mg/kg (estimated fetal weight)	1.0–2.5 μg/mL (DEA 1.5–2.0-fold higher)	0.1–0.3[b]	Proarrhythmia, thyroid disease, corneal microdeposits, lung fibrosis, hepatitis, neuropathy, myopathy	Proarrhythmia, transient thyroid dysfunction, corneal deposits, mild negative inotrope

[a]Dose adjust in renal failure
[b]Substantial reduction in hydropic fetuses

Amiodarone, a class III antiarrhythmic drug, acts by blocking the potassium channels, lengthening both the duration of the action potential and the cardiac refractory period. Importantly, this medication does not affect cardiac contractility. Despite a conversion success rate of 50–93 % in fetuses with tachyarrhythmia [41], amiodarone has numerous side effects which make this a less desirable drug choice (see Table 14.1). Because of the maternal and fetal risks, amiodarone is reserved for severe cases of drug-refractory fetal tachyarrhythmias in hydropic fetuses with ventricular dysfunction.

Other medications including *procainamide, propranolol*, and *mexiletine* have been used on a limited basis as an alternative transplacental therapy in fetuses with refractory arrhythmia. However, due to the complex side effect profiles of these medications, they are often reserved until other standard antiarrhythmic medications have failed.

Direct treatment with intravenous, intramuscular, or intraperitoneal fetal drug administration is reserved for the rare severely compromised fetus with a drug-refractory tachyarrhythmia. Because the presence of fetal hydrops can drastically reduce the transplacental transfer of some

antiarrhythmic medications, therapeutic fetal drug levels may not be attainable even in the setting of toxic maternal drug doses. To overcome this limitation, repeated fetal injections of digoxin, adenosine, or amiodarone, in addition to conventional transplacental therapy, have been successfully performed to resolve these complex drug-resistant tachyarrhythmias [30].

Postnatal Follow-Up

In fetuses with tachyarrhythmia that were medically treated in utero, approximately 50 % will have a recurrence in the neonatal period. For this reason, consideration of prophylactic antiarrhythmic treatment during the first 6–12 months is recommended to prevent recurrence. Clearly, any neonate with a documented postnatal recurrence of SVT should be treated for at least 6–12 months [4]. Alternatively, postnatal recurrence of atrial flutter is uncommon and postnatal antiarrhythmic prophylaxis is usually not indicated [30]. Only 10–20 % of infants will have the tachycardia persist beyond the first year of life [35, 42], and this decline in tachyarrhythmia rate is likely a result of maturation of the conduction tissue and myocardium.

Fetal Bradycardia

Introduction

Fetal bradycardia is defined as a sustained heart rate less than 110 beats/min [5]. This rhythm abnormality can result from either a slow atrial pacemaker with normal 1:1 AV conduction, or it can result from conduction block at the level of the AV node. The most common causes of sustained fetal bradycardia are sinus bradycardia, blocked premature atrial contractions, and atrioventricular block. Recognition of fetal bradycardia is critical as reduction in the fetal heart rate may cause a fall in fetal cardiac output, resulting in a compromised fetal circulation. Cardiac output can be further hampered when the fetus has associated structural cardiac anomalies and/or intrinsic myocardial disease. Compensatory mechanisms to maintain fetal cardiac output in the setting of bradycardia include development of cardiomegaly and ventricular hypertrophy in order to increase ventricular stroke volume [2]. However, should the fetal heart be unable to compensate for the fetal bradycardia, signs of congestive heart failure develop. The most severe state of congestive heart failure is hydrops which often precedes fetal demise.

Causes of Fetal Bradycardia

The etiology of fetal bradycardia is determined by simultaneous interrogation of the atrium and the ventricle using one of the abovementioned modalities to establish the AV relationship. Should a 1:1 AV relationship be demonstrated, the fetus is determined to have sinus bradycardia (Fig. 14.11). Transient sinus bradycardia is common during an ultrasonographic study and is associated with increased fetal vagal tone likely resulting from increased pressure on the maternal abdomen by the transducer [44]. With removal of the transducer, recovery of the normal fetal heart rate is regained and no further evaluation is required. However, if sustained fetal bradycardia is discovered during routine evaluation, further investigation must ensue. Should the fetal sinus bradycardia be associated with abnormalities of visceral or cardiac situs, it is likely that the rhythm abnormality is due to a congenital abnormality in the location or number of atrial pacemakers. Alternatively, causes of sustained sinus bradycardia in a normally structured heart include maternal hypothyroidism, abnormalities of the fetal central nervous system, intrauterine growth restriction, maternal use of β-blockers, fetal congenital long QT syndrome, sinus node dysfunction, or damage to the developmentally normal atrioventricular node caused by viruses or maternal SSA (Ro)/SSB (La) antibodies [45]. Any mother carrying a fetus with unexplained sustained sinus bradycardia should undergo further evaluation including a detailed family history, screening for an unrecognized maternal medical condition, and, if indicated, 12-lead ECG screening of parents and siblings of the fetus. If long QT syndrome is the suspected etiology, determination of the QT interval by a fetal

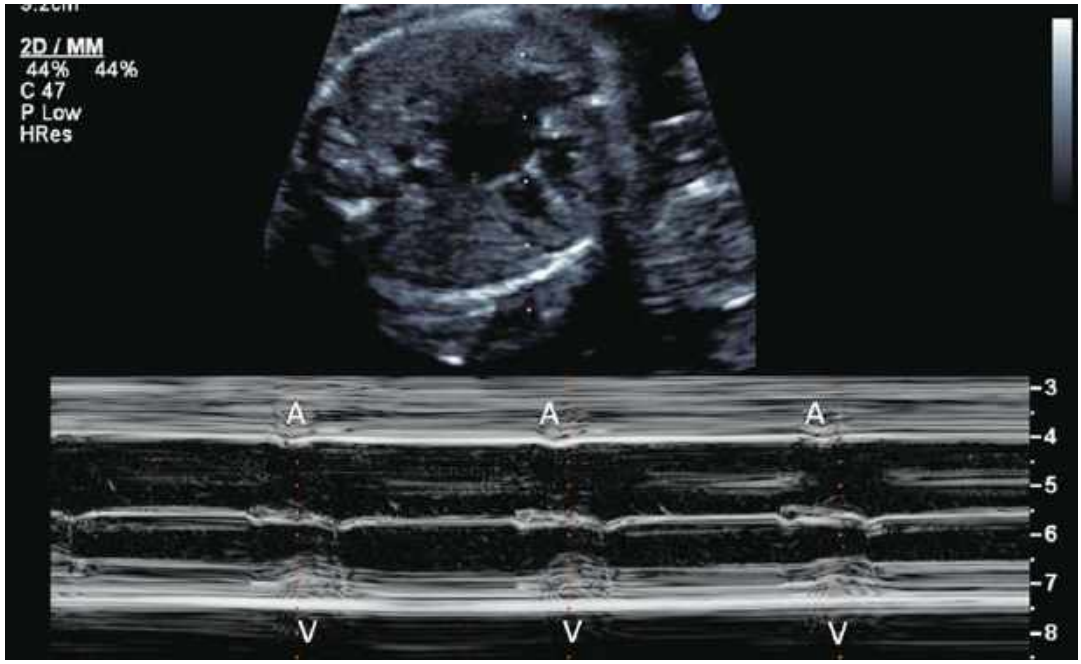

Fig. 14.11 M-mode tracing in a fetus with sinus bradycardia. A one-to-one relationship exists between the atrial (*A*) and ventricular (*V*) contractions at an abnormally slow heart rate

magnetocardiogram, if feasible, would confirm the diagnosis.

Blocked premature atrial contractions (PACs) are another cause of fetal bradycardia. The clinical presentation of fetuses with blocked PACs may either be an irregular heart rate owing to variable conduction of the ectopic atrial beats through the AV node or as a persistent regular bradycardia when a normally conducted atrial contraction is routinely followed by a PAC that is unable to conduct to the ventricle due to the refractory state of the AV node. Sinus bradycardia can be readily distinguished from blocked PACs because of the difference in the atrial rate. The atrial rate in blocked PACs is irregular with a shortened A-A interval between the first and second atrial beats whereas in sinus bradycardia the A-A interval is regular. Blocked PACs are usually well tolerated by the fetus and often spontaneously resolve over time. As mentioned previously, under the right circumstances atrial ectopy is known to trigger fetal tachyarrhythmias, and therefore, frequent auscultation of the fetal heart rate is recommended.

Heart block, another frequent etiology of fetal bradycardia, refers to a disturbance in the conduction of electrical impulses from the atria to the ventricles, usually occurring at the level of the AV node or the proximal His-Purkinje system. Heart block is classified based on severity:

- *First-degree AV block*: Conduction is slowed through the AV node, but there is still 1:1 AV conduction from the atrium to the ventricle.
- *Second-degree AV block*: There is a failure to conduct some of the electrical impulses from the atria to the ventricles. This category is subdivided into Type I (Wenckebach) and Type II (Mobitz II). Wenckebach presents as progressive lengthening of the AV conduction time until an isolated ventricular impulse is dropped. Mobitz II presents as occasional or repetitive absence of a ventricular impulse without any preceding lengthening of the AV conduction time.
- *Third-degree AV block or complete heart block (CHB)*: Complete interruption of electrical communication between the atria and

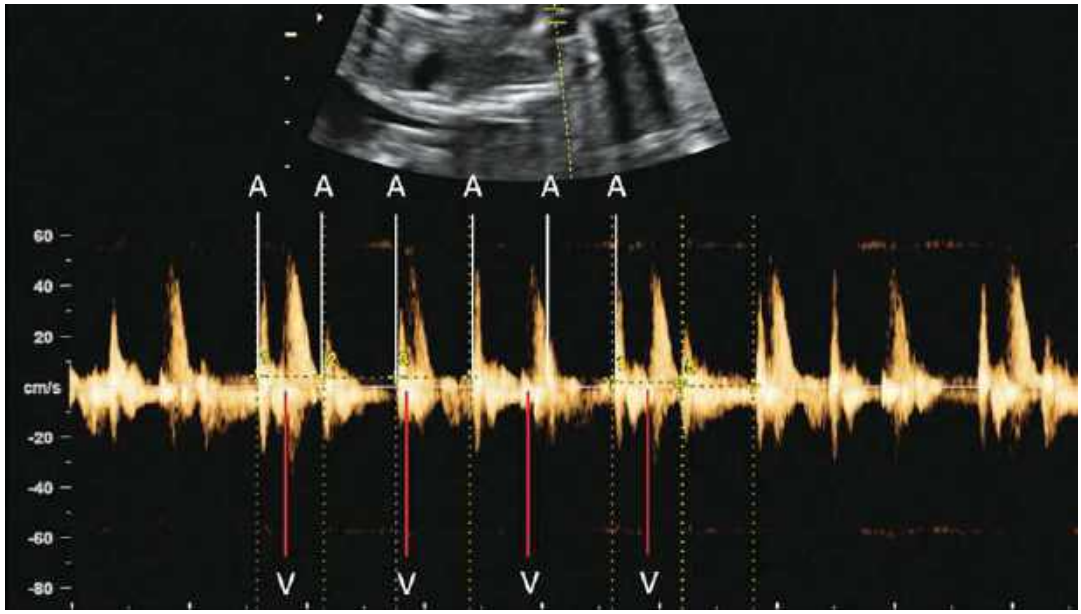

Fig. 14.12 Complete heart block demonstrated using an SVC/Ao Doppler tracing. The atrial contractions (*A*) occur at a regular and normal rate while the ventricular contractions (*V*) occur at a slower rate and are dissociated from the atrial contractions

ventricles with evidence of AV dissociation. In CHB, the mechanical action of the atria and ventricles is completely independent of each other (Figs. 14.12 and 14.13). CHB is the most commonly encountered form of AV block in the fetus, accounting for 40 % of major fetal arrhythmias.

In most cases, fetal heart block is caused by either a congenitally malformed conduction system associated with complex structural cardiac defects, immune- or infection-mediated inflammation, and fibrosis of the normal conduction system or, rarely, isolated nonimmune congenital AV block in a structurally normal heart [46]. This will be discussed in further detail below.

Complete Heart Block

AV Block and Structural Heart Disease

Heart block associated with structural heart disease is thought to result from an anatomical discontinuity of the electrical conduction system, either due to an initial lack of fusion between AV nodal tissue and the His bundle or due to a secondary interruption of the AV conduction axis [47]. Approximately half of cases of fetal CHB diagnosed in the prenatal period are associated with structural heart disease [44, 47]. Structural heart defects involving the atrioventricular junction such as atrioventricular septal defects (AVSDs) in the setting of left atrial isomerism and atrioventricular discordance (congenitally corrected transposition of the great arteries, congenitally corrected TGA) have been identified as the most common causes of complete heart block secondary to structural heart disease. Prognosis for fetuses with CHB and left atrial isomerism is extremely poor with a neonatal survival rate less than 20 % [47]. In contrast, CHB associated with congenitally corrected TGA in the presence of normal-sized cardiac chambers is better tolerated with the majority of fetuses reported to do well [47]. In the presence of coexisting major heart disease, fetal and neonatal survival is unlikely at heart rates <60 beats/min independent or in the presence of hydrops at the time of CHB diagnosis [47]. Transplacental treatment with a β-sympathomimetic agent to increase cardiac output has not been reliably demonstrated to improve outcome [48].

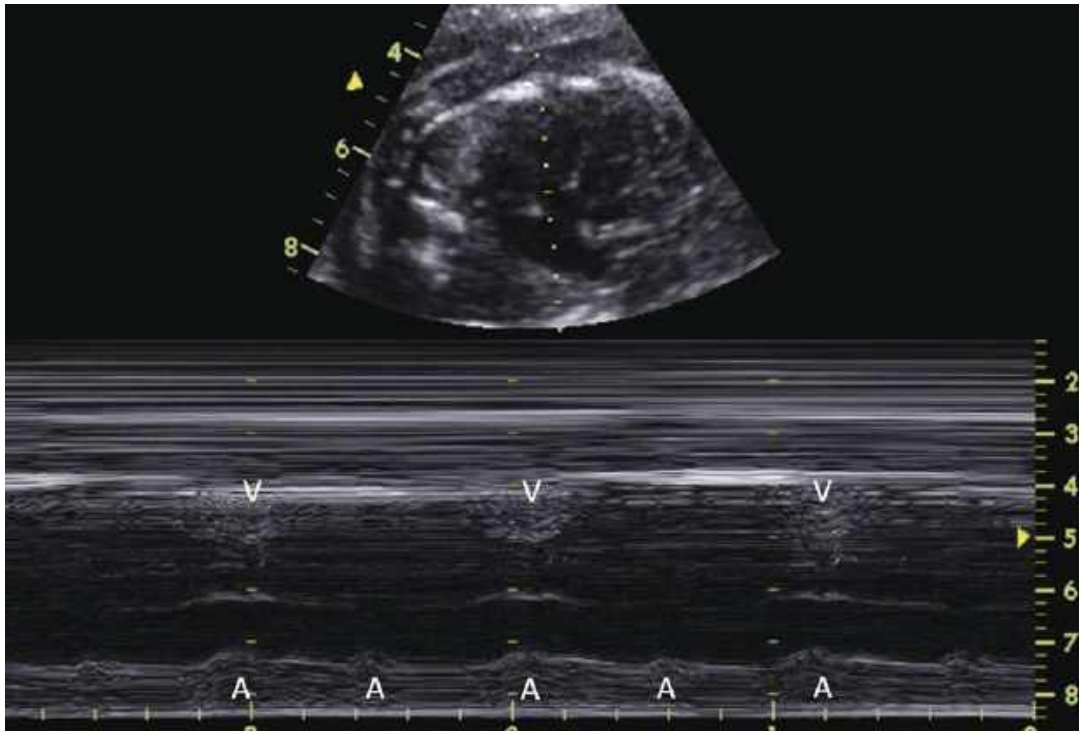

Fig. 14.13 Complete heart block demonstrated with an M-mode tracing. This tracing demonstrates atrioventricular dissociation with a regular and normal atrial (*A*) and a markedly slower ventricular rate (*V*)

Isolated Nonimmune AV Block. The estimated prevalence of isolated CHB in the structurally normal heart is 1 per 15,000–20,000 [49]. Of that population, maternal autoimmune disease is the cause of 90–99 % of all cases of CHB diagnosed before 6 months of age. Very rarely, CHB of unknown origin, in the absence of maternal antibodies, structural heart disease, or other overt cause, appears in the structurally normal heart. The long-term outcome of nonimmune, isolated CHB appears to be favorable with retrospective data demonstrating no patient death or development of dilated cardiomyopathy in this population [49]. At this time, the etiology and pathologic mechanisms of this disorder are not yet understood.

Immune-Mediated AV Block. The most common etiology of CHB in the structurally normal fetal heart is immune-mediated inflammation and fibrosis of the fetal conduction system from maternal SSA (Ro) and/or SSB (La) antibodies. These maternal antibodies are seen in the setting of maternal connective tissue disorders such as systemic lupus erythematosus (SLE) or Sjögren syndrome. In particular, fetuses with immune-mediated CHB are strongly linked to mothers with auto-antibodies to 48-kDa SSB/La, 52-kDa, and/or 60-kDa SSA/Ro ribonucleoproteins [50]. These antibodies are prevalent in nearly 2 % of pregnant women, most of whom are asymptomatic [51]. These maternal IgG antibodies typically cross the placenta between 18 and 25 weeks' gestation, but may start as early as 16 weeks' gestation [19, 44, 52, 53]. In susceptible fetuses, these antibodies may elicit an immune-mediated reaction, resulting in the progressive destruction of the fetal AV node, myocardial inflammation, endocardial fibroelastosis (EFE), and dilated cardiomyopathy [52, 53]. Approximately 2–3 % of fetuses whose mothers have these antibodies will develop fetal AV block [54]. The risk of recurrence for subsequent fetuses of affected mothers ranges from 8 % to 18 % [52]. Complete AV block is most

commonly detected between 20 and 24 weeks' gestation, but presentation later in pregnancy and even after birth is not unusual. The in utero mortality of fetuses with immune-mediated AV block secondary to maternal SSA/SSB antibodies has been reported to be between 7 % and 25 % [55]. However, if fetal immune-mediated CHB is combined with cardiomyopathy and evidence of EFE, the prognosis is quite poor with death or need for cardiac transplantation reported in 85 % [56].

Prenatal Screening for CHB

Detecting the onset of fetal heart block in antibody-positive mothers is a tremendous challenge, and unfortunately there are currently no reliable markers that predict which fetuses will develop immune-mediated cardiac complications. Initially, weekly screening echocardiograms around the time of placental antibody transfer were thought to be adequate to detect a gradual prolongation in the PR interval prior to eventual complete AV block. However, it is reported that some fetuses with normal PR intervals can develop CHB in a matter of days with no preceding PR-interval prolongation. The possibility of rapid evolution toward CHB might well be true, but this finding has been based on observations using PWD in the left ventricular chamber which may be unreliable in cases of first-degree AV block [15]. Additionally, prolongation of the fetal Doppler mechanical PR interval is not a definitive tool to detect early signs of autoimmune-associated fetal cardiac disease as first-degree heart block has been shown to rarely progress to more substantial heart block [48, 57, 58].

Newer techniques such as measurement of maternal anti-Ro antibody levels may prove useful to improve screening for mothers at higher risk of fetal CHB. One study demonstrated that antibody-related cardiac complications occurred exclusively in fetuses exposed to elevated anti-Ro antibody levels, irrespective of anti-La antibody levels [59–61]. Also, increased echodensity of the atrial wall and significant tricuspid regurgitation have been identified as other possible early markers of immune-mediated cardiac injury. These findings may represent early signs of cardiac inflammation that may proceed to congestive heart failure and hydrops [57].

Rationale for Treatment of Autoimmune-Mediated CHB

Risk factors for increased adverse outcome in autoimmune-mediated CHB include the evolution of fetal hydrops, myocardial disease including EFE, premature delivery, and ventricular heart rates $\leq$55 beats/min [48, 62]. Between 15 % and 20 % of fetuses with autoimmune-mediated CHB have additional diffuse myocardial disease associated with EFE and myocardial dysfunction [62]. Despite significant research efforts, the benefits of transplacental pharmacologic treatment for autoimmune-mediated CHB have not been proven in a prospective randomized trial [63, 64]. The rationale for maternally administered corticosteroids, particularly fluorinated glucocorticoids such as dexamethasone, as a potential treatment for autoimmune-mediated CHB is based on the presumed contribution of inflammation to the pathologic cascade resulting in fibrosis of the conducting system [65]. However, fetal CHB seems to develop quite rapidly and not surprisingly most fetuses undergoing evaluation are diagnosed with established CHB. In that case, the rationale for treatment in the fetus with irreversible CHB is primarily to temper myocardial inflammation and augment fetal heart rate in an effort to prevent congestive heart failure. Anecdotal reports of fewer cases of postnatal dilated cardiomyopathy among prenatally treated fetuses have also prompted in utero therapy [55]. At this time, the routine administration of transplacental therapy, particularly fluorinated steroids, for fetal CHB remains highly controversial due to the recognized toxic drug effects on both the mother and the developing fetus [57, 64].

Prenatal Treatment of CHB

Assorted prenatal therapeutic strategies have been attempted with variable success. Treatment options have been primarily aimed at prevention of immune-mediated fetal cardiac damage, augmentation of fetal cardiac output, and treatment of immune-mediated fetal inflammation.

Table 14.2 Antiarrhythmic therapy for fetal bradyarrhythmia – the most commonly used antiarrhythmic agents (Data obtained from the following publications: Friedman et al. [64], Buyon et al. [74, 75], Jaeggi et al. [48], Kaaja et al. [65], Saleeb et al. [63], Trucco et al. [56])

Drug name	Maternal dosage	F:M ratio	Side effect: maternal	Side effect: fetal
Corticosteroids, dexamethasone (immune-mediated heart block)	*Transplacental:* First 2 weeks: 8 mg/day PO Up to 30 weeks' gestation: 4 mg/day PO 30weeks–delivery: 2 mg/day PO	0.3	Adrenal gland suppression, hypertension, fluid retention, striae, diabetes, poor wound healing, increased susceptibility to infection	Oligohydramnios, growth restriction, concern for impaired neurodevelopment
β-agonists (immune-mediated heart block)	*Salbutamol PO:* 10 mg q 8 h (max dose 40 mg/day) *Terbutaline PO:* 2.5–7.5 mg q 4–6 h (max dose 30 mg/day)	0.5	Palpitations, diaphoresis, tremor, nervousness, dizziness, hyperglycemia	Neonatal hypoglycemia
Intravenous Immunoglobulin (IVIG) (immune-mediated heart block, EFE)	*Transplacental:* 1 g/kg (maternal weight) IV q 2–3 weeks (max dose 70 g/dose)		Headache, fever, nausea, chest pain, aseptic meningitis	None known

F:M fetal to maternal ratio, *PO* oral, *IV* intravenous, *IVIG* intravenous immunoglobulin

The therapeutic agents frequently used include fluorinated steroids, β-inotropic agents, immunoglobulin, and ventricular pacing (Table 14.2).

Fluorinated Steroids. Dexamethasone and betamethasone are both potent synthetic glucocorticoids that are easily transferred across the placenta to the affected fetus. Use of steroids in the treatment of autoimmune-mediated CHB is based on the assumption that an inflammatory process caused the disruption of AV nodal conduction and these steroids may reduce the immune-mediated tissue damage. While there have been case reports of improved AV block following steroid therapy [55, 66], oftentimes no improvement in heart rate can be demonstrated. Transplacental treatment with steroids has also resulted in resolution of effusions and fetal hydrops, despite no improvement in heart rate, suggesting that fetal fluid accumulations may be the result of immune-mediated inflammation and not congestive heart failure. The decision to treat with steroids is a difficult one as the maternal and fetal side effects of fluorinated steroids are not minor. Maternal side effects include glucose intolerance, oligohydramnios, impaired immune function, systemic hypertension, headache, insomnia, and changes in mood. Fetal exposure to steroids has raised concerns for hypoaldosteronism, growth restriction including reduced cerebral growth, as well as long-term neurodevelopmental impairments [67, 68]. Many advocate for the restriction of transplacental therapy to the compromised fetus [69, 70]. New proposed management strategies which taper the steroid dose around 30 weeks' gestation are now frequently implemented to reduce steroid-mediated side effects. Additional careful monitoring of the amniotic fluid level throughout gestation is essential.

β-*Sympathomimetics*. Oral salbutamol and terbutaline are the predominant β-agonists used to treat the fetus with a slow heart rate and/or myocardial dysfunction by acting to increase fetal heart rate and decrease systemic vascular resistance. Previous studies have demonstrated a less favorable outcome in fetuses with heart rates $\leq$55 beats/min [55]. Fetuses with CHB often respond to transplacental β-stimulation with

a small increase in the fetal heart rate of 5–10 beats/min, augmenting fetal cardiac output. However, treatment with β-agonists has not been proven to alter the risk of fetal or neonatal death. Although β-agonists are often well tolerated, mothers on maximal therapy often complain of mild tremor, palpitations, and sweating [48, 71]. To minimize maternal side effects, the dose of β-agonist can be adjusted to keep the maternal heart rate between 110 and 120 bpm. Should fetal heart failure develop despite maximum doses of β-agonist, some institutions suggest adding digoxin therapy based on data suggesting that digoxin prolongs gestation in fetuses with heart failure in sinus rhythm [55].

Intravenous Immunoglobulin (IVIG). IVIG is an established postnatal therapy for the treatment of autoimmune and inflammatory diseases such as SLE and Sjögren syndrome and has gained recognition in the treatment of some inflammatory-mediated cardiac disorders including Kawasaki disease and cardiomyopathy. IVIG is a blood product with a mode of action not clearly defined, but is believed to involve the inhibitory Fc receptor, part of a multistep process resulting in a reduced inflammatory state. Historically, the prognosis for a fetus with autoimmune-mediated cardiomyopathy and EFE, often in the setting of CHB, was poor. However, recent data now suggests that in utero treatment of these fetuses with IVIG, in addition to corticosteroids, potentially improves outcome with a reported overall patient survival of 80 % [56]. Although intravenous maternal IVIG therapy is well tolerated, it is not without risk as it exposes both mother and fetus to blood products.

Ventricular Pacing. Prenatal ventricular pacing has been attempted as a last resort effort in significantly compromised fetuses with minimal success. At this time, there are no reports of fetal survival beyond the intraoperative period. Work continues to be done to develop leads and devices to improve fetal pacing [72, 73]. Currently it is reported that approximately 66 % of fetuses with autoimmune-mediated CHB require permanent pacemaker placement in the newborn period [62].

Fetal Cardiac Intervention

15

Brian T. Kalish and Wayne Tworetzky

Abstract

Advances in imaging have revolutionized the field of prenatal diagnosis and greatly expanded our knowledge of the natural history of fetal disease. Prenatal diagnosis facilitates counseling and pregnancy decision-making, but it also evokes the potential for fetal therapy. The increased understanding of fetal structural heart disease, combined with improvements in angioplasty tools and maternal/fetal anesthesia, has made fetal cardiac intervention a reasonable therapeutic option for some patients.

Fetal cardiac intervention is a hybrid procedure that requires a well-coordinated team with obstetric, interventional catheterization, anesthesia, and ultrasound capabilities. Fetal cardiac intervention is currently employed for three conditions: aortic stenosis with evolving hypoplastic left heart syndrome, established hypoplastic left heart syndrome with intact or highly restrictive atrial septum, and pulmonary atresia with intact ventricular septum or hypoplastic right heart syndrome. The pathophysiology and rationale for intervention for each indication are discussed in this chapter.

Introduction

Advances in imaging have revolutionized the field of prenatal diagnosis and greatly expanded our knowledge of the natural history of fetal disease. Prenatal diagnosis facilitates counseling and pregnancy decision-making, but it also evokes the potential for fetal therapy. The increased understanding of fetal structural heart disease, combined with improvements in angioplasty tools and maternal/fetal anesthesia, has made fetal cardiac intervention (FCI) a reasonable therapeutic option for some patients.

FCI is a hybrid procedure that requires a well-coordinated team with obstetric, interventional catheterization, anesthesia, and ultrasound capabilities. FCI is currently employed for three conditions: aortic stenosis with evolving hypoplastic left heart syndrome (AS with eHLHS), established hypoplastic left heart syndrome with intact or highly restrictive atrial septum (HLHS with IAS), and pulmonary atresia with intact ventricular septum (PAIVS) or hypoplastic right heart syndrome. The pathophysiology and rationale for intervention for each indication are discussed separately below.

Aortic Stenosis with Evolving Hypoplastic Left Heart Syndrome

The most common FCI is balloon aortic valvuloplasty for mid-gestation fetal AS with eHLHS. The management of and short-term outcomes for HLHS have improved substantially in the last decade, with stage I survival for standard risk patients at select centers approaching 80–90 % [1–4]. However, this number should be viewed with caution as it represents only stage I survival and does not apply to most centers. Despite these advances in the neonatal care of HLHS, survivors of single-ventricle palliation are at risk for long-term complications and death, with many requiring cardiac transplantation in adolescence or adulthood [5, 6].

A subset of patients with mid-gestation valvar aortic stenosis will be born with HLHS. Typically, the heart is phenotypically near-normal early in gestation. An experienced ultrasonographer might detect early subtle changes such as left ventricular dysfunction, echogenicity, and flow disturbance if color Doppler is used. As the aortic stenosis progresses in mid-gestation, there is increasing left ventricular dysfunction with reversal of flow in the aortic arch and across the foramen ovale [7–9]. In the developing fetus, growth of the mitral valve (MV), left ventricle (LV), aortic valve (AV), and ascending aorta is partially dependent on load- and flow-mediated stimulus. The in utero left ventricular outflow tract obstruction presumably stunts left heart growth through progressive left ventricular dysfunction, myocardial damage, and impaired left heart flow.

In utero balloon dilation of the aortic valve has been shown to improve left ventricular function and left heart Doppler flow in a subset of fetuses with eHLHS [10, 11]. Early attempts at fetal aortic valve dilation were performed in the third trimester with generally poor outcomes [12]. The goal of fetal aortic valvuloplasty is to reduce secondary myocardial damage by relieving obstruction in the left ventricular outflow tract, thereby improving left ventricular function and facilitating blood flow through the left heart. The relationship between load, flow, and cardiovascular growth is supported by numerous animal experiments [13–17].

Not all fetuses with aortic stenosis progress to HLHS at birth. Those with preserved LV function and antegrade flow around the aortic arch can be treated postnatally. However, what might appear to be mild disease early in gestation usually progresses rapidly, and patients should be followed closely during gestation for evidence of progression. Given the risks of fetal intervention, caregivers should be prudent in selecting only those fetuses that are predicted to develop HLHS at birth. When assessing fetuses with AS as potential candidates for fetal intervention, there are two important questions: if left alone, will this progress to HLHS? Perhaps more importantly, if an intervention is performed, is the left heart salvageable? It is crucial to select fetuses with a high probability of developing HLHS [18, 19].

Anatomic measures alone are insufficient to make this distinction, as there might not be differences in Z-scores of left heart anatomic structures between fetuses with evolving HLHS and those that maintained a biventricular circulation postnatally. Rather, physiologic and functional aberrations such as reversed flow in the transverse aortic arch and foramen ovale, monophasic mitral inflow, and LV dysfunction are more predictive of progression to HLHS [18]. In general, fetuses that underwent aortic valvuloplasty have been a heterogeneous group: some patients have had dilated LV; some have smaller LV with echogenic endocardium; some have restrictive septa; some have mitral regurgitation; some have hydrops [10, 11]. This heterogeneity likely represents different stages of progression. Nevertheless, all candidates should have AS with severe LV dysfunction and flow aberrations, both of which predict a high probability of HLHS at birth. The ideal candidate will have a dilated LV, generating high LV pressures, and have minimal endocardial fibroelastosis (EFE).

Successful fetal aortic valvuloplasty improves the growth of the aortic valve, ascending aorta, and MV. However, this intervention does not necessarily promote LV growth [19]. There are several potential explanations for this: the LV has already been irreversibly damaged, the LV is less able to adapt than the AV and MV, or because the disease itself stunts LV myocardial growth. Most importantly, fetuses who undergo FCI commonly have pathologically dilated LV and, for the remainder of gestation, trend toward normal rather than grow from their dilated state [19]. Data from patients who do not undergo fetal intervention demonstrate that left heart dimensions shrink toward more severe hypoplasia [19]. Therefore, fetuses with a larger LV at the time of intervention are most likely to achieve biventricular circulation [19].

Aortic regurgitation (AR) is common following fetal aortic valvuloplasty and is, similar to the postnatal patient, associated with larger balloon diameter to annulus ratio [11]. The AR almost always improves significantly prior to birth, as opposed to post dilation AR in neonates, which is often progressive. The fetal environment may be more favorable for the resolution of AR due to accelerated healing and remodeling. Additionally, the regurgitant volume may be limited by low systemic vascular resistance and elevated LV end-diastolic pressure in the fetus.

Technical success of fetal aortic valvuloplasty approaches 75 % at high-volume centers, but this success rate is likely to vary significantly between centers as there is a substantial learning curve [19]. Technical failure is associated with shorter LV length and aortic atresia [19]. There is a not-insignificant (10 %) risk of periprocedural fetal demise. Recent studies demonstrate that 30–40 % of fetuses that underwent technically successful fetal aortic valvuloplasty achieve biventricular outcomes [19]. Patient selection criteria have evolved with increasing experience, and these statistics are likely to improve with increased understanding of the technical aspects of the procedure and the postnatal management of these patients.

The likelihood of biventricular outcome in children who formerly underwent fetal aortic valvuloplasty depends on several factors. Higher LV long-axis Z-score and higher LV pressure at the time of intervention are associated with biventricular outcome [19]. Less severe EFE is associated with greater increase in LV end-diastolic volume after fetal intervention [20]. More severe LV EFE at mid-gestation is associated with lower probability of postnatal biventricular outcomes [20]. Of note, fetuses with AS, severe MR, and LA dilation have a very poor prognosis, despite prenatal intervention.

Technical Considerations in Fetal Aortic Valvuloplasty

The technical aspects of fetal aortic valvuloplasty are summarized below, as has been described elsewhere [10, 11]. The general principles are the same for other fetal cardiac interventions, and modifications of these techniques for other lesions will be described in later sections. Of note, there is a tremendous learning curve in both the technical performance and teamwork of these procedures.

The majority of FCI can be performed percutaneously under maternal general or epidural anesthesia. General anesthesia allows for easier fetal positioning due to uterine relaxation, but epidural anesthesia has the theoretical advantage of reduced maternal risk. Maternal laparotomy can be used to improve fetal position and ultrasound resolution but is significantly more invasive for the mother; higher maternal BMI and anterior placenta may increase the need for laparotomy.

A fetal anesthesiologist oversees administration of intramuscular paralytic and narcotic to the fetus. Fetal positioning may be best accomplished prior to fetal anesthesia. The position of the fetus is of paramount importance to the technical success of the procedure. The fetus should be optimally positioned with left chest wall anterior, with the LV outflow tract parallel to the planned cannula tract [11]. It is inadvisable to enter the LV unless fetal position is optimal.

The cannula, guidewires, and balloon shafts should be premeasured and scored as an external reference for the location of the wire within the fetal heart [11]. The access cannula should be a sharp-tipped stylet to minimize tissue shearing, and it should be the lowest profile that can accept the desired balloon catheter. An ultrathin-walled 19-gauge cannula has been used with repeated success and minimal complications [11]. An obstetrician inserts the cannula through the maternal abdominal wall, uterine wall, and into the amniotic space under ultrasound guidance. The ultrasound should have both the entire cannula length and the LV included in the field of view.

The cannula tip is moved along the fetal chest wall to the intercostal space above the LV apex. Ideally, the cannula should puncture the LV apex aimed at the aortic valve. A rapid "thrust" should be used to pierce the LV apex to avoid tissue distortion. Once inside the ventricle, the cannula should be aimed toward the aortic valve. Blood return after the stylet is removed confirms position within the fetal heart. The guidewire with coronary artery balloon is passed through the cannula. The wire should be visualized in the ascending aorta and the balloon dilation catheter (BDC) advanced across the aortic annulus. The BDC should be positioned distally and then withdrawn in a stepwise fashion, inflating and deflating the balloon prior to repositioning. Following dilation, the BDC should be retracted to the cannula tip but not withdrawn into the cannula itself, as this can result in shearing of the balloon into the left ventricle. The BDC, cannula, and wire should all be removed simultaneously. The fetal heart rate and function should be monitored immediately after cannula removal, and the heart should be assessed for hemopericardium. These complications can be immediately intervened upon to prevent fetal decompensation. Hemopericardium should be drained if there is fetal hemodynamic instability. Attempts should not be made to drain a small-volume hemopericardium as this can result in further complications. Ultrasonography should be performed a few hours after the procedure to evaluate for fetal complications, and regular follow-up imaging is essential to determining the evolution of fetal heart function.

Hypoplastic Left Heart Syndrome with Intact Atrial Septum (HLHS with IAS)

HLHS with IAS is a highly lethal form of congenital heart disease. This high-risk subset of patients represents approximately 6 % of patients with HLHS [21]. Fetuses with this condition are often stable in utero but decompensate in the delivery room, with severe hypoxemia, acidosis, and pulmonary edema. Without early decompression of the left atrium, children with this lesion are likely to develop cardiogenic shock and die. Even under those conditions, approximately half of patients with this lesion will die in the nearly neonatal period [22]. Early surgical intervention with stage I procedure and atrial septectomy is advocated at some centers, but less than 20 % of those patients are alive at 6 months [23].

The goal of fetal intervention for this condition is twofold: (1) stabilize the neonate for physiologic fetal to neonatal transition and (2) potentially prevent ongoing damage to the pulmonary vasculature [24]. There is a notable

"delayed" mortality in patients with HLHS and IAS, and this has been attributed to damage from in utero pulmonary venous hypertension [21]. Elevated left-sided pressures may cause arterialization of pulmonary veins and dilation of lymphatics, both of which may complicate single-ventricle palliation procedures [21, 25, 26].

The first fetal intervention reported for fetuses with HLHS and IAS was balloon atrial septostomy [24]. In most cases, the fetal septum is approached through the right atrium. The introducer cannula or a 22-gauge Chiba needle (Cook Inc.) is used to puncture the septum. Wire is visualized across the septum, and a BDC is exchanged over the wire. The balloon is inflated numerous times as the catheter is advanced and retracted to ensure adequate dilation. Single-center experience cites >90 % technical success, and cases of technical failure have been due to an inability to reach the atrial septum from the maternal abdominal surface [27]. The most common complications are fetal bradycardia and pericardial or pleural effusion.

While the number of fetuses who have undergone this procedure remains relatively small, early results demonstrate increased postnatal oxygen saturation and less need for intervention prior to surgical palliation [27]. In the largest series to date, 58 % of patients who underwent fetal atrial septoplasty survived stage I palliation [27]. About one-third of patients avoided urgent postnatal atrial septoplasty and were medically managed prior to stage I palliation [27].

Recently, some centers have attempted to place a stent across the fetal atrial septum as a means of decompressing the left atrium [27]. In these procedures, the septum is punctured and a wire threaded across the septum. A BDC preloaded with a coronary artery stent is exchanged over the wire, positioned across the atrial septum, and the balloon is maximally inflated to deploy the stent. These procedures have only been performed in a handful of fetuses, so long-term outcomes are unknown. Stent misplacement or embolization is the most common complication. Poor visualization of the stent and septal distortion from cannula manipulation contribute to technical failure.

There are several advantages and disadvantages to fetal stent placement compared to balloon septostomy. Atrial recoil, especially in fetuses with thick septa, can contribute to septal defect closure after balloon septostomy, but the stent is much less susceptible to compression. Stent placement may be most suitable in fetuses with thick intact atrial septa.

Pulmonary Atresia with Intact Ventricular Septum (PAIVS)

Pulmonary atresia with intact ventricular septum is associated with hypoplastic right-sided structures, including the right ventricle, tricuspid valve, and right ventricular outflow tract. Most commonly, this results in redirection of flow away from the right heart, across the PFO with resultant right heart hypoplasia insufficient for a biventricular circulation. Rarely, when there is significant tricuspid regurgitation, this can result in elevated central venous pressure and hydrops. The objective of fetal intervention is to facilitate antegrade flow through the right ventricle, stimulating right heart growth and increasing the probability of eventual biventricular outcome.

Only a small subset of patients with this lesion will be candidates for fetal intervention, and the criteria for selecting this cohort are not as well defined. Fetuses with PAIVS fall into three broad categories: (1) those who have normal or enlarged right heart structures, (2) those with fibromuscular atresia of the RV outflow tract, and (3) those with hypoplastic right heart and an identifiable but atretic pulmonary valve.

Patients in category 1 will achieve biventricular outcome with postnatal therapy. This therapy usually includes perforation and balloon dilation of the pulmonary valve. A number of patients might require the addition of a Blalock-Taussig shunt or even right ventricular outflow tract muscle resection. Category 2 is the most severe form of this lesion, and they are not good candidates for fetal therapy. There is rarely an identifiable PV to perforate. Additionally, these fetuses commonly have coronary anomalies that complicate postnatal treatment.

These fetuses will require univentricular palliation and occasionally cardiac transplant for severe coronary artery disease. Category 3 is a heterogeneous population: some patients will achieve biventricular circulation after aggressive postnatal therapy with multiple surgeries and catheterizations, while others are destined for single-ventricle palliation. This last group of patients, in whom fetal intervention is technically possible, is the most likely to benefit from an in utero attempt to improve right heart growth and alter the natural history of the disease. Theoretically, it might be beneficial to intervene on the fetuses who will require multiple postnatal operations that pose significant risk of morbidity and mortality to the child. However, these risks only apply to the fetus, whereas fetal intervention poses added risk to the mother.

Percutaneous fetal intervention is technically challenging in fetuses with this lesion. The RV is small, hypertrophied, and difficult to access behind the sternum. The geometry of the RV outflow tract is such that there is a narrow curved segment directly inferior to the valve. The RV must be entered on a trajectory toward the atretic valve. The valve cannot be crossed with a wire alone; a sharp needle must be used to pierce the atretic valve and a balloon catheter inserted over a wire. The balloon is inflated across the valve and all instruments are removed from the fetus.

The largest series of fetal interventions for fetuses with PAIVS includes ten patients, the first four of which were technically unsuccessful [28]. The six fetuses that underwent successful pulmonary valvuloplasty had greater growth of the right ventricular length, tricuspid valve annulus, and pulmonary valve annulus as compared to control fetuses who did not undergo fetal intervention. Many questions regarding patient selection, however, have yet to be answered.

Fetal Hemodynamic Instability

Fetal hemodynamic instability is a common complication of fetal cardiac intervention, particularly in cases of transventricular puncture [29]. There are several potential etiologies for this phenomenon. Fetal hypoxia is a well-known cause of bradycardia. In particular, hypoxia in the carotid artery can trigger a chemoreceptor reflex. Hypoxia may also result from caval compression that prompts the release of fetal vasoactive and stress hormones [30]. Hemopericardium may contribute in a subset of fetuses. Another hypothesis is that fetal bradycardia results from a direct ventricular stretch response. This has been observed postnatally when the stimulation of ventricular stretch receptors mediates the Bezold-Jarisch reflex – a simultaneous withdrawal of sympathetic outflow and vagal efferent activity that causes hypotension and bradycardia [31]. There is evidence that reductions in ventricular preload can cause a similar reflex in fetal animal models, although transventricular puncture has been performed in fetal animals without bradycardia [30, 32].

A variety of methods have been used to prevent and treat fetal hemodynamic instability. Intracardiac atropine, as well as intramuscular and/or intracardiac epinephrine, is commonly used for fetal resuscitation. One concern with the use of epinephrine is reflex bradycardia, but this phenomenon has not been well studied.

Postnatal Management

Mothers should plan to deliver at a highly specialized center with high-volume congenital heart surgery, catheterization, and extensive experience with the medical management of neonatal heart disease. The proposed benefits of fetal cardiac intervention depend heavily on skilled postnatal management, as fetal intervention alone is unlikely to be sufficient to result in biventricular circulation. The management of these patients relies on familiarity in managing borderline left heart disease, a field that is only now emerging at select centers. A full discussion of this topic is beyond the scope of this chapter. Of note, however, in some patients with borderline left hearts, left ventricular rehabilitation, including endocardial fibroelastosis resection and mitral and aortic valvuloplasty, can improve LV performance [33].

Current Challenges and Future Directions

There is a notable learning curve in the technical performance of fetal cardiac intervention, with decreasing need for laparotomy and higher success rates after experience with the procedures. The last decade has seen significant growth in our understanding of the natural history of fetal cardiac lesions, and yet there is much we do not know about the biology of these conditions. Technological advancements in other fields, such as micro-instrumentation, may help to improve technical outcomes and further reduce fetal complications of FCI in the future.

In summary, the current ability to alter the natural history of severe heart disease in utero with minimal maternal risk represents a major advance for these select conditions.

Assessment of the Cardiac Patient: History and Physical Examination

16

Daphne T. Hsu and Welton M. Gersony

Abstract

The assessment of a patient with possible or known heart disease by history taking and physical examination is the purview of all pediatric cardiovascular subspecialists. The requirements for assessment depend on the subspecialty area of expertise, and are as varied as evaluation of a heart murmur by an outpatient cardiologist, evaluation of cyanosis by a neonatologist, assessment prior to surgical intervention by a pediatric cardiac surgeon or anesthesiologist, and evaluation of low cardiac output by a cardiac intensivist. This section will review the important history and physical examination components of a comprehensive cardiac assessment.

Keywords

Arrhythmias • Cardiac signs • Cardiac symptoms • Diastolic • Family history • Flow murmur • Heart failure • Medication history • Murmur • Myocardial ischemia • Regurgitant murmur • Surgical history • Systolic

Introduction

This section will review the important history and physical examination components of a comprehensive cardiac assessment. Effective history taking and physical examination are the foundations of the diagnostic process. The information obtained leads the cardiovascular physician in any setting to initiate a systematic and logical approach to the ordering of pertinent laboratory studies and the subsequent requirements for interventions. Furthermore, irrelevant tests can be avoided. This is especially important in the modern era of high medical costs. Skillful history taking and physically examination not only affect decisions as to which laboratory studies are necessary, but also the quality of the findings. Among patients with congenital heart disease, a focused echocardiogram carried out after a preliminary diagnosis has been made is a much more effective tool than when used initially as

a screening test. The importance of history and physical examination requires reemphasis; technologic advances have allowed the choices of tests that are offered to continue to expand.

Focused Cardiac History

The indications for cardiac assessment by a pediatric cardiovascular subspecialist can be broadly divided into three areas: (1) evaluation of the signs and symptoms of cardiac disease, (2) screening for cardiac disease in patients at risk, and (3) evaluation of the patient with known cardiac disease prior to intervention (Table 16.1). A focused cardiac history is the starting point for all patients undergoing cardiac assessment in any of these settings. Elements of the history include detailed information about the presence or absence of signs and symptoms, pertinent past medical history, and cardiovascular-related risk factors in the family history or review of symptoms (Table 16.2). Historical information as well as the physical examination is used to direct further testing and is the basis for deciding if a cardiac diagnosis requires further evaluation and management or is an incidental finding that does not require follow-up. In a patient with known heart disease, decisions to initiate medical or surgical therapies and assessments of clinical outcomes are based on changes reported in the history.

Signs and Symptoms of Cardiac Disease

A focused cardiac history includes detailed information about the onset, duration, severity, and associated signs and symptoms of the chief complaint. Although the underlying pathophysiology may differ, children with cardiac diseases can manifest symptoms due to heart failure, ischemia, and/or arrhythmias similar to adults (Table 16.3). The type and severity of symptoms that may be encountered vary, depending on the underlying disease and the age of the patient. For example, the first sign of heart failure in an infant or young

Table 16.1 Indications for assessment by a cardiovascular specialist

Evaluation of signs and symptoms in patients with suspected or known heart disease
• Heart murmur
• Cyanosis
• Heart failure

child is usually respiratory distress and poor feeding; exercise intolerance may be the first symptom noticed by an adolescent. The ability to report symptoms with precision is related to the stage of cognitive development. In the infant and young child, reliance on parental reporting is the norm, but during late childhood and adolescence, self-reporting is most important, and should be encouraged.

Heart Murmurs

The presence of a heart murmur can be the sentinel finding that leads to the diagnosis of a congenital or acquired heart disease. Pathologic heart murmurs are caused by turbulent flow in the heart or great vessels due to a left-to-right shunt, valvar insufficiency, or valvar or arterial stenosis. Flow turbulence may not be present in certain congenital heart defects, usually associated with cyanosis. Thus, the absence of a murmur does not preclude the presence of significant disease; the most severe defects may have no audible murmurs. The types of heart diseases associated with typical murmurs in children are listed in Table 16.4. A history of the signs and symptoms of heart failure or cyanosis can narrow the differential diagnosis in a patient with a heart murmur. In patients with known heart disease, a change in the murmur or the appearance of a new murmur may be a sign of hemodynamic or structural deterioration.

In childhood, benign (i.e., functional, innocent, nonorganic, "normal") heart murmurs are more common than pathologic murmurs [1, #3]. A history that is negative for the signs and symptoms of heart failure, cyanosis, or risk factors associated with heart disease does not enable the subspecialist to make the diagnosis of a benign heart murmur with certainty, since mild to moderate heart disease may be present. The presence of the classic auscultatory features of a benign murmur as well as normal heart sounds must be identified.

Table 16.4 Heart lesions associated with pathologic heart murmurs

Cardiomyopathy: dilated, restrictive, hypertrophic, tachycardia induced
Failed Fontan circulation

Cyanosis

A history of cyanosis not associated with respiratory distress is suggestive of an intracardiac or great vessel right to left shunt, particularly in the neonate. The onset, duration, severity, and location of the cyanosis are important factors used to distinguish cardiac from noncardiac causes, mainly pulmonary. In the recent recommendations for screening for critical heart disease in neonates, cardiac assessment is triggered by an oxygen saturation <90 % on a single reading or <95 % on three readings 1 h apart [2, #5]. Cyanosis in an older child with no known heart disease is most often an indication of pulmonary disease. Rare diseases such as Eisenmenger syndrome in previously unrecognized congenital heart disease, hereditary hemorrhagic telangiectasia, or orthodeoxia can present with cyanosis later in life.

Most complex cyanotic heart defects (single ventricle variants, complex ventricular septal defect, tetralogy of Fallot with small pulmonary arteries) are palliated in the neonatal or early childhood period. In this population, cyanosis will be present until the pulmonary and systemic circulations are separated. Increasing cyanosis in the child with palliated congenital heart disease is a major indication for re-intervention, particularly if accompanied by symptoms of tachypnea, tachycardia, or fatigue. The oxygen saturation and hemoglobin determination are additional measures used to monitor increasing cyanosis.

Heart Failure

Heart failure occurs in children as a result of a large left-to-right shunt, volume overload from valvar insufficiency, and myocardial dysfunction from pressure overload or primary myocardial disease. The common causes of heart failure in children are listed in Table 16.5. The prevalence of heart failure among children with congenital heart diseases and cardiomyopathies is increasing as the survival after open surgery improves and the medical treatment of cardiomyopathy has become more effective [3, #18].

Myocardial dysfunction is often biventricular in children with left-to-right shunt lesions or cardiomyopathy. The general symptoms of heart failure in children include fatigue, exercise intolerance, tachycardia, and failure to thrive. Tachypnea and dyspnea are common in all age ranges. Abdominal pain is an important symptom of heart failure in older children who can present with symptoms that suggest an acute abdomen [4]. In the presence of low cardiac output, symptoms of vomiting, dizziness, and fatigue may be present with no symptoms of systemic or pulmonary venous congestion, because the patient's intravascular volume is

deleted. In patients with congenital heart diseases associated with right heart failure, pulmonary symptoms of right heart failure such as hepatomegaly, abdominal pain, and edema may predominate. Patients with single ventricle physiology following the Fontan procedure have high systemic venous pressures, and may manifest symptoms of right heart failure with normal systemic ventricular function.

The presence of clinical heart failure is associated with worse outcomes in children with myocardial dysfunction [5, 6]. The use of a heart failure score has been proposed to risk-stratify the severity of heart failure and improve the monitoring of heart failure symptoms over time. Although the New York Heart Association Class and the Ross Heart Failure Class have been proposed for clinical use, neither has been validated as a predictor of morbidity or mortality in children [7, 8]. Nonetheless, the clinician should develop a consistent approach to tracking heart failure symptoms in order to improve the objective assessment of disease progression.

The preoperative cardiac assessment of a patient with known cardiac disease should include screening for the presence of heart failure symptoms. Clinical heart failure and myocardial dysfunction are important risk factors for worse outcomes following anesthesia and cardiopulmonary bypass. Identifying the patient at risk will allow the anesthesiologist and surgeon to target the pharmacologic and surgical approaches toward preserving myocardial function and preemptively managing postoperative heart failure.

Myocardial Ischemia

Chest pain is a common complaint in children, and is rarely due to myocardial ischemia. The characteristic symptoms of chest pain due to ischemia in older children and adolescents are similar to those found in adults. Dyspnea with exertion or syncope with exercise, rather than progressive chest pain, is more often an important presenting symptom of ischemia in children. In neonates with anomalous origin of the left coronary artery arising from the pulmonary artery, inconsolable crying and poor feeding is often present, but is usually noted only in retrospect.

Arrhythmia

A history of tachycardia occurring at rest with a sudden onset and termination is suggestive of a tachyarrhythmia. Young children with tachyarrhythmias may have a history of chest pain because of their inability to localize or describe the sensation of tachycardia. Symptoms associated with a tachyarrhythmia include dizziness, lightheadedness, and rarely syncope. The presence of syncope with a tachycardia is an important trigger for further evaluation because of the potential risk of a life-threatening event. Infants with rapid atrial tachycardias often are not recognized until symptoms of heart failure occur. Bradycardia due to various forms of sinus node dysfunction, or heart block, also may not be diagnosed until later in childhood.

Past History

Past Medical and Surgical History

In patients with known heart disease, it is extremely important to obtain a detailed past medical and surgical history that includes the dates and types of interventional procedures, the results of noninvasive and invasive testing, and any morbidities that occurred in association with prior procedures or anesthesia. Multidisciplinary review of the results of noninvasive imaging, catheterization, exercise stress-testing, and arrhythmia monitoring should be performed. Abnormalities of vascular access and other extracardiac structures that would impact on the technical performance of a catheter or surgical intervention should be documented.

A past medical history of any sequelae of infectious or inflammatory diseases that can affect the heart should be obtained. These include diseases such as endocarditis, rheumatic fever, arthritis, collagen vascular diseases, sickle cell disease, or cancer.

Medication Use

A history of prior and current cardiac medications should be obtained and medication reconciliation with calculation of the dosage/kg/day should be performed as part of the cardiac assessment.

Dose regimens in children require regular adjustments for body weight or size. The safe administration of medications not approved for use in children is challenging for several reasons. In many instances, the preparation of compounded liquid formulations is not standardized, and the stability of the formulation may not be well known. The correct dosage and therapeutic window has not been studied in all age rages. Adverse events due to cardiac medications are more common in children <4 years of age and, for drugs such as anti-arrhythmic agents, can have serious consequences [9, 10]. It is important to determine if long-standing drug treatment is still indicated, and, if so, does dosage require adjustment.

Prenatal and Birth History

A maternal history of medication use, systemic illness, genetic or metabolic disease, gestational diabetes, or other pregnancy-related complications may identify risk factors for neonatal congenital heart disease or cardiomyopathy. Review of fetal ultrasound and echocardiogram results provides detailed anatomic and functional information about the heart prior to birth and can document a fetal arrhythmia.

Results of genetic testing of the fetus and/or mother provide information about risk of congenital heart disease or cardiomyopathy and, in some cases, are of prognostic value. The birth history should include the onset and time-course of the signs and symptoms of heart disease. A history of birth-related complications that affect cardiac, pulmonary, or neurologic function will help differentiate the signs and symptoms of cardiac diseases from those due to noncardiac causes.

Cardiovascular Risk Factors

Family History

The increasing availability of comprehensive genetic testing has led to new discoveries of genetic defects associated with congenital heart diseases, cardiomyopathies, and arrhythmias [11–13]. Family history may identify patients and families at risk for cardiac events who should be evaluated by a clinical geneticist. A detailed family history focusing on the presence of inherited cardiac diseases such as hypertrophic cardiomyopathy, Marfan Syndrome, or long QT syndrome should be performed. If the family history is positive, a family tree should be completed to identify any affected first- or second-degree relatives, which could increase the probability of inheritance by the patient. If genetic testing identifies a mutation in an affected family member, every effort should be made to obtain the detailed results.

Review of Systems

In a patient undergoing assessment for possible heart disease, the review of systems will identify important noncardiac conditions that can alter the differential diagnosis of the signs and/or symptoms undergoing evaluation. In patients with known cardiac disease, the review of systems can identify important comorbidities that would impact treatment decisions and prognosis.

Neurodevelopment: Congenital heart diseases and cardiomyopathies are strongly associated with neurodevelopmental abnormalities [14]. Developmental delays or disabilities are found in the areas of cognitive and motor skills and psychosocial adjustment. The incidence of mild developmental abnormalities in children with heart diseases such as coarctation of the aorta, tetralogy of Fallot, or atrioventricular septal defect is 25 %. The majority of children with the most severe disease have developmental delays or disabilities, and 10–15 % have severe neurodevelopmental impairment. A history of risk factors for neurodevelopmental delay listed in Table 16.6 should trigger a more extensive neurodevelopmental evaluation.

Psychosocial: Long-term survivors of congenital heart disease surgery experience higher levels of behavioral and psychological disorders than the normal population [15, 16]. Depression and anxiety are common, along with disorders of body image and peer relations. Screening for behavioral and psychological disorders is an important element of the assessment of the cardiac patient.

Growth: Failure to thrive occurs in infants with heart failure [17, 18]. A nutritional and feeding history should be obtained as part of

Table 16.6 Categories of pediatric congenital heart disease at high risk for developmental disorders or disabilities (Adopted from Marino et al. [14])

Neonatal or infant open-heart surgery
Cyanotic heart disease
Suspected genetic abnormality or syndrome
History of mechanical support
Heart transplantation
Cardiopulmonary resuscitation
Prolonged hospitalization (>2 weeks)
Perioperative seizures
Significant abnormalities on neuroimaging
Microcephaly

a comprehensive assessment. Anatomic abnormalities of the gastrointestinal tract are common in complex heart diseases, as are oro-motor coordination and swallowing difficulties. Growth failure is common in children with genetic or metabolic syndromes. Screening for the presence of these abnormalities should be performed as part of the assessment of a child with possible or known heart disease.

Respiratory: Children with cardiac disease may have associated pulmonary disease. A careful history assessing for signs and symptoms of reactive airway disease, airway obstruction, or other structural airway abnormalities should be performed. The presence of stridor may be the first symptom of a vascular ring.

Hepatic: Abnormalities of hepatic function are increasingly being found in the older child and adolescent with congenital heart disease [19]. Liver disease is more prevalent in congenital heart defects associated with right heart failure. Systemic venous hypertension (e.g., Fontan procedure) is especially prone to this problem as they reach adolescence and early adult life. A history of hepatitis exposure should be taken, as there is a 10–15 % prevalence of hepatitis C among patients with congenital heart disease who had undergone open-heart surgery prior to 1992 [20].

Preventive care: A dental history includes the signs and symptoms of dental disease, the dental hygiene regimen, and the frequency of routine dental care. There is an increased risk of endocarditis and higher incidence of dental disease in children with complex congenital heart disease compared to normal children [21]. A history should also screen for risk factors for adult cardiovascular diseases such as obesity, smoking, hypertension, hyperlipidemia, or metabolic syndrome.

Physical Examination

Vital Signs

The cardiovascular examination begins with an analysis of the vital signs. Abnormalities in weight, height, heart rate, respiratory rate, and blood pressure are signs of heart failure in patients with cardiomyopathy or congenital heart diseases. Blood pressure abnormalities may also be a sign of an abnormal pathophysiologic state associated with congenital heart disease.

Somatic Growth

Weight- and height-for-age should be determined by plotting the values on the appropriate growth chart or calculating the z-score-for-age using CDC or WHO anthropometric data [22, 23]. Growth should be charted serially. Failure to thrive is defined as a weight- or height-for-age less than fifth percentile (z-score of −2 or greater), decreased growth velocity, or a weight deceleration that crosses two major percentile lines on the growth chart. In the absence of heart failure, growth abnormalities may be a sign of a genetic syndrome, as an example short stature is common in girls with Turner syndrome.

Heart Rate and Respiratory Rate

An elevated heart rate and respiratory rate are signs of heart failure in children. Infants have a limited stroke volume; thus, tachycardia may be more pronounced in the infant with cardiac compromise than in the older child. Updated normal percentile ranges for heart rate and respiratory rate were published in 2011 using values derived from a systematic review of observational studies in healthy children [24]. The revised values provide evidenced-based data that differ substantially from data published previously. At some ages,

the range of normal heart rate and respiratory rate is wider, leading to fewer patients classified as abnormal. The presence of a persistently elevated and fixed rate tachycardia in a patient with ventricular dysfunction may be a sign of a tachycardia-induced cardiomyopathy. Treatment of this rare type of tachycardia results in normalization of ventricular function [25].

Blood Pressure

Blood pressures should routinely be measured in the right arm with the appropriate size cuff while sitting quietly. At the initial exam, the leg blood pressure should always be recorded. If at an initial visit, blood pressures in the arms and legs should be remeasured in quick succession with the patient in a stable physiologic state. Coarctation of the aorta is the most common cause of hypertension, and must be diagnosed as early as possible. Lower extremity pulses are not necessarily absent. Blood pressure results adjusted for the height percentile should be compared to published normal values in children in order to identify patients with pre-hypertension and hypertension [26].

A narrow pulse pressure (the difference between the systolic and diastolic pressures is <25 % of the systolic pressure) and/or hypotension is a late sign of low cardiac output in patients with dilated or restrictive cardiomyopathy. A narrow pulse pressure is also present in a patient with cardiac tamponade as a result of pericardial effusion or constriction. An important sign of tamponade is the presence of pulsus paradoxus. Pulsus paradoxus is the result of impaired filling of the left ventricle during inspiration because of a pericardial effusion or other causes of a constrictive process. Pulsus paradoxus may be diagnosed when there is an exaggerated difference (>10 mmHg) between the normal first Korotkoff sound heard during expiration and the first sound heard during inspiration. The original label of "paradox" referred to the difference in the timing of the peripheral pulse and the heart sounds.

Abnormalities in blood pressure are associated with several congenital heart diseases. Systemic hypertension with a blood pressure gradient between the right arm and leg establishes the diagnosis of coarctation of the aorta, and the amount of the gradient is an indicator of the severity of the disease. However, the difference may be less obvious when there are significant aortic collaterals. A narrow pulse pressure is found in older patients with severe aortic stenosis. A widened pulse pressure is a sign of a large diastolic runoff in the aorta due to aortic insufficiency, a patent ductus arteriosus or an arteriovenous malformation is the most common cause.

Physical Examination

Inspection

The general inspection of the child with possible or known heart disease includes assessing for the signs of heart failure, cyanosis, and failure to thrive. Facial, skeletal, and limb abnormalities may be apparent that raise the suspicion of a genetic disorder. The chest should be inspected for surgical scars that can offer clues about the type of prior of surgical procedures that have been performed. The back should be inspected because of a higher incidence scoliosis following a median sternotomy.

Heart failure: Signs of heart failure on general inspection include failure to thrive with preserved height and decreased weight, cachexia, respiratory distress, peripheral edema, and lethargy or fatigue. If significant cardiomegaly is present, there may be chest asymmetry with a prominence of the left rib cage. Patients with cardiac tamponade or with pericarditis will be more comfortable in the sitting position and leaning forward.

Neck vein distension is a sign of increased central venous pressures. Jugular venous distension is difficult to determine in an infant. In an older patient, jugular venous distention is measured with the patient sitting upright at an angle of 30°.

Cyanosis: Central cyanosis is a bluish discoloration of the lips, mucus membranes, ear lobes, nail beds, and other locations where the skin is thin. Cyanosis is clinically apparent when the systemic oxygen saturation is <85 % or the level of circulating deoxygenated hemoglobin is >5 g/dL. As a result, cyanosis is diagnosed more

readily in the setting of polycythemia and is less apparent if anemia is present. Differential cyanosis of the upper and lower body is a sign of congenital heart defect with ductal-dependent systemic blood flow. Clubbing of the distal fingertips occurs with severe cyanosis and is characterized by a widening of the distal digits and loss of the angle between the nail and the nail bed.

Palpation

Cardiac: Cardiac examination includes palpation of the cardiac impulse. Displacement of the point of maximal impulse or a ventricular heave palpated to the right or left of the normal location is a sign of right or left ventricular hypertrophy. Displacement of the maximal impulse to the right chest will diagnose the presence of dextrocardia. A hyperdynamic precordium is present in the setting of ventricular volume overload. A thrill is best palpated with the distal palm or the metacarpal heads and is felt in the presence of high blood flow velocity. A thrill is a measure of increased severity in patients with semilunar valve stenosis or atrioventricular valve regurgitation. However, in patients with a ventricular septal defect, the presence of a thrill may indicate only a small, restrictive shunt. A suprasternal notch thrill is highly suggestive of valvar aortic stenosis, but not necessarily severe.

Abdomen and extremities: Hepatomegaly is an important sign of right heart failure and/or elevated right heart filling pressures. In patients with congestive heart failure, the liver may be tender because of the acute expansion of the capsule. Patients with a Fontan circulation often have hepatomegaly as a result of the increased venous pressure in the Fontan circuit. The presence of ascites is an indicator of worse right heart failure and, in the patient with a Fontan circulation, may be a sign of protein losing enteropathy. Pitting of the lower extremities also occurs in right heart failure and following the Fontan procedure.

Pulses: The quality of the pulse is an important indicator of the adequacy of cardiac output. A weak, thready pulse with decreased capillary refill is found in low cardiac output. A delay between the brachial and femoral artery pulses and diminished or absent femoral pulses are signs of a significant coarctation of the aorta. Bounding pulses are a sign of aortic runoff and most often occur in patients with aortic insufficiency, a patent ductus arteriosus, or an arteriovenous malformation.

Auscultation

Technique: Auscultation of the heart is a key element in the assessment of a child with possible or known heart disease. Every effort should be made to examine the child in a quiet and calm state. The tubing of the stethoscope must be intact and the earpieces should fit snugly. To hear higher pitched sounds, the diaphragm is placed firmly on the skin to create a seal with the skin. To hear lower pitched sounds such as mid-diastolic murmurs and extra heart sounds, the bell is placed lightly on the skin. Auscultation of the location and quality of heart sounds, and most murmurs is performed with the patient in a flat, supine position.

Position: A change in position may increase the intensity of a murmur by bringing the area of interest closer to the stethoscope. The murmur of aortic insufficiency is best heard at end-expiration with the patient leaning forward. The murmur of mitral insufficiency or stenosis is increased when the patient is lying in the left lateral decubitus position. Postural changes from squatting to standing accentuate the murmurs of mitral valve prolapse and hypertrophic cardiomyopathy.

Approach: Each clinician should develop a sequential approach to the cardiac examination that includes auscultating for heart sounds and murmurs at the apex, left lower sternal border, right lower sternal border, left mid-sternal border, left upper sternal border, right upper sternal border, clavicular regions, and the carotids. At each site, the quality of the heart sounds and the intensity and quality of the murmur should be noted. The location where the murmur is best heard and the areas of radiation are important clues to the underlying cardiac defect.

First heart sound (*S1*): S1 corresponds to the closure of the tricuspid and mitral valves. It is best heard in the more inferior locations in the chest and is usually single. In a normal older

individual, a normally split S1 may be heard. Mitral valve closure occurs first and is heard best at the apex and followed by tricuspid valve closure which is heard best at the left lower sternal border.

Second heart sound (*S2*): S2 is heard best at the left mid-sternal border and the left upper sternal border. S2 is normally split and is composed of aortic valve closure following by pulmonic valve closure. The split varies with respiration and is wider in inspiration when pulmonary valve closure is delayed due to venous return and increased right ventricular volume. The type of splitting or lack of splitting should always be described. An abnormal S2 is an important indicator of right ventricular volume or pressure overload. In patients with right ventricular volume overload, such as an atrial septal defect or partial anomalous pulmonary venous return, a constant increase in blood flow through the right heart delays pulmonic valve closure and the S2 is widely split and is most often fixed. Pulmonary hypertension hastens pulmonary valve closure; thus, the normal split may decrease or disappear as the aortic and pulmonic valves close simultaneously and a single, loud S2 is heard. Aortic valve stenosis can delay aortic valve closure, leading to a single, soft S2. In patients with complex congenital heart disease and only one semilunar valve, the S2 will be single. A loud single S2 is heard in transposition of the great vessels because the aortic is transposed anteriorly.

Third (*S3*) *and fourth* (*S4*) *heart sounds*: S3 and S4 are low-pitched diastolic sounds heard best with the bell. They correspond to early and late filling of the ventricles. S3 is heard in early/mid-diastole in the apical region. It can be a normal finding in children and adolescents. In a patient with heart failure and tachycardia, it is a sign of increased ventricular filling pressures (gallop rhythm). An S3 can also be heard in patients with volume overload of the left or right ventricles. In patients with constrictive pericarditis, the S3 is described as a "pericardial knock." S4 occurs later in diastole close to S1 during atrial contraction. It is heard best in adults in the apical region and occurs in the setting of elevated left ventricular filling pressures. It is rarely heard in infants or children and should not be confused with a split first sound in a normal heart.

Murmur algorithm. Figure 16.1 presents an algorithm for murmur evaluation that is based on the location of the murmur in the cardiac cycle, the acoustic quality of the murmur, and the location and radiation of the murmur on the chest wall. The initial step is to characterize timing of the murmur in the cardiac cycle. This is best done by determining the relationship of the murmur to S1 (beginning of systole) and S2 (end of systole) best heard at the left upper sternal border and inching slowly to the lower sternal border and apex, where initial identification may be difficult. Because of mechanical delay and normal tachycardia, the timing of the murmur relative to the pulse to determine if the murmur occurs in systole or diastole is not useful. The quality of the sound and the location and radiation of the murmur establish the underlying cardiac pathology (Fig. 16.2). By convention, the intensity of a systolic murmur is described on a scale of 1–6. The intensity of a diastolic murmur is described on a scale of 1–4 or 1–6.

Systolic murmurs: Systolic murmurs occur between S1 and S2. Systolic ejection murmurs are classified as ejection or holosystolic. The ejection murmur is a crescendo-decrescendo sound that starts in early systole and lasts a variable amount of during ejection of the blood from the ventricles. A systolic ejection murmur is diamond shaped, occurring as blood exits the ventricle through a stenotic or relatively stenotic outflow tract. The location where the ejection murmur is loudest, areas of radiation, and length are used to localize the murmur to the aortic or pulmonic area and determine severity. Long ejection murmurs are most significant, and can last until the end of systole. A holosystolic or pansystolic murmur occurs throughout systole from S1 to S2 and does not change in quality, although it may fade late in systole. Holosystolic murmurs are most often audible in patients with ventricular septal defects or atrioventricular valve regurgitation. They are heard at the left lower/mid-sternal border and apex. The murmur

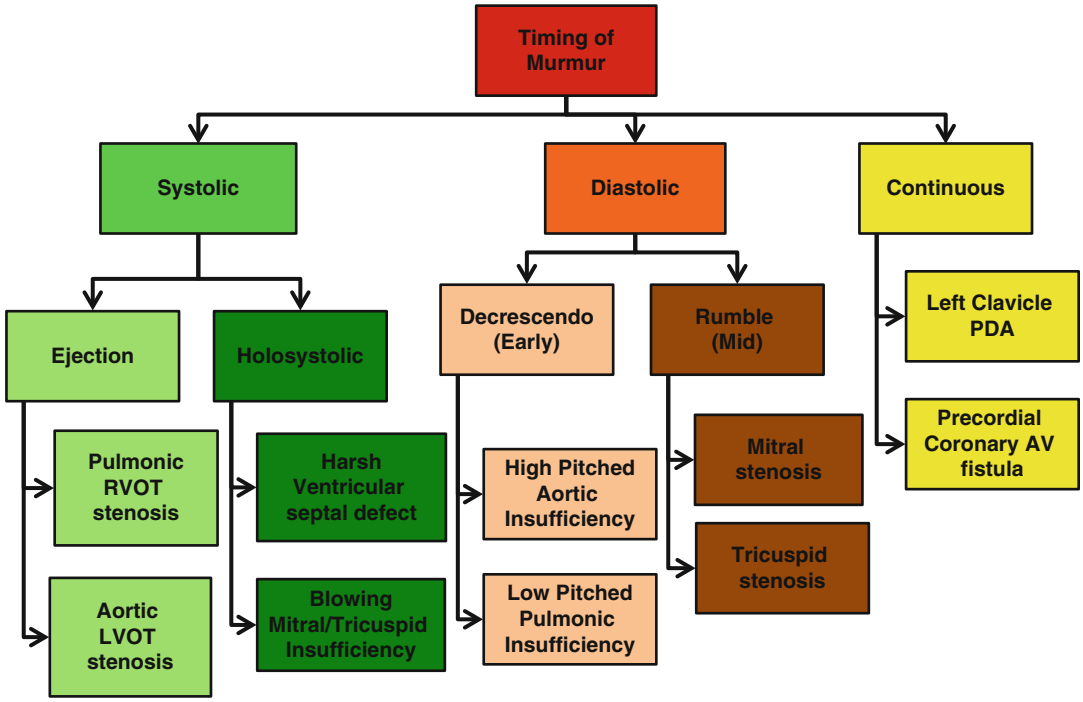

Fig. 16.1 Algorithm for evaluation of a heart murmur. *AV* atrioventricular, *LVOT* left ventricular outflow tract, *RVOT* right ventricular outflow tract

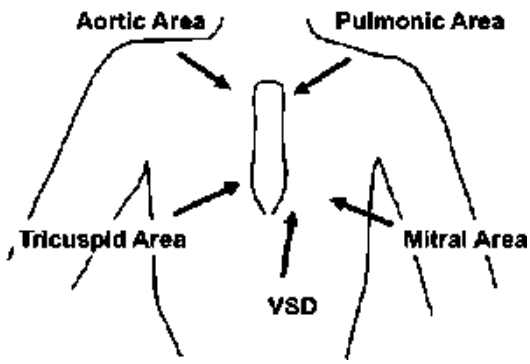

Fig. 16.2 Location of pathologic murmurs. *VSD* ventricular septal defect

associated with a ventricular septal defect is harsh and high-pitched and can radiate to the back. Tricuspid or mitral regurgitation murmurs are lower pitched, often are described as blowing, and may be identified by being loudest at the tricuspid or mitral areas and their pattern of radiation. The murmur of mitral insufficiency due to mitral valve prolapse has a holosystolic quality and a mitral location, but begins later in systole, beginning with a systolic click.

Diastolic murmurs: Diastolic murmurs occur between S2 and S1, and are either decrescendo or mid-diastolic. Decrescendo murmurs start simultaneously with S2 and decrease in intensity during diastole. They are heard best at the left mid-sternal border. Decrescendo murmurs are heard with aortic and pulmonic insufficiency. The murmur of aortic insufficiency is high-pitched, and pulmonary insufficiency is low-pitched. However, in the setting of pulmonary hypertension, the murmur of pulmonary insufficiency is high-pitched and has the quality of aortic insufficiency because of the markedly elevated pulmonary artery pressures. Mid-diastolic murmurs are low-pitched and heard best at the apex with the bell. They occur with stenosis or relative stenosis of the mitral or tricuspid valves. They are heard in the presence of large left-to-right shunts with increased flow across a normal mitral or tricuspid valve, or with significant valvar regurgitation.

Continuous murmurs: Continuous murmurs start at the beginning of S1 and are heard throughout S2 into diastole. A continuous murmur is a bruit and is heard in lesions where there is a direct connection between the arterial and venous circulations such as a patent ductus arteriosus or coronary arteriovenous fistula. The murmur of a patent ductus arteriosus is best heard in the left infra subclavicular region and has a "machinery" quality. The murmur of a coronary arteriovenous fistula is not prominent; it is heard best at the chest location that is close to the distal insertion of the fistula.

Flow murmurs: Most murmurs in children are not associated with heart disease and are referred to as functional or innocent. In young children, a flow murmur is a short systolic ejection murmur heard best at the left lower to mid-sternal border that does not radiate to the pulmonic or aortic areas. The quality of the murmur is most often vibratory and low-pitched, and the intensity is not greater than 3/6. In older children, a short flow murmur can be heard in the pulmonic outflow region. The absence of right ventricular hypertrophy or volume overload by electrocardiogram, and the lack of a widely split S2 or a diastolic murmur of relative tricuspid stenosis, can help distinguish this type of murmur from that of pulmonary stenosis or an atrial septal defect.

Venous hum: A venous hum can be mistaken for a continuous murmur. It is best heard in the clavicular region bilaterally. It is loudest when the patient is sitting and often disappears when the patient is supine or the head is turned to the side.

Pericardial rub: A pericardial rub is a sound that does not occur at a predictable interval in the cardiac cycle. It can be heard anywhere in the cardiac region and usually has a characteristic "rubbing or crackling," "extracardiac" sound that is higher pitched and variable in intensity and duration. A rub might also change quality with respirations.

Assessment of the Newborn

17

William Mahle

Abstract

Historically, the care of the newborn with congenital heart disease focused in large part on the diagnosis and delineation of the congenital heart anatomy. Now, with the ready availability of echocardiography, comprehensive assessment of intracardiac and great vessel anatomy can be completed expeditiously. Critical congenital heart disease frequently presents in the neonatal period. Most critical congenital heart lesions depend upon the need to maintain the patency of the ductus arteriosus to allow sufficient pulmonary or systemic blood flow. In recent years there has been an effort to enhance early detection of critical congenital heart disease with pulse oximetry screening.

Keywords

Brain natriuretic peptide • Critical congenital heart disease • Near-infrared spectroscopy • Pulse oximetry

Introduction

Congenital heart disease (CHD) occurs in 8 per 1,000 live births (Table 17.1) [1, 2]. CHD can be classified according to a number of schemes. Historically, these lesions have been considered based in large part upon the physiology, such as "left-to-right shunts" or "left heart obstructive lesions." Alternatively, lesions could be categorized based upon the need for intervention. Critical CHD has been defined variably but most commonly refers to lesions that require an intervention in the first month of life. It should be recognized that the majority of CHD lesions are not critical, and many never require surgical or transcatheter intervention. Yet, another way of classifying lesions, specifically critical CHD lesions, depends upon the need to maintain the patency of the ductus arteriosus to allow sufficient pulmonary or systemic blood flow. Understanding this categorization is of value once critical CHD is considered in the diagnosis of a neonate.

Historically, the care of the newborn with CHD focused in large part on the diagnosis and delineation of the congenital heart anatomy.

[c]Prevalence for critical CHD and all CHD is based on the number of infants and fetuses, not on the number of defects.

Table 17.2 CCHD lesions and associated clinical characteristics (Adapted from ref. [8])

Lesion	Hypoxemia	Ductus arteriosus dependent
Tetralogy of Fallot	Most	Uncommon
D-transposition of the great arteries	All	Uncommon
Double outlet right ventricle	Some	Some
Truncus arteriosus	All	None
TAPVC	All	None
Ebstein's anomaly	Some	Some
Right obstructive defects		
Tricuspid atresia	All	Some
Pulmonary atresia, intact septum	All	All
Pulmonic stenosis, atresia	Some	Some
Left obstructive defects		
Hypoplastic left heart	All	All
Coarctation of the aorta	Some	Some
Aortic arch atresia or hypoplasia	Some	All
Aortic valve stenosis (critical)	Uncommon	Some
Other major heart defects	Some	Some

TAPVC total anomalous pulmonary venous connection

Currently, with the ready availability of echocardiography, comprehensive assessment of intracardiac and great vessel anatomy can be completed expeditiously. Multiple imaging modalities are seldom required. However, in order to identify CHD, it is important to first recognize that a given newborn may have a heart condition. Obviously, such concerns are raised when a prenatal ultrasound suggests a heart defect. Also, there are physical examination findings that suggest CHD (see chapter dedicated to History and Physical Examination in this textbook). However, in some cases, the signs and symptoms of CHD may be very subtle or absent altogether. In such cases it is important to consider supplementary studies or assays to provide clues to congenital heart disease (Table 17.2).

In recent years there has been an effort to enhance early detection of CHD with pulse oximetry screening [3]. The strategy is based upon the principle that the majority of critical CHD lesions have some degree of hypoxemia but often do not manifest with overt cyanosis. Typically, the arterial saturations are less than 96 %, the lower limit of normal values at 24 h of life, but higher than 80 %, the saturation likely to produce obvious cyanosis in most neonates [4]. Given that many CHD lesions have subtle heart murmurs or no murmurs at all, the clinical exam can miss the diagnosis of life-threatening CHD. A number of studies have demonstrated that the routine assessment of an otherwise healthy newborn with pulse oximetry can identify neonates who would otherwise be discharged home to the newborn nursery only to later present with impaired systemic perfusion and in rare cases shock or death [5, 6].

The strategy of enhancing neonatal critical CHD detection with pulse oximetry is now employed in numerous birthing centers in the United States, Europe, and elsewhere. The technique uses commercially available oximeters, and screening can readily be incorporated into routine newborn care. Detailed algorithms for screening cutoffs have been published [7]. If the screen is positive, further cardiac evaluation is recommended. The most reliable way to establish the diagnosis is to obtain a complete echocardiogram prior to discharge home. When echocardiography is not readily available, caregivers must consider alternative strategies to assess the newborn with hypoxemia, which may involve transfer to a tertiary center in some cases.

A number of publications have detailed the strengths and weaknesses of this screening program. The false-positive rate, using a strategy of repeated measurements, is below 0.5 % [8]. It is important for the clinician to recognize that pulse oximetry screening has an overall sensitivity of just above 70 % for all critical CHD lesions and approximately 50 % for certain left heart lesions like coarctation of the aorta. As such, knowledge of a "passed" pulse oximetry screen should not eliminate the consideration of critical CHD, especially obstructive left heart lesions (Fig. 17.1).

Other screening tools that can be used in the assessment of the newborn with possible CHD are serum biomarkers. Serum b-type natriuretic peptide (BNP) is part of a family of natriuretic peptides that affect the cardiovascular system. The natriuretic peptides are produced primarily by myocardial tissue in response to wall stress, modifying vascular tone, and volume homeostasis. BNP activates the membrane-bound guanylate cyclase-A receptor, with resultant smooth muscle and cardiac myocyte relaxation properties. In adults, the use of BNP has been well demonstrated to be an accurate marker of cardiac disease and can be beneficial in differentiating pulmonary from cardiac disease in the acute care setting. BNP has become a routine assay in the management of children with known heart failure or low cardiac output.

BNP may be particularly valuable in the assessment of the newborn with suspected CHD. A common clinical scenario is the newborn with evidence of shock presenting at several days of age. Septic shock is the most likely etiology. However, the clinical features can overlap with the presentation of cardiac shock from critical CHD, such as hypoplastic left heart syndrome. It has been shown that serum BNP, which can be processed relatively rapidly in an emergency department, is an excellent discriminator of heart disease from other entities. Maher and colleagues found that at presentation, the median serum BNP exceeded 2,000 pg/nl for a number of critical CHD lesions, including coarctation of the aorta, whereas the median value for other neonates evaluated in the emergency department was less than 20 pg/nl [9, 10] (Fig. 17.2). This diagnostic assay is particularly valuable when the index of suspicion for critical CHD is low or when congenital heart echocardiography is not readily available. If the serum BNP suggests probable CHD or myocardial failure, the initial steps would be to initiate prostaglandin therapy and provide agents to enhance cardiac output such as inotropes.

A chest x-ray is often routinely obtained in an evaluation of a newborn to CHD. While the chest x-ray no longer plays a major role in the precise anatomic delineation of complex congenital heart disease, it still can provide several key diagnostic

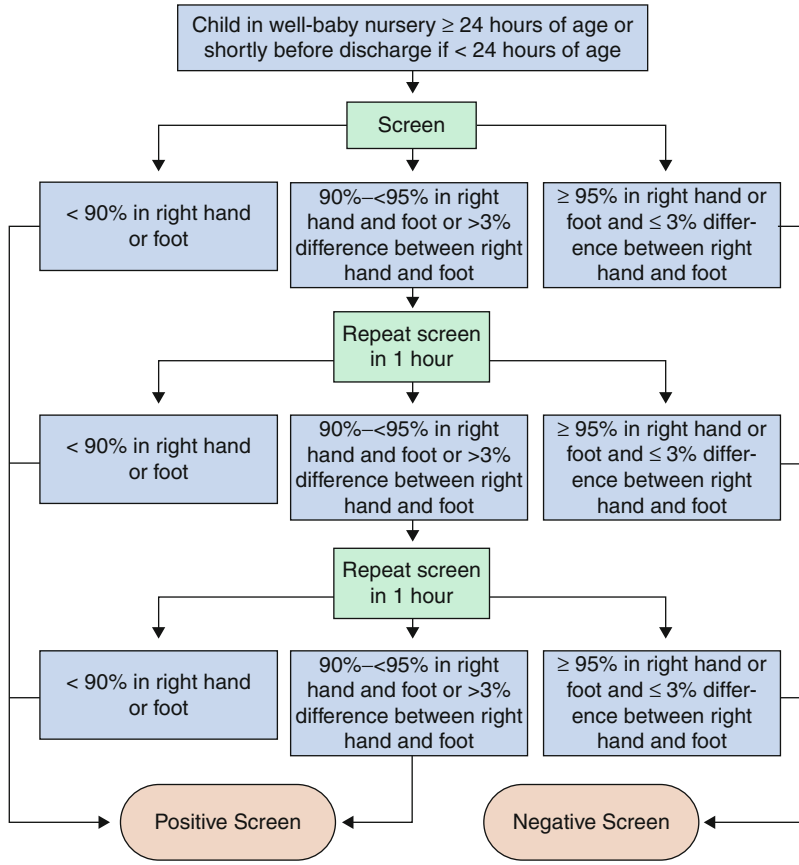

Fig. 17.1 Children in the well-baby nursery are screened at 24 h of life or later or shortly before discharge if discharged earlier than 24 h of life. An oxygen saturation measure less than 90 % in the right hand or foot is considered a positive screen (in the initial screen or in repeat screens). An oxygen saturation measure of 95 % or greater in the right hand or foot with 3 % or less absolute difference in oxygen saturation between the right hand and foot is considered a negative screen (in the initial screen or in repeat screens), and screening ends. If the oxygen saturation is 90 % or above but less than 95 % in the right hand and foot or the absolute difference in oxygen saturation between the right hand and foot is greater than 3 %, the screen is repeated in an hour. If the results are in the same range, the screen is again repeated in an hour. A third measure of oxygen saturation 90 % or above but less than 95 % in the right hand and foot or absolute difference in oxygen saturation between the right hand and foot greater than 3 % is then considered a positive screen http://www.cdc.gov/ncbddd/pediatricgenetics/pulse.html

insights that are valuable in assessing a newborn with suspected or known heart disease. In the newborn with suspected heart disease, the chest x-ray can be diagnostic when classic features are present such as the appearance of the right heart contour in severe forms of tetralogy of Fallot or in Ebstein's anomaly. On occasion, incidental findings on the chest x-ray may suggest cardiac or vascular disorders, such as the presence of a right aortic arch in a child with respiratory findings and a vascular ring.

The features that the chest x-ray can evaluate include the following:

Heart Size: Chest x-ray provides important insights into the overall heart size. Heart size is often described relative to the thoracic width. A satisfactory diagnostic chest x-ray typically shows the diagram at a level that of the 9th or 10th rib. Typically, the heart size is described as a cardiothoracic ratio. This is obtained by dividing the transverse diameter of a heart by the thorax based upon a posterior to anterior view.

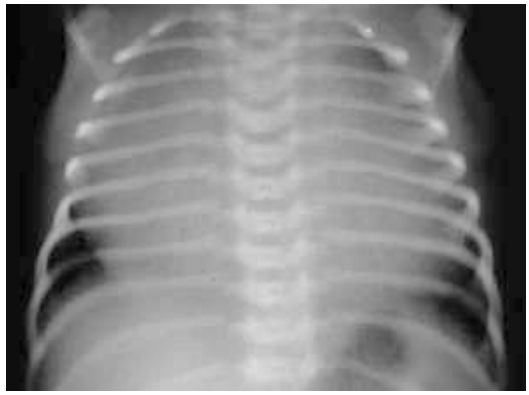

Fig. 17.2 This posterior to anterior chest film demonstrates marked cardiomegaly and is characteristic of Ebstein's anomaly

Fig. 17.3 This posterior to anterior chest film demonstrates normal heart size and normal cardiovascular markings in a newborn with hypoplastic left heart syndrome

Cardiomegaly is present when the cardiothoracic ratio exceeds 0.6 in infants. In some cases, such as Ebstein's anomaly, severe cardiomegaly is highly suggestive of the underlying cardiac defect (Fig. 17.3). An elevated cardiothoracic ratio is particularly valuable in identifying cardiomegaly when the left ventricle is enlarged but not always as accurate when the right ventricle is the chamber that is predominantly enlarged. In this situation, the AP view can appear normal even in severe lesions such as hypoplastic left heart syndrome (Fig. 17.4). Complementary orthogonal views can sometimes provide information about other cardiac chambers. The right atrial size is easily assessed in the AP view. The lateral projection is more valuable in assessing left atrial enlargement as evidenced by indentation of the esophagus or in advanced stages compression of the left main bronchus. Right ventricular enlargement is also seen in a lateral projection by filling of the retrosternal space. The presence of a thymus may limit the utility of this finding. Interpretation of the chest x-ray in the newborn always needs to consider the presence of the thymus which can be a relatively large structure and overlies the anterior right ventricle. The thymus may be confused for cardiac or great vessel structures. Absence of a thymus in a newborn would be supportive for the diagnosis of 22q11 deletion (DiGeorge syndrome).

Pulmonary Vascularity: The chest x-ray is particularly valuable in assessing pulmonary vascularity. In order to assess this properly, it is imperative that appropriate penetration of x-ray be performed. The clinician needs to be able to distinguish increased arterial markings from increased venous congestion. In some conditions, such as a large intracardiac shunt with a large ventricular septal defect, both these features may be present. However, in conditions such as total anomalous pulmonary venous connection, venous congestion is more prominent than increased arterial markings.

Chest x-ray is invaluable in the assessment of CHD lesions associated with cyanosis. The degree of pulmonary blood flow (decreased, normal, or increased) can provide important diagnostic information that is not available from echocardiography. The finding of decreased pulmonary markings prompts the clinician to look for lesions associated with limited pulmonary blood flow such as tetralogy of Fallot, pulmonary atresia or stenosis, or tricuspid atresia. Cyanotic infants

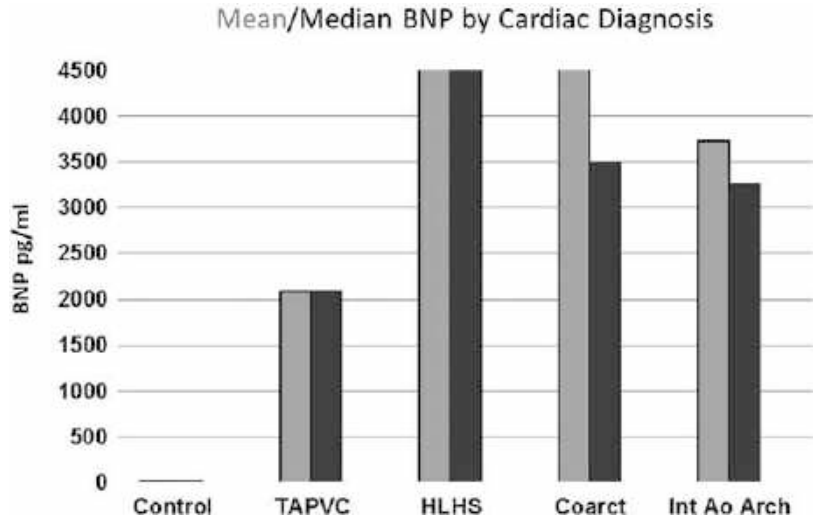

Fig. 17.4 The median and mean serum BNP values for four critical CHD lesions at presentation as compared to age-matched controls. COARCT, coarctation of the aorta; HLHS, hypoplastic left heart syndrome; Inter Ao Arch, interrupted aortic arch; TAPVC, total anomalous pulmonary venous connection (Adapted from Maher et al. [9])

with increased pulmonary blood flow are likely to have ductal-dependent systemic circulation or obstruction to pulmonary venous return. As such the chest x-ray serves as a critical complimentary imaging modality to echocardiography.

The chest x-ray also provides valuable insights into the great vessel anatomy. Arch sidedness can be determined with a high degree of accuracy on the chest x-ray. This is important since the delineation of great vessel structure and branching may present a challenge with echocardiography. A missed diagnosis of a right aortic arch or double aortic arch is one of the more common diagnostic errors seen in congenital echocardiography. The chest x-ray may prompt the clinician to further examine the great vessels structure with alternative imaging strategies such as CAT scan or a cardiac MRI study.

The chest x-ray also provides insights to abnormalities in cardiac position or situs such as mesocardia or dextrocardia. This is important in the setting of visceroatrial situs anomalies such as heterotaxy. In cases of right atrial isomerism, the relationship of the pulmonary artery to the bronchus is eparterial, and in left atrial isomerism, the relationship is hyparterial. Symmetry of the bronchial air pattern is seen in such cases. The left bronchus is longer than the right bronchus and may be a helpful clue in determining left or right isomerism. The chest x-ray is also helpful in identifying extracardiac anomalies which occur relatively commonly in association with both minor and major CHD lesions. These can include a feature such as eventration of the diaphragm or more severe variants such as diaphragmatic hernia. While such findings are not necessarily contraindications to a cardiac repair or palliation, preoperative identification is critical to successful planning of the surgical intervention.

Evaluation of the Newborn After Diagnosis of CHD is Made

Serum Laboratory Testing

Serum laboratory studies are essential to the assessment of a newborn to CHD. Typically the newborn assessment includes a complete blood count, a chemistry panel, as well as measures of the coagulation system.

The complete blood count is usually assessed in the newborn with suspected heart disease and may provide information that can aid in differential diagnosis and management. The serum hemoglobin is usually normal in a newborn or in an infant with heart disease (14–16 gm/dl). Anemia may be a sign of hemolysis or an underlying systemic disease. The presence of polycythemia can identify the recipient of a twin-twin transfusion at risk for pulmonary hypertension. The platelet count is typically normal in a newborn

with congenital heart disease. If thrombocytopenia is present, this may suggest newborn infection or rare genetic disorders such as Jacobsen syndrome [11]. The white blood cell count may help differentiate sepsis from CHD in a neonate who presents with shock. In such cases, addition of a CRP level may help identify a nascent infection. In addition, some investigators have suggested that the serum lymphocyte count may be a biomarker that can predict outcomes following surgery. A low serum lymphocyte count has been associated with an increased risk of mortality as well as complications in adult cardiovascular disease and CHD [12].

The results of an arterial blood gas are often helpful in a newborn with suspected heart disease. In a cyanotic newborn, a hyperoxia test can distinguish a neonate with a congenital heart defect from one with a primary pulmonary disease. A hyperoxia test is positive if the arterial oxygen tension is no higher than 60 Torr when 100 % oxygen is administered. Metabolic acidosis is one of the hallmarks of impaired systemic perfusion. Serum pH below 7.1 not uncommonly occurs in newborns with ductal-dependent systemic blood flow after the ductus has closed. This is particularly the case with a delayed diagnosis of lesions such as the hypoplastic left heart syndrome. Serum lactate is often the mechanism of acidosis in these cases because of impaired tissue perfusion leading to the formation of lactic acid [13]. Elevated serum lactate levels and acidosis prompt the clinician to institute measures to improve oxygenation and myocardial performance and decrease metabolic demand [14]. Serum bicarbonate is often administered to increase the serum pH, although the evidence to support a strategy remains somewhat controversial.

Serum BNP may be of value in the preoperative management of newborn with CHD [15]. The change in serum BNP following medical therapy has been shown to be predictive of subsequent outcome [16]. A persistently elevated BNP following the administration of prostaglandin E_1 in a ductal-dependent left heart lesion may justify instituting other interventions to improve cardiac output and decrease metabolic demand such as inotropic support and mechanical ventilation.

The continuous measurement of arterial saturation by pulse oximetry is universally performed in the newborn with critical heart disease. Newer generation oximeters can effectively measure the oxygen saturation even in low perfusion states [17]. Determining the optimal oxygen saturation in a newborn with congenital heart disease requires an understanding of the impact of the pulmonary and systemic vascular resistances on cardiac output and systemic blood flow. In ductal-dependent lesions, an oxygen saturation >85 % is indicative of a high pulmonary-to-systemic blood flow ratio which can lead to congestive heart failure and inadequate systemic perfusion. In patients with a ductal-dependent systemic circulation, such as hypoplastic left heart syndrome, the use of measures that increase pulmonary vascular resistance such as subatmospheric oxygen or hypercapnia (either with the administration of carbon dioxide or permissive ventilator settings) has been proposed to balance the pulmonary-to-systemic blood flow ratio. The arterial oxygen saturation is then titrated to a level that provides adequate tissue oxygenation yet limits the volume overload to the ventricle. Tabbutt and colleagues demonstrated that systemic oxygen delivery can be increased with a strategy of hypercapnia, but not with hypoxia [18]. Nonetheless, this strategy has been largely abandoned due to the resultant marked tachypnea. Avoidance of supplemental oxygen has been accepted as a relatively benign intervention that may maintain an elevated pulmonary vascular resistance in these cases. In newborns with ductal-dependent pulmonary blood flow, some investigators have attempted to limit pulmonary blood flow by lowering the prostaglandin E_1 to pharmacologically manipulate the size of the ductus arteriosus with inconsistent results. In cases where the balance of the pulmonary-to-systemic blood flow in ductal-dependent lesions is unacceptable, the best strategy may be to proceed with surgical palliation.

Arterial oxygen saturation is not a measure of tissue oxygen demands and hence is insufficient to accurately assess oxygen delivery. Mixed venous saturations combined with arterial saturations can provide more precise information

regarding oxygen delivery [19, 20]. However, mixed venous oxygen saturation may be difficult to obtain in mixing lesions, and repeated measures are not practical especially in a newborn. Near-infrared spectroscopy (NIRs) can be used to measure regional cerebral tissue oxygen saturation (rSO_2). This technique uses principles of optical spectrophotometry that make use of the fact that biological material, including the skull, is relatively transparent in the NIRS range. There are numerous publications regarding the use of both cerebral and splanchnic NIRS to monitor young children following congenital heart surgery [19, 20]. NIRS is also used by many centers prior to neonatal surgery to infer whether oxygen delivery is satisfactory. Some studies report that splanchnic NIRS can identify subjects at greatest risk of developing necrotizing enterocolitis [21]. The use of NIRS as a standard monitoring strategy has not been validated and is not routine at many centers.

Extracardiac abnormalities are common in newborns with critical CHD. Screening for neurologic, renal, gastrointestinal, skeletal, and genetic diseases should be considered, depending on the defect and the clinical situation. Many centers are performing brain imaging in newborns with critical CHD. The majority of centers in North America typically obtain a cranial ultrasound in a newborn prior to a heart surgery [22]. The rationale for this approach is that the preoperative detection of intracranial hemorrhage may identify newborns at risk for further hemorrhage when receiving anticoagulation during cardiac surgery. The utility of this practice has been called in to question because of data indicating that cranial ultrasound fails to identify significant parenchymal bleeding in many cases and the findings considered worrisome often turn out to be minor or artifactual. In addition, a number of studies have now demonstrated that preoperative parenchymal hemorrhage seldom extends after surgery using cardiopulmonary bypass [23]. Cranial ultrasound is useful in the detection of structural brain anomalies. Absence of the corpus callosum or hydrocephalus has been described in children with severe heart disease such as hypoplastic left heart syndrome [24]. Recent MRI studies, however, have suggested these brain lesions are relatively rare [25]. Therefore, unless a caregiver suspects a genetic syndrome with a high risk of structural brain anomalies, a preoperative cranial ultrasound is probably not indicated. Several large research studies have reported MRI evidence of brain injury in up to 20 % of newborns with critical CHD prior to neonatal surgery [23, 26]. Typically, the degree of brain injury is relatively mild with findings such as parenchymal hemorrhage or mild periventricular leukomalacia. Preoperative brain MRI imaging is not considered standard of care.

Renal ultrasounds are often performed prior to newborn infant heart surgery to identify structural anomalies of kidneys or a single kidney [27]. Similar to cranial ultrasound, the yield of these studies is a relatively low. A structural kidney abnormality with no evidence of impaired renal function is unlikely to alter the decision to take a child to the operating room for palliative or reparative heart surgery. Therefore, even though it is noninvasive and relatively inexpensive, a routine preoperative renal ultrasound is not indicated.

Abdominal ultrasound may also be used to look for intestinal anomalies such as malrotation. In cases of heterotaxy, malrotation may be present in up to 70 % of cases [28]. Many centers routinely screen for malrotation at the time of presentation. An elective Ladd's procedure may be performed to eliminate the possibility of volvulus [29]. The risk of volvulus in these cases is not known and may be low. Typically centers undertake such a procedure only after the definitive neonatal cardiac procedure has been performed. An abdominal ultrasound will also define that the splenic anatomy is often abnormal in the setting of heterotaxy. If asplenia or polysplenia is identified, use of prophylactic antibiotics can be instituted.

Assessment of the Athlete for Sports Participation

18

Joshua Kovach and Stuart Berger

Abstract

The assessment of the athlete for sports participation remains important as a means to identify those individuals who may have an underlying cardiovascular anomaly that increases their risk for sudden cardiac arrest during practice or competition. The basic requirements for assessment include a thorough history and physical examination. The use of a routine screening electrocardiogram (ECG) and/or echocardiogram remains controversial, though the specificity of ECG screening continues to improve as criteria specific to the athletic population are developed and tested. Given its versatility for screening for multiple structural and electrical cardiovascular anomalies, the ECG is often the first ancillary test performed when concern arises during the initial evaluation. Echocardiography, exercise stress testing, ambulatory ECG monitoring, and chest radiography provide additional diagnostic information when concerning historical or examination findings are uncovered.

Introduction

Athletic participation has many benefits for children and adolescents that promote both physical and mental health. Pre-participation screening for athletes is recommended in many states in the United States and has been legally required in Italy since 1982 [24]. A key component of screening the young athlete for sports participation revolves around the identification of underlying cardiovascular disease that may increase the athlete's risk for sudden cardiac arrest during sports participation. Although these diseases are thought to be relatively rare events, their reported incidence varies widely in the literature depending on the reporting mechanisms and the particular target populations [10, 13, 23, 25]. Indeed, underlying cardiovascular disease is the leading cause of sudden death during athletic competition [22]. These cryptic illnesses include both structural and electrical cardiovascular anomalies, such as cardiomyopathies, coronary arterial anomalies, and channelopathies. Screening efforts have been largely successful in identifying individuals with underlying cardiovascular disease so that appropriate intervention can be executed, but the sensitivity of screening has its limitations [2, 27]. Regardless of the extent to which screening is performed, there remains a small percentage of athletes who will unfortunately experience a sudden cardiac arrest [4, 26, 33].

Based on the most recent estimates [17, 24], there are over eight million competitive athletes in the United States participating at middle school, high school, collegiate, and professional levels. Both the American Heart Association (AHA) and the European Society of Cardiology (ESC) have published screening guidelines for athletic participation [3, 24], with the essential difference revolving around the inclusion of routine ECG screening. Most collegiate and professional sports leagues have developed individualized screening practices that are often more extensive than the routine screening performed in middle and high school athletes [24]. Despite screening efforts at these varying levels of competition, rare sudden cardiac events still occur and remain unpredictable. These events are quite traumatic to the family and community members involved. While there are often calls for enhanced screening protocols after an event or series of events, the efficacy of pre-participation screening remains limited due to the relative infrequency of events and the limited cost-effectiveness of widespread screening practices.

Causes of Sudden Cardiac Arrest

The physiologic changes associated with exercise inflict a number of stressful stimuli upon the myocardium. The demand of skeletal muscle for increased perfusion during periods of intense physical activity requires a compensatory increase in cardiac output. This is achieved by an increase in sympathetic tone to the conduction tissues that increases heart rate and accelerates conduction, as well as adrenergic stimulation of the myocardium itself that improves contractility and augments stroke volume. This compensatory stimulation in turn increases myocardial oxygen demand. The combination of increased metabolic demand with electrophysiologic alterations in membrane conduction and repolarization from sympathetic stimulation can result in significant myocardial vulnerability to ischemia or triggered arrhythmia in a susceptible individual. In many cardiovascular anomalies, this leads to the final common pathway of sudden arrest secondary to ventricular tachycardia and/or fibrillation. In patients with underlying connective tissue disorders, sudden cardiac arrest can occur because increased pressure generated during intense exercise leads to dissection or rupture of a dilated aorta.

The etiologies underlying sudden cardiac arrest in the athlete have been well described based on autopsy and population studies [4, 22, 25]. Hypertrophic cardiomyopathy consistently remains the primary cause in the United States. Other myopathies may also increase an

individual's risk, including arrhythmogenic right ventricular cardiomyopathy/dysplasia (ARVC/D), dilated cardiomyopathy (idiopathic or secondary), and left ventricular non-compaction. Acute myocarditis has also been identified at autopsy in a small number of individuals who have experienced sudden cardiac death. Associated congenital cardiac defects include anomalies of the coronary artery origins or branching and aortic valve stenosis. Various inherited channelopathies are also associated with sudden events, such as congenital long QT syndrome, catecholaminergic polymorphic ventricular tachycardia (CPVT), and Brugada syndrome. Additional arrhythmic causes could include Wolff-Parkinson-White (WPW) syndrome and progressive conduction deficits.

Table 18.1 AHA recommended 12 elements for pre-participation CV screening [24]

Personal history
1. Exertional chest pain
2. Unexplained syncope or near-syncope
3. Excessive exertional dyspnea or fatigue
4. Previous history of a heart murmur
5. History of systemic hypertension
Family history
1. Premature cardiac death prior to 50 years of age
2. Disability secondary to CV disease prior to 50 years of age
3. Knowledge of specific cardiac condition
Physical examination
1. Heart murmur
2. Absent or diminished femoral pulses
3. Physical manifestations of Marfan syndrome
4. Elevated blood pressure (brachial)

Screening for Cardiovascular Disease

According to current AHA recommendations [24], the initial screening of the athlete should be performed in the primary care setting prior to authorization for participation. The crux of screening revolves around a thorough history and physical examination, utilizing a 12-element screening protocol. Certain red flags have been identified that warrant additional evaluation by a subspecialist to further screen for underlying cardiovascular disease (Table 18.1). Unfortunately, compliance with these guidelines by general practitioners remains suboptimal [12]. Studies evaluating screening practices by general practitioners in the state of Washington have identified glaring inconsistencies in the execution of the pre-participation visit [17]. This has been attributed to incomplete education of providers, unfamiliarity with guidelines, or insufficient resources to perform screening appropriately. The use of screening tools to educate providers has improved their performance during screening, but overall compliance remains imperfect. In certain states, practitioners such as naturopaths or chiropractors are permitted to provide participation clearance [12]. In contrast, in Italy screening is performed solely by individuals with specific training in sports medicine [3, 4].

While many dangerous cardiac abnormalities can be diagnosed via ECG and/or echocardiography, studies have suggested that the sensitivity of the history and physical is low for certain diseases [2, 18, 27]. Channelopathies due to a primary spontaneous mutation or with variable penetrance may be clinically silent, and the family history may be negative. Individuals with HCM may not have symptoms or a positive family history, and the physical examination may be normal. This has led many centers, collegiate programs, and professional leagues to include mandatory ECG screening as part of their routine evaluation [19, 24].

Even with ECG and echocardiographic screening, false negatives can result if disorders such as HCM or channelopathies such as long QT syndrome are present. The distinction between compensatory ventricular hypertrophy in a trained athlete and HCM can be difficult to make. Certain channelopathy phenotypes can have subtle or transient findings on ECG, limiting the ability to make a diagnosis at a single point in time. Therefore, even if an athlete is cleared for sport participation, continued vigilance and

appropriate counseling of athletes, parents, and coaches is necessary to ensure that further steps are taken if concerning symptoms begin to manifest.

History

A thorough history should be performed, asking particularly about symptoms that occur during exercise or exertion. Symptoms of concern include reproducible chest pain, dizziness, palpitations, or dyspnea. Any episode of syncope during activity should be taken seriously and warrants further evaluation. Questions about joint laxity or hypermobility or previous vision problems should be pursued. The clinician should also take the opportunity to ask about any supplements or drugs that the athlete may be utilizing that could potentially be detrimental. Questions about murmurs noted on previous physical exams should be posed to the family. It is recommended that information provided by the athlete should be confirmed by a parent or guardian when possible.

In addition to personal history, a thorough family history should also be obtained. This includes particular attention to family members that died suddenly or unexpectedly before the age of 50 years. Previous studies have suggested that most sudden events during middle age and beyond are related to underlying atherosclerotic coronary artery disease [10]. A history of family members with early cardiac disability may suggest a possible underlying cardiomyopathy. Special consideration should be given to sudden events that were triggered with activity, swimming, or uncertain circumstances. A family history of pacemaker or implantable cardioverter-defibrillator (ICD) implant may suggest the presence of an underlying channelopathy or cardiomyopathy. A history of recurrent congenital deafness may raise suspicion for autosomal recessive forms of congenital long QT syndrome. Family history suggestive of connective tissue disorders should also be pursued, including relatives with recurrent vision problems, valvular or aortic anomalies, or joint hypermobility.

Physical Exam

The physical exam largely revolves around the cardiovascular exam, as many cardiovascular diseases of concern rarely involve other organ systems in an otherwise healthy patient. The exam should focus on accurate blood pressure measurement, the presence of murmurs or other abnormal auscultatory findings, evaluation of peripheral pulses and perfusion, and assessment for extracardiac manifestations of structural heart disease. Physical maneuvers to augment murmur auscultation, such as position changes and Valsalva, should be performed. Particular attention should be given to anatomic features of an underlying connective tissue disorder, such as limb-length discrepancy or pectus deformities. The basic diagnostic criteria and stigmata of Marfan syndrome are listed in Tables 18.2 and 18.3 [16].

Ancillary Testing During Screening

If concerning signs or symptoms are identified in the history and/or physical examination, additional testing may be warranted in order to arrive at a definitive diagnosis. The particular testing indicated and the extent of testing depend on the information uncovered during the primary evaluation.

Electrocardiogram

The ECG provides data that can be diagnostic of underlying structural heart disease, electrical anomalies, or cardiomyopathy. Studies have shown that there can be inconsistencies in the interpretation of the ECG by screening providers [14], though with specific training the diagnostic yield can improve significantly [6, 29]. Specific criteria have recently been developed by the ESC that better differentiate between the normal and benign ECG changes observed in the conditioned athletes from those that may signify underlying cardiovascular disease [5].

ECG Findings in the Athlete: Due to conditioning and changes in autonomic tone, there are

Table 18.2 Ghent criteria for the diagnosis of Marfan syndrome [16]

Positive family history of Marfan syndrome and one of the following criteria	Negative family history of Marfan syndrome
1. Ectopia lentis	1. Aortic root dilation Z ≥ 2.0 AND
	(a) Ectopia lentis
	(b) FBN1 mutation
	(c) Systemic score ≥7
2. Systemic score ≥7 (see Table 18.3)	2. Ectopia lentis and FBN1 mutation with known aortic root aneurysm
3. Aortic root dilation	
(a) Age ≥20 years; Z ≥ 2.0	
(b) Age <20 years; Z ≥ 3.0	

Table 18.3 Systemic features suggestive of Marfan syndrome [16]

Characteristic facial features
Myopia
Dural ectasia
Pneumothorax
Pectus deformity
Scoliosis or thoracolumbar kyphosis
Reduced upper segment to lower segment ratio
Mitral valve prolapse
Wrist and/or thumb sign
Reduced elbow extension
Protrusio acetabuli
Striae
Hindfoot deformity or pes planus

multiple benign alterations that are seen on the athlete's ECG [5, 7, 34]. Increased vagal tone can result in sinus bradycardia, sinus arrhythmia, and Mobitz I second-degree AV block (Wenckebach). Early repolarization patterns in the precordial leads are frequently found, with various patterns particularly observed in athletes of African descent. The benign hypertrophy observed in the heart of endurance athletes can manifest as increased S/R wave voltages in the precordial leads (Fig. 18.1). The use of increased precordial voltage criteria alone for LVH associated with HCM has a low specificity.

ECG in Cardiomyopathies: Because of the limited specificity of voltage criteria for HCM in athletes, attention has shifted instead to the other ECG changes associated with pathologic hypertrophy [5, 9]. These include T wave inversion in leads I and aVL or the left precordial leads, along with left axis deviation (Fig. 18.2). Deep Q waves >3 mm or wider than 40 ms in two or more leads may suggest septal hypertrophy. Left atrial enlargement can be observed when sufficient diastolic dysfunction has developed. Of note, dilated cardiomyopathy and LV noncompaction demonstrate similar electrical abnormalities to HCM, specifically left axis deviation, repolarization abnormalities, and left atrial enlargement.

The ECG criteria for ARVC/D remain among the most sensitive screening modalities for this inherited cardiomyopathy [20]. Abnormalities are primarily observed in the right precordial leads V1–V3 and include T wave inversion in these leads or slurring of the terminal S wave >60 ms (Fig. 18.3). An epsilon wave, which is a small depolarization after the QRS complex, is a major criterion for the diagnosis of ARVC/D. The presence of ventricular ectopy or nonsustained ventricular tachycardia originating from the superior RV with a left bundle branch block (LBBB) pattern is also highly supportive of this diagnosis. Occasionally an incomplete or complete right bundle branch block (RBBB) pattern can be observed as evidence of delayed RV depolarization secondary to the extensive fibrosis.

ECG in Channelopathies: Repolarization abnormalities are often indicative of an underlying channelopathy [8]. The most prevalent

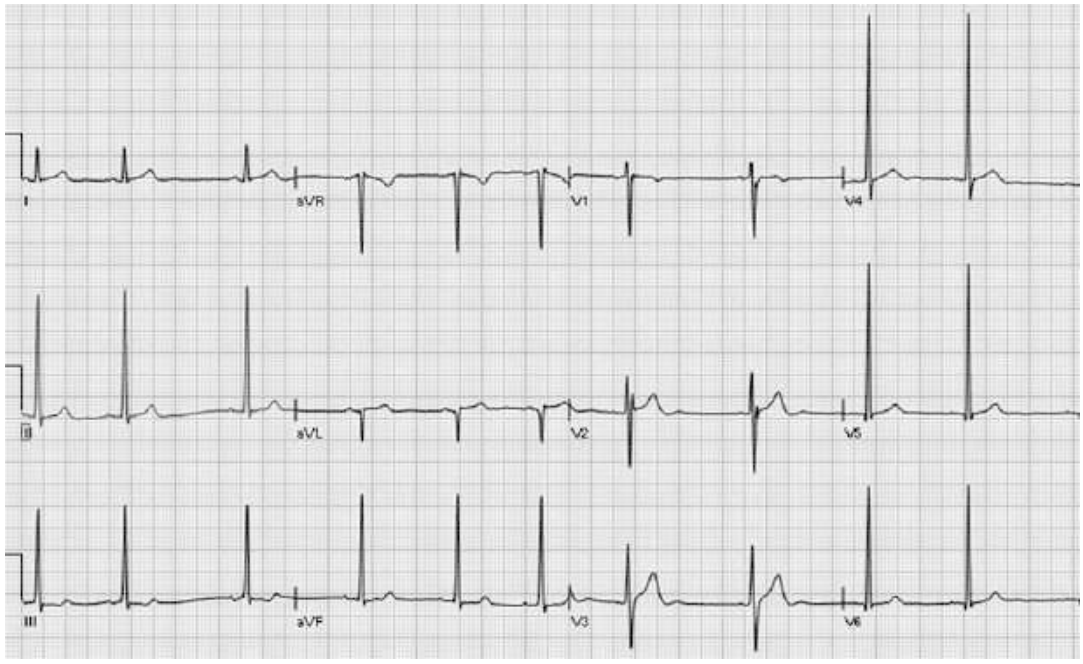

Fig. 18.1 An electrocardiogram from an athlete demonstrating voltage criteria for left ventricular hypertrophy, sinus bradycardia with sinus arrhythmia, and early repolarization pattern in the precordial leads

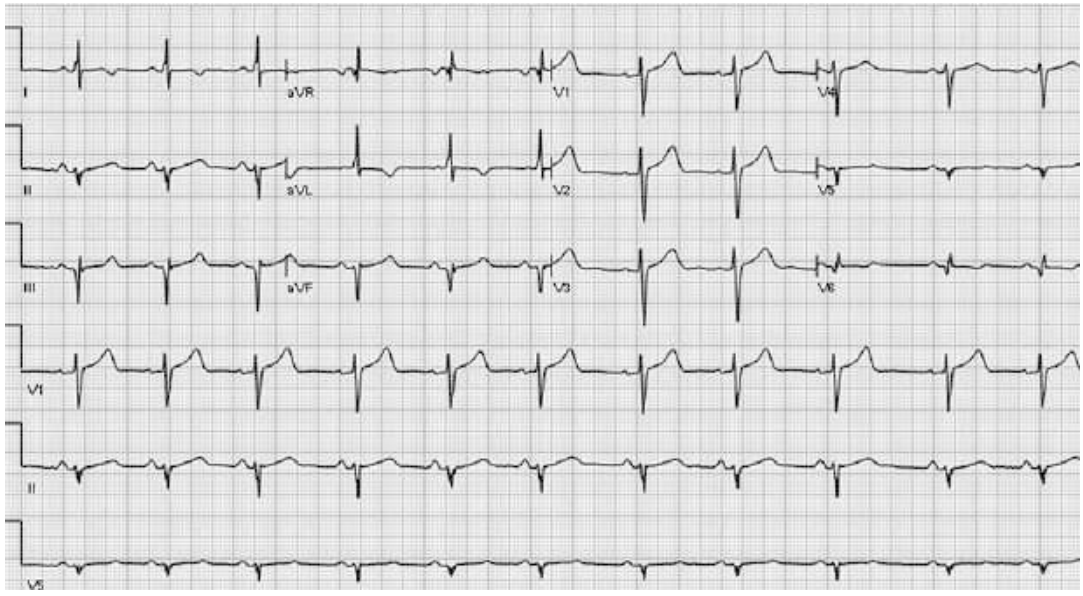

Fig. 18.2 An electrocardiogram from a patient with severe hypertrophic cardiomyopathy. His ventricular voltages are within normal range, though he has evidence of left axis deviation and T wave inversion in lead I

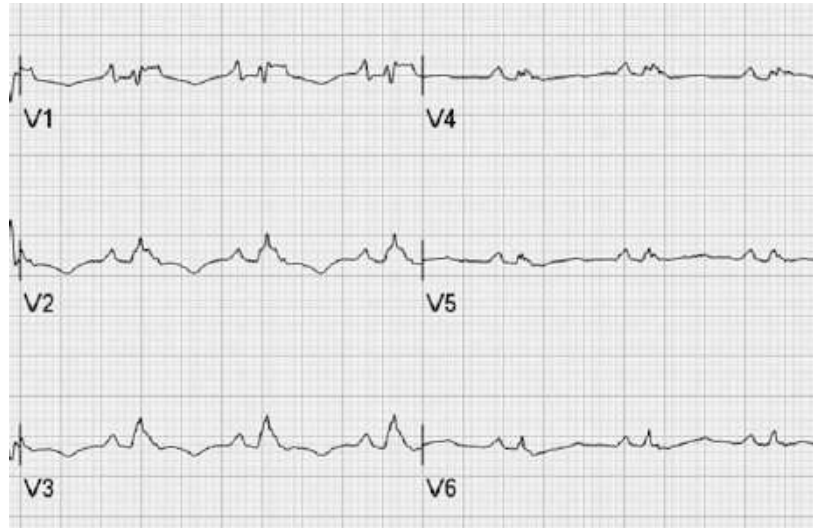

Fig. 18.3 Precordial leads from an electrocardiogram of a patient with arrhythmogenic right ventricular cardiomyopathy (ARVC), demonstrating T-wave inversion in leads V1–V3, RV conduction delay, and epsilon waves

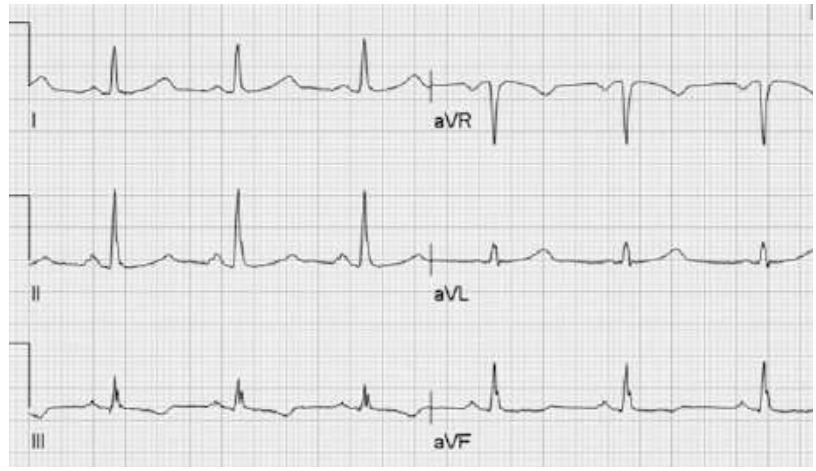

Fig. 18.4 An electrocardiogram from a patient with congenital long QT syndrome (LQT1), with a corrected QTc interval 490–500 ms

disease of concern is the congenital long QT syndrome (LQTS), with a current estimated prevalence of approximately 1:2,000 [32]. The diagnosis of LQTS is often based on the measurement of the QT interval on ECG, with the use of Bazett's formula ($QTc = QT/\sqrt{RR}$ (seconds)) to correct the QT interval for the underlying heart rate. Typically a QTc interval of <440 ms in males and 460 ms in females is considered normal. Some have extended this cutoff to a maximum of 470 ms. There is general agreement that a QTc > 480 ms is concerning and requires further evaluation (Fig. 18.4). The QT interval is best measured in leads II and V5, with the end of the T wave determined by the tangent of the downslope as it intersects the baseline. The phenotypic appearance of the ST segment can be highly suggestive of specific LQT mutations.

Rare potassium channel mutations that shorten the QT interval have been associated with ventricular fibrillation and are now termed short QT syndrome (SQTS). The QTc cutoff for the diagnosis of this rare channelopathy is <370 ms [11].

Brugada syndrome is represented by a characteristic QT phenotype in the right

Table 18.4 Normal and abnormal ECG features in athletes ([5]; Drezner et al. 2013)

Normal	Abnormal
1. Sinus bradycardia	1. T wave inversion
2. Sinus arrhythmia	2. ST segment depression
3. Ectopic atrial rhythm	3. Abnormal Q waves
4. Junctional escape rhythm	4. Marked sinus bradycardia (<30 bpm)
5. First-degree AV block	5. Left atrial enlargement
6. Incomplete right bundle branch block	6. Extreme right/left axis deviation
7. Early repolarization	7. Right ventricular hypertrophy
8. Voltage criteria for left ventricular hypertrophy	8. Ventricular preexcitation
	9. Complete right or left bundle branch block
	10. Nonspecific intraventricular conduction delay with QRS > 140 ms
	11. Long or short corrected QT interval
	12. Brugada repolarization phenotype in V1–V3
	13. Frequent premature ventricular complexes
	14. Sustained or non-sustained atrial or ventricular arrhythmia

precordial leads, including an RSR' pattern with coved or saddleback ST segment [1]. The phenotype can be clinically silent and may only manifest during periods of fever or with a sodium channel blocker challenge.

Other ECG Abnormalities: An incomplete RBBB pattern can be considered normal in athletes; however, a complete RBBB or LBBB (QRS > 120 ms) should always be considered abnormal and may be suggestive of underlying structural or conduction disease [5, 9]. Evidence of Mobitz II second-degree AV block is also highly concerning for underlying conduction disease that may become progressive over time (Table 18.4).

ECG in Routine Screening: The inclusion of ECG testing during routine athletic screening is highly controversial. The current ESC and International Olympic Committee guidelines recommend ECG screening as part of every athletic participation evaluation [3, 15]. In contrast, guidelines released by the AHA do not include routine ECG screening during evaluation, predominantly based on the low specificity of the ECG and the limited cost-effectiveness and logistical challenges that implementation of mass ECG screening in the United States would entail [24]. Data from the Veneto region of Italy demonstrated a reduction in the rate of sudden cardiac arrests after the inclusion of the ECG during athletic screening. This reduction in the rate of sudden events has been used as justification for inclusion of the ECG during routine screening in Europe [4, 28]. These results were not replicated in a study performed in Israel that included ECG and exercise testing during routine screening [33]. Maron et al. compared the data from the Veneto region to the sudden arrest data in Minnesota, USA, where routine ECG screening was not performed [26]. The rate of sudden arrest in Minnesota was well below the rate of sudden death observed in the Italian data and remained stable over time. This discrepancy led to the speculation that the decline in sudden arrest rates in Italy following the implementation of routine ECG screening may represent a return to baseline after an unexplained increase that was independent of the addition of ECG screening.

Recent studies have evaluated the diagnostic yield of the ECG when using the updated ESC criteria. The sensitivity and specificity for identifying underlying cardiovascular disease is superior to previously reported studies [6, 35]. This improved diagnostic yield may also improve the cost-effectiveness routine ECG testing as part of athletic screening in the USA, but this remains unclear [24, 36]. A study evaluating the use of ECG screening in Division I NCAA athletes

Fig. 18.5 Comparison of echocardiographic images between similar aged patients with athletic heart (*left*) and confirmed hypertrophic cardiomyopathy (*right*)

demonstrated cost-effectiveness in the ability to diagnose underlying cardiovascular disease [19]. The most common diseases identified were arrhythmias amenable to catheter ablation, and no individuals were diagnosed with hypertrophic cardiomyopathy. While these diagnoses validated the additional cost associated with ECG screening, not all the findings were associated with sudden death, and it remains unclear to what degree ECG screening may reduce the overall incidence of sudden cardiac arrest in athletes.

Echocardiogram

The presence of underlying structural disease can be easily established using standard two-dimensional echocardiography. The echocardiogram is the gold standard for the diagnosis of valvular abnormalities, particularly aortic stenosis or mitral valve prolapse. The proximal aortic root can be measured to ensure there is no dilation or aneurysm formation suggestive of an underlying connective tissue disorder. Although technically difficult at times, the origins of the ostia of the coronary arteries can often be visualized as well as the branching pattern of the left circumflex and left anterior descending arteries from the left main coronary artery.

The diagnostic challenge raised by echocardiography is differentiating the benign myocardial hypertrophic changes observed with athlete's heart from the pathologic alterations suggestive of hypertrophic cardiomyopathy (Fig. 18.5). A septal thickness between 12 and 15 mm has been identified as a "grey zone" where differentiation between benign and pathologic ventricular hypertrophy can prove difficult. There are multiple criteria that have been applied to attempt differentiation of the athletic heart from HCM. These include end-diastolic volume, asymmetric hypertrophy, mitral valve involvement, and left

atrial enlargement [21]. The presence of delayed gadolinium enhancement on a cardiac MRI is suggestive of HCM. If the diagnosis remains uncertain, then a period of deconditioning followed by repeat echocardiography should be used to demonstrate an appropriate reduction in LV mass consistent with athlete's heart.

Echocardiographic abnormalities are common and can be diagnostic of LV non-compaction or ARVC/D. Echocardiographic criteria for ARVC/D were recently updated as our understanding of this cardiomyopathy continues to evolve and improve the sensitivity of the criteria. Current criteria include an RVOT diameter >3.0 cm, failure of RV free wall shortening, and significant RV dilation [20]. If there is concern for abnormal RV motion or dilation, then MRI can be considered as an imaging adjunct to evaluate for fibrotic infiltration with delayed gadolinium enhancement in the RV myocardium and objectively measure RV volume and function.

Exercise Testing

Symptoms associated with exercise, particularly chest pain, palpitations, or dizziness, should be evaluated with exercise stress testing. This is typically performed with either standard treadmill testing or a bicycle ergometer using the modified Bruce protocol. The goal is to accelerate the patient's heart rate, increase sympathetic tone, and increase myocardial metabolic demand. Recreation of symptoms with concordant normal ECG monitoring can be reassuring that there is not an underlying ischemic or arrhythmic etiology causing the symptoms. The addition of pulmonary function testing can assist in screening for underlying respiratory abnormalities, such as reactive airway disease, restrictive or obstructive respiratory physiology, or disorders of respiratory control.

Exercise can induce ST segment changes in patients with a predisposition to ischemia, such as patients with HCM or coronary anomalies. Ventricular arrhythmias secondary to underlying cardiomyopathy or channelopathy can be triggered by exercise and range from simple ventricular ectopy to sustained ventricular tachycardia. Exercise testing has proven to be a useful adjunct in the evaluation of long QT syndrome as knowledge of phenotypic variations associated with different genetic mutations continues to grow. The behavior of the QT interval during peak HR and recovery can contribute significantly to the diagnosis of LQTS, particularly in borderline or ambiguous cases [31]. Exercise testing is potentially the best modality to screen for possible CPVT, as the baseline ECG is usually normal and ventricular ectopy or the bidirectional or polymorphic ventricular tachycardia associated with the disorder is often easily induced by exercise [30].

Ambulatory ECG Monitoring

Similar to exercise stress testing, ambulatory ECG monitoring can be performed to further evaluate any potential cardiovascular complaints at rest or with activity. The type and duration of testing depends on the type, frequency, and duration of symptoms. Frequent symptoms that are easy to provoke, or are relatively short in duration, can be easily captured on 24 or 48 h Holter monitoring. Less frequent symptoms may be better captured by a 30-day loop recorder or ambulatory cardiac telemetry monitor, or if the symptoms are well tolerated and longer lasting, a handheld event recorder can be utilized. Recently, monitors which allow for continuous monitoring during a 3-month period for evaluation of even more infrequent symptoms have become available.

For complaints that are persistent and troubling but too infrequent or difficult to capture using standard monitoring equipment, an implantable loop recorder (ILR) can be utilized. These monitors are small subcutaneous devices that can be placed in a pocket over the precordium and provide reliable heart rhythm recordings, with alarm values set as needed to record episodes of abnormal tachycardia or bradycardia. The information can be interrogated from the device using a standard pacemaker programmer and reviewed by the clinician.

The average longevity of an ILR is approximately 3 years, providing ample opportunity to attempt correlation of the patient's symptoms with the underlying heart rhythm.

Summary

Assessment for cardiovascular disease prior to sports participation is performed to identify patients at risk for sudden cardiac arrest during practice or competition. A careful personal and family history and physical examination looking for the signs and symptoms of cardiovascular diseases with a potential risk of myocardial ischemia, arrhythmia, or aortic rupture are the cornerstones of a pre-sports participation evaluation. Further evaluation, such as ECG, echocardiogram, exercise stress testing, or arrhythmia monitoring, is performed as indicated by the history and physical. There is controversy regarding the inclusion of an ECG as part of the routine screen, as the efficacy and the logistics of mass routine ECG screening continue to be debated. In the meantime, efforts to ensure the implementation of recommended history and physical examination screening protocols, as discussed in this chapter, as well as efforts at improving secondary prevention via education with regard to cardiopulmonary resuscitation (CPR) and the use of automated external defibrillators (AEDs) are critical.

Assessment of the Adult with Congenital Heart Disease

19

George Lui

Abstract

The outpatient assessment of the adult with congenital heart disease is focused upon the gathering of historical, clinical, physical, and testing data. Some patients will transition and transfer appropriately from pediatric to the adult healthcare system during periods of medical stability. Others will have fallen out of care and present with heart failure or arrhythmias from residual hemodynamic abnormalities. This chapter covers the assessment of the adult with congenital heart disease which is divided into two categories of palliated or repaired congenital heart disease and newly diagnosed congenital heart disease in the adult.

Keywords

Adult congenital heart disease • Arrhythmia • Cyanosis • Heart failure • Physical examination • Pregnancy

Introduction

The prevalence of adults with congenital heart disease (CHD) continues to grow as more children survive into adulthood [40, 42]. These adults face increasing morbidity and mortality from their original heart disease. They will encounter readmissions for arrhythmia, heart failure, catheterization and electrophysiology procedures, and repeat cardiac surgery. Additionally, they may develop a multitude of acquired diseases of adulthood such as diabetes, hypertension, and coronary artery disease. As such, these patients require a multidisciplinary team to care for them.

The outpatient assessment of the adult with CHD is focused upon the gathering of historical, clinical, physical, and testing data. Some patients will transition and transfer appropriately from pediatric to the adult healthcare system during periods of medical stability. Others will have fallen out of care and present with heart failure or arrhythmias from residual hemodynamic abnormalities. In one study, more than 20 % of patients had been lost to care by the time they reached adulthood [28]. They may come to the clinic with no history of their prior disease or surgical history. These patients pose a challenge to any clinician trying to evaluate their initial diagnosis and any residual hemodynamic abnormalities.

The history is the most crucial aspect of their assessment. It will help identify problems and establish the next steps in the evaluation of the patient's long-term care. The events surrounding the initial presentation of CHD can often be gleaned from the parents. However, if the parents are absent, this history may only be obtained through the medical chart. It is important to document the events of surgery including operative notes, catheterization, or electrophysiology studies performed during childhood and the most recent procedure. Gathering information regarding other adult illnesses is important including diabetes, hypertension, hepatitis B and C, asthma, cancer, chronic obstructive pulmonary disease, and HIV disease. An appropriate obstetric/gynecologic history includes number of pregnancies and miscarriages, length of gestation, method of delivery, and any complications. The clinician needs to review methods of contraception and guide the patient regarding risk for future pregnancies. Additionally, adults with CHD have an increased risk of psychosocial difficulties including depression and anxiety [25]. Therefore, a psychiatric history should include recent diagnoses, hospitalizations, and treatments. The social history incorporates the patient's vocation and daily activities such as exercise and diet. Alcohol, tobacco, and drug use should always be included. Immunizations are a standard part of the pediatric assessment but often overlooked in the medical history of an adult. Vaccinations such as tetanus, pneumococcus, and pertussis require updates. The family history outlines specific illnesses in the family such as CHD, coronary artery disease, cancer, and hypertension. Finally, a review of systems documents the presence or absence of common symptoms in each organ system. The assessment of the adult with CHD is a comprehensive health history because the long-standing cardiac disease can have implications on the whole person.

This chapter covers the assessment of the adult with CHD which is divided into two categories of palliated or repaired CHD and newly diagnosed CHD in the adult. General considerations are discussed regarding the complications related to a patient who has a history of operated CHD. Common presentations include heart failure, arrhythmia, stroke, endocarditis, hepatic disease, and cyanosis (Table 19.1). Pregnancy in an adult with CHD is also discussed below. Hospitalizations for adults with congenital heart disease have increased secondary to all these events [35]. Therefore, it is important to consider the clinical evaluation of these medical issues. The workup of an adult with repaired or palliated CHD is summarized in (Table 19.3). Finally, several congenital heart lesions present de novo in adulthood. The general evaluation and workup of these lesions are presented.

Repaired or Palliated Congenital Heart Disease in the Adult

Heart Failure

Heart failure is one of the most common presentations for an adult with a history of repaired or palliated CHD. Acquired heart failure in the adult population is primarily related to left heart failure secondary to ischemic or hypertensive heart disease. In the congenital population, the types and causes of heart failure are myriad. These types include volume or pressure overload, left-to-right shunts, valve regurgitation or stenosis, systolic or diastolic dysfunction, pulmonary vascular disease or obstruction, and cyanosis. Left heart failure can derive from left-sided obstructive or regurgitant valvular lesions, coronary anomalies, and myocardial dysfunction from prior operations. Right heart failure is seen in valvular disease such as Ebstein's anomaly or valvar pulmonic stenosis but also after primary congenital heart repairs such as the transannular patch repair for tetralogy of Fallot with residual pulmonary regurgitation and Fontan procedures for single ventricle with resultant low cardiac output and venous congestion. The right

ventricle is anatomically ill-suited for the pressure and work overload when it is the systemic ventricle as seen in transposition of the great arteries after atrial switch repair or congenitally corrected transposition of the great arteries. Heart failure occurs in approximately 32 % of patients with single or systemic right ventricles [36]. Twenty-six percent of all types of repaired CHD had significantly reduced exercise tolerance and elevated N-terminal-pro brain natriuretic peptide (NT-pro-BNP) in one study [32]. Finally, in addition to the broad mix of anatomic diagnoses and residual hemodynamic abnormalities from the primary repair, adults must also contend with acquired medical diseases that add risks to further myocardial dysfunction and heart failure such as diabetes, hypertension, and coronary artery disease.

Classic symptoms of heart failure include dyspnea on exertion, orthopnea, paroxysmal nocturnal dyspnea, or lower extremity edema. In patients who were reportedly asymptomatic, one study demonstrated significant reduction in peak VO_2 values [6]. Patients who were symptomatic and had reduced peak VO_2 in this study demonstrated the worse prognosis for hospitalization and death. On physical exam, the vital signs typically include tachycardia, tachypnea, or decreased oxygen saturation. Rales and pleural effusion are easily identifiable on auscultation of the lungs. Wheezing may also be a sign of heart failure. Classic signs such as an elevated jugular venous pressure may not be as helpful in the single ventricle patient who constantly has elevated venous pressures. Therefore, other signs on physical exam will need to focus on hepatomegaly, ascites, or lower extremity edema.

The clinical assessment of a patient with operated CHD should focus upon the cause of heart failure. An electrocardiogram may reveal an arrhythmia, myocardial ischemia, or intraventricular conduction defect. The chest radiograph typically demonstrates cardiomegaly as measured by cardiothoracic ratio; this method of quantifying cardiac size predicts mortality in adults with CHD [7]. The echocardiogram is the workhorse of diagnostic tools in CHD. This test provides data on the ventricular size and function as well as valvular abnormalities, intracardiac shunts, and residual abnormalities from prior repairs. It provides estimation of hemodynamic abnormalities. However, it is limited by echocardiographic windows, especially in the adult with CHD who has had prior repairs. Anatomic areas of difficulty in an adult include right ventricular size and function, aorta and its branches, pulmonary veins and arteries, and venous anatomy [43]. Therefore, other imaging modalities such as magnetic resonance imaging (MRI) and computed tomography (CT) are complementary in the evaluation of the adult with CHD and heart failure. Cardiac MRI overcomes many of the limitations of echocardiography with quantification of ventricular size and function, measurement of flow (e.g., Qp:Qs), and myocardial viability. However, cardiac MRI is limited by the cooperation of the patient to hold their breath and remain motionless as well as its contraindication in the setting of pacemakers and defibrillators. A patient in acute heart failure would not tolerate being in a cardiac MRI scanner. CT is an alternative modality that offers fast acquisition of cardiac structures and overcomes the limited echocardiographic windows. However, its limitation is radiation exposure which certainly influences the use of CT as a means to follow patients. These valuable modalities allow the clinician to hone in on a reversible cause of the patient's heart failure, which may allow further correction or palliation via catheterization, electrophysiology study/ablation, or cardiac reoperation. However, in some instances, there may not be an easily correctable solution, and medical therapy and ventricle assist devices/heart transplantation may be the final common pathway.

Arrhythmia

Arrhythmia is a common presentation in adults with CHD and includes atrial and ventricular arrhythmias, sinus node dysfunction, and heart block. The prevalence of atrial arrhythmias was estimated to be 15 % in one population-based study of adults with CHD [2]. Ventricular arrhythmias are less common but may result in a fatal outcome. Sudden cardiac death (SCD) accounts for the most common mode of death for patients with CHD [34, 37]. Arrhythmias are commonly seen in patients with a history of tetralogy of Fallot or transposition of the great

arteries. Residual hemodynamic abnormalities and a history of prior surgical repair place these individuals at greater risk for arrhythmias. It has become paramount to identify risk factors that may stratify patients at risk for SCD. For instance, patients with a history of repaired tetralogy of Fallot have an increased risk of SCD late after repair [31]. Some risk factors for SCD in TOF patients include QRS interval greater than 180 ms [14], right ventricular dilation secondary to pulmonary regurgitation [13], left ventricular systolic dysfunction [17], and elevated left ventricular end-diastolic pressure [21]. In contrast, patients with a history of transposition of the great arteries after atrial switch repair have a different set of risk factors for SCD including a history of atrial arrhythmias [20] and ventricular dysfunction [26]. The heterogeneity among different groups of CHD makes it challenging to risk stratify these patients as a group. Therefore, it is important to assess each lesion and its respective repair and residual hemodynamic abnormalities separately.

Signs and symptoms of arrhythmias are myriad. Patients are typically unaware of short runs of ventricular tachycardia that may place them at risk for SCD. Patients may complain of palpitations, exercise intolerance, dizziness, presyncope, or syncope. On physical exam, vital signs at the time of an arrhythmia demonstrate bradycardia, tachycardia, or a change in blood pressure. The patient may have an abnormal electrocardiogram that will identify the rhythm abnormality. However, more often, the patient is in the office with a normal rhythm, and the clinician must try to capture the arrhythmia in the outpatient setting. Other tests include ambulatory monitoring for 24–48 hours or event monitoring for weeks. However, one study suggested that non-sustained ventricular tachycardia on routine Holter monitoring in adults with CHD was not predictive of SCD [20]. Further risk stratification for SCD may require invasive testing such as an electrophysiology study with programmed electrical stimulation. In a cohort of TOF patients, the negative predictive value of programmed ventricular stimulation for sustained monomorphic VT was 88 % and polymorphic VT was 92 % [22]. Stress testing may be of assistance to provoke arrhythmias or demonstrate chronotropic incompetence that may be contributing to the patient's exercise intolerance. All of these tests allow the clinician to make further decisions regarding pacemaker or implantable cardiac defibrillator implantation. These tests can also allow the clinician to monitor medication responses. Finally, electrophysiology study with catheter ablation or surgical ablation is often the final pathway for many of these patients with tachyarrhythmias who fail medical therapy.

Neurological Complications

Neurological complications are not uncommon in the adult with repaired or palliated CHD and include transient ischemic attack (TIA) or stroke, brain abscess, intracranial aneurysm, and neurological sequelae from prior cardiac surgery. TIA/stroke is the most common neurological complication and often leaves this young population with significant residual sequelae as adults. Left-to-right shunts in the setting of residual atrial or ventricular septal defects can lead to paradoxical embolism from the venous into the arterial system and subsequently lead to cerebrovascular accidents. A pacemaker or implantable cardiac defibrillator lead can double the risk of stroke in the setting of these intracardiac shunts [21]. Atrial arrhythmias, prosthetic valves, and intracardiac devices are also risk factors for embolism and stroke. In a retrospective cohort of adults with CHD, there was an estimated event rate of 0.05 % per patient-year for a stroke [19]. In patients with cyanosis, there is a higher prevalence of stroke/TIA ranging from 7 to 14 % in a variety of studies [1, 5, 10]. The risk for stroke in patients with residual cyanosis from unrepaired or palliated CHD is likely multifactorial and related to erythrocytosis and hyperviscosity. Stroke remains a significant morbidity for patients with a history of congenital heart disease.

The history is critical in the initial assessment of a stroke because the timing of symptom onset will dictate potential therapies for ischemic strokes. Symptoms include abnormal speech, change in mental status, and facial and arm

paresis. There are many conditions which may mimic the presentation of a stroke including seizures, migraines, and hypoglycemia. The physical examination should focus on obvious neurological deficits, but there should also be a careful examination for causes of stroke including vascular bruits, signs of endocarditis, cholesterol emboli, and deep vein thrombosis. The clinical evaluation then includes studies to confirm the diagnosis of an ischemic stroke and rule out contraindications to thrombolytics. Noncontrast brain CT or MRI is done to rule out any evidence of cerebral hemorrhage. Time is of the essence in the evaluation of an acute stroke because intravenous thrombolytics are typically given within 3 hours of symptom onset. In the patient with a history of CHD, the clinician should consider the increased risk of bleeding with thrombolytic therapy.

Other neurological complications related to CHD include brain abscesses. Patients with a history of cyanotic congenital heart disease are at particular risk [11]. Signs and symptoms include headache, fever, and seizures. These symptoms should prompt an evaluation for infection including serial blood cultures before antibiotic therapy. The physical examination focuses upon neurological deficits but also evidence of endocarditis such as a new murmur, emboli to the fundi or digits, splinter hemorrhages, Janeway lesions, Osler's nodes, or Roth spots. An echocardiogram is indicated in any patient with CHD with a suspicion of endocarditis. The echocardiogram can identify vegetations on valves or sites of prior repair. In the adult, the transesophageal echocardiogram is the best modality for the detection of endocarditis. CT or MRI of the brain is indicated when there are concurrent neurologic symptoms or signs of emboli. Even after antibiotic therapy and evacuation of a brain abscess, many patients continue to have a seizure disorder secondary to scarring in the area of the abscess.

Intracranial aneurysms are another complication related to patients with a history of aortic coarctation. The prevalence is approximately 10 % in patients screened by MRI [3, 4]. The screening for intracranial aneurysms with serial brain MRA remains controversial. Finally, adults with CHD are at risk for acquired medical illnesses such as hypertension and atrial fibrillation that carry its own risk for neurological complications.

Prior cardiac surgery has long-term effects upon neurological development in infants and young children. Risks for attention deficit, anxiety, and depression have been recognized to be higher in the survivors of hypoplastic left heart syndrome [29]. The risk factors for adverse developmental outcomes are still being understood and include type of CHD, need for prolonged intensive care, prolonged cardiopulmonary bypass, prolonged hypoxemia, and multiple operations [41]. The array of developmental delay and behavioral abnormalities will have profound implications on a patient's ability to function independently and work as adults.

Pregnancy

Cardiovascular disease remains the most common cause of maternal death. Pregnancy in women with CHD is associated with increased maternal and fetal morbidity. The hemodynamic demands of pregnancy include a 30–50 % increase in cardiac output which can be as high as 80 % above pre-pregnancy levels during labor and delivery [33]. These hemodynamic changes may not return to normal for up to 1 month after delivery. There is also the increased risk of thromboembolism during pregnancy. Despite these challenges, most women with CHD have successful pregnancies. It is important to counsel patients prior to pregnancy about the risks to the mother and fetus.

The clinical evaluation of a pregnant woman with CHD is systematically approached by risk stratifying the patient by anatomic diagnosis, baseline characteristics, and residual hemodynamic abnormalities. Patients with simple forms of CHD such as an atrial septal defect or mild pulmonic stenosis tolerate pregnancy well. However, women with moderate or complex CHD are at increased maternal and fetal mortality and morbidity [8, 9, 23]. High-risk lesions carry 25–50 % mortality and include severe left ventricular outflow tract obstruction, cyanotic CHD, and Eisenmenger syndrome. Risk scores such as

the CAPREG index or ZAHARA model are helpful tools to risk stratify patients for cardiac complications based upon baseline characteristics of the patient [8, 38]. Additionally, chronotropic incompetence on an exercise test is associated with an increased risk for maternal cardiac and neonatal adverse events [27]. There is an increased recurrence risk of CHD in the fetus, as high as 50 % in Marfan syndrome. The long-term implications of pregnancy remain uncertain on the maternal condition.

Preconception counseling is based upon the patient's risk stratification. Discussions of contraception and planned pregnancy need to occur when patients are adolescents. Genetic counseling may be indicated to discuss the risk of CHD in the fetus. Finally, the care of these individuals should occur in a center which specializes in adults with CHD with multidisciplinary consultation of obstetricians, anesthesiologists, geneticists, and cardiologists to minimize the risk for the mother and fetus.

Hepatic Disease

Liver disease is recognized as a common complication in adults with CHD. Risk factors for hepatic disease include anatomic diagnosis and residual hemodynamic abnormalities. In individuals with a single ventricle and Fontan palliation, congestive hepatopathy and cirrhosis are a recognized complication of passive systemic venous return, low cardiac output, and increased central venous pressure [12, 16, 24]. There are reports of liver dysfunction and hepatocellular carcinoma in patients with repaired tetralogy of Fallot [30, 39]. These patients share the risk for chronically elevated systemic venous pressures with residual right ventricular dilation from pulmonary regurgitation. Other factors may contribute to the development of liver dysfunction including alcohol and viral hepatitis.

Early recognition of hepatic disease may assist in the management of residual cardiac abnormalities. A history should include risk factors of liver dysfunction such as medications, recreational drugs, blood transfusions prior to 1990, viral hepatitis, and alcohol consumption. The physical examination focuses upon evidence of liver disease including hepatomegaly, splenomegaly, jaundice, ascites, or encephalopathy. Other stigmata of chronic liver disease include spider nevi, palmar erythema, and gynecomastia. Liver function tests are typically the first laboratory studies to screen for hepatic disease. Elevations in transaminases represent hepatocellular injury that can be seen in settings of hypoxic injury to the liver. However, long-standing cirrhosis results in abnormalities of liver synthetic function and is typically represented by low serum albumin and elevation in prothrombin time and INR. Patients with Fontan circulation are at risk for liver cirrhosis and protein-losing enteropathy, both of which elevate their future risk of heart transplantation. Elevations in bilirubin can be seen in the setting of right heart failure and venous congestion but also can represent obstruction in the biliary tree. Adults with CHD with any abnormal liver function tests should prompt further workup on the liver but also recognize that residual hemodynamic abnormalities such as stenosis of conduits, right heart failure, and medications may be the culprit. Further imaging of the liver includes ultrasound, CT, or MRI. Percutaneous liver biopsy is the definitive study for determining the cause and severity of hepatic disease. Panels of blood test such as FibroSURE may offer a noninvasive method of estimating the degree of liver fibrosis [18]. Finally, there remains controversy regarding screening for hepatic disease in the adult with CHD. There are case reports of hepatocellular carcinoma in adults with repaired tetralogy of Fallot and Fontan [16, 30]. Therefore, in patients at risk for hepatic disease, it is important to monitor for signs of liver disease with serial laboratory testing including alpha-fetoprotein and imaging.

Cyanosis

Cyanotic CHD is a multisystem disorder. Patients may present with varying degrees of cyanosis depending upon the hemodynamic abnormalities. Individuals repaired as a child may present with mild cyanosis during exercise from residual shunts. Some patients are significantly cyanotic because of palliated aortopulmonary shunts. Finally, Eisenmenger syndrome results in

profound cyanosis secondary to reversed or bidirectional shunting across a large shunt and pulmonary vascular disease. Cyanosis has profound effects on all the end-organ systems including the brain, kidney, heart, liver, and hematologic systems.

One of the primary responses to cyanosis is physiologic secondary erythrocytosis. Signs and symptoms include headache, altered mental status, and visual disturbances. Secondary erythrocytosis can be broken into two forms: compensated where the patient is iron-replete with stable hemoglobin and decompensated where the hemoglobin is rising with the presence or absence of iron deficiency [15]. In general, phlebotomy can be considered in the setting of decompensated secondary erythrocytosis and hyperviscosity symptoms but should be avoided in the setting of an asymptomatic patient with a stable hematocrit even if the level is greater than 65 %. Routine phlebotomy should be avoided. The physical examination focuses upon complications of cyanosis including signs of neurologic abnormalities, bleeding, infection, ischemic complications, hyperuricemia, gout, central cyanosis, and clubbing. The cardiac exam typically reveals a right ventricular heave and loud P2. If there is a residual aortopulmonary shunt, then there will be a continuous murmur heard best in the back. If there is a large ventricular septal defect in the setting of Eisenmenger syndrome, there will be no murmur. Routine laboratory studies include complete blood count, coagulation panel, iron panel, uric acid, and renal function. A 6 minute walk test or cardiopulmonary exercise test is recommended to assess functional capacity. Some centers perform routine catheterization on patients with Eisenmenger syndrome prior to initiating pulmonary vasodilator therapy. Further diagnostic workup is driven by the patient's presentation whether it is hemoptysis and the need for CT imaging of the chest versus a change in mental status or neurological abnormality requiring CT or MRI of the brain. These patients most commonly die from hemoptysis, heart failure, and sudden death [5]. Therefore, some patients are considered candidates for heart and lung transplantation.

New Diagnosis of Congenital Heart Disease in the Adult

Most severe forms of CHD will present in childhood and require intervention prior to adulthood. However, there are a number of lesions that commonly present in adulthood (Table 19.2). These lesions include atrial septal defects, congenitally corrected transposition of the great arteries, Ebstein's anomaly, coronary anomalies, and occasionally coarctation of the aorta. These patients are typically asymptomatic and incidentally diagnosed on echocardiogram with the abnormality. However, a young patient with resistant hypertension to medical therapy should prompt an evaluation for coarctation of the aorta.

A patient with newly suspected CHD requires a thorough medical history. The story begins with the family. The parents are usually the best source for this information including any family history of CHD, teratogen exposure during pregnancy, and any signs of exercise intolerance or murmur as a child. Additionally, it is important to gather other acquired cardiovascular history from immediate family members including coronary artery disease, stroke, or sudden death. Then, the interviewer can move on to the patient's current symptoms: exercise intolerance, palpitations, dizziness, syncope, etc. The past medical history focuses upon risk factors for acquired cardiovascular disease including diabetes, hypertension, hyperlipidemia, kidney disease, and stroke/TIA. The social history includes the patient's vocation, exercise, sports, tobacco, alcohol, and illicit drug use. Recent changes in

lifestyle or stressors may help elucidate the underlying problem.

The physical examination focuses upon the diagnosis through inspection, palpation, percussion, and auscultation. Inspection identifies any prior surgical scars, syndromic abnormalities in the facies, stature, and extremities. Dextrocardia will have the maximal impulse in the right axillary line. A right ventricular heave can be appreciated in a patient with a dilated right ventricle and pulmonary hypertension. Percussion is important in the recognition of cardiac and abdominal malposition in addition to identifying the patient with hepatomegaly or splenomegaly. Finally, auscultation is primarily over the left and right chest but also should be positioned in the back, particularly underneath the left scapula to recognize a patent ductus arteriosus or coarctation of the aorta.

The workup continues with an electrocardiogram, chest radiograph, and echocardiogram to confirm the diagnosis. For instance, the first clue in an asymptomatic patient with an atrial septal defect is often the electrocardiogram that demonstrates a rightward axis and incomplete right bundle branch block. The chest radiograph offers signs of right heart dilation or enlarged pulmonary arteries from the increased flow. Finally, the echocardiogram confirms the diagnosis of an atrial septal defect and also offers important information regarding right ventricular size and function as well as an estimation of the pulmonary artery systolic pressure. While many patients with an atrial septal defect are asymptomatic, exercise testing may reveal decreased functional capacity by objectively assessing their exercise. Further testing such as MRI/CT or catheterization will be governed by the anatomy and hemodynamic abnormalities and potential treatment options for each new diagnosis of CHD.

Conclusion

More than 90 % of children with CHD will survive into adulthood because of the successes of prenatal diagnosis, cardiac surgery, and intensive care management. It is the caregivers' responsibility to ensure the continuity of care, quality of life, and improvement of outcomes in adults with CHD. This will be achieved by the multidisciplinary care that programs for adults with CHD offer with a focus on treating the whole person and family.

Basics of Pediatric Electrocardiography and Invasive Electrophysiology: Principles of Cardiac Testing

20

Robert H. Pass and Scott R. Ceresnak

Abstract

The pediatric electrocardiogram is the cornerstone of evaluation for all arrhythmia conditions and acute arrhythmia analysis and treatment. In the presence of an arrhythmia, additional modalities are available for capturing a paroxysmal rhythm disorder. The interpretation of the electrocardiogram is dependent on understanding the evolution of the electrocardiogram as the child ages. Electrocardiographic abnormalities that occur in children include Wolff-Parkinson-White syndrome, supraventricular tachycardia, complete heart block, junctional ectopic tachycardia, ventricular tachycardia, atrial flutter, atrial fibrillation, long QT syndrome, Brugada syndrome, and myocardial ischemic changes in patients with anomalous origin of the left coronary artery from the pulmonary artery. The indications for invasive intracardiac electrophysiology studies include the risk assessment of patients with ventricular or supraventricular tachycardia, the assessment of anti-arrhythmia drug efficacy, and the evaluation of unexplained syncope.

Basics of Electrocardiography and Invasive Electrophysiology

Evaluation of the electrophysiology of pediatric cardiac patients is an integral part of the complete evaluation of any heart problem. Though supplanted by imaging modalities such as angiography, echocardiography, and cardiac magnetic resonance imaging for the assessment of cardiac anatomy in the pediatric patient, the basic 12- or 15-lead electrocardiogram (ECG) remains the cornerstone of evaluation for all arrhythmia conditions and acute arrhythmia analysis and treatment. Though stated over 50 years ago, Nadas' comments regarding the ECG's central role as part of the "tripod" upon which rests clinical diagnosis in pediatric cardiology remain as true today as then [1].

Based upon the work of many prior investigators, Einthoven described the first string galvanometer which is commonly viewed as the true predecessor of the modern day ECG machine [2]. Improvements in electrocardiographic recording technology have allowed for miniaturization of the recording device. This has allowed for ECG recording in various hospital and out-of-hospital settings. The various forms of electrocardiographic recording include the basic ECG, 24-h ambulatory ECG recording ("Holter" monitoring), "event" recorders of various types, and, finally, telemetry [3–5].

By allowing for multiple (limb and parasternal) leads of simultaneous electrocardiographic recording, the ECG allows the clinician the ability to view both electrical depolarization and repolarization of the heart from various angles. The multiple angles of "electrical visualization" allow for various determinations such as rhythm assessment, hypertrophy, and axis determination of both the atria and ventricles as well as allow for greater accuracy when diagnosing arrhythmia conditions such as Wolff-Parkinson-White syndrome (WPW), long QT syndrome, or Brugada syndrome, to name but a few. There are many conditions or clinical situations in which there is simply no noninvasive or invasive substitute for the basic ECG in assessing the heart.

However, because of the ephemeral or intermittent nature of various cardiovascular arrhythmias or symptoms, the basic 12- or 15-lead ECG is, at times, simply impractical for the capture of various different arrhythmia conditions. For this reason, electrocardiographic surrogates have arisen. These typically provide between one and three leads of the ECG with the thought that capturing even a single lead of ECG during an intermittent event is superior to no tracing. There are an increasing number of these devices and they will be briefly described below (Table 20.1).

Holter Monitor

The simplest such device is the 24- or 48-h ambulatory ECG, or "Holter monitor" [6]. This device can typically record up to 3 leads of the basic ECG for 1 or 2 days continuously. The device will also allow for heart rate variability analysis [7–11]. For patients in whom there are daily symptoms, this form of monitoring is useful for capturing frequent sensations or arrhythmias [12, 13]. Typically, patients are given a "diary" which is usually a single sheet of paper on which daily activities and symptoms can be recorded and then double checked with the timed electrocardiographic tracings. Because it is continuously recording the entire time period, the onset and offset of arrhythmias can often be documented which can, in certain situations, be useful in determining arrhythmia mechanism.

Event Monitor

When symptoms are less frequent than daily, there are a virtual plethora of options for the cardiologist to use to try capture the event electrocardiographically. [14–19] The first of these is the so-called event recorder. These devices, which can be as small as a typical credit card, allow for the recording of any arrhythmia or sensation by placing the device directly to the

Table 20.1 Types of noninvasive electrocardiographic recorders and their strengths and weaknesses

Type of ECG recorder	Advantages	Disadvantages
Holter	Single day, full disclosure, onset and offset of arrhythmias, heart rate variability data, quantification of ectopic beats	Improper for infrequent symptoms (only 1–2 days)
Event recorder	Infrequent symptom capture, ease of use	Requires patient coordination and compliance, poor for very brief symptoms, some versions must be uploaded manually
Loop recorder	Infrequent symptom capture, ease of use, can automatically upload	Must wear ECG electrodes daily for 3–4 weeks, no full disclosure
Ambulatory telemetry	Infrequent symptom capture, ease of use, can automatically upload, full disclosure	Must wear ECG electrodes daily for 3–4 weeks
Implantable loop recorder	No need for ECG electrodes, minimal patient involvement in recording, ease of downloading of information	Requires surgical procedure, no full disclosure

chest and then pressing a button to record. The devices typically can record a few episodes of 30–60 s duration. Once recorded, the device can then be taken to a telephone, and the recording downloaded to a "central station" where the ECG tracing is generated. The main advantage of this form of recording is ease of use. The device is not affixed to the patient continuously and only needs to be applied at the time of symptoms. There are, however, several disadvantages of such a device. It is often challenging for the patient to carry the device continuously for 3–4 weeks, and when symptoms are very brief, such a device may not be practical to capture an episode, even if the device is immediately adjacent to the patient. These devices can also only record a single ECG lead, thus limiting the interpretation of the tracing compared to a typical 12-lead or 15-lead ECG.

Loop Monitor

The "loop recorder" was designed to address some of the disadvantages of the event recorder [20, 21]. This device is similar to the event recorder, but the patient typically wears ECG electrodes that are attached via cables to the device that is worn 24 h per day for a 3–4-week period. The device continuously records a period of time (typically 1–3 min of "looping") and also continuously erases this period of recording with new recording. When the patient has the sensation for which the recording is performed, a button can be pressed which will typically command the device to record the prior 30 or 45 s as well as the subsequent 30 or 45 s. This recording can then be sent, in similar fashion to the event recorder, over the phone, to a "central station" for conversion to an ECG tracing. Two newer variations of the loop recorder have become more common. So-called "automated" recorders can be programmed to work similarly to the "loop recorder" with the primary difference being that the device will also automatically record anything that it believes is an arrhythmia, typically using algorithms that are based upon heart rate ranges [22]. Thus, this sort of recorder will automatically record any preprogrammed activity that may represent an arrhythmia while also allowing the patient to override the system and record any symptoms that they may be feeling. This feature is particularly useful in young or incapacitated patients that are unable to press the button or for complaints such as syncope where the patient may be unable to press the button during an episode. Finally, newer technology allows for the device to automatically send the data to a central station using cell phone technology without the need for uploading by the patient.

Ambulatory Telemetry

More recently, with the advent of cellular phone technology, a newer technology that is often referred to as "ambulatory telemetry" allows for complete and total recording of a patient's heart rhythm with near "full disclosure" [23–26]. This allows the cardiologist to view not only device- and patient-commanded arrhythmias but the entire daily rhythm as well as rhythm and heart rate trends in similar fashion to a 24-h ambulatory "Holter" device, though for multiple days. There are some data to suggest that this form of arrhythmia monitoring may be superior in rhythm sensitivity for various different arrhythmia conditions [25, 26].

Implantable Loop Monitor

The final form of ambulatory monitoring is the so-called implantable loop recorder/ILR [27–32]. This device, which is a few inches in size, can be implanted beneath the skin in the left parasternal area in a minor surgical procedure. The device allows for single ECG lead recordings and can record data that can then be downloaded either in the physician office or over the telephone/Internet. The device can automatically record either bradycardias or tachycardias as defined by the physician and can also be patient activated. The indications for their usage are largely the same as for any of the ambulatory systems previously discussed above with the main advantage being that they require essentially no patient cooperation. As a general rule, these are best reserved for patients in whom the above modes of monitoring have failed or in patients who are highly noncompliant [33].

Atrial Wire Postoperative Studies

Following open heart surgery, any sort of arrhythmia may be potentially hemodynamically embarrassing. As a result, rapid and accurate diagnosis followed by treatment is imperative in the postoperative setting. The most important "test" for assessing postoperative arrhythmias is undoubtedly the 12- or 15-lead ECG as described above. However, there are situations in which it is challenging to accurately assess the relationship of atrial to ventricular depolarizations on the surface ECG alone. For this reason, atrial wire studies are often conducted, in addition to the 12-lead ECG, to help the clinician better assess this relationship and therefore better understand the nature of the arrhythmia.

At the time of surgery, it is common for a congenital heart surgeon to place one or two wires on the surface of the atrium and ventricle [34]. As these are directly touching the atrial myocardium, intracardiac recordings can be made at the bedside. Typically, a precordial lead (e.g., V1–V6) is used in addition to the standard limb leads. The precordial lead is usually attached to the metal atrial lead using an "alligator clip," resulting in a large atrial electrogram deflection on the ECG. By running the standard surface leads simultaneously, the relationship of the atrial depolarization to ventricular depolarization (as inscribed by the surface QRS) can be easily determined. Examples of rhythms in which atrial wire tracings can be useful would be JET or ventricular tachycardia in which the ventricular rate often exceeds the atrial rate. Incorporation of an atrial electrogram tracing in concert with the surface ECG (plus the response to pacing of the atrium or ventricle) is often all that is necessary to make accurate postoperative rhythm determinations.

Interpretation of the Electrocardiogram in Children

The basic approach to reading a pediatric electrocardiogram (ECG) should be systematic and consistent. There is no one "right way," but a methodical approach should be used in order to avoid missing any abnormalities. We would advocate a "12-step" approach with attention to the following details and findings (Table 20.2). There are published tables on the normal pediatric ECG values for heart rate, PR intervals, QRS axis, etc. based on patient age (Fig. 20.1),

Table 20.2 "12-step" approach to ECG interpretation

1. Relationship between Ps and Qs (P waves and QRS complexes)

10. Q waves
11. Calculation of intervals (PR, QRS, QTc)
12. Assessment of other abnormalities

but perhaps the most important consideration in reading an ECG in a pediatric patient is the understanding of the evolution of the ECG from infancy to adulthood [35–38].

The Evolution of the Electrocardiogram Throughout Childhood

The 15-lead ECG changes significantly throughout childhood. [35–38] Caregivers therefore cannot interpret the electrocardiogram of a pediatric patient without knowing the age of the patient. Understanding the changes seen on ECG throughout childhood is best done by understanding the evolution of cardiac physiology from fetus to adulthood, as the changes in the ECG reflect the changing physiology from the fetus, to the newborn, to the young child, and to the adult. The ECG thus evolves from primarily prominent right ventricular (RV) forces in the newborn period to primarily left ventricular (LV) dominant forces seen in late adolescence and adulthood. In the fetus, the right ventricle is the primary output for systemic blood flow, pumping roughly 65 % of the cardiac output to the body as the pulmonary resistance is elevated and blood flows from right to left through the patent ductus arteriosus [39]. This is reflected in the electrocardiogram of the newborn with prominent RV forces and a rightward QRS axis. As pulmonary resistances drop over the first few weeks of life, the RV forces on the ECG gradually diminish and this continues over the first few years of life. Left ventricular dominance predominates in later childhood and adolescence, ultimately taking the form of the typical adult ECG. The changes on the ECG during childhood are thus reflected in the QRS axis, the T wave patterns, and the prominence of RV and LV forces as illustrated below. In addition, the "normal" values for heart rate, PR interval, QRS interval, QTc interval, and amplitudes of the R and S waves in the right and anterolateral precordial leads also change with age.

Newborn

The ECG in the newborn reflects the importance of the RV in fetal life and shows prominent RV forces (Fig. 20.2). The QRS axis is usually rightward, between 30 and 180°. The prominent RV forces are demonstrated by tall R waves noted in V1 and the right precordial leads, V3R and V4R, with a relatively small S wave. The T waves are usually upright in V1, V3R, and V4R. In V6 there is often a small R wave with a more prominent S wave. The notable exception to this typical newborn ECG is in the ECG of a premature infant. The pulmonary vascular resistance of the neonate is typical lower than a full-term neonate, and the premature infant does not demonstrate the prominence of RV forces that are usually seen in the typical full-term newborn. The ECG of the premature neonate is perhaps more similar to that of an adolescent or adult pattern, with a more leftward QRS axis, minimal RV forces, and prominent LV forces.

Two Weeks

By 2 weeks of age, pulmonary vascular resistance has usually diminished and the RV pressures have started to decrease. This is reflected on the ECG with a change in the T wave morphology in V1, V3R, and V4R (Fig. 20.3). While upright in the newborn, the

Fig. 20.1 Table of normal ECG parameters during childhood [38]

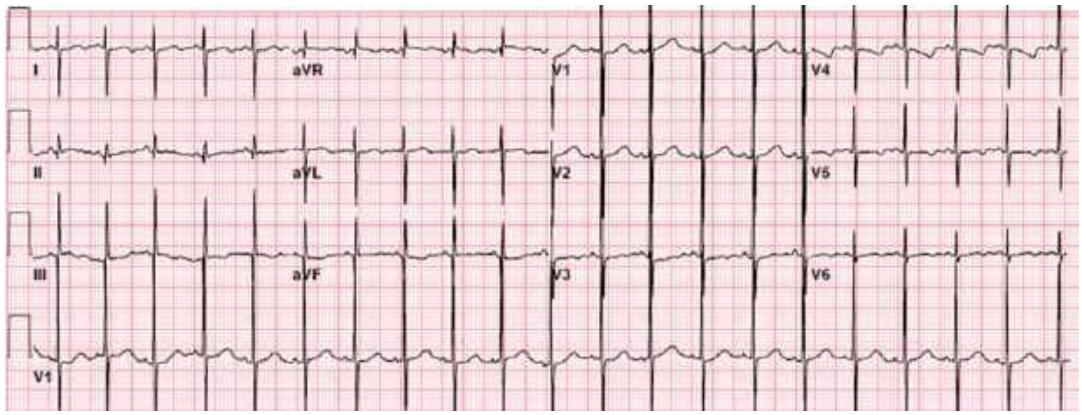

Fig. 20.2 Normal newborn ECG. Note the *right* axis deviation, prominent R wave in V1, and *upright* T wave in V1

T wave now becomes inverted in V1, V3R, and V4R. This T wave pattern, with inversion in V1/V3R/V4R, should persist throughout childhood into late adolescence. If the T wave were to remain upright in the newborn after 2 weeks of age, it would indicate possible right ventricular hypertrophy or RV hypertension.

One Year of Age

By 1 year of age, the RV forces are beginning to diminish with more prominent LV forces noted (Fig. 20.4). The QRS axis is usually slightly less rightward. The T waves remain inverted in V1/V3R/V4R. There is usually slightly more LV forces, with a slightly smaller R wave and slightly larger S wave in V1 and usually less S wave in V6.

Four Years of Age

By 4 years of age, the QRS axis has usually normalized (between 0 and 110°). There is again less RV prominence in the right precordial

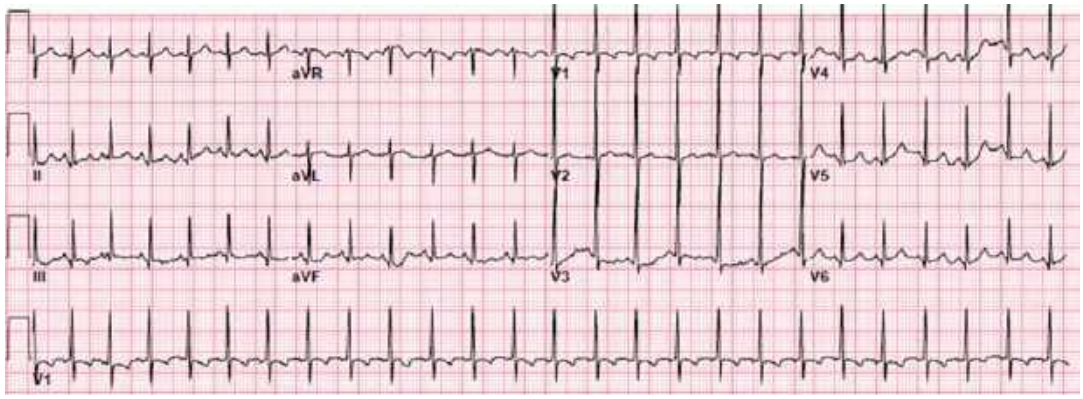

Fig. 20.3 Normal ECG of a 2-week-old infant. Note the *rightward* QRS axis, the prominent R wave in V1, and the inverted T wave in V1

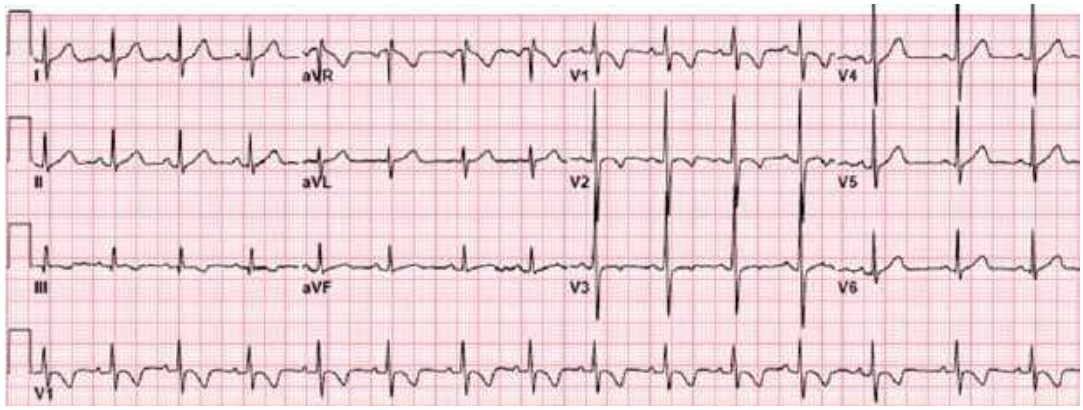

Fig. 20.4 Normal ECG in a 1-year-old. Note the more *leftward* QRS axis and more prominent LV forces in V6, though still a positive R/S ratio in V1 with an inverted T wave in V1

leads, with a more balanced R/S ratio in V1 (Fig. 20.5). The T wave in V1 has remained inverted. There should be little to no S wave in V6 with a predominant R wave in V6.

Note that the predominant change compared to the 1-year-old ECG is the more balanced R/S ratio in V1.

Twelve Years of Age

The ECG in a 12-year-old is similar to the adult, with the exception of the immature ("infantile") T wave pattern that is usually still present in V1, V3R, and V4R. The QRS axis should be predominantly leftward (between −15 and 110°). There is usually a small R wave and deep S wave with good R wave progression from a prominent S wave in V1 to a pure R wave in V6. The T waves are usually still inverted in V1 with upright T waves in V5/V6 (Fig. 20.6).

Late Adolescence: 18 Years of Age

By late adolescence the ECG takes the pattern of the normal adult (Fig. 20.7). The QRS axis is usually normal (−15 to 110°). The T wave now

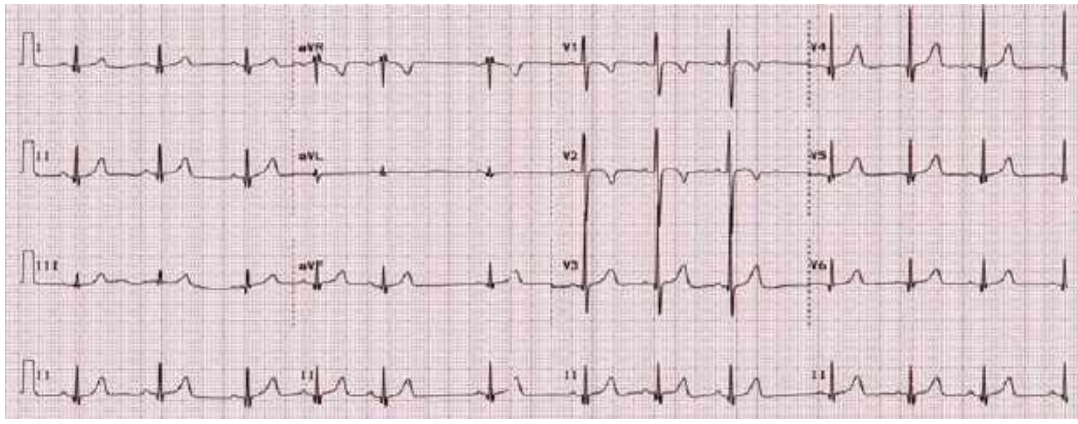

Fig. 20.5 Normal ECG in a 4-year-old

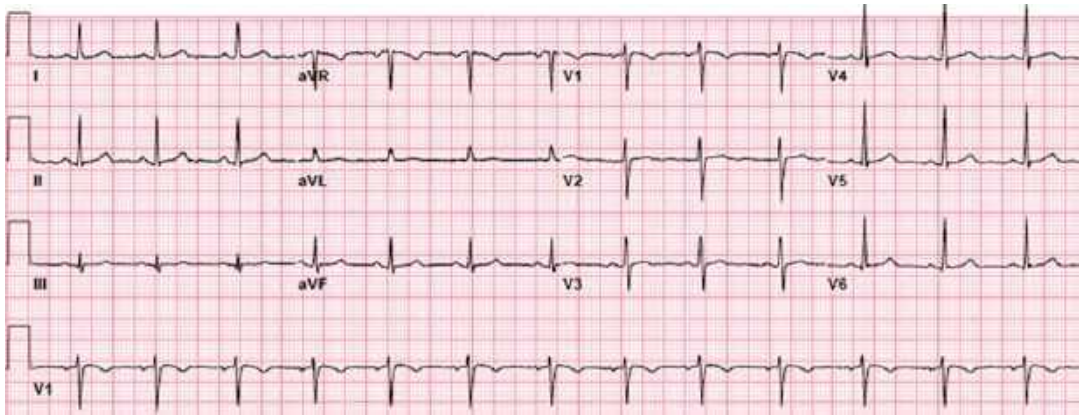

Fig. 20.6 Normal ECG in early adolescence. Note the similarity to the adult ECG, though with a juvenile T wave pattern in V1 with an inverted T wave

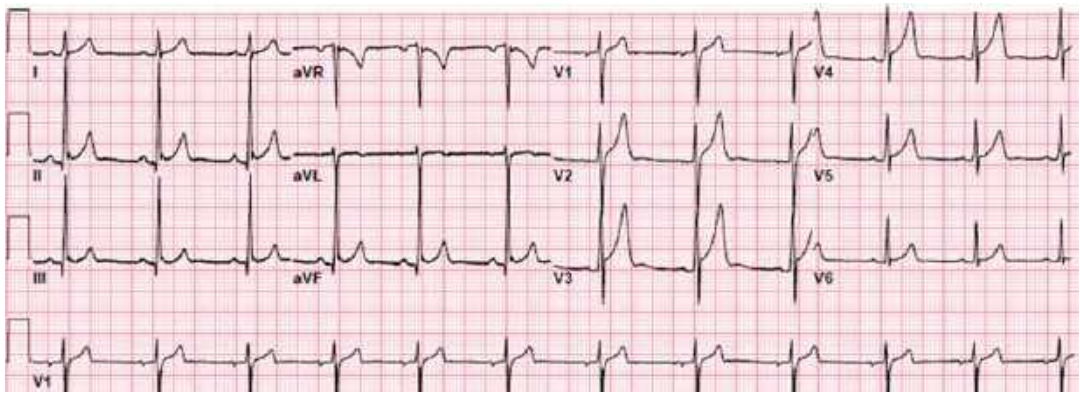

Fig. 20.7 Normal ECG in late adolescent and in young adults. Note the predominance of LV forces with an *upright* T wave in V1

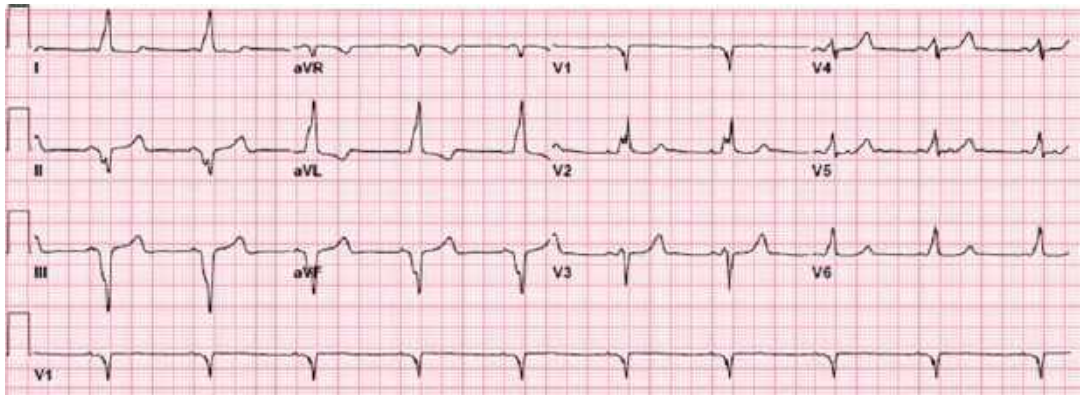

Fig. 20.8 ECG from a 17-year-old patient with palpitations and Wolff-Parkinson-White. Note the short PR interval, wide QRS complex, and delta wave (slurring of the QRS upstroke)

becomes upright in the right precordial leads though may remain inverted in V1. There is usually only a small R wave in V1 with a small S wave. Through the precordial leads there is progression from a deep S wave in V1 to a pure R wave in V6, so-called good R wave progression.

"Top 10" ECG Abnormalities

Wolff-Parkinson-White Syndrome

Wolff-Parkinson-White syndrome (WPW), or ventricular preexcitation, was first described in 1914 with the combined findings of a short PR interval, slurring of the initial upstroke of the QRS complex (delta wave), and a wide QRS associated with paroxysmal tachycardia (Fig. 20.8) [40]. The initial authors did not recognize that the etiology of WPW was the presence of an accessory pathway or extra electrical connection in the heart connecting the atrium and ventricle.

WPW occurs in approximately 0.1 % of the population and is slightly more common in males [41]. The main clinical problem in patients with WPW is the occurrence of supraventricular tachycardia (SVT), primarily AV reciprocating tachycardia (AVRT). The most common form of SVT in patients with WPW is typically orthodromic reciprocating tachycardia (ORT), with antegrade conduction down the AV node and retrograde conduction via the accessory pathway leading to a narrow complex tachycardia. A rarer form of tachycardia in patients with WPW is antidromic reciprocating tachycardia (ART), with antegrade conduction down the accessory pathway and retrograde conduction through the AV node causing a wide complex tachycardia. Both types of SVT can be terminated with vagal maneuvers, administration of IV adenosine, or anti-arrhythmic medications. Current treatment options for patients with WPW include the use of vagal maneuvers to terminate paroxysmal tachycardia, use of chronic anti-arrhythmic medications to prevent episodes of tachycardia, or invasive electrophysiology (EP) testing and ablation of the accessory pathway to permanently destroy the accessory pathway and cure patients of their condition. Ablation is a catheterization procedure performed via access in the femoral and occasionally internal jugular veins with a low risk of complications (1 % of less) and high success rate (88–97 %) [42].

In addition to the risk of developing SVT, patients with WPW have a small risk of sudden cardiac death, estimated to be 0.015 per patient year, or 0.1 % annual risk [41, 43]. Sudden death is believed to be secondary to atrial fibrillation with rapid conduction via the accessory pathway

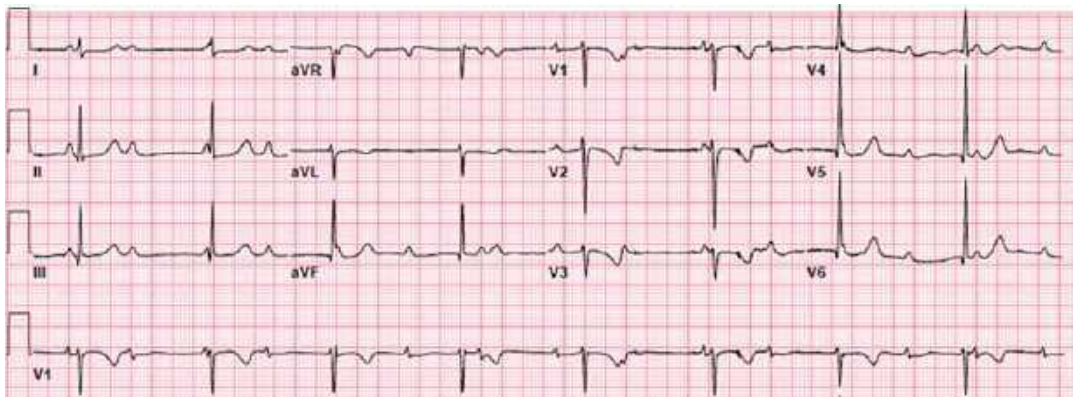

Fig. 20.9 ECG from a 4-year-old female with congenital complete heart block secondary to maternal lupus demonstrates an atrial rate of approximately 100 bpm with a narrow complex junctional escape rate of approximately 50 bpm. Note the regular RR interval with complete AV dissociation

leading to ventricular fibrillation [44, 45]. Invasive EP testing can help determine if a patient with WPW is at higher risk of sudden death. During testing atrial fibrillation is induced, and if the accessory pathway can conduct faster than 250 ms, this would place a patient in a higher-risk group [44]. Recent guidelines recommend exercise stress testing in patients over 8 years of age, and if there is no loss of ventricular preexcitation during the exercise test, invasive EP testing should be considered to determine if the accessory pathway was a "high-risk" pathway, with consideration of ablation in those high-risk patients or those with inducible SVT [12].

Complete Heart Block

Complete heart block (CHB), or third-degree AV block, is the failure of any atrial electrical impulses to be conducted to the ventricles (Fig. 20.9). While the SA node continues to fire regularly, there is no atrioventricular conduction with the result of an atrial rate that typically exceeds the ventricular rate. Patients may be able to maintain cardiac output and systemic blood flow via escape rhythms from within the His-Purkinje system, resulting in a narrow complex escape rhythm, or from within the ventricles, resulting in a wide complex escape rhythm [46].

In children, the most common etiology of CHB is secondary to damage to the AV node and conduction system during surgery for repair or palliation of congenital heart disease (postsurgical CHB) [47]. Other forms of congenital heart disease also have a risk of patients developing heart block, such as heterotaxy syndrome and congenitally corrected transposition of the great vessels (L-TGA), which carries a 1–2 % annual risk or roughly 30 % lifetime risk of developing CHB [48, 49]. Additional acquired causes include infectious diseases such as Lyme disease and other forms of myocarditis, infiltrative diseases such as Hunter's or Hurler's syndromes, thyroid dysfunction, and cardiomyopathies [50–52]. In neonates, the most common cause of CHB is congenital AV block secondary to maternal lupus. Maternal anti-Ro and anti-La antibodies cross the placenta and lead to damage of the conduction system in utero [53, 54].

Treatment of AV block depends on the heart rate, associated factors (such as presence of congenital heart disease), and escape rhythm. In older patients (teenagers and adults), treatment is placement of a permanent pacemaker. In those with postoperative CHB, a period of waiting of 7–10 days should be observed prior to placement

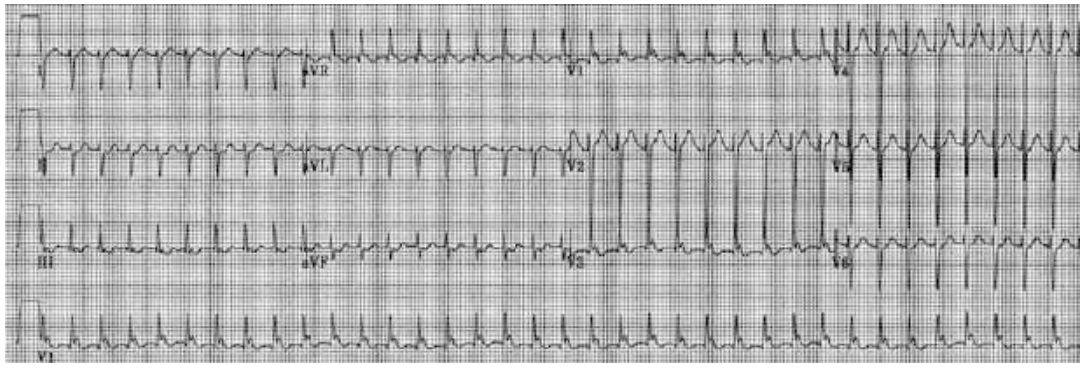

Fig. 20.10 ECG from a 4-month-old female following operative closure of a ventricular septal defect with junctional ectopic tachycardia (JET) at a rate of 215 bpm. The QRS complex was identical to that seen upon arrival to the intensive care unit when in sinus rhythm. Note that there is 1-to-1 ventriculoatrial conduction through the AV node retrograde as seen by the inverted retrograde P waves immediately following the QRS complex in lead III (and upright and more clearly seen in lead V1)

of a permanent pacemaker, as roughly 65 % of patients can recover atrioventricular conduction during this time [46, 55]. In neonates and young children, in the presence of a narrow complex escape rhythm and an adequate heart rate (>55 bpm), placement of a permanent pacemaker can often be delayed until the early teenage years, when the risk of syncope and sudden cardiac death increase.

Junctional Ectopic Tachycardia

Junctional ectopic tachycardia, commonly referred to as JET, is a tachycardia arising from the AV node or His-Purkinje system (Fig. 20.10) [56, 57]. The rhythm is characterized by a QRS complex that is identical to that seen in sinus rhythm, and there is a ventricular rate that is faster than the atrial rate (though in children with preserved AV nodal conduction properties there can be 1:1 retrograde ventriculoatrial conduction).

JET most commonly occurs in children following open heart surgery for congenital heart disease [56–58]. It can cause hemodynamic embarrassment with associated acidosis and poor urine output. Cardiac lesions more commonly associated with JET include ventricular septal defects (VSD), tetralogy of Fallot (TOF), atrioventricular canal repair (AVC), and other lesions that can lead to postsurgical trauma and edema to the His-Purkinje system [56–58].

JET is usually a self-limited disorder in the postoperative period and resolves after 48–72 h. Acute treatment usually involves sedation and pain control, careful cooling and temperature control, electrolyte repletion, minimizing exogenous catecholamines (including IV dopamine, epinephrine, and others), and atrial pacing at a rate faster than the JET rate to improve hemodynamics by providing AV synchrony [59, 60]. Failure of these techniques to resolve or control JET can then lead to treatment with an antiarrhythmic medication such as IV procainamide or IV amiodarone [61–63].

Ventricular Tachycardia

Ventricular tachycardia (VT) is a wide complex tachycardia arising from the ventricles (Fig. 20.11). Electrocardiographic clues to the diagnosis of VT include AV dissociation, a superior QRS axis, fusion beats, and a markedly wide QRS complex (>140 to 160 ms). Though the differential diagnosis for a wide complex tachycardia include ventricular tachycardia, supraventricular tachycardia with

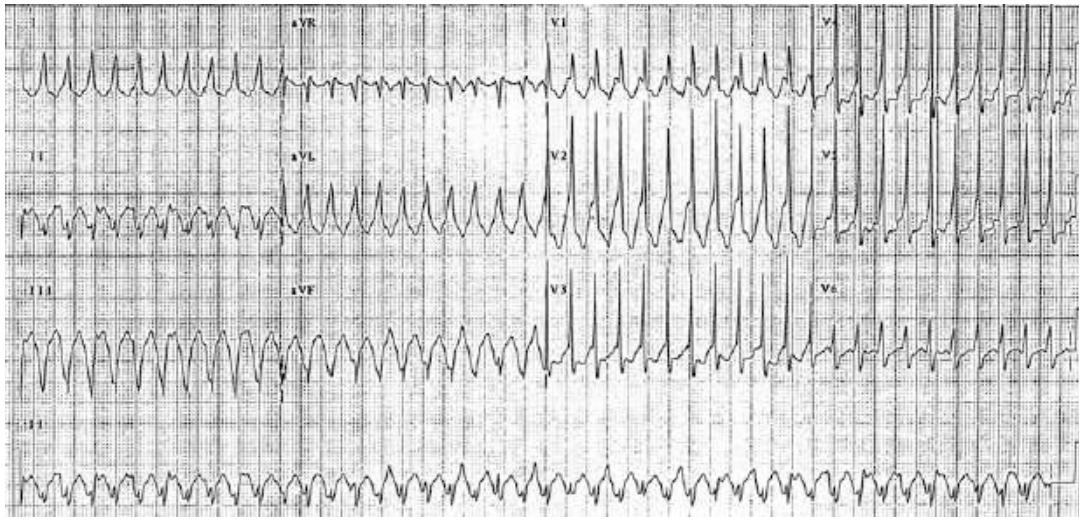

Fig. 20.11 ECG from a 6-month-old female after complete repair of tetralogy of Fallot with ventricular tachycardia at a rate of 230 bpm. The wide complex rhythm has a *left* bundle branch morphology with a superior axis and AV dissociation (as seen in lead II) and a change from a baseline postoperative *right* bundle branch block morphology

aberration, antidromic tachycardia (in a patient with WPW), a paced rhythm, and sinus tachycardia with electrolyte abnormalities or an underlying bundle branch block, it is generally recommended to presume that a wide complex rhythm is ventricular tachycardia until proven otherwise.

Treatment of VT depends in large part to the hemodynamic status of the patient. The hemodynamically stable patient can be given IV lidocaine, procainamide, or amiodarone. The VT could also be terminated with synchronized cardioversion using 2–4 J/kg. The hemodynamically embarrassed patient would require urgent cardioversion.

Supraventricular Tachycardia

Supraventricular tachycardia (SVT) is a regular, narrow complex tachycardia (Fig. 20.12) [64]. The most common cause of SVT in neonates and young children is AVRT mediated by an accessory pathway [64, 65]. In adolescence, the etiology begins to shift to the more common adult form of SVT, AV nodal reentry tachycardia (AVNRT) [65]. If the electrocardiogram is carefully scrutinized, and it can sometimes clue the reader into the diagnosis. In AVRT, there are often retrograde P waves, while in AVNRT the VA time in tachycardia is usually less than 70 ms and there are no discernible retrograde P waves [66]. SVT can often be distinguished from sinus tachycardia by the fixed rate, absence of discernible P waves or P waves with an abnormal axis, and rapid rate greater than 220 bpm. It is not uncommon for SVT rates in neonates to exceed 280–300 bpm.

Acute treatment of hemodynamically stable SVT involves the use of vagal maneuvers, such as ice to the face in neonates, exhalation against a closed glottis, or forcible exhalation. Rapid administration of IV adenosine (0.1 mg/kg) through a large bore IV that is as close to the heart as possible with a 3-way stopcock and a large flush will often terminate SVT [67]. Other anti-arrhythmic options include calcium channel blockers, beta-blockers, digoxin, procainamide, or Class III agents (amiodarone or sotalol) [68–70]. Anti-arrhythmic failure or hemodynamic instability should prompt synchronized cardioversion with 0.5–1 J per kilogram.

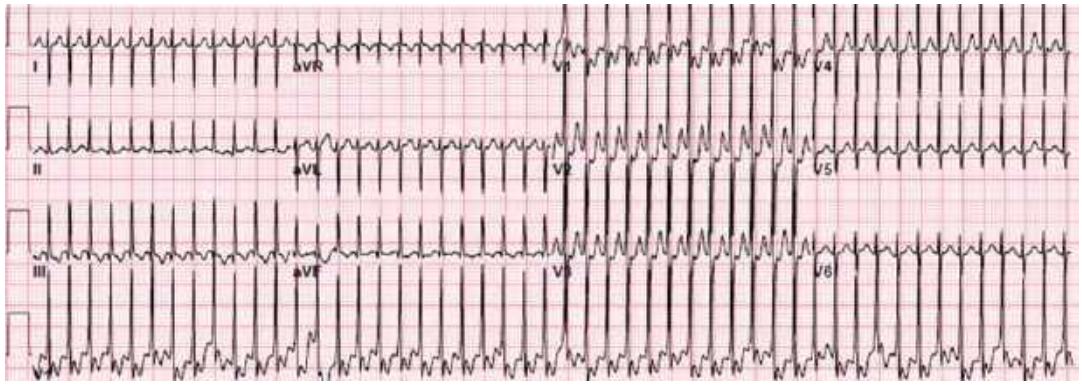

Fig. 20.12 ECG from a 2-day-old male with sudden onset tachycardia demonstrates SVT at a rate of 300 bpm. Note the retrograde P waves in V1 indicating the likely diagnosis of AVRT, the most common cause of SVT in a neonate

Fig. 20.13 ECG is from a 2-day-old female with tachycardia and atrial flutter at an atrial rate of roughly 450 bpm and a variable 2:1and 3:1 ventricular response rate. The rhythm is best seen in the rhythm strip of lead II. Note the classic sawtooth pattern of atrial activation that is commonly seen in atrial flutter

Long-term treatment can involve one of three different treatment strategies: (1) use of vagal maneuvers to terminate tachycardia, (2) use of medications (beta-blockers, calcium channel blockers, flecainide, or sotalol) to prevent episodes of tachycardia, or (3) EP study and ablation to prevent any future episodes of SVT [70].

Atrial Flutter

Atrial flutter, or intra-atrial reentry tachycardia (IART), is caused by areas of slowed conduction in the atria leading to a reentrant loop or propagation of atrial activation. The ECG typically demonstrates a sawtooth, regular pattern of atrial activation with an atrial rate of 200–400 beats per minute with constant or variable ventricular activation (Fig. 20.13). Atrial flutter is rare in children, though more common in those patients with repaired or palliated congenital heart disease, especially single-ventricle patients after Fontan palliation and patients who have undergone atrial switch procedures for transposition of the great vessels (e.g., Mustard or Senning procedures) [71–74].

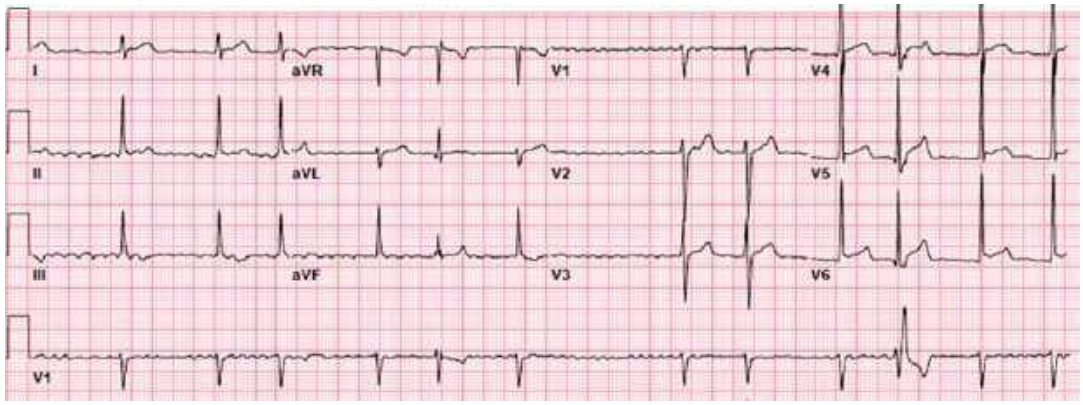

Fig. 20.14 ECG from a 17-year-old male with a 2-week history of palpitations. Note the irregularly irregular rhythm with disorganized atrial activity that is consistent with atrial fibrillation (AFIB). The rhythm strip in V1 also shows a common finding in AFIB, a wide complex beat that is often mistaken for a PVC. This represents "Ashman's phenomenon," or a wide complex beat that conducts with aberration after a long pause, and is not a PVC

Treatment of atrial flutter often depends on the patient presentation and the duration of the tachycardia. Atrial reentry for periods of greater than 24–48 h can be associated with the risk of development of an atrial thrombus and possible stroke. Patients with tachycardia that has clearly been present for less than 24–48 h have a low risk of thrombus formation and stroke and can undergo synchronized cardioversion with 0.5–1 J per kilogram [75]. Medical cardioversion with anti-arrhythmic agents such as Class IC agents (flecainide) or amiodarone could also be attempted [76]. With an unknown duration of tachycardia or tachycardia present for longer than 48 h, treatment options include performing a transesophageal echocardiogram (TEE) to rule out an atrial thrombus followed by immediate synchronized cardioversion or alternatively rate control with beta-blockers, digoxin, and/or calcium channel blockers, anticoagulation, and cardioversion in 6 weeks. Long-term treatment could involve anti-arrhythmic medications or possible curative treatment via catheter or surgical ablation.

Atrial Fibrillation

Atrial fibrillation (AFib) is the most common arrhythmia seen in adults, but is rare in the pediatric population. AFib is characterized by rapid and disorganized atrial activation with no clear, regular discernible P waves and an irregularly irregular QRS response (Fig. 20.14). In children, AFib is more commonly seen in patients with underlying congenital heart disease or a cardiomyopathy, though can rarely occur in children with structurally normal hearts, a condition known as lone AFib [77]. The management and treatment is similar to that of atrial flutter.

Long QT Syndrome

Long QT syndrome is a cardiac channelopathy leading to abnormal ventricular repolarization and ECG findings of prolongation of the corrected QT interval (QTc). These patients are at increased risk of serious ventricular arrhythmias (e.g., torsades de pointes). In general a QTc greater than 450–460 ms is considered abnormal (Fig. 20.15). Additional ECG findings that can help in the diagnosis of long QT syndrome include T wave abnormalities (e.g., tall or peaked T waves, bifid T waves, long ST segments with late T wave development), bradycardia, and T wave alternans. A prolongation of the QTc on ECG can be caused by

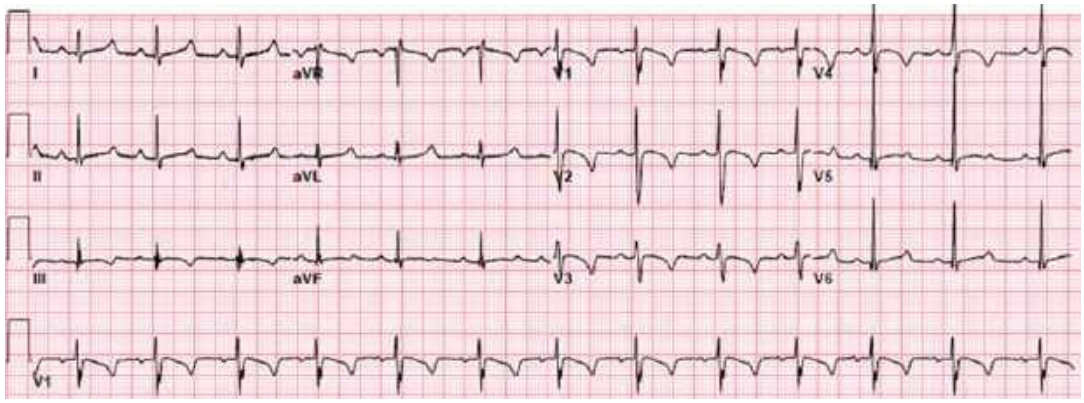

Fig. 20.15 ECG from a 5-year-old female obtained after the sudden cardiac deaths of her father and brother. The patient has a QTc of 520 ms with a long flat ST segment and was diagnosed with long QT syndrome

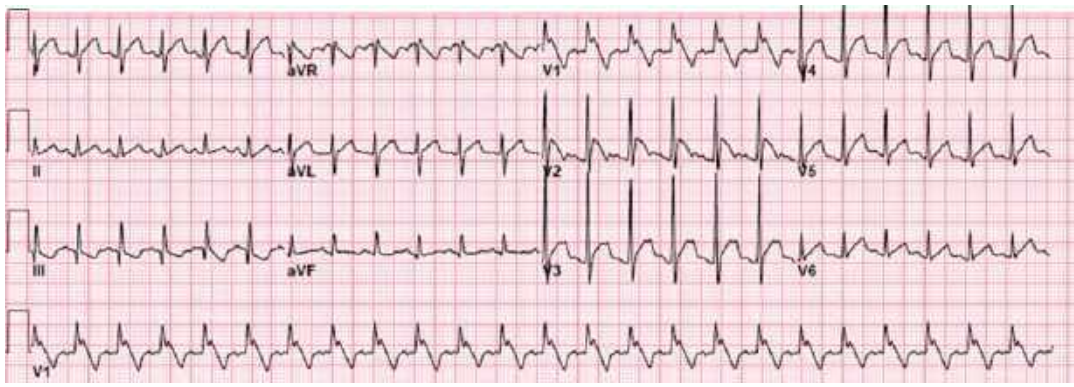

Fig. 20.16 ECG from a 4-year-old male obtained after a syncopal episode. Note the RSR' pattern in V1/V2 with a coved ST segment in V2 that is classic for Brugada syndrome

a true channelopathy or via an acquired cause, such as medications or electrolyte disturbance.

The clinical presentation in children and adolescents with long QT can vary from syncope and seizures to sudden cardiac death. Treatment usually entails use of a beta-blocker which has been demonstrated to decrease the risk of sudden cardiac death, avoidance of medications that prolong the QTc, and possible placement of an implantable cardioverter-defibrillator (ICD) [78, 79]. Specific genotype and long QT subtype therapy may include exercise restriction, avoidance of specific triggers, anti-arrhythmic therapy (Na channel blockers), and stellate ganglionectomy [80, 81].

Brugada Syndrome

Brugada syndrome was first described as a finding in patients surviving cardiac arrest in the late 1980s and early 1990s [82, 83]. The ECG findings in Brugada syndrome involve ST elevation in V1 through V3 with an RSR or RBBB pattern (Fig. 20.16). The syndrome is a heritable channelopathy that can lead to sudden death and most commonly occurring during sleep. The syndrome is one of the most common causes of sudden death in Southeast Asian populations.

Treatment options are limited in patients with Brugada syndrome. Avoidance of fever is a mainstay of treatment, as fever may precipitate

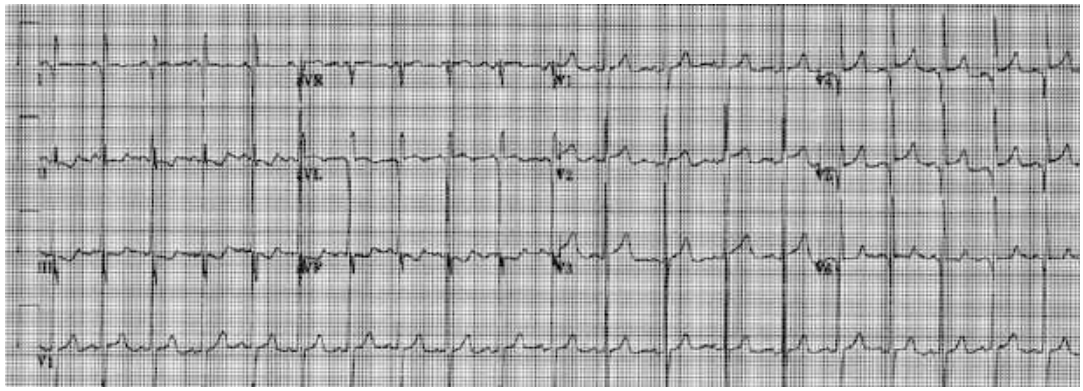

Fig. 20.17 ECG is from a 2-month-old female who presented with sweating, irritability, and feeding intolerance and was found to have an anomalous left coronary artery arising from the pulmonary artery (ALCAPA). Note the deep Q waves in leads I and AVL and also in V4/V5/V6 that are indicative are prior *left* ventricular myocardial infarction. Other notable findings include evidence of RV hypertension with an *upright* T wave in V1 and ST/T wave abnormalities in the inferior and lateral leads

malignant ventricular arrhythmias. ICDs may be indicated in certain patients to prevent sudden cardiac death from ventricular tachycardia and ventricular fibrillation (VF).

Anomalous Left Coronary Artery from the Pulmonary Artery

An anomalous left coronary artery arising from the pulmonary artery (ALCAPA) is a rare congenital anomaly [84]. As pulmonary resistance falls over the first several weeks of life, there is a steal phenomenon whereby coronary blood flow preferentially flows away from ventricular myocardium to the pulmonary artery, leading to myocardial ischemia and myocardial infarction [84]. Affected infants often present in the first 4–6 weeks of life with irritability, sweating or tachypnea, and with feeding and respiratory difficulties. The ECG in these infants often reflects a pattern consistent with an infarct of the left ventricle with deep Q waves in the lateral leads (I and AVL), diffuse ST/T wave changes, and LV enlargement (Fig. 20.17) [85]. Infants with ALCAPA require surgical repair, and the poor ventricular function, LV enlargement, and mitral regurgitation that frequently occur as a result of the LV infarct usually resolve over a period of months to years [86–89].

Basic Notions of Electrophysiology: Intracardiac Electrophysiology

Introduction

Though once viewed as an investigational pediatric procedure reserved either for research purposes or evaluation of arrhythmias that were not decipherable using noninvasive methods, the intracardiac electrophysiology study (EPS) has developed in the past two decades into a commonly performed study for both diagnostic and interventional purposes. [65, 90, 91] The rise of the EPS has been closely linked to the increasing ubiquity of catheter ablation, which has now become the treatment of choice for the management or cure of serious arrhythmias in children and adults [92–94]. When used in concert with noninvasive assessment techniques, it is rare that a patient's arrhythmia mechanism cannot be fully elucidated by the pediatric electrophysiologist, thus leading to more properly tailored arrhythmia therapies.

Table 20.3 Common indications for electrophysiology study

1. Ventricular stimulation study to determine the ease of inducibility of potentially life-threatening ventricular arrhythmias in patients thought to be at possible risk of sudden cardiac death
2. Risk assessment in the setting of WPW, performed either via an intracardiac catheter or via an esophageal pacing catheter
3. Assessment of anti-arrhythmic drug efficacy
4. Evaluation of unexplained syncope

Table 20.4 Indications for ablation in children

1. Curative treatment of accessory AV connections (e.g., WPW, concealed accessory pathways)
2. Curative treatment of AV nodal reentrant tachycardia (AVNRT)
3. Curative treatment of «automatic arrhythmias (e.g., ectopic atrial tachycardia, ventricular tachycardia, some forms of junctional tachycardia)
4. Palliative or curative treatment of intra-atrial reentrant tachycardia in the postoperative patient (e.g., atrial flutter in a Fontan patient)

Indications

The intracardiac EPS has evolved from a procedure that was initially exclusively diagnostic in nature to one that is more commonly used for therapeutic purposes. With the advent of catheter ablation and the comprehensive array of noninvasive electrophysiologic monitors, it is increasingly uncommon for EPS to be performed for exclusively diagnostic purposes. However, despite this trend, the EPS is perhaps still the best means of providing certain diagnostic electrophysiologic data to the clinician. The most common diagnostic indications for EPS are shown in Table 20.3.

As the diagnostic indications for EPS have receded over the recent two decades, the therapeutic indications have widened and broadened. The reason for this is that the types of arrhythmias amenable to transcatheter ablation have grown and the general safety of ablation for the pediatric patient has improved for children of increasingly younger age. [95, 96] Though once viewed as a procedure for only the most recalcitrant or dangerous of arrhythmias, ablation has now become, for many common pediatric arrhythmia substrates, the treatment of choice. Indications for ablation in children are listed in Table 20.4.

Technical Aspects

Invasive EP procedures are typically performed in a cardiac catheterization laboratory and, in children, are usually performed with sedation or general anesthesia. Patients must be properly assessed prior to catheterization in order to evaluate suitability for an invasive procedure including anesthesia. This assessment must include a complete history and physical examination to rule out noncardiac conditions that might increase the risk of any invasive procedure. Unless an EP study is planned to test anti-arrhythmic drug efficacy, anti-arrhythmic drugs should be discontinued at least 5 half-lives prior to the procedure. Those patients with life-threatening arrhythmias may require hospitalization prior to ablation when anti-arrhythmic therapies are discontinued temporarily.

Assessment of the patient undergoing electrophysiologic study must be made by the anesthesiologist providing sedation prior to the procedure. Careful choice of anesthetic technique is imperative as certain agents are either pro-arrhythmic or may potentially reduce arrhythmia inducibility [92, 97, 98]. Additionally, it is often useful to have copies of a patient's resting surface ECG as well as tachycardia tracings in the laboratory in order to have them as a means of comparison during the procedure.

Once in the catheterization laboratory, extensive monitoring and safety precautions are taken. Radiolucent defibrillation pads are affixed prior to catheterization to allow for rapid cardioversion or defibrillation. Blood pressure monitoring, oxygen saturation monitoring, and full 12-lead ECG monitoring are standard for these procedures. Some laboratories will monitor blood pressure continuously with placement of

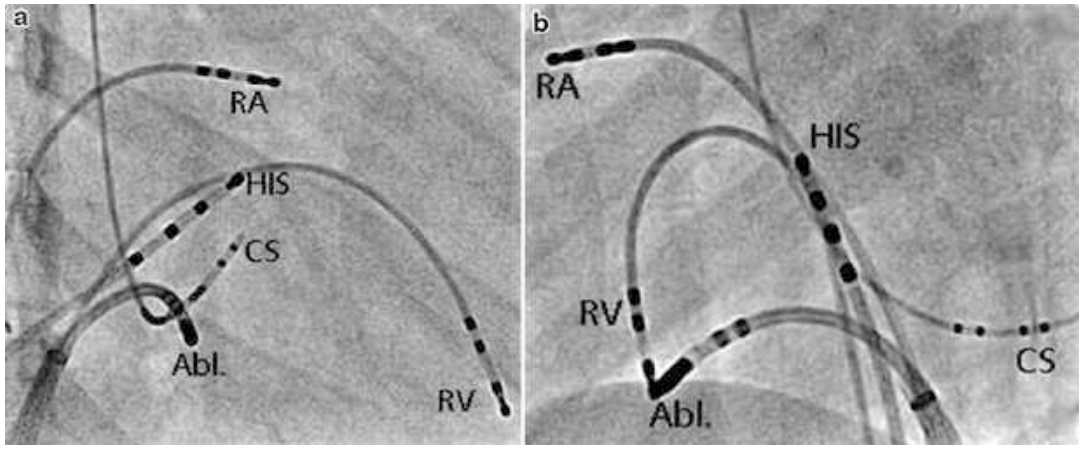

Fig. 20.18 RAO (**a**) and LAO (**b**) views of standard EP catheters in position with the ablation in *right* posterolateral location (*RA* right atrium catheter, *RV* right ventricle catheter, *His* His catheter, *Abl*. ablation catheter, *CS* coronary sinus catheter)

a small catheter either centrally (e.g., femoral artery) or peripherally (e.g., radial artery).

Proper laboratory staffing is essential to ensure patient safety during EP testing and ablation. Typically, most laboratories will have a trained electrophysiology nurse as well as laboratory technologist in addition to one or two electrophysiologists. Many laboratories prefer having 2 electrophysiologists with one operator at the table moving catheters and the other analyzing signals as well as conducting pacing maneuvers. As already noted, proper anesthesiology personnel who are knowledgeable about the management of cardiovascular arrhythmias are preferred.

After induction of anesthesia, catheters are typically placed using modified Seldinger technique in the femoral veins as well as the internal jugular or subclavian vein. The number of diagnostic catheters used can vary depending upon the type of invasive electrophysiologic study planned. For diagnostic studies, the operator typically uses one or two catheters which can be positioned in different locales in the heart during the procedure. For ablation procedures, it is routine to place between 4 and 5 multipole electrical catheters in the heart. The catheters are typically advanced to the heart and placed in standard locations. These include the right atrium, right ventricular apex, HIS position, and coronary sinus. The final catheter is usually the ablation catheter (Fig. 20.18). Fluoroscopy is most commonly used to position catheters in the heart during EP study and ablation. Recently, use of adjuncts such as three-dimensional mapping systems and intravascular echocardiography has been advocated by some groups to the reduce radiation dose associated with these procedures [99]. Three-dimensional electroanatomical mapping systems (e.g., CARTO Biosense Webster) are also useful when mapping complex arrhythmias such as atrial reentry or ventricular arrhythmias of any sort.

Central to all electrophysiologic testing is a programmable stimulator and electrophysiologic recording system. Programmable stimulators allow for provocative pacing maneuvers which can be used to induce arrhythmias as well as assess conduction characteristics of the atrium, ventricle, AV node, and accessory pathways. Most such devices should allow for programmable characteristics such as pulse width, current, and cycle length. By convention, most pacing in the heart is performed at two times the diastolic pacing threshold. The electrophysiologic recording system should be capable of recording multiple channels of information simultaneously. These would include the surface ECG as well as electrograms recorded from all of the intracardiac catheters. Optimally, the computer should allow for recording and display of all signals at varying

Fig. 20.19 Example of AH (45 ms) and HV (50 ms) intervals

paper speeds from 25 mm/s to 400 mm/s. Standard filtering should allow for filtering of all waveforms below 30 Hz and above 500 Hz in order to properly remove electrical "noise" from recordings.

The final critical device for invasive EP procedures is an ablation generator for either radiofrequency (RF) energy or cryoenergy. Most laboratories have the ability to do either, as RF current and cryoenergy have distinct and separate indications, and these are typically based upon specific patient and arrhythmia characteristics.

Interpretation

Interpretation of complex intracardiac tracings is beyond the scope of this chapter. However, basic concepts are important and relevant. After placing catheters as noted above, baseline resting intracardiac conduction time intervals are recorded. This includes recording of the surface ECG as well. These are often useful in helping make an initial diagnosis of preexcitation as well as providing a baseline as a means of comparison following ablation and catheter manipulation within the heart. The most important two intracardiac measurements are the AH and HV intervals (Fig. 20.19).

The AH interval allows the electrophysiologist to assess AV nodal function and is the measurement from the low right atrial electrogram to the earliest onset of the rapid His deflection in that same electrical pair. As the AV node is electrically silent and as the AV node conducts the electrical impulse from the low right atrium to the bundle of His, the AH interval is used as a surrogate of AV nodal function. A normal AH interval in children is between 50 and 100 ms. It is typically lengthened in patients with AV nodal injury ("first-degree heart block") and also as a result of certain drugs (e.g., digoxin). The second important intracardiac measurement is the HV interval which measures conduction from the proximal His to ventricular myocardium via the Purkinje system. It is measured from the rapid His deflection to the earliest ventricular activation in any lead on the recording system, including surface or intracardiac. A normal HV interval in children is typically between 30 and 50 ms. HV intervals can be prolonged in patients with conduction disorders such as infiltrative myopathies or in patients who have undergone congenital heart surgery and sustained injury. The interval can be shortened in preexcitation conditions such as WPW.

Assessment of the pattern of conduction (both antegrade and retrograde) can be made in sinus rhythm and with ventricular pacing. When conduction is deemed "concentric," the conduction proceeds both antegrade and retrograde earliest in the His catheter pairs, suggesting that the conduction is either via the AV node or an accessory pathway located near to the AV node (Fig. 20.20). If, however, the conduction is "eccentric," the earliest signals can be seen in a location other than the "central" His catheter. If earliest in the coronary sinus pairs, the possibility of a left-sided accessory pathway would be raised. If earliest in the proximal coronary sinus

Fig. 20.20 Example of a patient with WPW and a *left*-sided accessory pathway. The tracings on the *left* show a patient in sinus rhythm with no preexcitation and a normal AH and HV intervals. The tracings on the *right* in a patient with WPW demonstrate an HV interval of 0 ms with earliest ventricular activation in the CS5–6 pair indicative of a *left*-sided accessory pathway

Fig. 20.21 Orthodromic reentrant tachycardia with a *right*-sided pathway. Note that the earliest atrial depolarization in tachycardia is the high right atrial pairs suggesting a *right*-sided pathway location

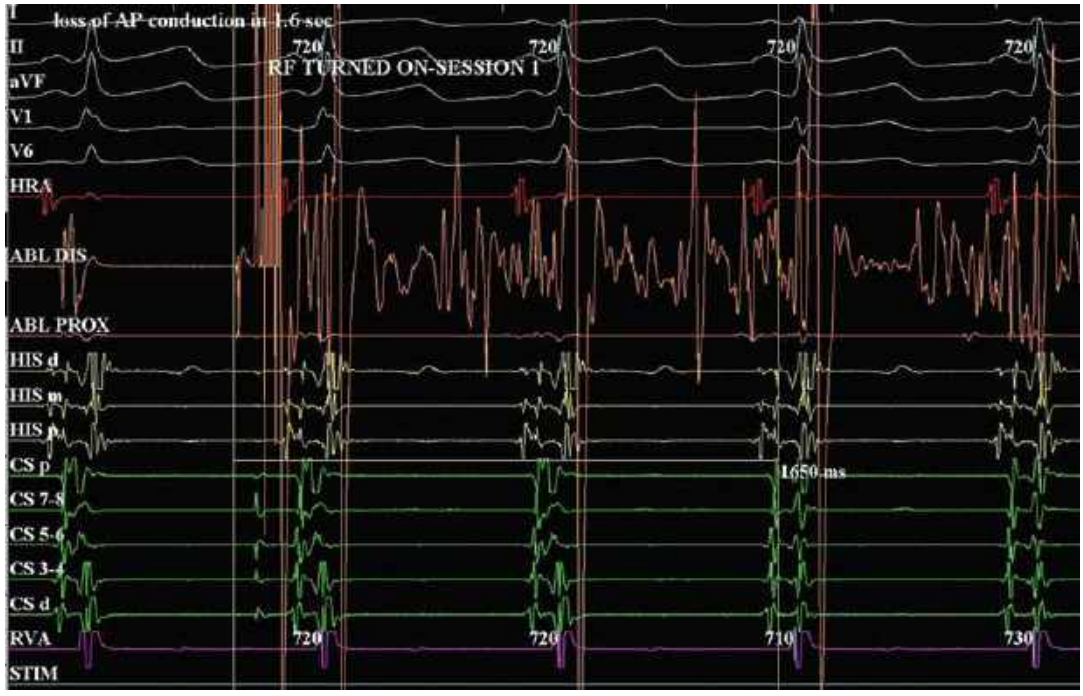

Fig. 20.22 Loss of AP conduction in a patient with WPW and a *left*-sided pathway. In this example radiofrequency energy is turned on producing a notable artifact on the ablation catheter (ABL DIS) and loss of accessory pathway conduction in less than 1.650 s. This is best seen by the change in the QRS morphology in surface lead V1 and the change in intracardiac conduction seen in the coronary sinus lead CS5–6

or in a catheter placed on the tricuspid annulus away from the atrial septum, the possibility of a right-sided accessory pathway would be raised (Fig. 20.21).

Once the above measurements and observations have been made, provocative testing is typically conducted. This includes determination of refractory periods of the atrium, AV node, accessory pathways (if present), and ventricle. Additionally, refractory periods of the ventricle, AV node, and accessory pathways (if present) are also routinely measured and recorded.

Following the above maneuvers, mapping of the arrhythmia substrate is performed (Fig. 20.22). Following mapping and ablation, it is routine to test for at least 20–60 min to confirm that the ablation was successful and there are no other mechanisms for tachycardia. If these two criteria have been established, catheters and vascular sheaths are removed and the patient awakened from anesthesia/sedation.

Overview of Therapies

Over the past 25 years, pediatric cardiac electrophysiology has markedly evolved from a predominantly diagnostic specialty to an interventional one. With the advent of catheter ablation, it is now possible to permanently cure most non-channelopathy-induced arrhythmias that previously required lifelong drug therapy. Ablation has become the treatment of choice for most supraventricular arrhythmias in children above the age of 5–8 years, and the technology has even been applied safely and effectively to younger and smaller patients [93, 94, 100–102]. The understanding of channelopathies has blossomed in recent decades, and the possibility for

personalized, gene-directed therapies is no longer the stuff of fiction [103, 104]. It is anticipated that continued work in the molecular genetics of channelopathies will continue to yield new therapies aimed at the source of arrhythmias in these patients.

From the perspective of device-based therapy, the technological advances in pacemakers and implantable defibrillators have allowed for expansion of their use in even the smallest patients [105, 106]. Additionally, newer data are helping refine which patients are most appropriate to receive these devices [107, 108]. Newer, less invasive technology is allowing further expansion of device therapy to patients who were not previously considered candidates, but further studies will be needed to demonstrate if this anticipated expansion in therapies will be justified or appropriate [109–111].

Echocardiographic Assessment of Cardiac Disease

21

Sarah Chambers and Leo Lopez

Abstract

Echocardiography is the mainstay for the assessment of cardiac structure and function in patients with possible or known heart disease from fetal life to adulthood. The indications for echocardiography include signs and symptoms such as cyanosis, heart failure, arrhythmia, the presence of systemic or syndromic disorders associated with cardiac abnormalities, and a family history of inherited cardiac diseases. In patients with known heart disease, the echocardiogram provides important information about the effects of the disease on cardiac hemodynamics and function and is used to direct medical and surgical therapies. Two- and three-dimensional imaging delineates the structures of the heart and their relationships to each other. Color, pulsed wave, and continuous wave Doppler can identify abnormal patterns of blood flow and can estimate pressure gradients between chambers. Assessment of cardiac function is performed using two- and three-dimensional imaging and Doppler modalities. Quantitative echocardiography provides important information about the size and function of the vessels and chambers.

Introduction

Echocardiography is the mainstay for the assessment of a patient with possible or known cardiac disease. In the current era, the diagnosis of congenital heart disease is usually made by echocardiography, either prenatally by fetal echocardiography or postnatally with transthoracic echocardiography. In addition to the anatomic assessment of the heart, the echocardiogram provides detailed information on hemodynamics and cardiac function. The indications for the performance of a pediatric echocardiogram are varied and span a wide range of symptoms, physical examination findings, results from other diagnostic modalities, and associated disease states.

Suspected Congenital Heart Disease

Fetal Echocardiography: The indications for fetal echocardiography include a suspected anomaly on obstetric ultrasound, a first-degree relative with congenital heart disease (i.e., sibling or parent of the fetus), a maternal condition or exposure known to increase the risk of congenital heart disease in the fetus, fetal arrhythmia, hemodynamic compromise in the fetus, and extracardiac or chromosomal abnormalities in the fetus associated with an increased risk for congenital heart disease. A more extensive list of indications for fetal echocardiography can be found in the "American Society of Echocardiography Guidelines and Standards for Performance of the Fetal Echocardiogram" by Rychik et al., published in 2004 [1], and in "A Practical Guide to Fetal Echocardiography" by Abuhamad and Chaoui [2].

Transthoracic Echocardiography: There are many indications for a pediatric transthoracic echocardiogram. These include physical signs and symptoms such as cyanosis (especially desaturation not responsive to oxygen stimulation or hyperoxia test), respiratory distress, poor feeding, exertional chest pain or syncope, exercise intolerance, failure to thrive, oxygen saturation and/or blood pressure differential between the pre- and postductal measurements, congestive heart failure, and hemodynamic compromise. Findings from other diagnostic modalities such as an abnormality on an electrocardiogram or cardiomegaly on a chest x-ray are also indications for a pediatric echocardiogram. A detailed list of indications for the performance of an echocardiogram (in pediatric and adult age groups) can be found in the joint guidelines and standards document for the clinical application of echocardiography [3]. Another discussion of pediatric-specific indications can be found in "The Guidelines and Standards for the Performance of a Pediatric Echocardiogram" from the American Society of Echocardiography [4].

Suspected acquired heart disease in children is another indication for pediatric echocardiography. Examples include Kawasaki disease, infective endocarditis, rheumatic heart disease, pericarditis, myocarditis, and cardiomyopathies (hypertrophic, dilated, and restrictive) [4]. Pediatric arrhythmias may be associated with structural heart disease, such as cardiomyopathy, Ebstein's anomaly, or atrioventricular canal defects. Sustained arrhythmias can affect cardiac function with an increased risk for the development of an intracardiac thrombus, a contraindication for cardioversion prior to anticoagulation therapy. Therefore, a known arrhythmia is another indication for an echocardiogram in a pediatric patient.

A pediatric echocardiogram is also indicated if there is a known disease state or familial disorder that carries an increased risk for congenital heart disease. Chromosomal abnormalities such as trisomy 21 and 22q11 deletion, some metabolic or storage disorders, and a first-degree relative with a congenital heart

disease are examples of such indications. Some cardiomyopathies including dilated and hypertrophic cardiomyopathy (HCM) can be familial, so a first-degree relative with known cardiomyopathy is also an indication for an echocardiogram.

Evaluation of Known Heart Disease (Congenital or Acquired)

Serial echocardiograms are performed in patients with known congenital or acquired heart disease to monitor the effects of the structural abnormality on cardiac size and function, to help guide the clinical decision regarding the need for possible surgical or catheterization-based intervention, and to evaluate the effect and sequelae of any interventions [5]. Transthoracic echocardiography is often used to help guide interventions at the bedside, such as pericardiocentesis and balloon atrial septostomy. Patients undergoing surgical repair often have a transesophageal echocardiogram intraoperatively to evaluate the anatomy, the surgical repair, and the ventricular function. Transesophageal echocardiography is also used during certain catheter-based interventions (such as device closure of an atrial septal defect) to help guide the interventional cardiologist during the procedure.

Noncardiac Disease States that Can Affect the Heart

Systemic illnesses such as systemic lupus erythematosus, systemic and pulmonary hypertension, HIV infection, and sickle-cell disease carry an increased risk of cardiac effects, and echocardiography is performed to monitor cardiac function and hemodynamics [4]. Exposure to cardiotoxic drugs (such as anthracycline chemotherapeutic agents) can affect ventricular function acutely and later in life, and therefore, this is an indication for serial -echocardiograms. Any patient who is a potential donor for heart transplantation requires echocardiographic evaluation. Patients with sepsis or thromboembolic events who have indwelling catheters may also merit an echocardiogram to evaluate the cardiac function and to search for intravascular or intracardiac thrombi [4].

Technical Aspects

Imaging Modalities

Echocardiography can be performed by positioning the ultrasound probe on the chest (*transthoracic imaging*), in the esophagus (*transesophageal imaging*), on the heart itself with the chest open (*epicardial imaging*), and within the heart or vascular system during a cardiac catheterization (*intracardiac imaging*). While most echocardiographic evaluation in pediatric patients is accomplished by transthoracic imaging, there are some scenarios in which these more invasive methods may be required.

Transesophageal echocardiography is most commonly performed during a cardiac procedure to confirm the anatomic diagnosis, assess the pre- and post-procedural cardiac structure and function, and for guiding catheter-based interventions such as device closure of an atrial septal defect. Transesophageal echocardiography is also performed in patients with suspected cardiac disease in whom the transthoracic windows do not allow adequate visualization of the heart, such as patients with suspected congenital heart disease, possible endocarditis, or possible intracardiac thrombus formation (such as in sustained tachycardia). A thorough list and discussion of the indications and contraindications for a pediatric transesophageal echocardiogram can be found in "Indications and Guidelines for Performance of Transesophageal Echocardiography in the Patient with Pediatric Acquired or Congenital Heart Disease" from the American Society of Echocardiography [6].

Epicardial echocardiography can be performed during surgery while the chest is open in patients in whom a transesophageal echocardiogram is contraindicated because of technical considerations such as an esophageal stricture or a Nissen fundoplication. In some

disease states such as pulmonary venous abnormalities, the transesophageal ultrasound probe sits in the esophagus posterior to the heart and may create distortion of the anatomy and interfere with the surgical repair.

Intracardiac echocardiography (ICE) has become routine in the adult cardiac catheterization laboratory and is emerging as a useful modality in the pediatric cardiac catheterization laboratory. In this modality, a catheter with an ultrasound probe at the tip is advanced intravascularly into the heart to image the cardiac structures.

Sedation

A typical pediatric echocardiogram usually requires 20–60 min to complete depending on the complexity of the heart disease and the level of patient cooperation. Teenagers and older children are usually cooperative and younger children can be distracted by videos, music, or games. Conscious sedation may be needed in infants and young children. Chloral hydrate, midazolam, and pentobarbital have been reported to be safe and effective in babies and young children for oral outpatient sedation [7–11]. The American Academy of Pediatrics has published guidelines for the monitoring and management of pediatric patients undergoing sedation for procedures [12, 13]. Children older than 3 years of age who are unable to cooperate for the study may require the use of moderate or deep anesthesia.

Ultrasound Physics

Echocardiography utilizes ultrasound waves to create images of the heart based upon the physical properties of sound waves and the principle of piezoelectricity. A sound wave travels at a known velocity through any given medium, and this velocity is specific to that medium. Ultrasound waves travel at a frequency above 20 kHz (the audible frequency range is 20 Hz–20 kHz). In the late 1800s, Pierre Curie and his brother Jacques discovered piezoelectricity [14], which is a property of certain crystalline materials wherein mechanical compression of the crystal by sound waves produces an electric charge between opposite surfaces. Conversely, if an electric charge is passed through the crystal, a physical distortion of the crystal occurs and a sound wave is generated. Examples of piezoelectric materials are ferroelectrics, barium titanate, and lead zirconate titanate.

An ultrasound wave is produced by passing an electrical signal through an array of piezoelectric crystals that are located at the tip of the ultrasound probe. As described above, this causes the crystals to deform and to vibrate at a frequency that produces an array of ultrasound waves. These ultrasound waves are focused into an imaging beam which is projected into the patient; the ultrasound waves travel through the soft tissue of the body at a known velocity (1,530 m/s) [15]. Ultrasound waves obey the laws of optical reflection and refraction: as they travel through a medium, they are either absorbed (attenuated), refracted, or reflected. Any reflected ultrasound waves that encounter the ultrasound probe deform the piezoelectric crystals, generating an electrical current that is analyzed by a central processing unit (CPU) and converted to a video image.

Image Production

An array of ultrasound waves can be focused into an imaging beam such that the reflected waves that return to the ultrasound probe are from a tissue target within the body such as the heart. The CPU uses the "time of flight" interval and the amplitude of the wave to construct the video image [15]. "Time of flight" is the interval between the transmission of the imaging beam and the detection of the reflected wave and is directly related to the distance of the structure [being imaged] from the ultrasound probe. This is represented as the depth at which the structure is displayed on the imaging screen. The amplitude of the reflected wave represents the energy contained within the wave and is proportional to the density of the reflected tissue. This is measured by the size of the electric current generated and is represented as "brightness" on the imaging screen. Thus, a very dense structure (such as bone) will appear bright on an ultrasound image, and

a structure without much density (such as blood) will appear dark. Interestingly, gas reflects almost all of the energy from an ultrasound wave and therefore also appears bright on the imaging screen. Structures that lie beyond bone or gas cannot be seen by ultrasound imaging, as the ultrasound waves cannot reach them.

Image Acquisition

A high-frequency ultrasound wave allows smaller structures to be accurately evaluated with better spatial resolution, but it also results in more attenuation of the ultrasound energy, resulting in less penetration into the tissue. Using this principle, high-frequency ultrasound is often used to perform echocardiograms on babies and infants, but a lower frequency is usually required to image the heart of an adult patient as the distance of the cardiac structures from the chest wall is significantly larger.

Doppler

Ultrasound technology uses the Doppler principle to calculate the velocity of a moving object. In echocardiography, the moving object is most often blood or myocardium. The Doppler principle describes the phenomenon in which the frequency of a wave reflected off a moving object is related to the velocity and direction of the moving object relative to the observer. Christian Doppler first described this phenomenon while studying distant stars, and it is a basic principle of astrophysics. The example frequently used in teaching the Doppler principle involves the change in pitch of a fire engine siren (or train whistle) as the fire engine approaches and then moves away from an observer on the street. When the fire engine is moving towards the observer, the perceived frequency of the siren increases and is greater (i.e., higher pitch) than the actual frequency of the transmitted sound wave. Conversely, as the fire engine passes the observer, the perceived frequency of the siren decreases and therefore appears to change to a lower-pitched sound. In ultrasound, the Doppler effect can be used to display the direction and velocity of moving objects (such as blood or myocardium) in relation to the ultrasound probe.

Mathematically, the frequency shift (Δf) described by the Doppler effect is related to the velocity of the moving object (V), the frequency of the transmitted wave (f_t), the speed of the wave through the medium (c), and the cosine of the angle of interrogation (θ), which is the angle between the transmitted wave and the direction of the moving object. This equation is called the Doppler equation:

$$\Delta f = 2\, f_t \times [V \times \cos\ \theta]/c]$$

If Δf is known, the equation can be solved for V:

$$V = (\Delta f \times c)/[(2\ ft) \times \cos\ \theta]$$

This equation is used to calculate the velocity of blood flow or myocardial tissue within the body. It is important to note the inverse relationship between the cosine of the angle of interrogation and the velocity of the moving structure. Mathematically, the cosine of zero is one. Therefore, the most accurate calculation of blood flow or myocardial velocity is when the blood or myocardial tissue is traveling parallel to the ultrasound wave. Conversely, the cosine of 90° is zero, so the velocity of blood or myocardial tissue traveling perpendicular to the ultrasound wave cannot be calculated.

Using Doppler to Estimate Pressure

The Bernoulli equation describes the fluid dynamics of a flow restrictor [15]. In echocardiography, this principle can be applied to a fixed obstruction (e.g., aortic or pulmonary stenosis) or a fixed communication between high-pressure and low-pressure systems (e.g., a ventricular septal defect). The Bernoulli equation states that the pressure difference between two points on either side of a flow restrictor is proportional to the difference between the squares of the velocities at those two points. The equation has many additional terms to describe flow acceleration, convection acceleration, and viscous friction. There is also a constant representing the mass density of the material in question. For echocardiographic purposes, a modified Bernoulli equation is used

in which it is assumed that the flow acceleration at each point and the viscous friction of the blood on the walls of the vessel are negligible; this equation is

$$\Delta P = 0.5\rho\,(V_2{}^2 - V_1{}^2)$$

Further simplification is possible as it is known that in a person with a normal hemoglobin level, 0.5ρ (density) is equal to 4 [15]. Therefore, the equation is

$$\Delta P = 4\,(V_2{}^2 - V_1{}^2)$$

Finally, if the proximal velocity is relatively low (generally accepted as low if it is less than 1 m/s), then V_1 can be ignored. Thus, the pressure gradient across a fixed obstruction can be estimated by Doppler echocardiography using the equation

$$\Delta P = 4\,V_2{}^2$$

Doppler Modalities in Ultrasound

In echocardiography, the different options for Doppler evaluation are pulsed wave (PW), continuous wave (CW), tissue Doppler (TD), and color mapping. PW Doppler is used to estimate blood flow velocity at a certain point in space, for example, at the mitral inflow. Its advantage is that it allows the interrogation of flow at a focused location; however, it is of limited use in assessing high-velocity flow. CW Doppler is used to estimate the velocity of flow along a line in space (e.g., along the entire left ventricular outflow tract and ascending aorta). While CW Doppler does not localize flow as specifically as PW Doppler, it can evaluate much higher velocities. TD uses PW gating to evaluate the velocity of ventricular myocardium during the cardiac cycle and is used in the evaluation of ventricular function.

Color mapping creates a two-dimensional map of blood flow with the selected area of interest using multiple PW Doppler points. The map contains information about the direction of blood flow related to the ultrasound probe (blue flow is away from the probe and red flow is towards the probe) as well as the velocity of the flow (encoded as the shade of blue or red). One mnemonic to remember the direction of the blood flow is "it *blue* me away." Other students use the simple term BART: blue away, red towards [16]. If the velocity of the blood flow is greater than the limits of the Doppler scale, a phenomenon called "aliasing" occurs in which the color map shows a combination of all the colors. Depending on the scale limits, this can demonstrate high velocity or turbulent flow.

Echo Interpretation

Segmental Approach to Pediatric Echocardiography

Pediatric echocardiographers can encounter an almost limitless combination of structural cardiac anomalies that include abnormalities of situs, atrioventricular or ventriculoarterial connections, septal structures, valves, and great vessels. In order to ensure a complete evaluation of the cardiac anatomy and to ensure accurate communication of the nature of each (often unique) combination of structural abnormalities, pediatric cardiologists have developed the segmental approach to pediatric echocardiography. This approach, also called the "sequential" or "systematic" approach, analyzes the situs, alignments, connections, and morphological abnormalities of each cardiac segment [17]. There are three main cardiac segments (atria, ventricles, and great vessels) and two connecting segments (the atrioventricular canal/junction and the infundibulum or conus) [17]. The segmental approach describes each segment's position, anatomy, and function as well as the connection of each segment to the others.

Cardiac Position: The segmental approach starts by describing the position of the heart in the chest. Levocardia describes a heart located in the left hemithorax with the apex pointed towards the patient's left. Conversely, dextrocardia

describes a heart located in the right hemithorax with the apex pointed towards the right. Some patients have a normal orientation of the axis of the heart, with the apex pointed leftward, but the heart itself is located in the right hemithorax. This may be due to congenital abnormalities of other organs that displace the heart within the thorax. Examples include left congenital diaphragmatic hernia, right lung hypoplasia, or left congenital cystic adenomatoid malformation. In this case, the heart position would be described as dextroposition, and the echocardiographer might specify that the apex of the heart points to the left.

Abdominal and Atrial Situs: After describing the position of the heart in the chest, the echocardiographer moves on to describe abdominal and atrial situs. Abdominal situs solitus describes the normal position of abdominal organs with the liver on the patient's right and the stomach bubble on the patient's left. In atrial situs solitus, the hepatic veins, inferior vena cava, right superior vena cava, and coronary sinus drain to the right-sided right atrium and the pulmonary veins drain to the left-sided left atrium. The delineation of abdominal and atrial situs becomes important in conditions such as heterotaxy in which the sidedness of the body (often including the heart) has not developed normally.

Segmental Approach: The echocardiographer then moves on to a stepwise evaluation and description of the segments of the heart beginning with the systemic and pulmonary veins and moving progressively through the atria and atrioventricular septum, atrioventricular valves, ventricles and interventricular septum, ventricular outflow tracts, semilunar valves, and great vessels. The description of the ventricles not only should include the anatomy and function of each ventricle but also should evaluate the looping of the ventricles.

Ventricular Looping: As the heart develops during fetal life, the bulbus cordis (or primordial outflow tract) loops to the right to form the right ventricle and the primitive ventricle loops to the left to become the left ventricle; this is called *D*-looping of the ventricles. If the looping occurs in the other direction, the anatomic right ventricle is on the patient's left and the anatomic left ventricle is on the patient's right; this is called *L*-looping of the ventricles. In 1980, Dr. Richard Van Praagh described his use of the principle of chirality to evaluate the looping of the ventricles [18]. In ventricular *D*-looping (seen in normal hearts), the palmar aspect of the *right* hand can be placed over the right ventricular surface of the ventricular septum with the thumb in the inlet of the tricuspid valve and the fingers pointing up into the right ventricular outflow tract. In ventricular *L*-looping, this is not possible. Rather, the *left* hand can be placed such that its palmar aspect is over the septal surface with the thumb in the tricuspid valve and the fingers in the right ventricular outflow tract. While this seems straightforward when evaluating the normal heart, it becomes a valuable tool in determining the morphology of a single ventricle in complex structural heart disease [19].

Atrioventricular Connection: In addition to describing the structure of each segment and any abnormalities (such as a ventricular septal defect, a stenotic pulmonary valve, or a coarctation of the aorta), the echocardiographer must describe the connection of each segment relative to the other cardiac structures. When evaluating the atrioventricular junction, the observer must determine whether the connections between the atria and the ventricles are concordant or discordant. Concordant atrioventricular connections mean that the right atrium is connected to the right ventricle through the tricuspid valve. Similarly, the left atrium is connected to the left ventricle through the mitral valve. An example of discordant atrioventricular connections is congenitally corrected transposition in which the right atrium is connected to the left ventricle through the mitral valve and the left atrium is connected to the right ventricle through the tricuspid valve. If there is only one atrioventricular valve in a biventricular heart (e.g., in complete atrioventricular canal defects), the atrioventricular concordance can be determined by the position of the atria relative to the ventricles [20]. If an atrium is located more than 50 % over the inflow of a ventricle, it is said to be

committed to that ventricle [20]. Univentricular connections are more variable and can be described as a double inlet (two atria emptying into one ventricle such as in double inlet left ventricle), single inlet (one atrium emptying into one ventricle through one atrioventricular valve, such as in tricuspid atresia), or common inlet (when the anatomy does not fall into either of the above categories) [20].

Ventriculoarterial Connection: The ventriculoarterial connection can also be described as concordant or discordant. An example of discordant ventriculoarterial connection is *d*-transposition of the great arteries in which the left ventricle pumps blood across the pulmonary valve to the main pulmonary artery and the right ventricle pumps blood across the aortic valve to the ascending aorta. Another example of discordant ventriculoarterial connection is double outlet right ventricle in which the right ventricle pumps blood across the pulmonary and aortic valves. When describing ventriculoarterial connections, the position of the semilunar valves relative to each other is also important. In the normal heart, the aortic valve is posterior and rightward relative to the pulmonary valve; in *d*-transposition of the great arteries, the aortic valve remains rightward but is usually anterior to the pulmonary valve. However, in the spectrum of congenital heart diseases, it is possible for the aortic valve to be leftward of the pulmonary valve and for the semilunar valves to have an anterior-posterior or a side-by-side orientation. Understanding this relationship is imperative in accurately describing the intracardiac anatomy.

Basics of Transthoracic Echocardiography

Two-Dimensional Imaging

Two-dimensional ultrasound imaging of the heart has become the mainstay of the diagnosis of congenital heart disease. With this technology, the operator takes a three-dimensional structure that is moving and evaluates its anatomy using a two-dimensional video image in real time. There are different windows on the body from which it is possible to image the heart along a two-dimensional plane. The third plane is visualized by moving the transducer in "sweeps" across the third plane in order to create a mental reconstruction of the three-dimensional structure of the heart. Standard views and sweeps have been developed by the American Society of Echocardiography (ASE) so that even the most complex defects can be understood by those interpreting the images [4].

There are five main echocardiographic windows used to obtain the images of the heart: the subcostal (or subxiphoid) view, the apical view, the parasternal view, the suprasternal notch view, and the right parasternal view. Each window is broken down further by the plane of imaging relative to the left ventricle or aorta. The apical window can demonstrate the four-chamber view and the two-chamber view, and the other windows can demonstrate the long axis and the short axis of the heart. When looking at a pediatric echocardiogram, it is important to orient oneself to the anatomic representation presented on the screen; i.e., which direction on the screen represents the patient's right or left side anteriorly or posteriorly. Additionally one must recognize the directionality of the sweep, which provides the third dimension in imaging the heart with two-dimensional echocardiography. Figures 21.1–21.6 demonstrate some of the standard views and sweeps in a pediatric echocardiogram.

Color Mapping

Color mapping sweeps of all intracardiac structures are routinely performed during a complete pediatric echocardiogram. Color mapping can demonstrate the presence of an atrial or ventricular septal defect, valve stenosis or regurgitation, a patent ductus arteriosus, and the flow velocity across the pulmonary arteries and aortic arch. It is also useful in the evaluation of pulmonary and systemic venous return and coronary artery anatomy. When color mapping appears "turbulent" (i.e., a mix of blue, yellow, and red), it means that the flow velocity exceeds

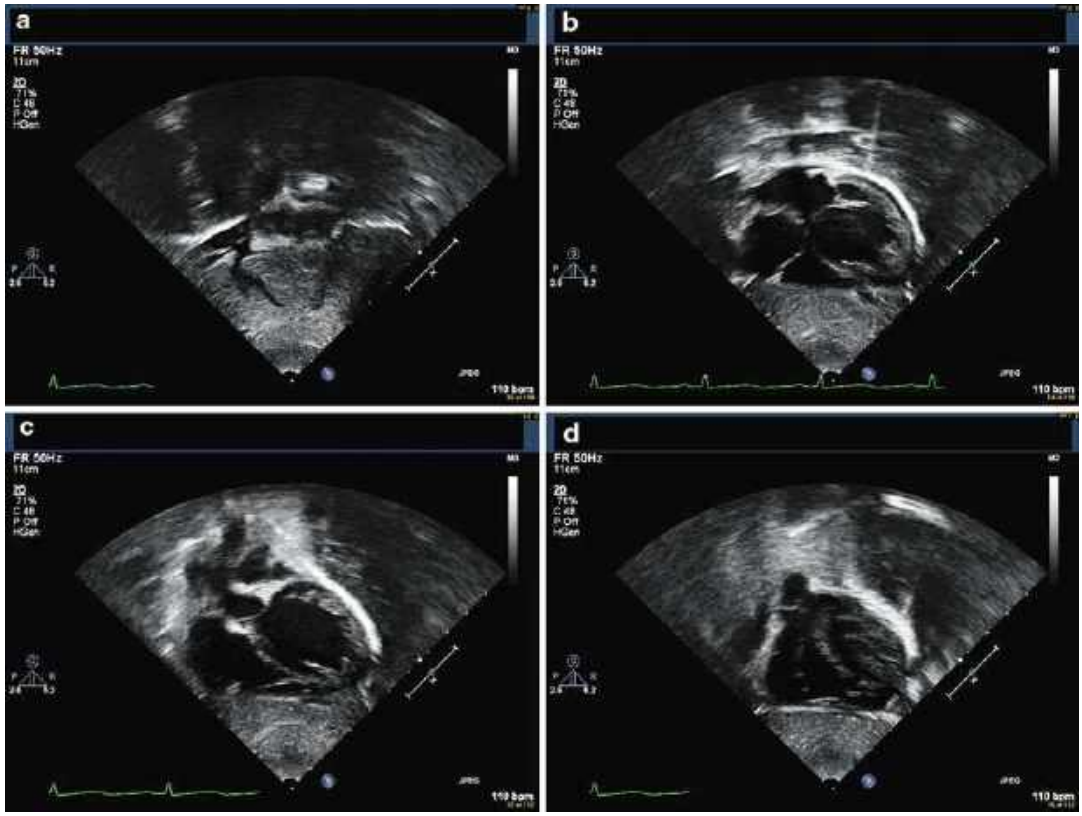

Fig. 21.1 Subcostal long-axis view, sweeping from posterior (**a**) to anterior (**d**)

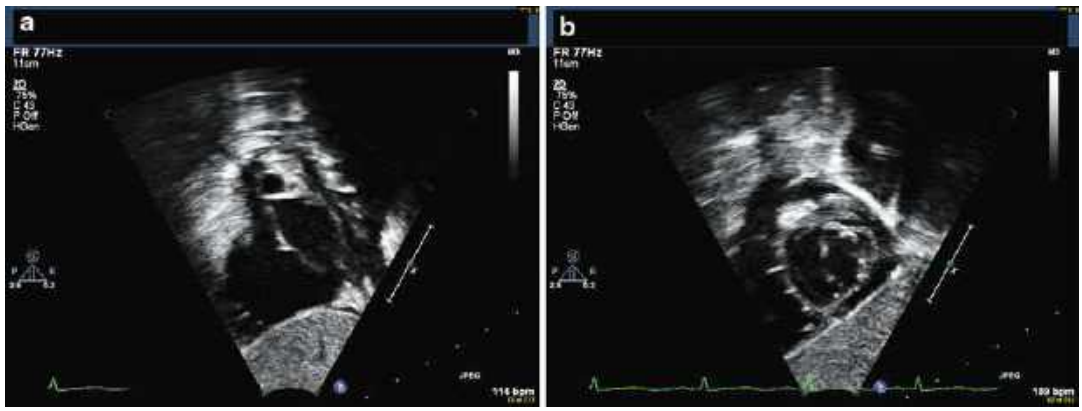

Fig. 21.2 Subcostal short-axis view, sweeping from right (**a**) to left (**b**)

the peak velocity that can be accurately measured by Doppler interrogation (known as the Nyquist limit). If flow turbulence is seen, it is important to further evaluate using spectral Doppler (PW or CW) to determine the true velocity of flow, as the color scale can be limited by technical factors such as patient size and depth of the color Doppler box.

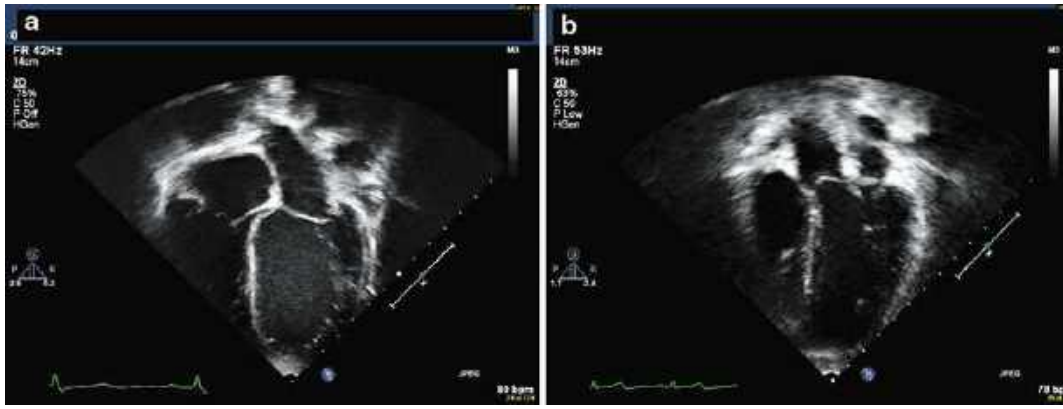

Fig. 21.3 Apical view, sweeping from the level of the atrioventricular valves (**a**) anteriorly to the level of the left ventricular outflow tract. (**b**) Sweeping posteriorly from the atrioventricular valves would demonstrate the coronary sinus, and sweeping anteriorly from the left ventricular outflow tract would demonstrate the right ventricular outflow tract

Quantification Measurements of Two-Dimensional Images

Accurate and reproducible echocardiographic measurements of cardiac structures are used to assess the degree to which an abnormality is affecting cardiac function. During catheter or surgical procedures, echocardiographic measurements are used to decide which intervention is most appropriate and provide quantitative data to help in the correct sizing of devices, catheters, or prosthetic valves.

Measurements in children are complicated by the fact that the size of normal cardiac structures is dependent on the size of the patient [21–24]. Accordingly, echocardiographic measurements have been adjusted (or "indexed") for the patient's body surface area (BSA) and age, which has been shown to better represent somatic growth than height or weight alone [21]. To more easily distinguish normal from abnormal and quantify the degree of abnormality, measurements are often expressed as a z-score. The z-score represents the number of standard deviations from the mean value in the normal population. Thus, a z-score of +2 or −2 represents a measurement that is 2 standard deviations above or below the mean, frequently recognized as the thresholds for "normal." In the practice of the authors, a z-score between ±2 and 3 is generally considered mildly abnormal, between ±3 and 4 is considered moderately abnormal, and more than 4 is considered severely abnormal, though there are little to no clinical outcome studies validating this grading system. The American Society of Echocardiography has published "Recommendations for Quantification Methods During the Performance of a Pediatric Echocardiogram" in 2010 [21]. Table 21.1 lists the standard cardiac measurements and describes their applications. Figure 21.7 is an example of measurement of the aortic annulus, sinotubular junction, and root.

The Interpretation of Doppler Evaluation

Spectral Doppler evaluation is routinely used to evaluate the flow along the pulmonary veins,

Table 21.1 Common cardiac measurements on a pediatric echocardiogram

Measurement	Technique/view/timing	Application
Left atrial area and length	Apical 4-chamber and apical 2-chamber views	LA volume
	End-diastole	
Mitral valve annular diameter	Apical 4-chamber view	MV size
	Maximum diameter in diastole	
Tricuspid valve annular diameter	Apical 4-chamber view	TV size
	Maximum diameter in diastole	
Left ventricular end-diastolic and end-systolic area	Parasternal or subcostal short axis	LV ejection fraction
	End-diastole and end-systole	
Left ventricular end-diastolic and end-systolic length	Apical 4-chamber view or subxiphoid long axis	LV ejection fraction
	End-diastole and end-systole	
Left ventricular epicardial area	Parasternal or subxiphoid short axis	LV mass
Left ventricular epicardial length	Apical 4-chamber or subxiphoid long axis	LV mass
Tricuspid annular plane systolic excursion (TAPSE)	M-mode	RV systolic function
	Apical 4-chamber view at tricuspid annulus	
Right ventricular fractional area change (FAC)	Apical 4-chamber view	RV systolic function
	End-diastole and end-systole	
Aortic valve annular diameter	Parasternal long-axis view	Aortic valve size
	Maximum diameter in systole	
Aortic root diameter	Parasternal long-axis, high left or high right parasternal views	Aortic root size
	Maximum diameter in systole	
Aortic sinotubular junction diameter	Parasternal long-axis, high left or high right parasternal views	Aortic sinotubular junction size
	Maximum diameter in systole	
Ascending aorta diameter	Parasternal long-axis, high left or high right parasternal views at the level of RPA	Ascending aorta size
	Maximum diameter in systole	
Pulmonary valve annular diameter	Parasternal long or short axis	Pulmonary valve size
	Maximum diameter in systole	
Main pulmonary artery diameter	Parasternal short-axis view	Main pulmonary artery size
	Maximum diameter in systole	
Proximal branch pulmonary artery diameters	Parasternal, high left parasternal or suprasternal short axis	Branch pulmonary artery sizes
	Maximum diameter in systole	

atrioventricular valves, ventricular outflow tracts, branch pulmonary arteries, and aortic arch. Both pulsed wave (PW) Doppler evaluation and continuous wave (CW) Doppler evaluation are generally performed on these structures.

Pulsed Wave Doppler: PW Doppler of the flow in the descending aorta is used to evaluate for the presence of aortic arch obstruction. Normal flow in the descending aorta is pulsatile with a brisk upstroke and a brisk return to baseline (Fig. 21.8). If there is aortic arch obstruction (e.g., aortic coarctation), the flow is blunted and resembles a sine wave. If there is a significant diastolic runoff from the aorta, as seen in moderate aortic regurgitation or a large patent ductus arteriosus, there is holodiastolic flow reversal seen.

Continuous Wave Doppler: Quantification of a pressure gradient can be obtained by tracing a CW Doppler pattern to measure a mean gradient (e.g., across an atrioventricular valve; Fig. 21.9) or by measuring the peak

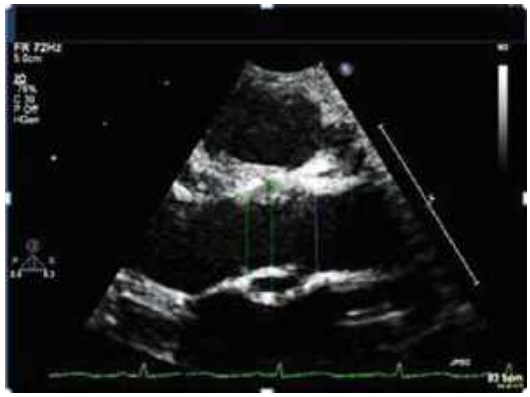

Fig. 21.7 Two-dimensional measurement of the aortic annulus, root, and sinotubular junction. The measurements are made from the parasternal long-axis view at the maximum diameter in systole

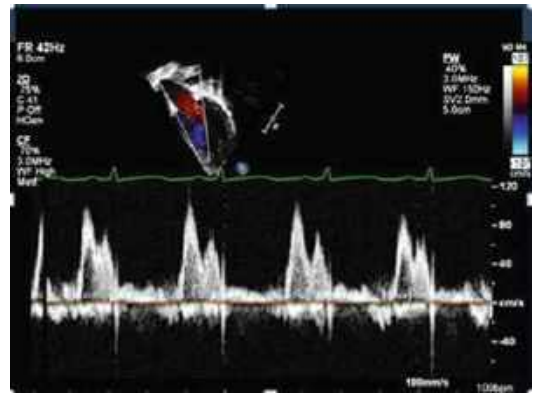

Fig. 21.9 Pulse wave Doppler tracing of the flow across the mitral valve. The first peak is the e wave, which represents early diastole, and the second peak is the a wave, which represents atrial systole

Fig. 21.8 Pulse wave Doppler tracing of the flow in the descending aorta

instantaneous pressure gradient (e.g., across the aortic valve or a branch pulmonary artery). The Doppler evaluation of a tricuspid regurgitant jet can be used to estimate the right ventricular systolic pressure. If there is no tricuspid stenosis, the estimated right ventricular systolic pressure is equal to the pressure gradient from the right ventricle to the right atrium (calculated using the modified Bernoulli equation) plus the right atrial pressure. In a patient with normal central venous pressure, this is assumed to be 5 mmHg. Evaluation of the flow across a ventricular septal defect (VSD) or a patent ductus arteriosus (PDA) can also estimate the right ventricular systolic pressure. In the presence of a VSD, Doppler evaluation of the shunt flow velocity can estimate the pressure gradient between the right and left ventricles; if there is a gradient between the two ventricles, the VSD is said to be restrictive. If one knows the systolic blood pressure (taken at the time of the Doppler measurement), the right ventricular systolic pressure can be estimated by subtracting the gradient across the VSD from the systolic blood pressure. Similarly, the gradient across a PDA can be used to estimate the systolic pressure in the main pulmonary artery and, in the absence of pulmonary stenosis, the systolic pressure in the right ventricle. A list of the most common Doppler measurements and their applications can be found in Table 21.2.

Evaluation of Ventricular Function

The evaluation of ventricular function is an important aspect of echocardiography. In many structural heart defects, changes to the inherent shape of the ventricles as well as changes in loading conditions present a challenge to the assessment of ventricular function. In order to evaluate and interpret the echocardiographic measures of ventricular function, one must understand both the physiology of ventricular

Table 21.2 Common Doppler measurements on a pediatric echocardiogram

Structure	Doppler mode/location	Measurements	Application
Pulmonary veins	PW – gate >5 mm from ostium	S-, D-, A-wave velocities and duration of A-wave reversal	LV diastolic function
		Mean gradient	Pulmonary vein stenosis
Tricuspid valve	CW	Mean gradient	Tricuspid stenosis
	PW – measure at leaflet tips in diastole	E- and A-wave velocities	RV diastolic function
		Peak instantaneous velocity of tricuspid regurgitant jet	RV systolic pressure
Mitral valve	CW	Mean gradient (trace the flow)	Mitral stenosis
	PW – measure at leaflet tips in diastole	E- and A-wave velocities	LV diastolic function
		S-wave velocity	LV systolic function
	Tissue Doppler	e' and a' velocities	LV diastolic function
		s' velocity	LV systolic function
Semilunar valves	PW – below, at, and above the valve	Peak instantaneous velocity at each location	Ventricular outflow tract obstruction
	CW across the right ventricular outflow tract	Peak instantaneous velocity	(subvalvar, valvar, or supravalvar)
Ascending aorta	CW – across ascending aorta	Peak instantaneous velocity	Aortic outflow obstruction
Aortic arch	CW – across ascending aorta and across aortic isthmus (If acceleration use PW to determine the location of stenosis)	Peak instantaneous velocity	Aortic arch obstruction
Descending aorta	PW – at level of diaphragm		Aortic arch obstruction
			Diastolic flow reversal
VSD	CW – parallel to flow	Peak instantaneous gradient in systole	RV systolic pressure
PDA	PW – in PDA between aorta and pulmonary artery		Direction and pattern of flow
	(CW – if velocity too high for PW scale)	Peak instantaneous velocity in systole	Pulmonary artery systolic pressure

function and the limitations of the echocardiographic techniques used in its evaluation.

Evaluation of Left Ventricular Systolic Function

Fractional Shortening: Traditionally, the geometry of the left ventricle has been conceptualized as a prolate ellipsoid that contracts by radial shortening, longitudinal shortening, and torsion [25]. The radial shortening is quantified by measuring shortening fraction. The echocardiographer measures the left ventricular end-diastolic diameter (LVEDD) and the left ventricular end-systolic diameter (LVESD) on a short-axis view of the left ventricle, usually from the parasternal window. Both measurements should be performed at the level of maximal left ventricular diameter, which is often at the mitral valve leaflet tips or chordae in young children and at the level of the papillary muscles in older children and adults [21]. The formula used to calculate shortening fraction is

$$\text{Fractional Shortening (FS)} = (\text{LVEDD-LVESD})/\text{LVEDD} \times 100\%$$

Historically, M-mode measurements provided better temporal and spatial resolution than two-dimensional imaging. However, obtaining an M-mode across the line crossing the midline of the septum and posterior wall is often very

difficult on a pediatric echocardiogram [21]. The American Society of Echocardiography guidelines for the measurement of left ventricular shortening fraction in pediatrics recommend that two-dimensional images be used for the measurement of the end-diastolic and end-systolic diameters averaged over three cardiac cycles [21]. The normal left ventricular shortening fraction generally ranges between 28 % and 38 % [26].

There are several limitations to the use of shortening fraction to measure systolic function. The shortening fraction is a load-dependent measurement and can be significantly affected by changes in preload or afterload. Increased preload (such as found in ventricular septal defect or patent ductus arteriosus) will increase the LVEDD, and increased afterload (such as in aortic coarctation) may result in the earlier closure of the aortic valve which then increases the LVESD. The method used to determine the fractional shortening is limited in the presence of septal dyskinesis that may be found in patients after cardiopulmonary bypass, patients with right ventricular volume overload (such as an atrial septal defect), or patients with a bundle branch block [26]. The Shortening fraction also only evaluates radial shortening and does not account for longitudinal motion or torsion of the left ventricle.

Ejection Fraction: Volumetric measures of left ventricular contraction involve the calculation of the ejection fraction, or the percent change in left ventricular volume from diastole to systole. Unlike shortening fraction, this calculation takes into account the radial and longitudinal shortening of the left ventricle. However, the ejection fraction of the left ventricle is also load dependent and is limited in its evaluation of patients with increased preload or afterload. The two main methods of calculating ventricular volume are the Simpson biplane method and the "bullet" (or 5/6 area-length) method. The Simpson biplane method uses orthogonal views of the left ventricle (from the apical 4-chamber and the apical 2-chamber views) and calculates the left ventricular end-diastolic volume (LVEDV) and the left ventricular end-systolic volume (LVESV) by dividing the ventricle into slices and summing the slices. The bullet method assumes the left ventricle to be a prolate ellipsoid and uses the area of the left ventricle from the short-axis view and the length of the ventricle from the apical 4-chamber view to calculate the left ventricular volume at end-diastole and end-systole. Left ventricular volume is calculated in this approach by using the following formula: Volume = 5/6 (Area × Length)

The ejection fraction is then calculated by the following formula:

$$\text{Ejection Fraction} = (\text{LVEDV-LVESV})/\text{LVEDV} \times 100\%$$

A normal ejection fraction ranges between 56 % and 78 % [27].

Doppler Evaluation: There are non-geometric methods to evaluate left ventricular systolic function using Doppler measurements. Myocardial acceleration during isovolumic contraction (IVA) can be calculated from tissue Doppler evaluation of the mitral annulus and evaluates the contractility of the left ventricular myocardium. Some studies have suggested that it is relatively unaffected by loading conditions [26]. Studies on subsets of patients have shown that IVA may be clinically useful in evaluating right ventricular function in patients with repaired tetralogy of Fallot [28] and in evaluating for rejection in pediatric heart transplant recipients [29]. Another Doppler measurement of ventricular function is the myocardial performance index (MPI) or Tei index which uses the isovolumic contraction time (ICT), the isovolumic relaxation time (IRT), and the total ejection time (ET) to evaluate global ventricular function. This measurement uses systolic and diastolic parameters. The calculation is

$$\text{MPI} = (\text{ICT} + \text{IRT})/\text{ET}$$

The MPI is calculated using simultaneous Doppler measurements of the atrioventricular valve inflow and the ventricular outflow tract (Fig. 21.10). In children, the normal values for MPI for the left ventricle are 0.35 ± 0.03 [26].

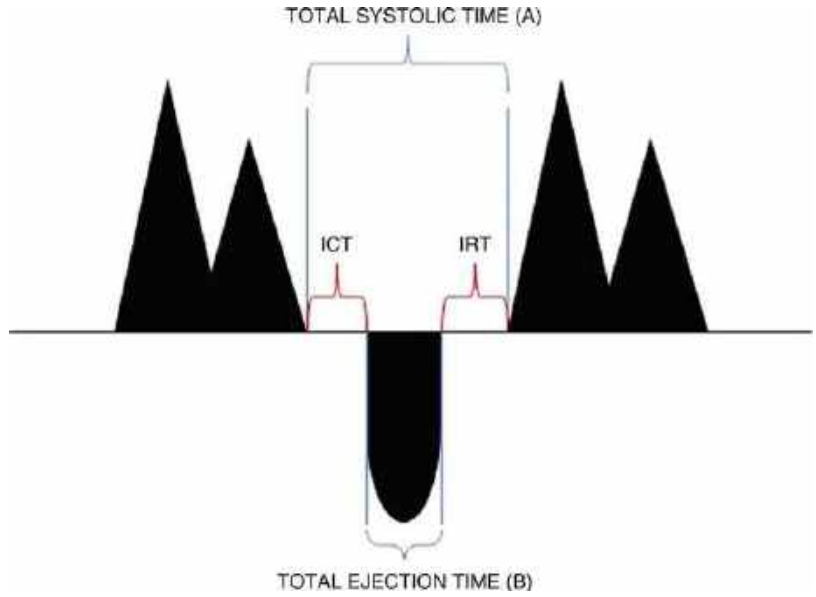

Fig. 21.10 Calculation of the myocardial performance index (MPI) using simultaneous PW measurement of the mitral inflow (MV) and the aortic outflow (AO). The sum of the isovolumic contraction time (*ICT*) and the isovolumic relaxation time (*IRT*) is calculated by subtracting the total ejection time (ET), represented by measurement *B* from the total systolic time, represented by measurement *A*. As MPI = (ICT + IRT)/ET, using these measurements MPI = (A – B)/B

As MPI evaluates combined diastolic and systolic components of ventricular function, the patient does require further evaluation in order to determine which aspect of ventricular function is abnormal. While it does not assume standard left ventricular geometry, MPI is sensitive to changes in preload and afterload [27].

Regional Wall Motion: The evaluation of left ventricular regional wall motion is performed much less frequently in the pediatric population than in the adult population. There are however certain pediatric patients for whom this is indicated. Examples of patients in whom regional wall motion should be evaluated include patients who have had surgical intervention involving the coronary arteries (e.g., arterial switch procedure for transposition of the great arteries, repair of anomalous left coronary artery from the right sinus of Valsalva, and repair of anomalous left coronary artery from the pulmonary artery) and teenage patients with cardiac chest pain (especially in the setting of cocaine use or triptan medication for migraines). In 2002, the American Heart Association proposed a 17-segment model of the left ventricle to evaluate regional wall motion of the left ventricle [30]. Five echocardiographic views are required for this evaluation: parasternal short-axis views at the base of the heart (at the level of the mitral valve), the mid-cavitary portion (at the level of the papillary muscles), and the apex, as well as apical 4-chamber and 2-chamber views. A complete description of the 17-segment model can be found in the American Heart Association consensus statement [30].

Strain and Strain Rate: Newer techniques such as strain and strain rate (using either tissue Doppler or speckle tracking) represent additional quantification methods for the analysis of left ventricular regional wall motion. There are described normal reference ranges for children [31], and these methods have also been studied in patients who have had repair of an anomalous left coronary artery from the pulmonary artery (ALCAPA) [32] and in those with hypertrophic cardiomyopathy associated with Friedreich's ataxia [33]. However, these modalities have not become standard practice in pediatric echocardiography at this time.

Evaluation of Left Ventricular Diastolic Function

Left ventricular diastolic function is evaluated primarily using Doppler parameters. Most of these measurements are load dependent and their accuracy depends upon the parallel

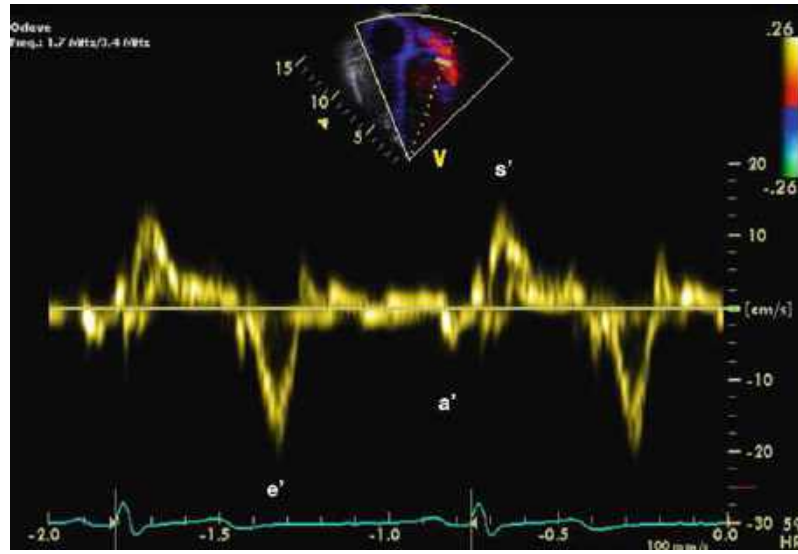

Fig. 21.11 Tissue Doppler (TD)

alignment of the Doppler beam with the structure being evaluated. Pulsed wave Doppler interrogation of the mitral inflow and pulmonary venous flow and tissue Doppler evaluation at the medial and lateral mitral annulus are mainstays in the evaluation of left ventricular diastolic function in pediatric patients.

Mitral Inflow: The peak *E* wave (during early diastole) and *A* wave (during atrial systole) velocities, the *E*/*A* ratio, the isovolumic relaxation time (time from aortic valve closure to mitral valve opening), and the deceleration time (time from peak *E* wave velocity to its return to baseline) are all measures that reflect ventricular diastolic function; however, these measurements are all sensitive to loading conditions. If there is fusion of the *E* and *A* waves, as occurs relatively often in children due to their fast heart rates, the accurate measurement of some of these parameters may be limited.

Pulmonary Venous Flow: The pulmonary venous Doppler tracing consists of a systolic wave (*S*), a diastolic wave (*D*), and an atrial contraction wave (*A*), which is opposite in direction from the first two components and denotes flow reversal in the pulmonary vein during atrial contraction. In neonates, the pulmonary venous *a* wave can be absent with continuous antegrade flow in the pulmonary veins during the cardiac cycle; however, a distinct *A* wave is usually seen in older children and adults. When diastolic dysfunction develops, the left atrial pressure increases and there is less antegrade flow across the mitral valve with an increased reliance on atrial contraction for left ventricular filling. As such, there is increased velocity and duration of the pulmonary venous *A* wave. The standard measurements of pulmonary venous Doppler tracing recommended by the American Society of Echocardiography are the peak *S*, *D*, and *A* wave velocities and the duration of the *A* wave [21].

Tissue Doppler: Tissue Doppler (Fig. 21.11) evaluation of the mitral annulus tracks the longitudinal motion of the mitral valve during the cardiac cycle. The peak annular velocities in early diastole (*e*') and during atrial contraction (*a*') are both parameters of diastolic function, whereas the *s*' velocity is an indicator of systolic function.

Diastolic Dysfunction: The adult literature has demonstrated a pattern in the evolution of diastolic function based upon the Doppler parameters. In the early stage of diastolic dysfunction, the *E*/*A* ratio decreases to less than 1 (i.e., the peak *A* wave velocity is greater than the peak *E* wave velocity) [34]. However, as diastolic

dysfunction progresses, this returns to a normal ratio (termed "pseudonormalization") before progressing to restrictive physiology with an *E*/*a* ratio >1.5 [34]. The ratio of the peak mitral *E* wave velocity and the peak annular velocity in early diastole (*E*'), denoted as the *E*/*e*' ratio, has emerged as a useful measure of left ventricular diastolic function. There are reference ranges for the *E*/*e*' ratio in different pediatric age groups [35]. A general rule of thumb is that a ratio <8 is normal, >12 is abnormal, and 8–12 is possibly abnormal. The peak mitral annular velocity in early diastole (*E*') has been shown to be relatively preload independent [34, 36, 37] and the *E*/*e*' ratio correlates well with pulmonary capillary wedge pressure in adults [38], which reflects left ventricular end-diastolic pressure.

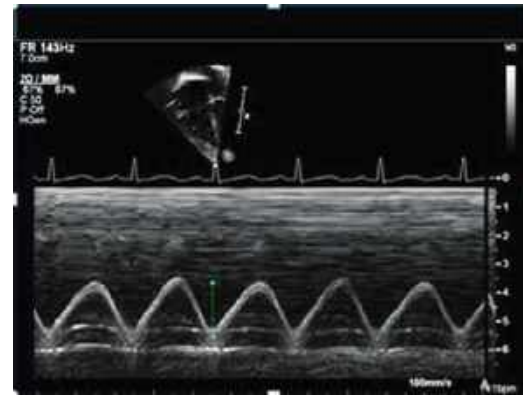

Fig. 21.12 Tricuspid annular plane systolic excursion (TAPSE) is used to evaluate right ventricular systolic function. The apical displacement of the lateral tricuspid valve annulus is measured on an M-mode tracing

Evaluation of Right Ventricular Systolic and Diastolic Function

The evaluation of the right ventricle (RV) presents many challenges to the echocardiographer, due in no small part to its anterior and retrosternal position and its complex geometry. Cardiac magnetic resonance imaging (MRI) has become the gold standard in the evaluation of right ventricular size and systolic function, and the best echocardiographic methods are still a topic of debate and research in the field. The guidelines from the American Society of Echocardiography for RV function on a pediatric echocardiogram include right ventricular fractional area change and tricuspid annular plane systolic excursion (TAPSE). The calculation of RV fractional area change involves the end-diastolic (RVED) and end-systolic (RVES) area of the RV measured from the apical 4-chamber view but is limited by the exclusion of the right ventricular outflow. The formula used for fractional area change is

$$\text{RV Fractional Area Change} = (\text{RVEDarea} - \text{RVESarea})/\text{RVEDarea} \times 100\%$$

TAPSE measures the longitudinal excursion of the tricuspid valve annulus during systole (Fig. 21.12) and has been demonstrated to correlate well with ejection fraction measured by two-dimensional echocardiography and by radionuclide angiography in adults [21, 39, 40]. There are published normal reference values for TAPSE in children [41], and the predominance of longitudinal shortening in the contraction of the RV makes this a promising measurement. However, some studies have suggested that the RV contraction pattern changes with RV dilation and hypertrophy, which would limit the accuracy of TAPSE [26].

The myocardial performance index (MPI), described above for the evaluation of left ventricular systolic and diastolic function, can also be measured in the RV using the pulse wave Doppler or tissue Doppler tracing of the tricuspid inflow and the PW Doppler tracing of the RV outflow tract.

The diastolic function of the RV can be evaluated by PW Doppler interrogation of the tricuspid inflow and measurement of the isovolumic relaxation time (IVRT) [21]. Restrictive physiology in the RV is suggested by antegrade flow across the pulmonary valve at end-diastole [42, 43].

Evaluation of Pericardial Effusion

The pericardial space, between the visceral and parietal pericardium, usually contains a very small amount of lubricating fluid. The accumulation of a larger amount of fluid in the pericardial space is termed a pericardial effusion. If a pericardial effusion accumulates rapidly, it can lead to cardiac tamponade in which there is restricted ventricular filling and decreased cardiac output causing hemodynamic compromise. Cardiac tamponade is generally related to the rate of fluid accumulation: a slow accumulation of very large fluid volumes in the pericardial space can be well tolerated from the hemodynamic perspective. Patient history, physical examination, and chest x-ray often lead to suspicion for a pericardial effusion, but echocardiography is the main tool for the diagnosis and grading of a pericardial effusion.

Two-Dimensional Imaging: Pericardial fluid, like blood, does not reflect ultrasound waves and, therefore, appears black on an ultrasound image. In evaluating a pericardial effusion by echocardiography, the effusion should be demonstrated and measured from the subcostal, apical, and parasternal windows. A small effusion is usually a small rim of fluid that lines the inferior or posterior border of the heart. A small inferior effusion is best seen from the subcostal long-axis view and a posterior effusion from the apical or parasternal windows. A moderate or large pericardial effusion is usually circumferential, with the heart sometimes appearing to float freely in the fluid.

Hemodynamic Effects: The hemodynamic effects of a pericardial effusion can be assessed using two-dimensional imaging looking for early diastolic right ventricular collapse and late diastolic right atrial wall collapse. Right atrial wall collapse in late diastole is very sensitive for the diagnosis of tamponade (90 %), but not very specific [44]. Other measurements to evaluate for possible impending tamponade include increased respiratory variation in transvalvar flow (similar in physiology to pulsus paradoxus) and abnormal diastolic flow across the pulmonary and hepatic veins. A variation of mitral valve *E* wave velocity of greater than 30 % with respiration should raise concern for cardiac tamponade. A reversal of diastolic flow in the hepatic veins (such that there are two peaks of flow reversal in the hepatic veins during one cardiac cycle) is also concerning for cardiac tamponade. It is important to recognize that cardiac tamponade is a clinical diagnosis. In a patient with a known pericardial effusion, the goal of echocardiography should be to evaluate for signs of impending hemodynamic compromise so that intervention can be performed in a planned manner before tamponade would necessitate an emergent procedure.

Pericardiocentesis: Echocardiography is often used to guide pericardiocentesis. The angle of the transducer when imaging the pericardial effusion can help to guide the needle trajectory. The guidewire for a catheter can then be visualized in the pericardial space, after which agitated saline injection into the pericardial catheter can confirm catheter placement in the pericardial space and decreased pericardial effusion can be demonstrated at the end of the procedure.

Transesophageal Echocardiography

In 2005, the American Society of Echocardiography published guidelines for the performance of a pediatric transesophageal echocardiogram (TEE) [6], including standard views and structures to be demonstrated. The windows for transesophageal echocardiography are transgastric (in which the ultrasound probe is advanced into the stomach and anteflexed to image the heart) and retrocardiac. From the retrocardiac window, the ultrasound probe can be moved inferiorly and superiorly in the esophagus to show different levels of the heart. Other planes of the heart can be evaluated by manipulating the angle at which the imaging beam is directed.

Intraoperative Transesophageal Echocardiography

Intraoperative TEE evaluation is usually performed by pediatric cardiologists, though in some centers it is performed by pediatric cardiac anesthesiologists with pediatric cardiology backup [45]. Preoperative TEE is performed to confirm the cardiac anatomy and evaluate the function and other physiologic measures (such as estimation of RV systolic pressure) for postoperative comparison. TEE evaluation during rewarming prior to coming off or following cardiopulmonary bypass is used to evaluate cardiac function, anatomy, and for the presence of any intracardiac air. Underfilling of the ventricles while on cardiopulmonary bypass can contribute to the appearance of poor systolic function and to the absence of dynamic outflow tract obstruction, and if these findings are present, reevaluation after weaning off bypass and after volume resuscitation should be performed. Postoperative TEE is also performed to evaluate for residual shunts or residual stenosis.

Transesophageal Echocardiogram During Interventions

TEE has become an important tool in the performance of interventions in the cardiac catheterization lab, including device closure of atrial septal defects, ventricular septal defects, and baffle leaks (e.g., in a patient with a Mustard or Senning repair). Many interventional cardiologists use balloon sizing of the atrial septum and have found simultaneous color mapping by TEE to look for the cessation of flow across the defect to be very useful in the determination of the size of the defect. TEE is also often used to evaluate for the presence of intracardiac thrombus prior to cardioversion in patients who present with atrial arrhythmia or supraventricular tachycardia. In young children, adequate imaging to evaluate for intracardiac thrombi may be obtained by transthoracic imaging, but older children and teenagers usually require transesophageal imaging.

Three-Dimensional Echocardiography

Recent advances in ultrasound technology have given rise to the ability to image the heart in three dimensions in real time. The images are displayed using voxels (representing a small volume element) as opposed to pixels (the elements that compose a two-dimensional image) [46]. In the most current version of three-dimensional (3D) echocardiography, depth is represented by a changing color spectrum that represents how close or far the structure is from the screen. Software packages have been developed that allow the echocardiographer to perform measurements such as left ventricular volumes and mass on the 3D dataset.

In congenital heart disease, 3D echocardiography can delineate structural abnormalities and can help to guide clinical decision-making and interventions. 3D imaging has become increasingly useful in the evaluation of atrioventricular morphology such as in patients with double-orifice mitral valve or Ebstein's anomaly [46]. Hlavacek et al. demonstrated that 3D imaging of patients with atrioventricular septal defects provided useful information in describing leaflet anatomy and location of additional septal defects [47]. Studies comparing 2D and 3D imaging of atrial and ventricular septal defects have shown that 3D imaging improves the accuracy of size measurement [48]. Manipulation of a 3D echo dataset allows for demonstration and measurement of atrial and ventricular septal defects in novel planes and for reconstruction of vascular structures (such as the aortic arch) [46]. The temporal resolution of 3D echocardiography has improved substantially in recent years, and real-time 3D echo (either transthoracic or transesophageal) can be used during echo-guided interventions such as device closure of an atrial septal defect [46].

Fetal Echocardiography

A complete fetal echocardiogram involves a full assessment of the fetal cardiac anatomy and function as well as an evaluation of fetal hemodynamic status using Doppler measurements. A fetal echocardiogram should begin with an evaluation of fetal position and situs using the relative position of the fetus in relation to the mother to determine the fetal left and right sides. Fetal situs is evaluated using the position of the fetal stomach and the fetal heart. As in two-dimensional echocardiography, a series of imaging views allows for a full evaluation of the three-dimensional fetal heart. These views include the four-chamber view (obtained from a transverse section through the fetal thorax), the equivalent of the short-axis and long-axis views to evaluate the pulmonary and aortic outflows, the bicaval view to evaluate the vena cavae and the atrial septum, and the ductal and aortic arch views (obtained using a sagittal or parasagittal plane through the fetal thorax). The four-chamber sweep can demonstrate all four cardiac chambers, the flap of the foramen ovale bowing into the left atrium, the offsetting of the tricuspid and mitral valves, the morphology of the right and left ventricles, the crossing outflow tracts, and the arch sidedness. The other views allow for a complete assessment of the remaining cardiac structures.

Quantification of fetal cardiac structures is performed using reference ranges based upon gestational age and reported using z-scores. PW Doppler is used to evaluate the atrioventricular valves and the ventricular outflows as well as the aortic and ductal arches. Evaluation of ventricular function can be qualitative or can be quantified using M-mode or two-dimensional-derived shortening fraction. MPI can also be calculated using simultaneous Doppler evaluation of atrioventricular valve inflow and ventricular outflow. Reference ranges for MPI in mid-gestation fetuses are available [49]. Doppler evaluation of the umbilical artery and vein, ductus venosus, and middle cerebral artery provides information about the hemodynamic status of the fetus and can alert the clinician to hemodynamic compromise before clinical signs of hydrops fetalis (such as pericardial effusion) become apparent.

The fetal rhythm can be evaluated using Doppler tracings of the cardiac outflow (at the aortic or pulmonary valve) and the cardiac filling (at the systemic veins, pulmonary veins, or atrioventricular valves). The PR interval can be estimated in the fetus using the mechanical PR interval, which is the time from the beginning of atrial contraction (the mitral or tricuspid *A* wave) to the opening of the semilunar valve. A comprehensive chapter dedicated to fetal echocardiography can be found elsewhere in this textbook.

Exercise Testing in the Assessment of the Cardiac Patient

22

Jonathan Rhodes

Abstract

Exercise testing has an indispensable role in the assessment and management of patients with congenital heart disease. It provides important quantitative information about the health of the cardiovascular system and may uncover problems or disease processes that are not apparent at rest. The indications for exercise testing include the evaluation of arrhythmias, chest pain, and exercise capacity. It can be used to monitor the effectiveness of therapies for arrhythmias, pulmonary hypertension, or heart failure. The common modalities used include the six-minute walk test, treadmill testing with electrocardiographic monitoring, and cardiopulmonary exercise testing. In addition to assessing exercise endurance, the cardiopulmonary exercise test provides important insights into the factors limiting exercise performance in children with heart disease.

Introduction

Most of the tests employed to assess the cardiovascular status of a patient are performed while at rest, often in the supine position. Although valuable, these tests do not necessarily inform the cardiologist about the patient's cardiovascular condition when performing more than sedentary activities. To obtain this information, the physician relies on historical information from the patient (or the patient's parents) about typical physical activities, exercise tolerance, and symptoms during exercise. However, patients with congenital heart disease (CHD) often have impaired cardiovascular function from birth and may never have experienced "normal" exercise tolerance. Their perception of what constitutes normal exercise capacity can be distorted and

their responses to the questions posed by the pediatric cardiologist unreliable. Indeed, a recent study of asymptomatic young adults with CHD found that their exercise capacity, when assessed with formal cardiopulmonary exercise testing (CPET), was comparable to older adults with congestive heart failure (CHF) secondary to acquired heart disease [1]. This uncertainty is compounded when evaluating a child or when responses to questions must be filtered through a parent and are therefore influenced by the parent's misperceptions or fears.

Hence, to reliably assess a patient's exercise function and cardiovascular response to exercise, objective measurements of exercise performance must be obtained. This is an important issue for physicians caring for patients with CHD, as the primary function of the cardiovascular system is to provide blood flow and oxygen to the body in quantities sufficient to meet the body's metabolic needs. This function is maximally stressed when the metabolic rate is increased, a condition that occurs most commonly during exercise. Exercise testing can therefore provide important quantitative information about the health of the cardiovascular system and may uncover problems or disease processes that are not apparent at rest. Serial exercise testing can also detect progression of cardiovascular disease or responses to therapy that are undetectable and/or not quantifiable with other testing modalities. Other important clinical questions (Table 22.1) are also helpfully informed by data from exercise tests. Exercise testing has therefore acquired an indispensable role in the assessment and management of patients with CHD.

Table 22.1 Questions assessed by pediatric exercise testing

How does the patient's condition compare to normal subjects?
How does the patient's condition compare to his/her past status? How does it compare to others with similar diagnoses?
What causes a patient to stop exercising? Is the patient limited by cardiovascular, respiratory, musculoskeletal, metabolic, hematologic, emotional, or other factors? If the patient's ability to exercise is limited by the function of his/her cardiovascular system, which specific cardiovascular factors are responsible for the limitation?
If the patient's ability to exercise is limited by respiratory or other factors, can the pathophysiologic processes responsible of the poor exercise function be identified more clearly?
What interventions might improve the patient's exercise function? Can the effectiveness of these interventions be assessed?
Does exercise pose any risk for this patient?
Can anything be done to minimize these risks and can the effectiveness of these risk-lowering strategies be assessed?

Equipment and Personnel

A pediatric exercise physiology laboratory should be equipped with a treadmill and/or cycle ergometer. This equipment should be adjustable so that it could comfortably accommodate adults as well as children as young as 6–8 years of age. A 12- or 15-lead ECG monitoring system capable of displaying at least three leads simultaneously in real time should be available for arrhythmia monitoring and the assessment of ST changes. Instantaneous "superimposition" scanning of median ECG complexes from selected leads is also desirable as it can facilitate the identification of ST segment changes during exercise. It should also be equipped with a metabolic cart capable of measuring oxygen consumption ($\dot{V}_{O_2}$), carbon dioxide production ($\dot{V}_{CO2}$), minute ventilation ($\dot{V}_E$), and end-tidal gas concentrations in children and adults. Appropriately sized blood pressure cuffs and pulse oximeters should also be available. There should be sufficient space within the laboratory for other ancillary equipment (echocardiograms, noninvasive cardiac output devices, near-infrared spectroscopy, and others). For safety purposes, oxygen, suction, and an emergency alarm switch should be present in the laboratory; an emergency resuscitation cart should be readily available [2].

A physician familiar with pediatric cardiology and exercise physiology and with training in cardiopulmonary resuscitation should be immediately available for all tests. Physicians

should be present and/or supervise testing of high-risk patients. Most low-risk testing can be performed by trained exercise physiologists without direct in-laboratory physician supervision [2].

Types of Exercise Tests

Exercise testing modalities vary depending upon the clinical questions that need to be addressed and the sophistication of the technology that is employed.

The Six-Minute Walk Test (6MWT)

The 6MWT has been used extensively in CHF and pulmonary hypertension drug trials. It is easy to perform, mimics activities of daily living, and does not require sophisticated testing equipment. The test requires a patient to walk as far as possible in 6 min. The course is a straight path 30 m in length; the patient must turn and then resume walking at the end of the course. In practice, the course is usually set up in a corridor or other public space near the exercise laboratory, outpatient office, or inpatient ward. Although the patient is encouraged to cover as much ground as possible during the test, the pace should not be directly influenced by the examiner. The patient may stop and rest if necessary. Portable pulse oximetry may be incorporated into the test, but the patient's heart rhythm and electrocardiogram are not monitored. Nasal cannula oxygen may be administered during the test, in which case an assistant wheels an oxygen tank for the patient throughout the test. The primary measurement derived from the test is the distance walked in the 6 min. The patient's heart rate, oxygen saturation, and rate of perceived exertion may also be recorded [3].

The 6MWT is, for all but the most limited patients, a submaximal test. Consequently, although it correlates fairly well with peak $\dot{V}_{O_2}$ in highly symptomatic patients, its utility and validity in patients with mild or moderate impairment is questionable [4, 5]. Indeed, the reliability and meaning of the 6MWT for patients who can walk more than 400 m has been challenged [5]. In addition, the test is strongly influenced by patient motivation and other factors (such as leg length, body weight, orthopedic issues, or the ability to turn quickly at the ends of the course) unrelated to the cardiopulmonary system. It is difficult to control for or to quantify the influence of these variables on the outcome of the test. Hence, for any individual patient, the test has a rather small "signal to noise ratio." Although these issues are mitigated somewhat in drug trials that include large numbers of patients, they make the interpretation of an individual's test (or serial studies in one individual) ambiguous and difficult. On account of these considerations, the utility of the 6MWT in children with CHD is limited. Finally, although the incidence of serious adverse events during a 6MWT is extremely low, it seems imprudent to have highly symptomatic patients exercise to (or near) the limit of their capabilities without electrocardiographic or blood pressure monitoring.

Exercise Testing with Electrocardiographic Monitoring

Exercise testing with ECG monitoring is an appropriate and potentially useful modality for the evaluation of patients with known or suspected rhythm disturbances. It is most commonly undertaken on a treadmill using the Bruce protocol. Other treadmill protocols or bicycle protocols may also be employed. In patient with Wolff-Parkinson-White syndrome, the sudden disappearance of preexcitation during a progressive exercise test implies that the accessory pathway is incapable of rapid conduction and suggests that the patient is at low risk for sudden death secondary to a rapidly conducting atrial tachyarrhythmia [6]. In patients with prolonged QT syndrome, the QT interval may not shorten appropriately as the sinus rate increases during exercise; in many cases, patients with normal or mildly prolonged corrected QT intervals at rest may be found to have unambiguous prolongation (with or without ventricular ectopy) during exercise [7, 8]. Similarly, patients

with catecholamine-sensitive polymorphic ventricular tachycardia typically develop increased ventricular ectopy during exercise. In this setting, serial tests may be helpful to assess the response to beta-adrenergic blockade or other therapeutic interventions [9]. Exercise testing may also uncover a propensity for rhythm disturbances in other conditions such as myocardial ischemia, Brugada syndrome, arrhythmogenic right ventricular dysplasia, cardiomyopathies, and CHD [10]. In patients with structurally normal hearts and benign ventricular ectopy, the ectopy is suppressed as the sinus rate rises during exercise [11].

Among pediatric patients, exercise testing with EGG monitoring by itself does not have sufficient sensitivity or specificity for the detection of myocardial ischemia [12, 13]. For this question, it is best to add stress echocardiographic or myocardial perfusion imaging to the testing protocol.

Pulse oximetry may be incorporated into this testing modality to detect and quantify exercise-related arterial desaturation. Repeated cuff blood pressure determinations should also be undertaken to detect abnormal blood pressure responses to exercise. At peak exercise, systolic blood pressure typically exceeds resting values by 50–75 %. In contrast, diastolic pressure changes little during exercise. Systolic blood pressure should not exceed 220 mmHg at peak exercise for adult males and 180 mmHg for adult females. Blood pressures at peak exercise tend to be lower in children [14].

For patients with coarctation of the aorta, a pre- and postexercise upper-to-lower extremity blood pressure gradient can also be determined. Similarly, for patients with known or suspected exercise-induced asthma, pre- and postexercise spirometry can be incorporated into the protocol.

An exercise test with EGG monitoring can also provide information regarding a patient's exercise capacity. The relevant metric for the Bruce treadmill protocol is the endurance time. Nomograms based upon the patient's age and gender are available for calculating the predicted, normal endurance time [15]. However, for pediatric subjects, the normal range tends to be quite broad and the clinical utility of this index is therefore somewhat limited. Furthermore, endurance time is heavily influenced by factors unrelated to the cardiopulmonary system (e.g., obesity, orthopedic issues, patient motivation) and therefore often may not provide reliable information regarding a patient's cardiopulmonary status. This issue is particularly relevant to pediatric exercise testing, as it is often difficult to confidently ascertain whether a child has expended an optimal effort (a child's self-reported symptoms are subjective and potentially unreliable indicators of effort expenditure). Furthermore, for many patients with CHD, the peak heart rate (HR) during exercise cannot be used as an index of patient effort because these patients often have sinus node dysfunction and/or are on medications that may impair the chronotropic response to exercise. Hence, the ability of exercise testing with EGG monitoring to provide objective, quantitative information regarding a patient's exercise capacity is suboptimal; it also provides little information regarding the factors that may be responsible for a CHD patient's exercise intolerance.

Prediction equations are also available for the peak work rate achieved on progressive bicycle protocols (the metric analogous to the endurance time on a Bruce treadmill protocol) [16]. However, some of the factors that limit the utility of the treadmill endurance time as an index of exercise intolerance also apply to the peak work rate.

Cardiopulmonary Exercise Testing (CPET)

In addition to the data obtained on standard exercise test with EGG monitoring, a CPET acquires data from expiratory gas (metabolic cart) analyses. Most modern metabolic carts measure the volume of gas expired by the patient, on a breath-by-breath basis, along with the instantaneous CO_2 and O_2 concentrations. From these data, the $\dot{V}_E$, $\dot{V}_{CO2}$, and $\dot{V}_{O2}$ can be calculated. End-tidal pCO_2 and pO_2 levels can also be

measured. A wealth of clinically valuable information can be derived from these data. The manner in which these data may be integrated into the care of the patient with congenital heart disease and used to address some of the clinical questions commonly confronted by the pediatric cardiologist will now be analyzed.

How Does the Patient's Exercise Function Compare to Normal Subjects?

Peak $\dot{V}_{O_2}$: For a progressive exercise test, the patient is encouraged to exercise until he/she can no longer keep up with the speed/elevation of the treadmill or the resistance on the cycle ergometer. As the exercise intensity increases during the test, the patient must generate more and more ATP to provide the chemical energy needed to perform the mechanical work of exercise. This in turn engenders a progressive increase in the patient's $\dot{V}_{O_2}$ (and $\dot{V}_{CO_2}$). The $\dot{V}_{O_2}$ at peak exercise is therefore closely related to the maximal intensity of exercise that an individual can achieve. Because the peak $\dot{V}_{O_2}$ is (usually) limited by the amount of oxygen that can be delivered to the exercising muscles by the cardiopulmonary system, it is generally considered to be one of the best CPET parameters of cardiopulmonary function. However, to interpret peak $\dot{V}_{O_2}$ data, caregivers must take into the account the fact that peak $\dot{V}_{O_2}$ is influenced by the patient's height, weight, age, and gender. This is generally done by employing an equation that uses these variables to generate a predicted peak $\dot{V}_{O_2}$ value and then calculating the percentage of that value achieved by the patient during the exercise test. The prediction equation should be generated from a demographically similar (normal) patient population, using similar equipment and protocols (peak $\dot{V}_{O_2}$ tends to be 5–10 % higher on a treadmill compared to a cycle ergometer). For quality assurance purposes, an exercise laboratory should test a number of normal subjects and ensure that the peak $\dot{V}_{O_2}$ measured by the laboratory agrees with the prediction equation(s) employed by the laboratory [17]. It is important to note that merely normalizing a patient's peak $\dot{V}_{O_2}$ for the patient's body weight can often be misleading. Adipose tissue consumes virtually no oxygen. Hence, an obese person's weight-normalized peak $\dot{V}_{O_2}$ will be disproportionally depressed. Similarly, postpubertal females have more adipose tissue than their male counterparts, and normal weight-normalized peak $\dot{V}_{O_2}$ values are therefore correspondingly lower.

Peak Work: Most people convert chemical energy into mechanical energy with a similar level of efficiency. Consequently, the amount of work performed at peak energy is a good index of a patient's exercise function and can serve as an independent validation of the patient's peak $\dot{V}_{O_2}$ data. This quantity is readily measured on a cycle ergometer, as it is primarily determined by the amount of work required to overcome the resistance in the pedals. On a treadmill, however, the amount of mechanical work performed is dependent upon factors such as the patient's weight, how much the patient leans on the guide rails, or the efficiency of the patient's gait. It is therefore more difficult to reliably quantify the amount of work performed on a treadmill exercise test; this constitutes one of the major advantages of a cycle protocol compared to a treadmill.

$\dot{V}_{O_2}$ *Max and Respiratory Exchange Ratio* (*RER*): For peak exercise data to be valid, the patient must expend a true, peak effort (relying on data from a suboptimal study often leads to erroneous conclusions). A number of criteria can be applied to exercise test data to determine whether an adequate effort was expended. For patients without a chronotropic defect or an arrhythmia, a heart rate at peak exercise >85 % of the patient's predicted peak heart rate is suggestive of an adequate effort. Many patients with CHD, however, have impaired chronotropic function secondary to their disease, surgical history, or medications. Peak heart rate criteria are therefore often unhelpful. In most cases, data from expiratory gas analysis is more informative. For instance, during a progressive exercise test, there comes a point where an increase in work rate no longer engenders an increase in $\dot{V}_{O_2}$ (i.e., the $\dot{V}_{O_2}$ plateaus). The $\dot{V}_{O_2}$ at this plateau is the $\dot{V}_{O_2}$ max, the patient's true cardiovascular limit.

Hence, if a plateau is observed, the patient has indeed expended a maximal effort. The concept of $\dot{V}_{O_2}$max is more applicable to a (ramp) cycle protocol, where the work rate is continually increasing, as opposed to the Bruce treadmill protocol, where the work rate increases in stages every 3 min. The respiratory exchange ratio (RER, the ratio of $\dot{V}_{CO_2}$ divided by $\dot{V}_{O_2}$) can also be used to objectively ascertain whether or not an adequate effort has been expended. As an individual exercises at intensities above the ventilatory anaerobic threshold (VAT), $\dot{V}_{CO_2}$ rises out of proportion to the concomitant increase in $\dot{V}_{O_2}$ because anaerobic metabolism does not consume oxygen but does produce lactic acid which in turn buffers bicarbonate and thereby indirectly produces CO_2. During a progressive exercise test, the further one exercises beyond the VAT, the higher the RER rises; an RER $>$ 1.09 at peak exercise is considered to be indicative of a good effort. If a patient does not achieve a peak RER $>$ 1.09, his/her cardiovascular limit has not been reached. The patient may have expended a good effort and stopped exercising because of non-cardiovascular (e.g., pulmonary, orthopedic, neurologic) factors; however, in these cases, one should be cautious about making inferences regarding the patient's cardiovascular system solely on the basis of his/her peak exercise data [18].

Ventilatory Anaerobic Threshold (*VAT*): For patients who do not expend an adequate effort, it is often worthwhile to determine the $\dot{V}_{O_2}$ at the ventilator anaerobic threshold (VAT). During a progressive exercise test, the VAT occurs when the amount of ATP that the muscles can generate from aerobic metabolism (which, of course, is limited by the amount of oxygen delivered to the muscles by the cardiovascular system) can no longer fulfill the energy requirements of the exercising muscles. At that point, the muscles begin to rely upon anaerobic metabolism to supply an increasing fraction of the ATP they require. The VAT therefore is a reflection of the cardiovascular system's ability to provide oxygen to the exercising muscles and is therefore a good index of the health of the cardiovascular system. Expiratory gas analysis can detect the disproportionate increase in $\dot{V}_{O_2}$ that occurs at the VAT (see above). Because it occurs at submaximal exercise (generally ~60–65 % of $\dot{V}_{O_2}$max), the VAT may be identified even if a patient does not expend an optimal effort [19, 20]. In children with CHD, the VAT is often depressed in a manner similar to, although milder than, the peak $\dot{V}_{O_2}$ [21]. It is rare for the $\dot{V}_{O_2}$ at the VAT to be depressed to <40 % of predicted *peak* $\dot{V}_{O_2}$ unless the patient has a condition that impairs oxygen delivery to the muscles. Equations for calculating predicted values for the $\dot{V}_{O_2}$ at the VAT are also available [22].

Serial CPETs can provide objective evaluations of a patient's exercise function over time. In pediatric patients, the important influence of growth and puberty-related changes upon CPET parameters must be taken into account. In most cases, it is best to focus upon % predicted values, rather than absolute or weight-normalized values. Serial studies should also be used to objectively and quantitatively assess the impact of therapeutic interventions upon a patient's exercise function.

What Factors Caused the Patient to Stop Exercising?

During a progressive exercise test, most normal subjects stop exercising because of a cardiovascular limitation, i.e., their cardiovascular system is unable to increase oxygen delivery sufficiently to meet the metabolic demands of the exercising muscles. For patients with cardiovascular disease, this cardiovascular limitation is usually even more profound. Oxygen delivery at peak exercise is determined by the heart rate (HR) and forward stroke volume (SV) at peak exercise, as well as the arterial O_2 saturation and hemoglobin concentration. CPET allows clinicians to make reasonable inferences regarding the factors that may be contributing to a patient's cardiovascular limitation.

In normal subjects, HR increases linearly, in proportion with $\dot{V}_{O_2}$ from baseline levels to the patient's peak HR. For treadmill exercise, predicted peak HR may be estimated from the

equation: Peak HR = 220 – age (in years); peak HR tends to be ~5–10 % lower than these values on a cycle ergometer [16]. Patients with a chronotropic defect cannot increase their HR up to normal values and will have a low peak HR despite expending a good effort (as evidenced by a RER > 1.09 at peak exercise).

Oxygen Pulse (O_2P): The SV response to exercise can be assessed by calculating the oxygen pulse (O_2P, equivalent to the $\dot{V}_{O_2}$/HR) at peak exercise [23]. The relationship between the O_2P and the (forward) SV is best understood by dividing both sides of the Fick equation by HR:

$$\begin{aligned}\dot{V}_{O2}/HR = O_2P &= (CO/HR) \times (O_2 \text{ extraction}) \\ &= SV \times (CaO_2 - CvO_2)\end{aligned}$$

where CO is the cardiac output, CaO_2 is the arterial oxygen content, and CvO_2 is the mixed venous oxygen content. CaO_2 and CvO_2 are determined by the arterial and mixed venous oxygen saturations, respectively, the hemoglobin concentration, and a negligible amount of dissolved O_2. The hemoglobin concentration and arterial saturation of most patients with repaired CHD are normal; hence, CaO_2 has approximately the same value for most patients. Furthermore, at peak exercise, oxygen extraction is maximized and mixed venous oxygen saturation at peak exercise varies little across a wide spectrum of cardiovascular function; hence, CvO_2 at peak exercise assumes approximately the same value for most patients, and O_2P at peak exercise is therefore directly proportional to SV at peak exercise. Of course, SV at peak exercise is influenced by the patient's size, age, and gender. However, predicted values for the O_2P at peak exercise can be calculated by dividing the patient's predicted peak $\dot{V}_{O_2}$ (in ml/min) by the predicted peak HR (in bpm). For patients in whom the assumptions inherent in this analysis (i.e., normal arterial O_2 saturation, normal hemoglobin concentration, and normal oxygen extraction at peak exercise) are valid, the oxygen pulse reliably reflects the forward stroke volume at peak exercise. Arterial desaturation, anemia, or polycythemia will distort the relationship between the O_2P and SV. Rare conditions that impair the uptake of oxygen by the mitochondria (e.g., Barth's syndrome) and/or the release of O_2 from hemoglobin (e.g., some glycogen storage diseases and other metabolic defects which impair lactate production and thereby prevent the physiologic right shift of the hemoglobin-oxygen dissociation curve that occurs as lactic acidosis accumulates during exercise) will also distort this relationship. Finally, it must be noted that the relationship between O_2P and SV holds only at peak exercise; at lower levels of exercise, oxygen extraction is not maximized and the O_2P therefore does not reliably reflect the SV.

In patients with chronotropic defects, the SV (and O_2P) at peak exercise tends to be higher than normal, solely on the basis of the Starling mechanism (i.e., at lower heart rates, the ventricle has more time to fill and the SV will be correspondingly higher). Consequently, in patients with a chronotropic defect, the presence of an O_2P at peak exercise that is in the normal range in fact reflects an impairment of the stroke volume response to exercise.

Numerous factors (e.g., systolic dysfunction, diastolic dysfunction, valvular dysfunction, elevated systemic or pulmonary vascular resistance) may impair the stroke volume response to exercise. A low O_2P at peak exercise does not distinguish between these etiologies. However, when combined with data from other testing modalities, reasonable inferences regarding the causes of a subject's SV impairment can usually be made.

Pulmonary Function Testing by CPET

CPET can also detect abnormal breathing patterns and reveal the extent to which respiratory factors are contributing to a patient's exercise intolerance. The interpretation of CPET respiratory data is enhanced by baseline spirometric measurement, which should be obtained as a component of all CPETs. In addition to providing information concerning the patient's lung function, these measurements assist in the interpretation of CPET data.

Maximum Voluntary Ventilation (*MVV*): Some laboratories also measure the maximum voluntary ventilation (MVV, the maximum amount of air an individual can breathe in one minute) prior to a CPET. This parameter is calculated by asking the subject to maximally hyperventilate for 12 s and multiplying the amount of air the patient exhaled during that period by five. Practically, this maneuver is very difficult for most patients to perform properly, and measurements obtained in this manner are very effort dependent [21]. It has been found, however, that in subjects who perform a good MVV maneuver, the MVV derived from this maneuver can be approximated by multiplying the FEV1 (measured on baseline spirometry) by 40 [24, 25]. In normal subjects, the $\dot{V}_E$ at peak exercise is usually ~55–80 % of the subject's maximal MVV (i.e., normal subjects have a 20–45 % "breathing reserve" at peak exercise). For patients in whom respiratory factors are contributing to exercise intolerance, the breathing reserve at peak exercise tends to be low.

Tidal Volume at Peak Exercise: In normal subjects, the tidal volume at peak exercise increases to ~55–65 % of the subject's forced vital capacity (FVC) [24]. In patients with air trapping secondary to obstructive lung disease, tidal volume at peak exercise is often depressed. In contrast, tidal volume tends to be higher, relative to baseline FVC, in patients with restrictive lung disease.

End-Tidal pCO2 ($P_{ET}CO_2$): The end-tidal pCO2 ($P_{ET}CO_2$) during exercise is another clinically useful CPET parameter. In normal subjects, $P_{ET}CO_2$ approximates arterial pCO_2. Therefore, at rest and at lower levels of exercise, $P_{ET}CO_2$ is ~40 mmHg. As exercise-continues beyond the VAT, a progressive metabolic (lactic) acidosis accumulates; in response, a compensatory respiratory alkalosis develops and $P_{ET}CO_2$ falls. Patients with severe lung disease may not be able to increase their $\dot{V}_E$ sufficiently during exercise and may develop abnormally high $P_{ET}CO_2$ levels. In contrast, in patients with ventilation/perfusion (V/Q) mismatch, air from alveoli with poor perfusion (and hence low $P_{ET}CO_2$) will dilute air coming from better-perfused alveoli, and hence, $P_{ET}CO_2$ will be abnormally low [26].

$\dot{V}_E/\dot{V}_{CO_2}$ Slope: During a progressive exercise test, $\dot{V}_E$ increases linearly, in proportion to $\dot{V}_{CO2}$, until a point, above the VAT, when the progressive compensatory respiratory alkalosis begins to develop. The slope of the linear portion of this relationship (the "$\dot{V}_E/\dot{V}_{CO_2}$ slope") is another clinically useful CPET parameter. It is literally the additional number of liters of air a subject needs to breathe out in order to excrete an additional liter of CO_2. It is therefore a measure of the efficiency of gas exchange during exercise. It tends to be elevated in patients with V/Q mismatch and in patients with physiologic right-to-left shunts. Obstructive or restrictive lung disease may have a variable effect upon the $\dot{V}_E/\dot{V}_{CO_2}$ slope. This parameter has been found to possess important prognostic value in a variety of cardiovascular disorders (see below) and can be accurately ascertained even in patients who do not expend a maximal effort on the CPET [18].

Can the Exercise Test Data Help Determine a Patient's Prognosis?

A number of CPET parameters have been found to possess prognostic value in patients with various forms of CHD. Peak $\dot{V}_{O2}$ has been found to be an independent predictor of death and/or hospitalization for patients with repaired tetralogy of Fallot [27], patients who have undergone atrial switch procedures for transposition of the great arteries [28], patients with pulmonary hypertension [29, 30], and patients with CHF [31]. Among patients with Fontan surgery, a peak $\dot{V}_{O2}$ <16.6 ml/kg/min was associated with a mortality risk 7.5-fold higher than patients with peak $\dot{V}_{O2}$ above this value. A $\dot{V}_{O2}$ at the VAT <9.0 ml/kg/min had similar prognostic power. In addition, a peak HR <122.5 bpm

was associated with a 10.6-fold increase in mortality. Fontan patients who did not have any of these risk factors had an intermediate-term (4.0 ± 2.0 years) survival of 98 % [32].

The $\dot{V}_E/\dot{V}_{CO_2}$ slope has also been found to possess prognostic value in patients with CHF [31], pulmonary hypertension [29, 30], and repaired tetralogy of Fallot [33, 34] and patients who have undergone atrial switch procedures for transposition of the great arteries [35]. In patients with CHF, disease progression is associated with progressive V/Q mismatch and impairment of gas exchange across the alveolar-capillary membrane. These pathophysiologic changes in turn cause $\dot{V}_E/\dot{V}_{CO_2}$ slope to become progressively elevated. Similarly, in patients with pulmonary hypertension, progressive pulmonary vascular disease results in more severe V/Q mismatch and progressive elevation of the $\dot{V}_E/\dot{V}_{CO_2}$ slope. In patients with repaired tetralogy of Fallot, $\dot{V}_E/\dot{V}_{CO_2}$ slope elevation has been linked to the presence of branch PA stenosis [26, 34]. In these patients, who almost always have incompetent pulmonary valves, the residual branch PA stenoses exacerbate RV pressure and volume overload. These unfavorable hemodynamics probably account for the association between mortality and $\dot{V}_E/\dot{V}_{CO_2}$ slope elevation. In patients with atrial switch procedures, the $\dot{V}_E/\dot{V}_{CO_2}$ slope elevation is likely related to the systemic ventricular dysfunction and associated CHF to which these patients are prone. In some of these patients, V/Q mismatch secondary to pulmonary vascular disease and/or pulmonary venous obstruction may also play a role.

Although very common among Fontan patients, $\dot{V}_E/\dot{V}_{CO_2}$ slope elevation does not appear to be associated with increased mortality in this population [32]. This observation is probably due to the fact that the $\dot{V}_E/\dot{V}_{CO_2}$ slope elevation encountered in these patients is to a large extent due to V/Q mismatch secondary to the absence of normal pulmonary artery pulsatility (a condition common to all Fontan patients) and, in contrast to the aforementioned conditions, is not strongly related to disease progression.

Summary

Exercise testing can provide valuable information to physicians caring for patients with CHD and unique insights into a patient's cardiovascular status. Special considerations relevant to children and adolescents must be taken into account when applying this technology to pediatric patients.

Cardiac Catheterization: Basic Hemodynamics and Angiography

23

Diego Porras, Lisa Bergersen, and Jeff Meadows

Abstract

A basic understanding of the acquisition and interpretation of hemodynamics and imaging is essential to understand the anatomy and physiology of congenital heart disease. This requires knowledge of normal intracardiac saturations and pressures and the calculations used for flow and resistance. All cardiologists must clearly understand not only the basis of the calculations but also the limitations intrinsic to them.

Hemodynamics

Oxygen Saturation Measurement

The measurement of oxygen saturations within the cardiovascular system provides a wealth of information about where, how much, and in which direction blood is flowing, as well as the ability of the lungs to effectively exchange gas. In trying to understand the relevance of oxygen saturations to hemodynamic assessment, it is best to not simply memorize what normal saturations are but understand why. In this way, it's much easier to figure out what's going on when they are not what you expect and what the limitations of common assumptions are.

Red Blood

Starting from the lungs where the blood receives oxygen, normal pulmonary venous oxygen saturations are typically greater than 97 %. The reason why is fairly obvious. With normal ventilation and perfusion matching and a healthy basement membrane and under normal flows, there is sufficient time and proximity for effective exchange of gas between the alveoli and pulmonary capillary bed, the driving force of which is the partial pressure of oxygen. The partial pressure of oxygen, in turn, determines the hemoglobin saturation via the

dissociation curve. Low oxygen saturations in the pulmonary veins are usually the result of "lung disease." By this we mean anything that interferes with the above process resulting in a greater or lesser extent of ventilation:perfusion (VQ) mismatch. Common causes include airspace disease (pulmonary edema, pneumonia, etc.), true intrapulmonary shunts (AVMs), or, in patients with congenital heart disease, systemic venous-to-pulmonary venous collaterals (the last one depends on where in the pulmonary veins you sample).

It's fairly common to have mild left lower pulmonary vein desaturation, typically due to mild VQ mismatch in areas of lung compressed by the heart in supine patients on the cath lab table. If the pulmonary veins are fully saturated, then, in the absence of admixture with deoxygenated blood (right-to-left blood flow), the left atrial oxygen saturation will be the same as the pulmonary veins. Thus, normal pulmonary venous oxygen saturations and low left atrial saturations suggest a right-to-left shunt at the atrial level (or you could have an intact atrial septum, right-to-left flow at a ventricular septal defect (VSD), and important mitral regurgitation). The point is that before you hit a capillary bed, you don't drop oxygen saturations in blood without some kind of physiologic right-to-left process, and where that change occurs tells you where the shunt is. For example, normal left atrial saturations and low left ventricular saturations suggest right-to-left flow at a ventricular septal defect (VSD), while a normal ascending aorta oxygen saturation with a lower descending aorta suggests right-to-left flow at a patent ductus arteriosus, which is always abnormal in postnatal life. Conversely, if you have normal oxygen saturations in the aorta, then it is reasonable to assume normal oxygen saturations in the left ventricle, left atrium, and pulmonary veins (at least on average).

Blue Blood

Systemic arterial blood returns from the body to the systemic venous system via superior (SVC) and inferior venae cavae (IVC). It is important to remember that while the SVC saturation is often referred to as a "mixed venous saturation," it is not. The true mixed venous saturation is the most distal saturation prior to any left-to-right shunt. So in a normal heart with no defects, this would be the pulmonary arteries, where a normal oxygen saturation is typically in the mid-70s. In a patient with a patent ductus arteriosus (without important pulmonary regurgitation), it would be the right ventricle. In the cardiac intensive care unit, an SVC saturation is usually easy to come by and is often used in place of a true mixed venous sample. With a few other measurements and assumptions, the SVC saturation can serve as an indication of the cardiac index.

Inferior vena cava blood is notoriously poorly mixed and oxygen saturations vary a fair degree due to streaming from abdominal organs with greater or lesser degrees of oxygen consumption.

Systemic venous blood is desaturated relative to systemic arterial blood, and the degree of desaturation is dependent upon only a few things: (1) the systemic arterial oxygen saturation, (2) the hemoglobin concentration, and (3) the body's oxygen consumption. The systemic arterial saturation and hemoglobin concentration are usually easily obtained. Measurement of oxygen consumption (VO_2) requires special equipment and is often assumed. However, studies have clearly shown that, especially in infants, assumed VO_2 is often nowhere near the measured VO_2 (see section on "The Fick Method").

Probably one of the most common questions to a new trainee in the cath lab is "why is the mixed venous oxygen saturation low?" Examination of the above shows that the answer can only be one, or a combination of, four things: low arterial oxygen saturation, low cardiac index, low hemoglobin, or a high VO_2. Frequently, there are competing factors. Single-ventricle patients who are early in their course of life usually have low systemic arterial saturations, secondary polycythemia, and a variable cardiac index. You should go into the cath lab knowing the hemoglobin and systemic arterial saturations, so when someone asks you about a low systemic venous saturation, you can quickly give a qualitative answer. A quantitative answer will be given in the section "The Fick Method" below.

A change in oxygen saturations in the systemic venous/right heart system can only be in one direction, up, and that change means some source of left-to-right shunting (you're adding red blood to blue blood). The location where the oxygen saturation increases tells you where the shunt is. So an increase in oxygen saturations from the high SVC to the low SVC would classically suggest an anomalous pulmonary vein to either the SVC or innominate vein. Likewise, an increase in oxygen saturations from the right ventricle to the pulmonary artery would suggest a PDA with left-to-right flow.

Of course, assessment of oxygen saturations in this manner must be performed with simultaneous consideration of pressure and resistance. For example, the usual direction of flow for a PDA is left to right (because pulmonary vascular resistance is lower than systemic vascular resistance, see below), so in a patient with a PDA, you would expect oxygen saturations to increase from the right ventricle (RV) to the pulmonary artery (PA). But if you have severe pulmonary hypertension (more correctly, severe elevation of pulmonary vascular resistance relative to systemic vascular resistance), the flow through the PDA could be right to left, so there would be no significant increase in oxygen saturations from the RV to PA but rather a decrease in oxygen saturations from the ascending aorta to the descending aorta.

Pressure Measurements

Accurate recording and interpretation of intracardiac pressure waveforms is paramount in a complete hemodynamic assessment. Optimizing pressure waveforms for analysis requires some knowledge of the means by which these are transmitted and recorded, a complete understanding of which requires consideration of the sensitivity, natural frequency, and frequency response of the system.

Pressures and Waveforms

Right Atrial Pressure (RAp)

"Normal" right atrial pressure varies widely in response to a myriad of factors, including volume and respiratory status, heart rhythm, structure, and function. "Normal" mean right atrial pressures for a child can be considered anywhere between 3 and 6 mmHg, although lower, and occasionally negative values, particularly with inspiration or airway obstruction (snoring), are not infrequent. Many children with congenital heart disease (CHD) have elevated RAp, particularly those with right-sided lesions such as tricuspid regurgitation or right ventricular outflow tract obstruction, which have resulted in decreased ventricular compliance and diastolic dysfunction.

The normal right atrial pressure waveform consists of two, and sometimes three, positive waves (a, c, and v) followed by three negative deflections (x, x′, and y, respectively) (Fig. 23.1). The "a" wave results from atrial contraction (and is therefore absent in situations like atrial fibrillation). Increased "a" waves are most frequently seen in situations of atrioventricular valve (AVV) stenosis and atrioventricular dissociation when the atrium contracts against a closed AVV. Relatively increased "a" waves can occur with atrial contraction into noncompliant ventricles. The "x" descent follows the "a" wave and denotes atrial relaxation followed by AVV closure. The "c" wave is sometimes evident and occurs during ventricular systole as the closed AVV bulges into the atrium. While of physiologic interest, the clinical significance of the "c" wave is limited. The subsequent x′ descent reflects the combined effects of continued atrial relaxation and descent of the AVV during continued ventricular contraction. The "v" wave follows, denoting atrial filling while the AVV is still closed. The opening of the AVV followed by atrial emptying is represented by the "y" descent. The "y" descent is characteristically slowed in AVV stenosis. The subsequent period of slow or minimal ventricular filling with little change in atrial pressure (open AVV) is termed diastasis and is quickly followed by atrial contraction ("a" wave). RA pressures should drop with inspiration during spontaneous respiration, the absence of which is the hemodynamic equivalent of Kussmaul's sign.

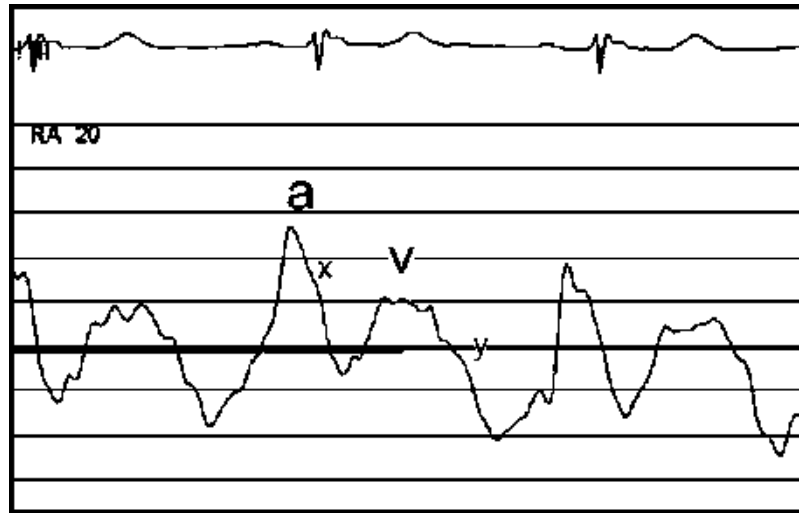

Fig. 23.1 Normal RA pressure waveform with a dominant a wave

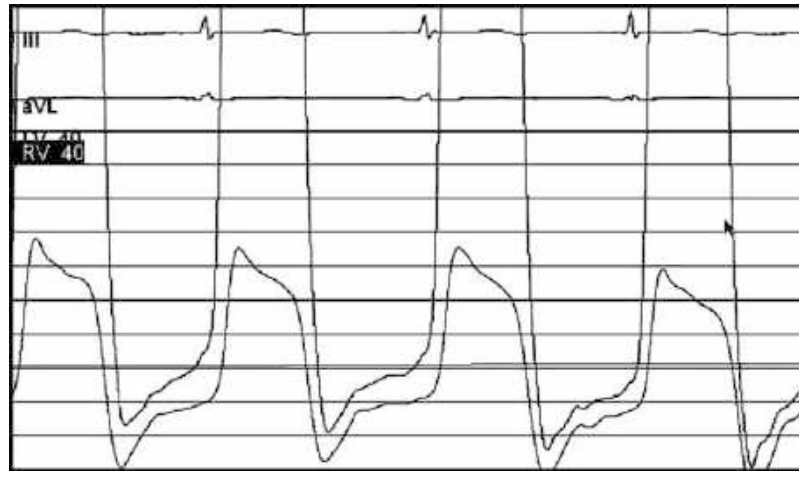

Fig. 23.2 Normal RV and LV pressure waveform

Right Ventricular Pressure (RVp)

Normal (subpulmonary) right ventricular pressure also varies considerably with age, respiratory status, and heart rhythm, structure, and function. Peak systolic pressure is typically 20–30 mmHg. End-diastolic pressure is typically equal or just slightly less than the right atrial "a" wave at 3–6 mmHg (Fig. 23.2).

The right ventricular waveform is marked by a rapid rise during isovolumic contraction, followed by the peak systolic pressure before isovolumetric relaxation and a fall to minimum diastolic pressure (often near zero). There is a slow rise during diastolic filling during which a small RV "a wave" inflection may be seen as a result of atrial contraction just prior to end diastole and subsequent isovolumic contraction.

This "a wave," sometimes referred to as the "atrial kick," frequently is accentuated in patients with 1st-degree AV bock. Peak RV systolic pressure is elevated in the presence of any downstream obstruction including right ventricular outflow obstruction (subPS or valvar PS), main or branch pulmonary artery stenosis, elevated pulmonary vascular resistance (pulmonary

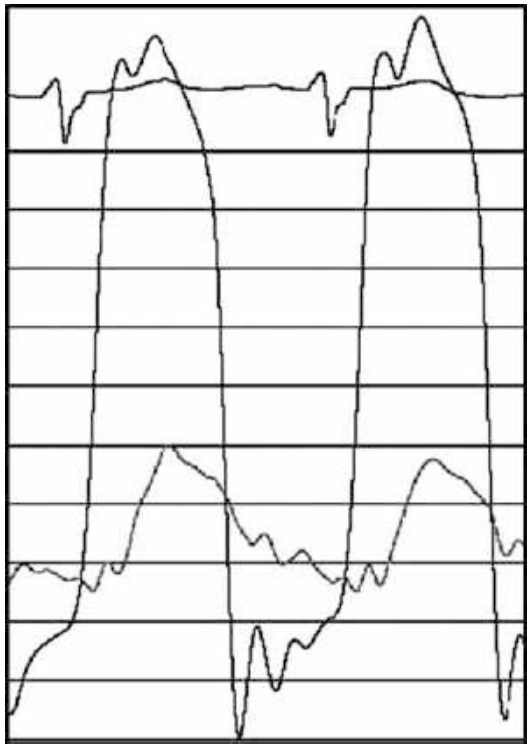

Fig. 23.3 Normal PA pressure waveform

hypertension), or any lesion causing significant pulmonary venous or left atrial hypertension.

Pulmonary Artery Pressure (PAp)

The mean pulmonary artery pressure is usually less than 20 mmHg, with a systolic peak equal to or slightly less than that of the RVp. The pressure pulse is characterized by a relatively slow upstroke, peak systolic pressure, a small dicrotic notch, and slow fall to end diastole. The pulmonary artery pressure tracing provides in a single waveform significant insight into both right and left heart hemodynamics (Fig. 23.3). Accepting that you arrived at the PA through the right atrium and ventricle, a peak systolic pressure significantly lower (>10 mmHg) than RV pressure denotes right ventricular outflow tract obstruction deserving of further characterization to distinguish subvalvar, valvar, or supravalvar stenosis. Normally, there is a demonstrable diastolic pressure gradient between the PA and RV, the absence of which suggests truly "free" pulmonary regurgitation. Otherwise, the PA diastolic pressure more typically approaches the LA pressure.

Elevated PA pressures can occur with either increased pressure and flow (e.g., VSD), increased resistance (e.g., pulmonary vascular occlusive – hypertensive disease), or downstream obstruction (e.g., left atrial hypertension). As such, it is important to use precise and unambiguous terminology. Remember that "pulmonary artery hypertension," that is, high pulmonary artery pressure, is not synonymous with high pulmonary vascular resistance. For example, elevated PA pressures can occur with an unrestrictive VSD and normal pulmonary resistance. Full hemodynamic assessment is critical to distinguish between these, as important management decisions are based upon the ability to manipulate the underlying process (e.g., you can replace/dilate a stenotic mitral valve but you cannot as easily replace end-stage pulmonary vascular occlusive disease-affected lungs).

Pulmonary Capillary Wedge Pressure (PCWp)

A good pulmonary capillary wedge pressure (PCWp, also called pulmonary artery occlusion pressure) resembles the left atrial pressure and waveform (see below) with a time delay of somewhere between 0.02 and 0.08 s (Fig. 23.4) unless there are significant collaterals or pulmonary vein stenosis. As such this waveform should have interpretable "a" and "v" waves and normal respiratory variation. An "underwedged" tracing usually has exaggerated systolic peaks as PAp is transmitted around the catheter. An "overwedged" PCWp typically lacks identifiable waveform morphology with a high drifting mean pressure.

Left Atrial Pressure (LAp)

In the normal heart, LA pressure is higher than RA pressure, with mean pressures ranging between 6 and 9 mmHg. Even with respiratory variation, LAp is never normally below atmospheric pressure (Fig. 23.5).

The right and left atrial pressure waveforms are similar (see above), but the "v" wave is usually dominant in the left atrium, ostensibly

Fig. 23.4 Normal PCWP LV waveform

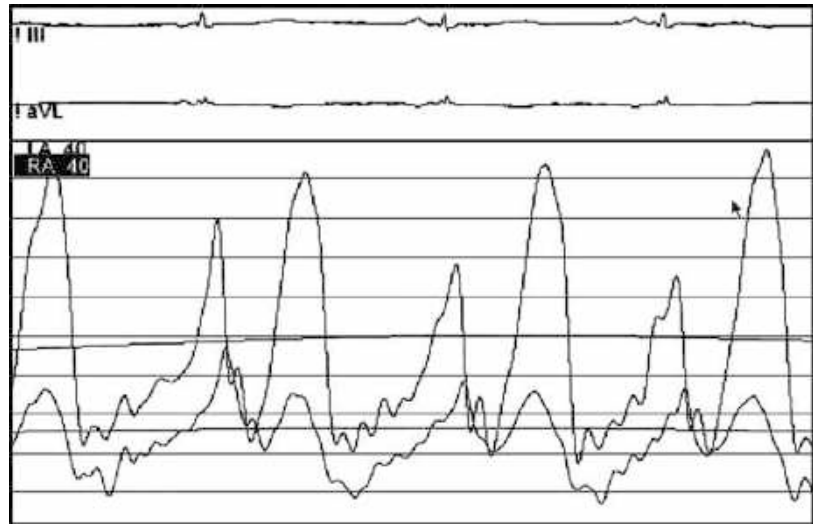

Fig. 23.5 Simultaneous RA and LA pressures in a patient with mitral valve disease

because of pulmonary venous contraction (e.g., the left atrial "a" wave is dominant in TAPVC). Increased "a" waves may be seen in mitral stenosis or in situations of poor LV compliance. Prosthetic mitral valves in the supra-annular position characteristically result in an increased "v" wave, probably due to the combined effects of a small, noncompliant LA and pulmonary venous contraction. However, increased "v" waves are more classically seen in mitral regurgitation. Overall, increased LAp can result from any of the above situations, significant left-to-right shunts, or LV diastolic dysfunction.

Pulmonary Vein Wedge Pressure (PVWp)

The pulmonary venous wedge pressure (PVWp) operates under the same principle as the PCWp, but in the opposite direction, and provides a reasonable estimate of PAp (albeit often slightly underestimating), when the mean pressure obtained is less than 15 mmHg (above this it is imprecise). When the PAp is a major reason for

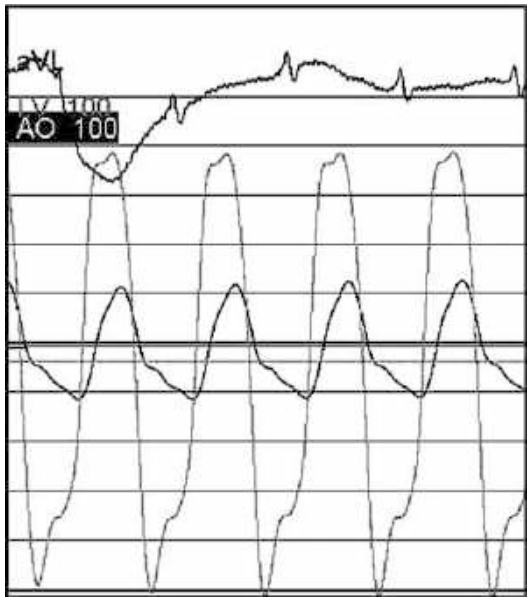

Fig. 23.6 LV and AO waveform in a patient with aortic stenosis

the catheterization and the patient is potentially unstable or access to the PAs may make them so, this can provide a quick estimate.

Left Ventricular Pressure (LVp)

The left ventricular pressure (LVp) varies with age and a host of structural and hemodynamic factors. Obviously, the peak systolic pressure should equal the ascending aortic pressure, failing which there is subvalvar, valvar, or supravalvar obstruction that warrants further characterization. The LV end-diastolic pressure (LVEDp) is a crude but valuable marker for LV diastolic health in that elevated LVEDp (>10–12 mmHg in children) suggests poor diastolic ventricular properties and/or LV failure. Similarly, a steep slope of the diastolic portion of the LV waveform suggests poor ventricular compliance (see Fig. 23.6 vs. Fig. 23.4). "Normal" pressures vary according to age, with a progressive increase in the average LVEDp as patients progress to old age.

Aortic Pressure

The aortic pressure pulse varies uniquely in morphology in health and disease, much of which is due to timing and magnitude of reflected waves. Generally, there is systolic rise, peak aortic pressure, and a variable dicrotic notch on the downstroke. A widened pulse pressure (systolic minus diastolic pressure) is characteristic of "runoff" lesions, including significant aortic (or neoaortic) regurgitation, PDA, surgical shunts, or significant aortopulmonary collaterals. More commonly in adults than children, a widened pulse pressure may be seen in the setting of arterial stiffening and bradycardia. In contrast, a decreased or "narrow" pulse pressure may be seen in low-cardiac-output states and/or tamponade.

Assessment of Flows and Resistance

Calculated systemic and pulmonary flows (and their ratio) are important components of almost all catheterizations. The most common methods for obtaining these include calculations utilizing the methods originally conceived by Adolph Fick and thermodilution (dye dilution being abandoned some time ago). Both of these have their assumptions and limitations that are important to remember.

The Fick Method

In 1870, Adolph Fick described a method for calculation of blood flow. He never tested his theory, but subsequent physiologists have and the "Fick method" remains an important means of determining cardiac output. Indeed, the Fick method probably is the most common means by which cardiac flows are calculated in the pediatric catheterization lab.

Derivation of the equation is simple, and if the concept rather than equation is understood, the strengths and limitations of this method will never be forgotten. Stated simply, the total uptake (or release) of a substance by an organ is the product of blood flow to that organ and the concentration difference of the substance in the arteries and veins leading into and out of that organ. So, using arterial and venous oxygen content and oxygen consumption, one can easily calculate flow. Therefore, if oxygen content is

Oxygen Content (mL O_2/dL Plasma)
$= O_2$ bound to Hb + dissolved O_2
$= 1.36 \times \text{Hb} \times \text{saturation} + 0.003 \times PaO_2$

- 1.36 mL is the oxygen-carrying capacity of 1 g of hemoglobin.
- The relatively small amount of dissolved oxygen in plasma is 0.003 mL O_2/dL plasma/mmHg PaO_2.
- If the saturation is 98 %, then use 0.98 in the formula, not 98.

Then, the important equation becomes

$$\textbf{Cardiac Output}\ (\text{CO};\ \text{L/min}) = \frac{\textbf{O}_2\ \textbf{consumption}\ (\text{mL}\ O_2/\text{min})}{\textbf{AV}\ \textbf{O}_2\ \textbf{content difference}\ (\%\ \text{mL}\ O_2/\text{dL}) \times \textbf{10}}$$

*Multiplication of the denominator by 10 is necessary to convert dL to L, if the hemoglobin is measured as g/dL.

Using these principles, both systemic and pulmonary flows can be calculated using the appropriate arterial and venous parameters. For pediatric catheterization, we most often express the indexed flow (to BSA), distinguishing between cardiac output (CO; L/min) and cardiac index (Qs; L/min/m^2). Since the VO_2 tables are usually indexed,

$$\textbf{Index Systemic Flow}\ (\text{Qs})$$
$$(\text{or}\ \textbf{Cardiac Index}) = \frac{\textbf{O}_2\ \textbf{consumption}\ (\text{mL/min/m}^2)}{\textbf{Systemic arterial}\ \textbf{O}_2\ \textbf{content} - \textbf{Mixed venous}\ \textbf{O}_2\ \textbf{content}}$$

$$\textbf{Indexed Pulmonary Flow}\ (\text{Qp})$$
$$= \frac{\textbf{O}_2\ \textbf{consumption}\ (\text{mL/min/m}^2)}{\textbf{Pulmonary venous}\ \textbf{O}_2\ \textbf{content} - \textbf{Pulmonary arterial}\ \textbf{O}_2\ \textbf{content}}$$

Tip: The Hgb and the oxygen-carrying capacity of Hgb (the 1.36) are essentially the same in the arterial and venous samples. If you do not have to include dissolved oxygen, you can make approximate calculations during the case easier by doing half the math ahead of time. One way is the following: Divide the VO_2 by the product of the Hgb and 0.136 (includes correction factors). This gives you a number which when divided by the relevant AVO_2 difference quickly gives you the indexed flow.

For example, an adult has a VO_2 of 125 mL/min/m^2 and a Hgb of 12.8 g/dL.

The number derived as described above is 125/(12.8*0.136) = 72. If the MVO_2 saturation is 79 % and the aortic saturation is 99 %, then 72/(99 − 79) = ~3.6 L/min/m^2.

Qp:Qs Calculation

In patients with structural heart disease, mixing is common (and often necessary), making important the concept of the ratio of pulmonary to systemic blood flow (also known as Qp:Qs). Conveniently, much of the above formulae cancel out leaving a simple equation:

$$\textbf{Qp} : \textbf{Qs} = \frac{\textbf{Aortic saturation} - \textbf{Mixed venous saturation}}{\textbf{Pulmonary vein saturation} - \textbf{Pulmonary artery saturation}}$$

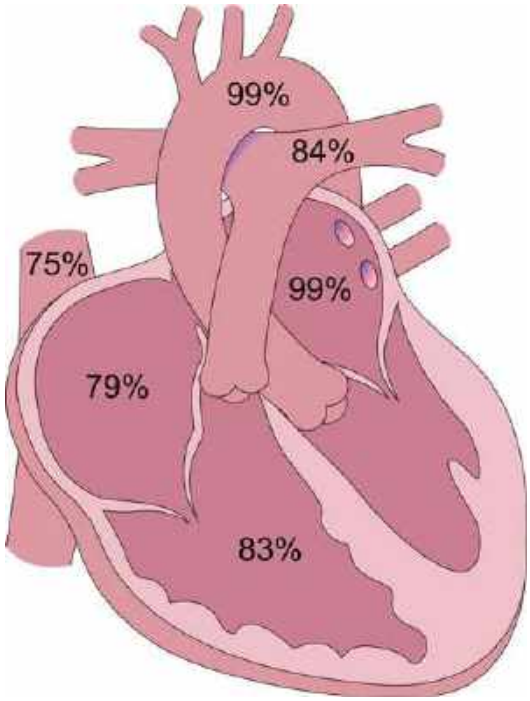

Fig. 23.7 ASD with saturation measurements

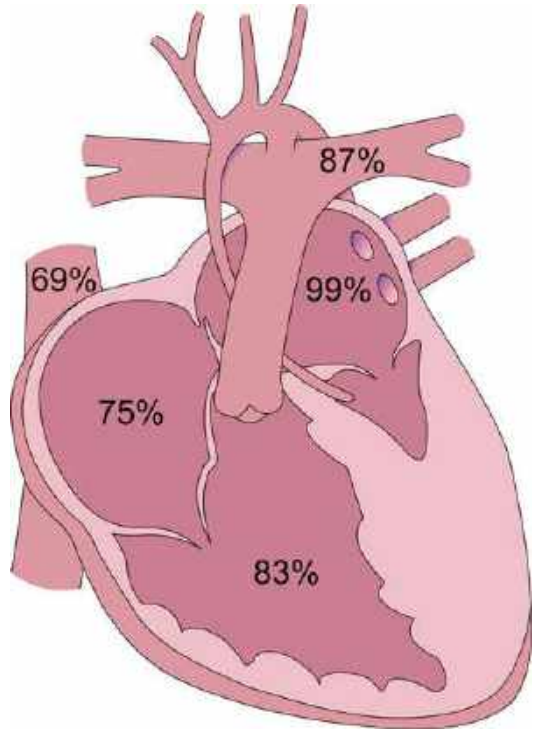

Fig. 23.8 HLHS with saturation measurements

For example, take a situation where the only structural problem is an atrial septal defect (ASD) (Fig. 23.7). In performing a hemodynamic run, you find an SVC (mixed venous) saturation of 75 % with PA saturations of 84 % and equal pulmonary vein and aortic saturations of 99 %. The net Qp:Qs in this patient is $(99 - 75)/(99 - 84) = 1.6$.

Now consider a patient with hypoplastic left heart syndrome (HLHS) who has had a first-stage palliation with a Stansel anastomosis, atrial septectomy, and right BT shunt (Fig. 23.8).

In this patient, you only need to know the SVC, pulmonary vein (sometimes assumed), and aortic saturations in order to calculate the net Qp:Qs because the only source of pulmonary blood flow is the BT shunt; therefore, the pulmonary artery saturation is equal to the aortic saturation. So, with an SVC saturation of 69 %, pulmonary vein saturations of 99 %, and an aortic saturation of 87 %, the net Qp:Qs is ~1.7. This is a similar net Qp:Qs as the ASD above but obviously the physiology is completely different. To give you an idea of how changes in mixed venous and arterial saturations affect Qp:Qs in a patient with this kind of shunted physiology, consider the chart below (a pulmonary venous saturation of 100 % has been assumed).

	Qp:Qs	Arterial saturation (%)
MV sat 50 %	0.5	67
	1	75
	2	83
	3	88
MV sat 70 %	0.5	80
	1	85
	2	90
	3	94

Thermodilution

First introduced in the 1950s, the principle involves determining the extent and rate of thermal changes in the bloodstream related to injection of a fixed volume of fluid at a set temperature upstream. From this temperature-time curve and knowledge of the magnitude of the initial heat change, the volume rate of flow can be calculated in a manner analogous to that used for dye and other indicator-dilution methods.

Resistance Calculations

The concept (and reality) of resistance to blood flow is important in patients being considered for many surgical interventions. Using the results of your flow calculations above and your pressure measurements, you can assess resistance. Doing so involves a simple variation on Ohm's law where R = V/I becomes

$$\textbf{Resistance} = \Delta\textbf{Pressure}/\textbf{Flow}$$

Therefore, PVR or the pulmonary arteriolar resistance is given as

$$(\textbf{PVR}) = \frac{\textbf{mean PAp} - \textbf{mean LAp}}{\textbf{Qp (indexed)}}$$

- Normal PVR < 2 WU.m^2

Using the same principles, systemic vascular resistance is

$$(\textbf{SVR}) = \frac{\textbf{mean Aop} - \textbf{mean RAp}}{\textbf{Qs (indexed)}}$$

- Normal SVR 15–20 WU.m^2

Constrictive, Restrictive, and Tamponade Physiology

The physiologic changes that accompany these disease processes have long been of clinical and intellectual interest to cardiologists. The following are general characteristics of each. Remember that there is some overlap with these findings and sensitivity can be lacking. Therefore, appropriate evaluation and conclusions require a complete knowledge of the clinical scenario. Since effusions are usually easily demonstrable by echocardiography, the usual difficulty arises from distinguishing restriction (myocardial disease) from constriction (pericardial disease).

Constrictive Pericardial Disease

While this is a relatively uncommon process in pediatric cardiology, it may be more common in adults with CHD, and it remains an important consideration in any patient with unexplained diastolic dysfunction.

Classic findings include elevation and equalization of right and left atrial and ventricular end-diastolic pressures. There may be loss of the normal RAp decline with inspiration (Kussmaul's sign). RA waveforms demonstrate a preserved "x" and prominent "y" descent, often with equal "*a*" and "*v*" waves, giving the classic appearance of the "M" or "W" sign. Both RV and LV pressure waveforms demonstrate an early and prominent diastolic "dip" and rapid rise to a "plateau" resulting in the classic "dip and plateau" or "square root" sign. In patients with tachycardia, this sign may be difficult to appreciate. In such cases, the prolonged diastole that follows an induced PVC will occasionally unmask this phenomena. RV end-diastolic pressure is frequently $>1/3$ RV systolic pressure, but RV and PA systolic pressures are usually only moderately elevated. Relative hypovolemia can rarely mask some of these findings, and in those cases they may be elicited by rapid infusion of volume. The sensitivity of these findings is quite high (90–95 %) but the positive and negative predictive values range widely, from 4 % to 92 %.

Characteristic respiratory variations (during spontaneous respiration) may provide the most sensitive and specific criteria for constrictive disease and may be of particular use in distinguishing constrictive from restrictive disease. The first of these is the finding of ventricular discordance, or "ventricular interdependence," manifest by an inspiratory increase in systolic RVp with simultaneous decrease in systolic LVp (in contrast to the normal state where RV and LVp rise and fall together). Also, it has been suggested that in constrictive pericardial disease, normal changes in intrathoracic pressure are prevented from being fully transmitted to the intracardiac structures. As such, there is a decrease in the early diastolic transmitral gradient (LA or PCWp minus minimum LV early diastolic pressure) with inspiration, whereas normally there is no change. The latter finding may be subtle and may require the use of high-fidelity catheters to be appreciated, but the former finding

is reported to have positive and negative predictive values in the 95–100 % range.

Restrictive Disease

Hemodynamic findings in restrictive disease can mimic those of chronic constrictive disease. The "M" sign and Kussmaul's sign may be seen, but atrial pressures tend to be higher than those observed with constrictive disease. Likewise, the "dip and plateau" sign may occasionally be seen with restriction, although LV diastolic pressures tend to remain higher than those of the RV (lack of equalization). Secondary pulmonary hypertension is more common in restriction than constriction, and therefore, RV and PA systolic pressures can be higher.

Effusive Pericardial Disease (and Tamponade)

We do not usually evaluate intracardiac hemodynamics in patients with isolated pericardial effusions. However, occasionally, you will have reason to catheterize a patient who happens to have some degree of pericardial fluid, and you will need to know its significance. Perhaps more importantly, prompt recognition of the hemodynamic alterations that signify unrecognized heart perforation during a case leading to progressive tamponade is imperative. In these cases, the following are important to consider.

High pericardial pressure exerts its primary hemodynamic effect by impeding right heart filling. There is equalization of atrial and ventricular end-diastolic pressures, closest during inspiration (during spontaneous respiration), and a gross reduction in intracardiac volumes (both end-diastolic and end-systolic volumes are reduced). With respect to the RA waveform (and jugular venous pressure), classically, there is loss of the "y" descent (poor early diastolic filling), attributed to a fixed intracardiac volume. *Pulsus paradoxus* may be observed in aortic pressure tracings, with a >10 mmHg systolic pressure decline with inspiration. Of note, close attention to a pulse oximetry tracing may show exaggerated respiratory variation as well. Fortunately, in contrast to restrictive and constrictive disease, effusive disease with tamponade is acutely remediable, although in rare cases relief of tamponade can reveal underlying restrictive or constrictive disease.

Angiography

Introduction

In this section, standard angiographic projections and method of acquisition are reviewed, followed by example angiograms outlining lesions optimally viewed by different imaging angles. Alterations in these angles are often necessary in congenital heart disease based on the unique anatomy of the patient.

Standard Angiographic Projections

Rotation of the image intensifier to the patient's left is considered a positive degree of rotation (also referred to as "x° of LAO"), while rotation to the right is negative (also referred as "x° of RAO") (see Fig. 23.9). Cranial and caudal tilt is self-explanatory (still refers to the position of the image intensifier). Viewed from this perspective, it becomes clear why "shallow LAO" is usually between +1° and +30° while "steep LAO" is between +61° and +89° LAO.

Frontal "camera"		Lateral "camera"	
Frontal/ posteroanterior (PA)	0°	Straight lateral	90°
Right anterior oblique (RAO)	Usually −20–30°	Left anterior oblique (LAO)	20–70°
"Sitting up"	0° frontal	Long axial oblique (*not* LAO)	70° lateral
	+20–30° cranial		+30° cranial
"Laid back"	0° frontal	Hepatoclavicular (4-chamber)	45° lateral
	+30° caudal		+45° cranial
		Aortic orifice view	100–120° lateral
			+20–30° caudal

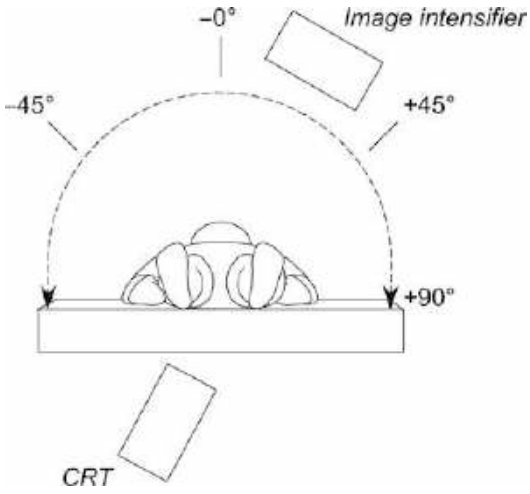

Fig. 23.9 Imaging angles

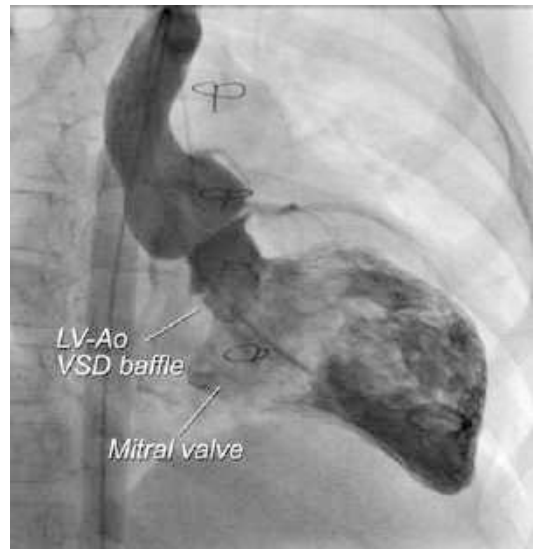

Fig. 23.10 RAO ventriculogram

When to Use Which View

Frontal/PA View

Best used for:

- Systemic venous anatomy (RSVC, LSVC, IVC)
- Pulmonary venous anatomy
- RV anatomy and distal PA anatomy
- Descending aortography and aortopulmonary collaterals
- Single-ventricular morphology (especially initial imaging)

Detriments:

This is not an "axial" view. There is commonly superimposition of structures of interest.

That is, the RV outflow tract overlies the branch PAs and the ventricular and atrial septa are poorly outlined.

Right Anterior Oblique (RAO)

Superimposes normally positioned atrioventricular valve annuli. Used in electrophysiology lab for mapping (Fig. 23.10).

Best used for:

- Good delineation of outlet/anterior muscular VSDs and the infundibulum
- LV outflow tract imaging for sub-AS (including AV canal gooseneck)
- LV function and quantification of MR and AR
- An alternative view for measuring PDAs
- Aortic valve annulus measurements

"Sitting Up"

Based on old practice of moving the patient's position rather than cameras

Best used for:

- Improved imaging of MPA and branch PAs, with less superimposition (Fig. 23.11)
- Pulmonary stenosis, for annulus measurements
- Seeing full length of RPA (especially with RAO 20–30°)

"Laid Back"

Best used for:

- Alternate view to image proximal branch PAs
- PAs arising from conduits (up to 60° caudal) (Fig. 23.12)
- Coronary arteries from Ao, e.g., dTGA

Lateral

Best used for:

- Excellent view of RV outflow tract/pulmonary valve/MPA (Fig. 23.13)
- Good imaging of PDA and coarctation

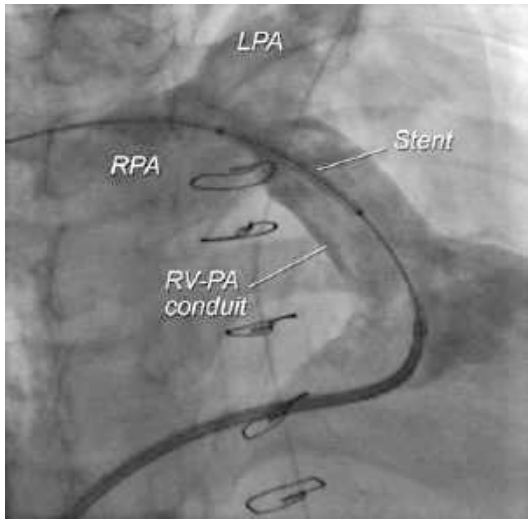

Fig. 23.11 Sitting-up angiogram

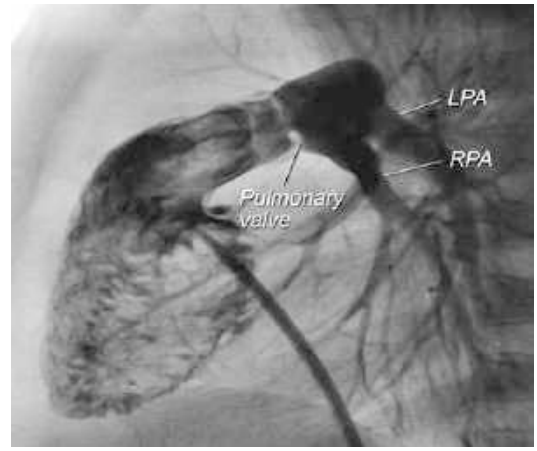

Fig. 23.13 Lateral angiogram

Fig. 23.12 Laid-back angiogram

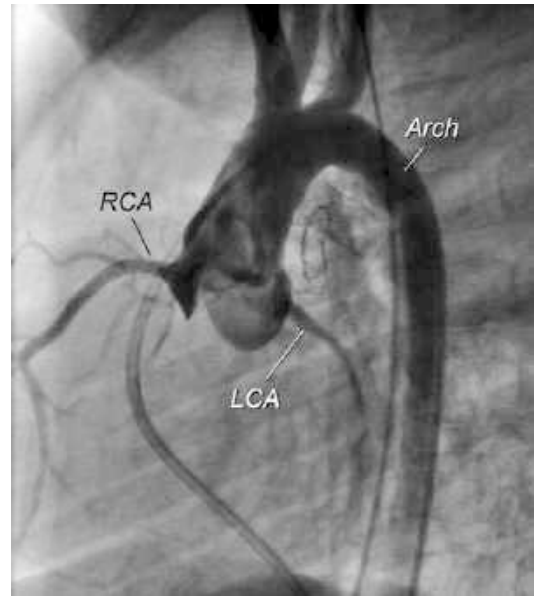

Fig. 23.14 Left anterior oblique

- Coronary artery origin and course
- Distal PA anatomy

Left Anterior Oblique

Not to be confused with long axial oblique. Generally refers to the rotation along the lateral plane and does not denote use of cranial or caudal angulation.

Best used for:

- Elongating aortic arch, which may help for PDA or coarctation (Fig. 23.14)
- Lengthening LPA (caudal angulation may help)
- Truncal valve anatomy
- Proximal LPA anatomy

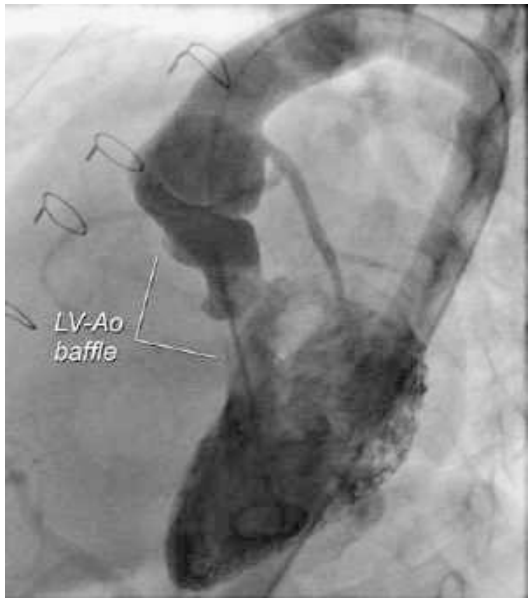

Fig. 23.15 Long axial oblique angiogram

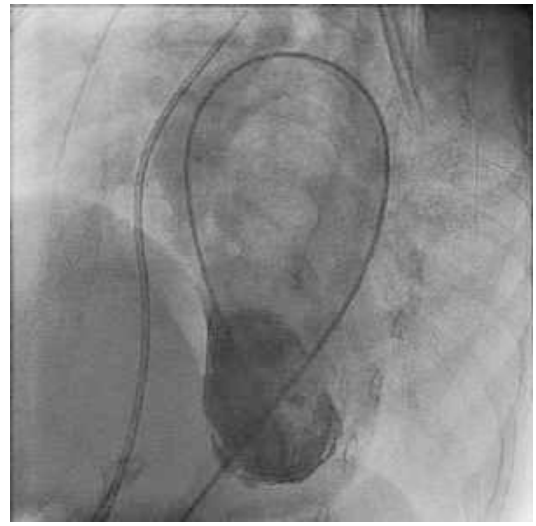

Fig. 23.16 Hepatoclavicular angiogram view

Long Axial Oblique

Gives LV image similar to that found in parasternal long axis view by echo

Best used for:

- LV function and MR
- Sub-AS, AS, and supra-AS (Fig. 23.15)
- Annulus measurement for aortic valve dilation
- VSD imaging (membranous/conoventricular/anterior and mid-muscular)

Hepatoclavicular (4-Chamber)

Gives image analogous to that found on apical 4-chamber echo view and looks at the crux of the heart

Best used for:

- ASDs (especially with catheter in right upper pulmonary vein)
- Endocardial cushion defects (ECD)
- Inlet/posterior muscular VSDs
- AV valve anatomy and regurgitation (Fig. 23.16)
- LV-to-RA shunt
- The origin of the LPA

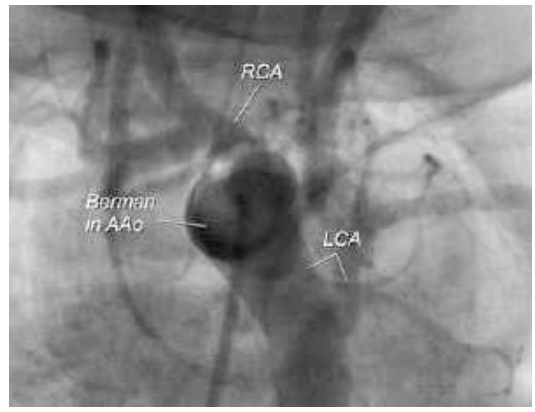

Fig. 23.17 Aortic orifice view

Aortic Orifice View

Similar to parasternal short axis echo view

Best used for:

- Looking at coronary artery origins, especially with antegrade ascending aorta injection with an inflated Berman catheter (Fig. 23.17)
- Giving nice view of aortic valve cusps

Coronary Angiography

Angiographic Projections

The types of projections used vary significantly, based on the indication for catheterization. In general, selective coronary artery imaging is used when there are questions about the course and caliber of the coronary arteries. In a heart with normal ventricular and arterial relations, there are standard projections which are recommended to image each coronary artery. The goal of all of these is to be in a position which is tangential to area of interest, thereby lengthening the course of the coronary artery in that region. Ideally, you should examine more than one view of each region, as stenoses and aneurysms are not always uniform around the circumference of the vessel. However, before demonstrating typical angiographic projections, it is often useful to remember the appearance of normal coronary angiography in straight PA and lateral (Figs. 23.18 and 23.19).

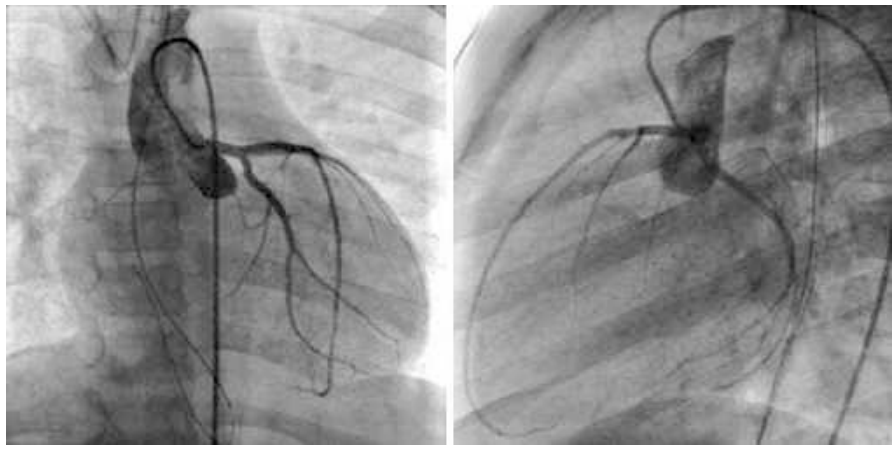

Fig. 23.18 Left coronary artery angiography (=Fig. 74 nL LCA angio)

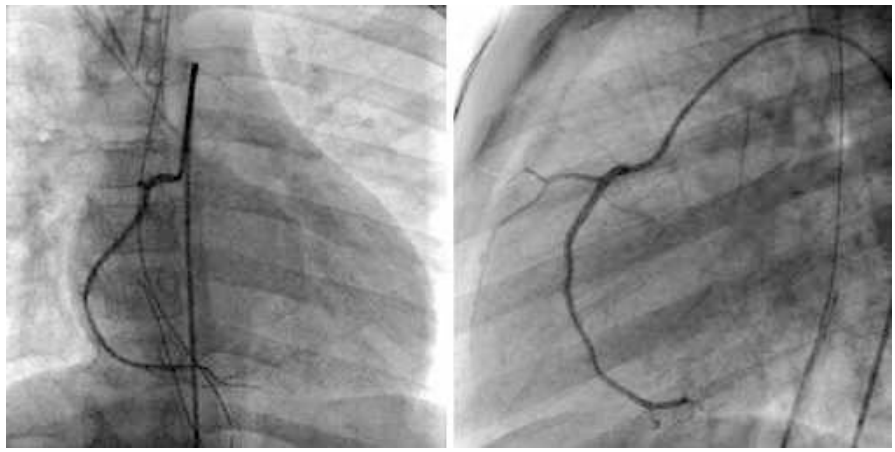

Fig. 23.19 Right coronary artery angiography (=Fig. 75 normal RCA angio)

Specific Angiographic Projections

Left Main Coronary Artery

The LCA is often best seen in the "spider view" obtained with the following camera angle: 45–60° LAO + 15–25° caudal (Fig. 23.20). The proximal course can also be seen with 15° RAO + 25° caudal angles (Fig. 23.21).

Left Anterior Descending Artery

The LAD may have to be visualized using several views, due to its length. One of the three best views of the LAD is 15° RAO + 25° caudal; the entire length of the LAD will be well seen with septal perforators and diagonals clearly delineated. The other nice view is 10° RAO + 40° cranial (Fig. 23.22). A view similar to the hepatoclavicular view (45° LAO + 25–35° cranial) will elongate the interventricular septum and show the middle and terminal portions of the LAD (Fig. 23.23).

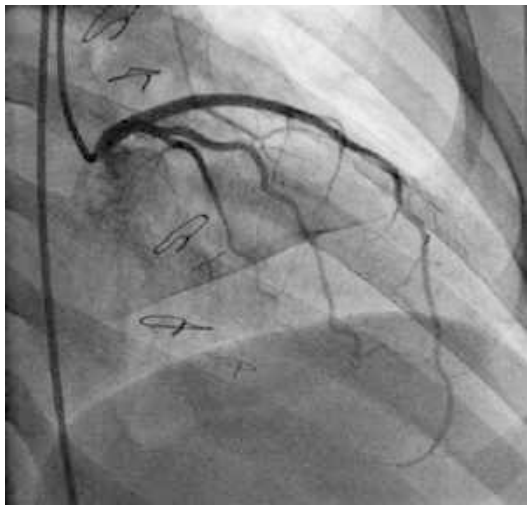

Fig. 23.20 LCA system, RAO cranial

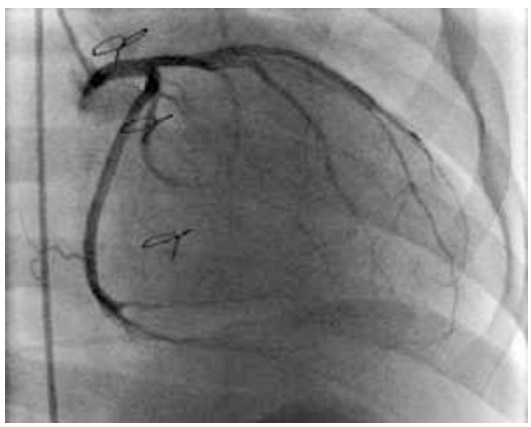

Fig. 23.21 LCA system, RAO caudal

Fig. 23.22 LCA system, LAO cranial

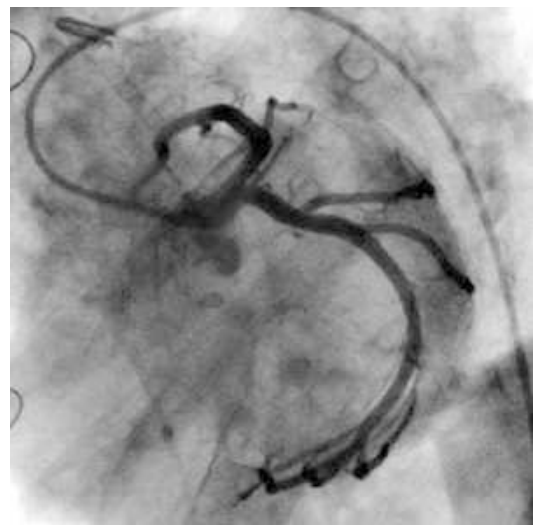

Fig. 23.23 LCA system, LAO caudal

Left Circumflex Artery

The circumflex is best seen with the RAO and LAO views with caudal angulation (Figs. 23.21 and 23.20, respectively). LAO with caudal angulation (spider view) will cause the beam to look up the barrel of the left ventricle, outlining the course around the posterior AV groove (Fig. 23.20).

Right Coronary Artery

The proximal RCA is best seen in either the LAO or straight lateral projections (right panel of Fig. 23.19). To lengthen the course of the mid-RCA, use the RAO projection. The posterior descending is best seen with 30° LAO + 30–45° cranial angulation.

Typical Sequence of Angiograms

LCA System

10° RAO + 40° cranial: excellent of LAD and okay of Cx

45° LAO + 25° caudal: excellent of LCA, prox LAD/Cx, and good of distal Cx

15° RAO + 25° caudal: excellent of LMCA/LAD and Cx

45° LAO + 25° cranial: very nice LAD and Cx

RCA System

AP: nice view of midportion RCA

Lateral: excellent proximal RCA and midportion RCA

30° RAO: excellent midportion RCA

30° LAO + 30–45° cranial: excellent distal RCA/PDA

Note: In a biplane lab by alternating cranial/caudal positions with the AP/lateral cameras, you will avoid the cameras interfering with each other

Specific Examples

D-Transposition of the Great Arteries (dTGA)

Sufficient coronary detail is usually apparent by echocardiography but angiography remains important in select cases. Coronary angiography in dTGA is usually performed one of two ways. The first takes advantage of the fact that the aorta arises from the RV, allowing easy access from the central venous system. In this case (either before or after a BAS if required), a Berman™ catheter is advanced antegrade out the RV to the ascending aorta. From here appropriate balloon inflation will subtotally occlude flow and a power injection will force contrast retrograde, filling the coronary arteries. The best angle for an initial angiogram is usually the "laid-back" view. This provides an excellent "on-end" view from the bottom of the great arteries and well characterizes their relation to each other (the PA filling slightly later from the PDA). Adjust the cameras as necessary. The other approach is the usual retrograde approach with either an appropriate ascending aortogram or selective coronary injections.

There is a broad spectrum to coronary variation in dTGA (Fig. 23.24). The term "usual" is preferred to "normal" (because they are certainly not normal) for the most common situation in which the LCA arises from the leftward and anterior-facing sinus and the RCA arises from the posterior-facing sinus. However, it is a better practice to describe the anatomy with more detail, by clearly describing the origin, relationships, and proximal course of the coronary arteries.

Pulmonary Atresia with Intact Ventricular Septum (PA/IVS)

Although other criteria play significant roles, one key element in decision making for patients born with PA/IVS is the presence or absence of right ventricular-dependent coronary circulation (RVDCC). The presence of RVDCC precludes safe RV decompression. Because of the unusual situation in PA/IVS, detailed coronary angiography requires imaging both from the aorta and from the RV. With the small RV volumes seen in many patients with PA/IVS, often a simple hand injection suffices to detail RV sinusoids and coronary communications as the case may be. Angiography of the aortocoronary connections and courses should follow. In the most extreme cases, there may be no direct

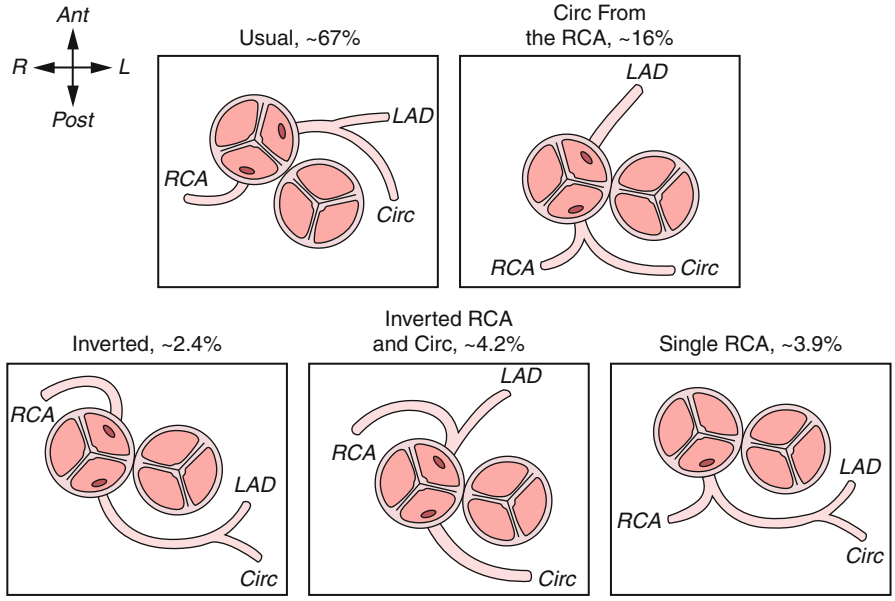

Fig. 23.24 Coronary anatomy in dTGA (adapted from Wernovsky et al. [2], with permission)

communication between the coronary arteries and the aorta (i.e., atresia of the orifices).

The definition of right ventricular coronary dependence has not been unanimously agreed upon. However, it has been shown that:

- RV decompression in the setting of coronary fistulae without stenosis of the origins or distal coronary vessels does not appear to result in death or LV dysfunction.
- RV decompression in the setting of coronary fistulae and stenosis in both the RCA and LCA/circ systems frequently results in death.

Anomalous Connection of the Left Coronary Artery and the Pulmonary Artery (ALCAPA)

The straightforward name of this lesion belies the complexity and diversity of anatomy and physiology possible under this heading, and in actuality, while the LCA is the most common coronary involved (≈5 % RCA) in anomalous connection (preferred over "origin" due to developmental reasons) to a PA, any coronary artery may be so connected. This anomaly usually occurs in isolation, although it has been described with a variety of congenital cardiac lesions. The connection to the PA is usually at the facing PA sinus but can occur to the MPA or either proximal branch PA, and the normally connected coronary artery is usually quite dilated. Selective angiography of the normally connected coronary artery usually shows the anomalously connected coronary filling retrograde via collaterals. An aortogram or selective injection in the left and noncoronary cusps also may be performed.

Right from the Left, Left from the Right, and Variations

Imbedded in the spectrum of variation of coronary origin and course are those that are abnormal, defined as those occurring in less than 1 % of the population, or those that carry some identifiable risk to the patient. The most frequent of these are anomalous origin of the LCA from the right coronary sinus and anomalous origin of the RCA from the left coronary sinus, the former being worse. Identification of these is performed in the usual way, with care taken understanding that the coronary orifice may be narrowed ("slit-like") or eccentrically located within the sinus; this can be diagnosed with intravascular ultrasound. Selective hand injection in the aortic cusp from which the

coronary artery should but does not arise may be desirable. Identification of an intramural coronary artery course can be difficult by selective angiography and may be best characterized by CT angiography which has the advantage of imaging both the contrast-filled arteries and the walls of the great vessels.

Coronaries Through a Stansel or in an Unrepaired HLHS

On occasion, imaging of the coronary arteries following a Stansel anastomosis is required. More rarely, you'll need to see them in unrepaired HLHS. The catheters and techniques to do so will greatly depend upon the underlying cardiac malformation and the surgical technique utilized in performance of the anastomosis. In patients with HLHS, the native ascending aorta may be quite small, resembling in some situations a "common coronary" itself. In these situations, simple injection into the native ascending aorta often provides beautiful anatomic detail (Fig. 23.25).

Tetralogy of Fallot (ToF)

The most frequent coronary consideration in patients with tetralogy of Fallot is exclusion of a coronary artery crossing the RV outflow tract. The most common variants of concern are dual LADs and an LAD from the RCA with an anterior course. Significant or unusual conal branches also should be identified.

Conduits

There are a variety of cardiac malformations that require placement of a conduit to the pulmonary arteries (including TOF/PA). In these situations,

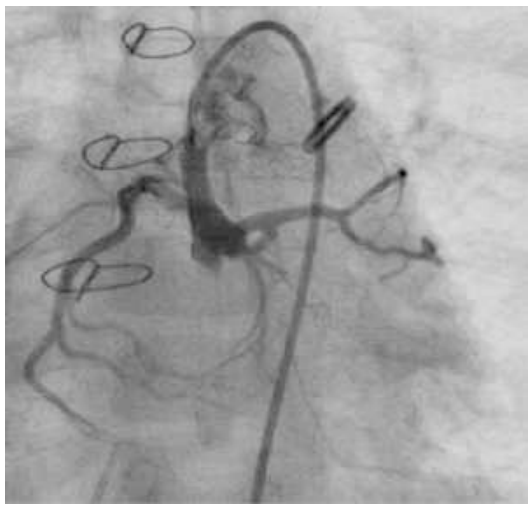

Fig. 23.25 Coronary angiography in HLHS

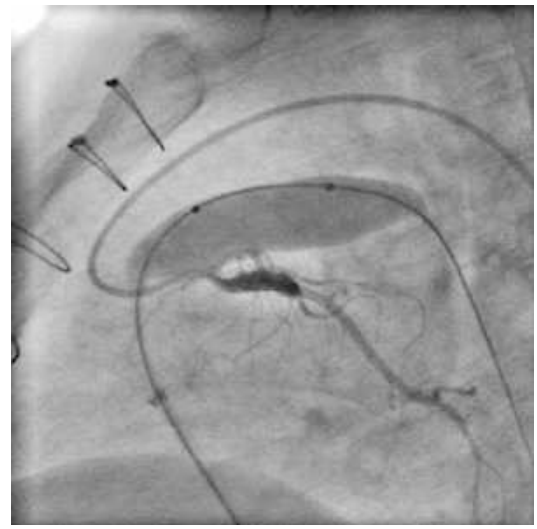

Fig. 23.26 Evaluation of the coronaries prior to RVOT stent placement

Fig. 23.27 Posttransplant coronary vasculopathy

if intervention upon the conduit is considered, it is frequently wise to assess the relationship of the coronary arteries to the conduit prior to intervention, as a conduit stent can easily compress a coronary artery (e.g., LAD from RCA), with expected results (Fig. 23.26).

Posttransplant Vasculopathy

The vasculopathy of posttransplant coronary artery disease typically consists of concentric myointimal proliferation that often involves the entire length of the vessel, including intramyocardial branches. Angiographically, coronary vasculopathy usually manifests as small, occasionally beaded vessels with tiny, short, and sparse intramyocardial branches. Less often, discrete stenoses or filling defects are seen (Fig. 23.27).

Summary

This chapter is a brief overview of the basics of hemodynamics and angiography in congenital heart disease. The section was adapted from the Manual for Catheterization of Congenital Heart Disease [1]. The pressure tracings were provided courtesy of Dr. Barry Keane.

Keywords

3D imaging • Blood flow quantification • Cardiac magnetic resonance imaging • Cardiac-gated balanced steady-state free precession • Cine imaging • cMRI • Congenital heart disease • Diastolic function • MRI • Myocardial delayed enhancement • Myocardial viability • Systolic function • Tissue characterization • Ventricular function

Introduction

The past decade has witnessed an increasingly important role for cardiac MRI (cMRI) in the diagnosis and management of patients with congenital and acquired heart disease. While echocardiography remains the first-line imaging modality in children and adults with congenital heart disease because of its portability and real-time high resolution of anatomic and physiologic data, it is limited by a lack of acoustic windows and large body size. In contrast, cMRI is not limited by acoustic windows or body size and offers comprehensive, noninvasive three-dimensional (3D) imaging of cardiac and extracardiac structures. In addition, cMRI provides a quantitative assessment of cardiac function, flow, and myocardial perfusion and viability in a single examination while avoiding the ionizing radiation of cardiac catheterization. This chapter aims to introduce the reader to common indications for cMRI, basic imaging sequences used in cMRI, scanning environment, and clinical applications of cMRI in the pediatric population with congenital and acquired heart disease.

Indications for Cardiac MRI

Cardiac MRI is rarely used as the first or sole diagnostic test for heart disease in children or young adults. Rather, it is typically used in conjunction with echocardiography in situations where the acoustic windows are suboptimal or extracardiac vascular structures cannot be imaged. cMRI is particularly useful in the older postoperative congenital heart disease patient, because larger body habitus and prior surgical interventions interfere with the ability to produce high-quality echocardiographic images. Cardiac MRI can also be used in lieu of a diagnostic cardiac catheterization because of its ability to

Table 24.1 Indications for cardiac MRI

Suboptimal acoustic windows
Evaluation of extracardiac vascular structures such as systemic veins, pulmonary veins, aorta, pulmonary arteries, venous anomalies, and aortopulmonary collaterals
Evaluation of postoperative extracardiac structures such as extracardiac conduits or cavopulmonary connections
An alternative to diagnostic cardiac catheterization is required to obtain hemodynamic information or visualize extracardiac anatomy
Diagnostic information for which cMRI offers unique advantages such as blood flow measurement, tissue characterization, or myocardial tagging
Possible airway anomalies associated with cardiac disease

provide quantitative information about ventricular function, blood flow, and regurgitant fraction. Techniques such as delayed gadolinium enhancement imaging and myocardial tissue tagging offer unique ways to assess ventricular fibrosis and function that are not available from other modalities (Table 24.1).

Evaluation for Cardiac MRI

When deciding to order a cMRI examination, the clinician should take into consideration the patient's age, hemodynamic condition, and the resources available at the local institution for performing the cMRI. In infants and young children, echocardiography provides detailed information about cardiac anatomy and function and is rarely limited by suboptimal acoustic windows. In addition, pediatric patients in general and neonates in particular have faster heart rates and smaller body size than adults which requires the MRI specialist to have expertise in optimizing the cMRI sequences and in expedited imaging planning. Depending on the circumstances, children younger than 7 years of age often need sedation or general anesthesia to remain still in the magnet bore for the duration of the study. In this case, the importance of the information provided by the examination must be carefully weighed against the risk of sedation or general anesthesia. The need for general anesthesia or sedation, the rapid heart rate, and the excellent images available by echocardiography limit the role of cMRI in infants and children younger than 7 years of age. In this age group, cMRI is usually reserved to delineate extracardiac vascular anatomy or complex spatial relationships or to evaluate for airway abnormalities associated with cardiac disease.

Basics of Cardiac MRI Scanning

Magnetic resonance imaging takes advantage of the abundance of hydrogen atoms found in human tissue. Each hydrogen atom acts like a magnet with its own angular momentum. When placed in a static magnetic field, such as the bore of a magnet, the angular momentum precesses or spins around the axis of the magnetic field. The strength of the magnetic field in scanners used for cMRI is either 1.5 Tesla (T) or 3 T. This is around 60,000 or 30,000 the strength of the earth's magnetic field, respectively. Using much weaker but rapidly varying magnetic field gradients and short radiofrequency (RF) pulses causes protons to absorb and emit radiofrequency energy. The energy is then measured and stored in an array of numbers called k-space and translated into an MR image using the Fourier transformation. The way the magnetic field gradients and RF pulses are applied to produce an image with specific characteristics is called a pulse sequence. The cMRI sequences and techniques used in clinical practice often acquire data over several heartbeats. This leads to image blurring if cardiac and respiratory motion are not taken into account. There are several ways to overcome this limitation. Cardiac synchronization, also known as cardiac gating, is commonly achieved by synchronizing the signal acquisition to a particular time point in the cardiac cycle using the patient's ECG signal (obtained using MRI-compatible ECG leads) or finger pulse oximetry [1–3]. Respiratory motion is usually addressed by patient breath-holding combined with fast imaging techniques. The breath is held preferably at end-expiration for 5–10 s with each data acquisition set. Conventional imaging techniques acquire only one phase encoding step

(one line of k-space) per heartbeat. Fast imaging techniques allow more than one line of k-space to be filled out with each beat, thus shortening the acquisition time. Alternatively, in patients who are unable to hold their breath, the data is acquired several times and then averaged to compensate for respiratory motion. Finally, "real-time" imaging, also known as "single shot" ultrafast acquisition, obtains the whole imaging in a single cardiac phase in a single heartbeat, eliminating the need for cardiac or respiratory compensation. This technique comes at the expense of worsening temporal and spatial resolution [4–6].

Most centers rely on sedation or general anesthesia in infants and children younger than 7 years of age to ensure that the patient remains still in the scanner and eliminate motion artifact. In addition to younger age, an older patient with a lower developmental age and maturity level may also require the use of sedation or general anesthesia to obtain an optimal study. The decision to perform cMRI under sedation or general anesthesia involves careful analysis of potential risks and benefits. It is important that there is a detailed discussion between the anesthesia or sedation team and the clinician caring for the patient regarding the patient's hemodynamic status and other comorbid conditions. A variety of drugs are available for sedation such as chloral hydrate, midazolam, propofol, and pentobarbital. The main disadvantages of these agents are the high failure rates (early awakening of the patient), the increased risk of respiratory depression or airway obstruction from an unprotected airway, and image degradation because of the inability to breath-hold [7]. With general anesthesia, the airway is protected, adequate sedation is achieved, and breath-holding maneuvers are possible. However, performing a cMRI examination under general anesthesia can be challenging because of limited access to the child and ventilation equipment during the study, the risk to the staff and patient safety with the use of ferromagnetic equipment, and the potential for RF interference with monitoring equipment [8, 9]. Regardless of the method of sedation used, it is very important to have a team experienced in taking care of patients with cardiovascular disease in addition to MRI-compatible monitoring equipment and anesthetic machines. An alternative method of scanning newborns is the "feed and scan" technique in which infants are fed, and then the operator has to wait until the young patient falls asleep. The technique is time consuming because of the unpredictable "induction times" and has a high failure rate.

Cardiac MRI Safety

The magnetic fields, gradients, and radiofrequency pulses used in cMRI pose risks to patients and staff, requiring meticulous safety procedures. Patients and parents accompanying the patient into the scanner room should be screened to identify implanted devices that might be hazardous in the MRI environment. Access to the scanner should be restricted. Healthcare providers and technicians working in the cMRI scanner must complete an MRI safety course introducing them to MRI safe practices prior to accessing the scanner.

The main safety concerns are listed in Table 24.2. In any MRI scanner there is an immediate projectile missile effect of ferromagnetic material which can be fatal. The magnet is always on, even if it is not being used. Thus, it is important to use MRI-compatible equipment in the scanner room. Neurovascular clips, pacemakers, automatic implantable defibrillators, cochlear implants, metal in the eye, retained shrapnel, and neurostimulators are contraindications to MRI although certain models may be safe. The presence of implanted cardiac pacemakers or implantable cardioverter defibrillators (ICDs) is considered a relative contraindication for MRI [10]. The magnets may induce arrhythmias, bradycardias, or tachycardia in patients with pacemakers or ICD. Even the pacemaker wires alone are contraindicated. Heart valves, sternotomy wires, surgical clips, stents, intravascular coils, and occluding devices are considered weakly ferromagnetic. They also become immobilized by surrounding fibrous tissue. Certain centers wait for a period of several weeks after implantation or surgery prior to exposing the patient to

Table 24.2 Cardiac MRI risks

Immediate projectile missile effect of ferromagnetic material
Movement malfunction or heating of implantable devices
Peripheral nerve stimulation caused by the fluctuating magnetic field gradients
Hearing loss
Electrical and thermal burns caused by the RF fields

MRI [10–13]. This has not been supported by any conclusive published data. When in doubt, various resources, such as the website http://mrisafety.com, are available to check a device's safety within an MRI scanner.

Other risks of cMRI include peripheral nerve stimulation caused by the fluctuating magnetic field gradients. To reduce those side effects, the patients should not have their hands clasped because it creates a closed loop and can induce nerve stimulation. The person's hands should be positioned by their side. For the same reason, the ankles should not be crossed. The cMRI produces acoustic noise as current is passed through the gradient coils during image acquisition. All patients and other personnel in the scanner room should wear hearing protection in the form of earplugs or headphones during scanning. The RF fields can cause electrical and thermal burns. Transdermal patches with metallic backing must be removed prior to scanning to avoid burns. Dark tattoos have been reported to cause heating.

There are no known hazardous effect of static magnetic fields <3 T to biological tissues [14]. Pregnancy is considered a relative contraindication to cMRI although limited studies have not shown a hazardous effect on the embryo [15].

Common Applications of Cardiac MRI

Anatomy

Several available sequences allow anatomic imaging by cMRI. They provide an accurate delineation of segmental intracardiac anatomy, extracardiac vasculature, coronary artery origins and proximal course, airway abnormalities, and complex spatial relationships.

Black Blood Imaging

Cardiac-gated spin echo pulse sequences are used to produce static images in which flowing blood appears dark, hence the name black blood imaging. Other tissues appear as varying shades of gray. These sequences are effective for the assessment of the two-dimensional morphology of the blood vessels and cardiac chambers [15, 16]. Black blood imaging is also useful for elucidating the relationship between the airway and blood vessels and identifying airway abnormalities associated with various airway diseases or airway problems occurring as a complication of congenital heart disease [17]. Black blood imaging is less susceptible to artifact from metallic biomedical implants (e.g., sternal wires, stents, prosthetic valves) and turbulent flow compared to gradient echo cine and 3D imaging. The conventional spin echo sequences require long scan time; however, the development of turbo spin echo or fast spin echo sequences has allowed faster data sampling and shorter acquisition times. The black blood imaging technique provides images with high spatial resolution and excellent blood-myocardium contrast. Black blood imaging is also useful for tissue characterization and is thus used in evaluation of cardiac tumors, cardiomyopathies, and pericardial disease.

Cine Imaging or Cardiac-Gated Balanced Steady-State Free Precession (SSFP)

Cine imaging uses cardiac-gated balanced steady-state free precession (SSFP) or fast gradient echo sequences to produce multiple images over the entire cardiac cycle in an anatomic region. These can then be displayed in a cine loop format to demonstrate the motion of the heart and vasculature over the cardiac cycle. This imaging technique is also known as bright blood imaging since flowing blood produces a bright signal, while the myocardium and vessel wall are relatively dark. Cines can be performed in any plane to assess the dynamic function of any structure including the outflow tract valves and great arteries and to evaluate the systemic and pulmonary venous anatomy, atrial and ventricular septum, and intracardiac baffles and pathways (e.g., following Fontan, Mustard, Senning, or

Rastelli procedures). Stenotic and regurgitant jets are identified as dark signal voids or dephasing jets. Cines are also important in assessing ventricular function.

3D Imaging

3D datasets with high spatial resolution can be achieved via MR angiography (MRA) with gadolinium-based contrast agents or via 3D balanced-SSFP sequence [18]. Regardless of the method used, the data is acquired as isotropic voxels, so that the images can be viewed with the same spatial resolution in any anatomical plane. With MRA, the gadolinium-based contrast is initially infused through a peripheral intravenous line. After a certain time delay, two or more 3D data acquisitions are then obtained without cardiac gating using a 3D fast gradient echo sequence lasting 15–30 s while the patient holds their breath or ventilation is suspended in an intubated patient. Time-resolved 3D contrast-enhanced MRA is a newer angiographic technique that captures information about the dynamics of blood flow through the right and left heart using a small volume of contrast [19]. 3D balanced-SSFP sequence is a navigator-gated free-breathing cardiac-triggered technique that does not require contrast [20]. It is obtained with free breathing over approximately 5 min where the motion of the diaphragm is monitored by a navigator pulse. The data is only obtained if the position of the diaphragm falls within a predefined narrow window. Regardless of the method used, the 3D dataset is then processed on dedicated workstations, and 3D models are reconstructed. 3D imaging is ideal to evaluate the extracardiac vascular anatomy such as great vessels, collateral vessels, systemic and pulmonary veins and their 3D spatial relationship to the tracheobronchial tree, and other thoracic structures [21–23]. It is also useful in assessing intra-atrial systemic and pulmonary baffles (such as in Mustard or Senning operations and cavopulmonary connections), as well as for imaging of the outflow tracts (such as in repaired TOF or the arterial switch operation) [24, 25]. The 3D information obtained can help plan interventional and surgical techniques.

Coronary Artery Imaging

Several MRI techniques are available to evaluate the origin and the proximal epicardial course of the coronary arteries. According to the American Heart Association, 3D MRA is the preferred modality for delineating congenital anomalies of the coronary arteries [26]. 3D MRA imaging has also been successful in the visualization of coronary artery aneurysms in children and young adults with Kawasaki disease [27]. Good correlation between coronary MRA and X-ray coronary angiography has also been reported for ectatic coronary arteries (distinct from Kawasaki disease) among adults [28]. The most widely used technique involves navigator-gated free-breathing cardiac-triggered MRA gradient echo sequence without contrast [29]. Image acquisition is performed in mid-diastole, which is determined a priori by visual inspection of cine images perpendicular to the long axis of the proximal/mid-right coronary artery. In addition, the diaphragm motion is tracked with the navigator so that the image data is only collected when the end-expiration position of the diaphragm coincides with the period of coronary diastasis. β-blockade prolongs the period of coronary diastasis and may help to improve the quality of coronary MRA images. Typical examination times for free-breathing 3D navigator coronary MRA are 7–15 min. Recently, 3D a whole-heart coronary MRA approach has gained rapid acceptance on the basis of promising initial results [30]. The spatial resolution is somewhat lower (usually >1 mm in-plane and through-plane resolution), data are collected over approximately 100 ms of each cardiac cycle (with potential for blurring), and scan times are lengthy (10–15 min), thereby mandating the use of navigator echoes [30].

Ventricular Function

Cardiac MRI is considered the gold standard for the measurement of ventricular volume and systolic function. It is superior to echocardiography

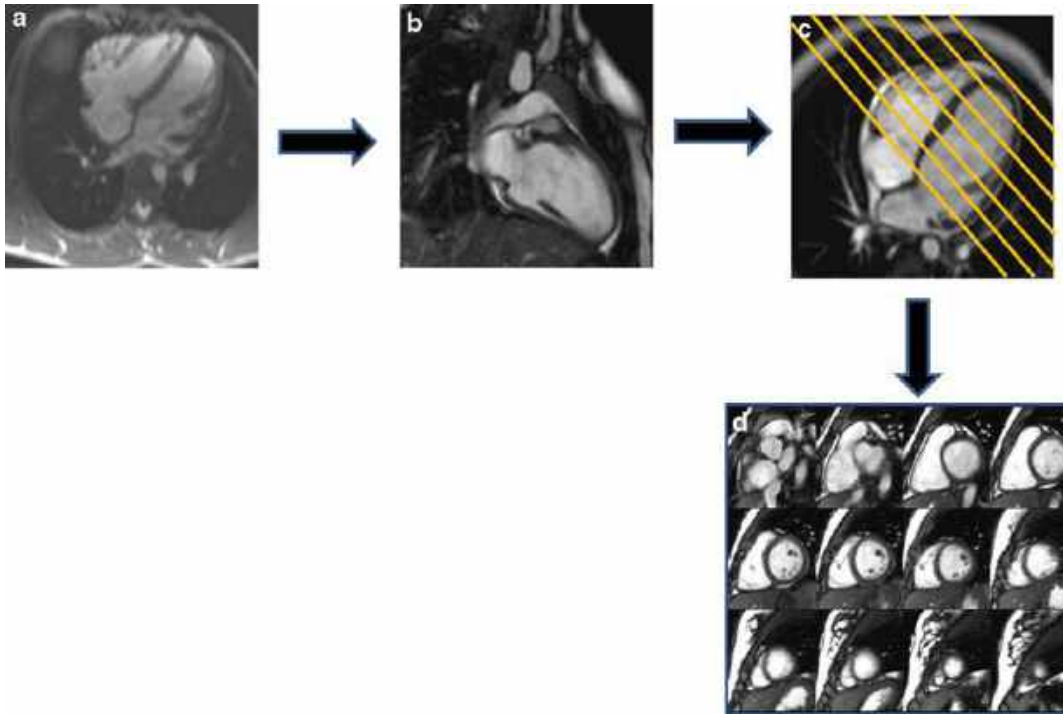

Fig. 24.1 Ventricular short-axis cine images. (**a**) A 2-chamber left (**b**) is obtained by subscribing a plane through the midpoint of the mitral valve and the left ventricular apex on an axial or transverse scout image (**b**) Using the 2-chamber left a fake 4-chamber (**c**) is obtained by prescribing a plane as shown. (**c**) The short axis plane (**d**) is prescribed from the 4-chamber plane end-diastolic frame extending from the atrioventricular groove to the apex

in the evaluation of the right ventricle in congenital heart disease [31]. Cine images, mainly ECG-triggered SSFP sequences, are used because they provide clear distinction between the myocardium and the blood pool.

Systolic Function

The most common method for determining ventricular volumes is the multiple short-axis summation method. This method consists of the acquisition of contiguous slices of short-axis cine datasets from the base of the left ventricle to the apex, covering the myocardium completely [32]. Figure 24.1 depicts the process of obtaining the short-axis cine images. The endocardial volume is calculated by contouring manually the blood endocardium border of each slice at end diastole and end systole, respectively, excluding the left ventricular papillary muscles and the major trabeculations of the right ventricle. This renders the contouring process more efficient and reproducible [33]. The volume of each slice is then calculated as the product of the cross-sectional area of each slice and its thickness. The end-diastolic and end-systolic volumes are calculated by summing the volume of each slice at end diastole and end systole, respectively. The ejection fraction and stroke volume can then be derived from the end-diastolic and end-systolic volumes. The cardiac output can also be calculated as the product of the stroke volume and the heart rate at the time of acquisition. The ventricular mass is calculated by contouring the end-diastolic epicardial border to calculate the end-diastolic epicardial volume, subtracting the end-diastolic endocardial volume, and multiplying by the specific gravity of the myocardium (1.05 g/mm^3). The left ventricular papillary

muscles can be included in the left ventricular mass calculation. The multiple short-axis summation method makes no geometric assumptions and has been shown to provide excellent accuracy [34] and low inter-study variability [35] especially in abnormally shaped ventricles; SSFP-based normal values are available for healthy adult subjects [36]. Normal values of ventricular dimensions in children have not been published. A less commonly used approach to calculating left ventricular volumes involves acquiring multiple horizontal long-axis slices of the entire LV myocardium. It has been shown to yield similar inter-observer variability values [37].

Software packages that allow semi-automated post-processing are available through most MR scanner vendors and some third part vendors. In the absence of arrhythmia, the reproducibility of cMRI for anatomical and functional parameters is higher than that of echocardiography [38]. This has lead to a decrease in the sample size needed to measure treatment effects on ventricular volumes, function, or mass when cMRI is used in research studies compared to echocardiography [39–41].

Diastolic Function

A few approaches have been undertaken to examine diastolic dysfunction with cMRI, but none is currently being widely used in routine clinical imaging. One promising technique is myocardial tagging. Magnetic field saturation bands or tags that appear as dark lines or stripes are applied to the myocardium in a grid-like fashion at end diastole, and the deformation of this grid is used to assess regional wall motion and strain [42, 43]. It has been used to characterize patterns of wall motion and strain in patients with ischemic and valvular heart disease as well in functionally single ventricles [44, 45]. However, the analysis software is currently too complex for daily routine use. Tissue phase mapping of the myocardium has been suggested as an alternative for diastolic function assessment. This method measures myocardial tissue velocity in 3D space, which can be used to measure diastolic wall motion with low inter-observer variability [46]. Cardiac MRI myocardial feature tracking (cMRI-FT) is a recent and promising technique for tissue voxel motion tracking on SSFP images similar to echocardiographic speckle tracking to derive circumferential and radial myocardial mechanics [47, 48].

Blood Flow Quantification

Cardiac MRI allows the noninvasive quantification of blood flow across valves, shunts, and vessels. The technique used is an ECG-gated velocity-encoded cine (VEC) MRI sequence or velocity-encoded phase-contrast (PC) sequence. In this sequence, the imaging plane is prescribed perpendicular to the vessel or valve. Multiple images are reconstructed across the cardiac cycle in which the signal from the hydrogen nuclei in a specific region within the prescribed plane is proportional to the mean velocity. Using specialized post-processing software, the flow rate is calculated as the product of the mean velocity and the cross-sectional area of the region of interest. Slice positioning and velocity encoding must be optimized [49]. The velocity can be underestimated if the slice is not perpendicular to the region of interest or if there is significant dephasing or aliasing secondary to turbulent flow. If these parameters are rigorously controlled, flow can be assessed in large and small arteries and systemic and pulmonary veins [49, 50]. In addition, free-breathing sequences are preferred over breath-held sequences although the acquisition time is shorter in the latter (10–14 s compared to $\sim$ 2 min). Breath-holding alters the intrathoracic pressure and thus affects flow measurements [51].

Clinically, VEC MRI is an important element of functional assessment by CMRI. Aortic and pulmonary valve regurgitant fractions can be calculated; the context of atrioventricular valve regurgitation and knowledge of the ventricular stroke volume combined with knowledge of the forward arterial flow volume from that ventricle allows for calculation of mitral or tricuspid valve regurgitant fraction. It is also helpful in the calculation of cardiac output and Qp/Qs [52]. With appropriate

combinations of arterial and venous flow volume assessment, the technique allows accurate assessment of interatrial, interventricular, arterial, and venous shunt volumes. VEC-CMRI measurements show a strong correlation with other invasive measurements of cardiac output such as thermodilution or Fick principle [52–61]. Although not part of routine clinical practice 3D and 4D (time-resolved 3D), phase-contrast flow velocity acquisitions are being used to understand the multidimensional flow patterns seen in dilated aorta in bicuspid aortic valve [62, 63] and to evaluate Fontan pathway hemodynamics [64, 65]. One of the main hurdles to applying this technology clinically is the length of the acquisition time (around 10 min).

Myocardial Ischemia and Perfusion

Cardiac MRI currently offers two clinically used methods for the detection of myocardial ischemia, dobutamine stress cMRI, and first-pass perfusion studies with a vasodilatory stress agent (adenosine). Perfusion studies in the pediatric population are not commonly indicated in children, and their use is rare. Indications for pharmacological perfusion cMRI in children include suspected ischemia secondary to congenital coronary abnormalities, such as anomalous origin of the origin of the coronary artery from the pulmonary artery or from the opposite sinus of Valsalva, or acquired coronary artery disease, such as Kawasaki disease. Other indications include suspected ischemia following surgical transfer of the coronary arteries in congenital heart procedures such as the arterial switch operation.

Dobutamine stress cMRI imaging is performed with protocols similar to dobutamine stress echocardiography with the administration of increasing doses of dobutamine up to 40–50 μg/kg/min. The goal is to evaluate regional wall motion abnormality at rest and under pharmacologically induced stress. This method is used to identify ventricular myocardium that is at risk for coronary artery hypoperfusion. ECG-gated breath-held cine SSFP images are acquired with incremental increases in dobutamine. In adults with congenital heart disease, dobutamine stress cMRI has been used to aid in decision making for the timing for intervention, for example, in the population of patients with repaired tetralogy of Fallot [66, 67] and to evaluate the functional reserve of the systemic right ventricle in patients with repaired transposition of the great vessels or corrected transposition of the great vessels [68–70]. In the pediatric population, there is very little data regarding the use this technique in children with congenital disease. A small study in children demonstrated that dobutamine stress cMRI is feasible and provides high-quality imaging of all ventricular wall segments with low inter-observer variability [71]. Compared to stress echocardiogram, dobutamine stress cMRI is more sensitive and specific [72].

Myocardial perfusion can be also assessed by first-pass perfusion cMRI at rest and during stress with coronary vasodilatation induced by adenosine or dipyridamole. Following administration of the coronary vasodilatory agent, the enhancement pattern of the myocardium is determined by administering the contrast agent gadolinium and acquiring multiple images of the heart in the same anatomical position and point in the cardiac cycle in successive heartbeats. Usually images are obtained in short axis but long-axis images may also be acquired in order to evaluate apex of the heart. Well-perfused myocardium exhibits a bright signal, and hypoperfused myocardium remains dark. Vasodilation is used to mimic the effect of exercise stress on the myocardium. By comparing the pattern of myocardial enhancement at rest and post-vasodilator administration, a perfusion reserve index can be calculated with low inter- and intra-observer variability [73]. When compared to myocardial scintigraphy, vasodilator stress cMRI is highly sensitive and specific in adults with coronary artery disease while avoiding radiation exposure and prolonged imaging time (45 min vs. two sessions of scintigraphy) [74, 75].

Myocardial Viability

Myocardial delayed enhancement (MDE) imaging has become the principal cMRI technique to assess viability. The method, first described by

Simonetti et al. [76] and first used by Kim et al. [77], is based on the delayed gadolinium contrast enhancement of nonviable cardiac tissue. It is usually performed 10–20 min after the injection of the gadolinium-based contrast, at which time normal myocardium appears dark, and nonviable myocardium appears bright. The proposed mechanism for the difference in enhancement is the timing of extravasation of the contrast agent and its accumulation within the extravascular extracellular (interstitial) fluid. Scarred areas with an increased volume of interstitial space will present a larger distribution volume for the incoming contrast agent [78–80] and lead to slower extravasation rates and delayed reabsorption of contrast agent into the vascular space [81].

MDE correlates well with the infarction tissue ex vivo pathologic examination in animal models [82, 83] and is highly reproducible [84]. The technique is well established in adults with ischemic cardiomyopathy [85]. In adults with nonischemic cardiomyopathy such as hypertrophic cardiomyopathy, the extent of MDE is associated with increased risk of arrhythmias and sudden death [86]. MDE has also been shown to have a high diagnostic accuracy in patients with acute myocarditis [87]. Viability MDE imaging is gaining recognition in the pediatric and the congenital heart disease population. In patients with previously repaired tetralogy of Fallot, MDE is associated with right ventricular dysfunction, exercise intolerance, and hemodynamically significant arrhythmia [88, 89]. Similarly, the extent of MDE in patients with transposition of the great arteries after an atrial switch is associated with systemic right ventricular dysfunction [90]. Post-Fontan operation MDE is associated with dilated and hypertrophied systemic ventricles, systolic dysfunction, regional dyskinesis, and ventricular arrhythmias [91].

Tissue Characterization

Cardiac MRI can discern even minor changes in tissue composition and provides an excellent platform to assess myocardial architecture, pericardium, blood vessel walls, and extracardiac tissue. Cardiac MRI is particularly helpful in the evaluation of cardiomyopathies and myocarditis. MDE in ischemia is usually restricted to the perfusion territory of the affected coronary artery and primarily involves the subendocardium with possible extension to the subepicardial region. In comparison to that seen in ischemia, the scarring in hypertrophic cardiomyopathy is also primarily subendocardial, but in a noncoronary distribution pattern in both the hypertrophied and nonhypertrophied myocardium. In myocarditis, the pattern of MDE is usually patchy and spares the subendocardial region. Myocardial edema can also be evaluated by measuring the water tissue content on specific cMRI sequences and can be helpful to identify patients with myocarditis. The presence of edema indicates an acute rather than a chronic process and usually precedes myocardial necrosis. It is a more sensitive marker of myocarditis, while the presence of MDE is more specific [92]. Non-compaction cardiomyopathy can also be evaluated using cMRI imaging of the myocardial wall. Peterson et al. [93] reported that a non-compacted/compacted myocardium ratio of >2.3 in diastole distinguished pathological left ventricular non-compaction from other causes of hyper-trabeculation, with a specificity and negative predictive value of 99 %.

Tissue characterization by cMRI is of important value in the diagnosis of aortic disease, in particular aortic dissection. 3D contrast MRA is an excellent tool for the assessment of aortic aneurysms and has high sensitivities and specificities for the diagnosis of aortic dissection [94]. The combined use of different sequences with and without fat suppression, perfusion imaging, and assessment of contrast uptake allow for noninvasive tissue characterization of cardiac and pericardial masses in adults and the pediatric population [95, 96].

Conclusion

Cardiac MRI is a major tool in the noninvasive assessment of cardiovascular disease in the pediatric population. Technological advances in image acquisition and resolution has led to

improvement in real-time imaging. The development of cMRI-compatible catheters and devices in addition to real-time imaging can help overcome some of the obstacles of the hybrid MR/X-ray catheter suite (XMR). XMR is emerging as an alternative to the conventional cardiac catheterization laboratory in both children and adults with cardiovascular disorder. It reduces the amount of radiation exposure to both patients and medical staff by using cMRI for the imaging component of the procedure [97, 98]. In addition, there is a growing body of work on real-time exercise stress cMRI with the used of MRI-compatible ergometers [99].

Assessment of the Pediatric Patient with Chest Pain

25

Devyani Chowdhury

Abstract

Chest pain is one of the most common diagnoses seen by an outpatient cardiologist. In a patient with no known heart disease and chest pain, the incidence of cardiac disease is very low. The occurrence of chest pain with exercise raises the level of concern, especially when associated with sports. The assessment of chest pain involves a thorough evaluation for causes of ischemia, inflammation, aortic root dissection, and arrhythmias. The history, physical examination, and electrocardiogram are cornerstones in the assessment of chest pain. Further testing with echocardiography, exercise stress testing, arrhythmia monitoring, or other imaging modalities is performed as indicated by the initial evaluation.

Arrhythmias • Arrhythmia monitoring • Aortic dissection • Chest pain • Exercise • Echocardiography • Electrocardiogram • Exercise stress testing • History • Inflammation • Ischemia • Physical examination • Sports • Sudden death • Syncope

Introduction

Chest pain as the presenting chief complaint to the pediatric cardiologist is second only to heart murmur. It occurs frequently in older children and adolescents and is a source of concern for both the family and the primary care provider. The high profile of a sudden death in an athlete can evoke an intense reaction in the community, causing increased anxiety whenever symptoms of chest pain appear, particularly during exercise. "Heart pain," as described by children, accounts for nearly 13 % of all pediatric emergency room visits in the USA each year [1, 2]. On the other hand, the incidence of hospital admission for acute myocardial infarction (AMI) in adolescents is estimated at merely 157 events per year [3]. The most common causes of noncardiac chest pain in children include musculoskeletal (35 %), pulmonary (15 %), gastrointestinal (5 %), psychogenic (5–10 %), and idiopathic (35 %).

Although rarely found, cardiac causes such as myocardial ischemia, pericarditis, arrhythmias,

and aortic dissection must be considered in the differential diagnosis of the patient with chest pain, particularly on exertion (Table 25.1). Ischemic chest pain may be present in patients with the diagnosis of left ventricular outflow tract obstruction, hypertrophic cardiomyopathy, myocarditis, coronary artery anomalies, Kawasaki disease, or primary pulmonary hypertension. Adrenergic-sensitive arrhythmias such as supraventricular tachycardia, catecholaminergic ventricular tachycardia, and some forms of long QT syndrome may also present as chest pain in a child who is unable to differentiate the chest discomfort of tachycardia from chest pain. In patients with known heart disease, the level of suspicion for a cardiac cause of chest pain is higher, particularly if there is a known predisposition for ventricular hypertrophy, coronary insufficiency, or tachyarrhythmias.

Unlike in the adult population, chest pain in children is mostly noncardiac. It is, however, very important to rule out a cardiac etiology as a cause of the chest pain. It is not unexpected that both the patient and the referring physician seek reassurance from the pediatric cardiologist. When evaluating pediatric patients with chest pain in the outpatient cardiology office, a thorough history, physical examination, and an electrocardiogram are often considered baseline testing to create a risk profile. In patients with exercise-induced chest pain or known heart disease who may be at risk for arrhythmias or cardiac ischemia, additional testing such as a resting echocardiogram, 24-h Holter monitoring, event monitoring, or exercise stress testing may be necessary to establish the underlying cause of the chest pain.

History

This history is the most important element in the assessment of a child with chest pain. A thorough history should be performed to establish the presence of signs or symptoms of ischemia or arrhythmia and to identify any risk factors for inherited diseases associated with cardiomyopathies, connective tissue disorders, arrhythmias, congenital heart diseases, or sudden death. If the chest pain is found to be noncardiac, the ability of the pediatric cardiologist to offer reassurance to the patient, family, and referring provider will be greatly enhanced if a thorough history has been obtained and specific concerns can be addressed during the consultation.

Signs and Symptoms: The symptoms commonly found in patients with noncardiac chest pain are listed in Table 25.2. Chest pain at rest that is brief and resolves spontaneously is very rarely due to a cardiac cause. A history of chest pain in the left apical area that is described as sharp or catching and is associated with deep inspiration is often referred to as "Texidor's twinge" and is hypothesized to be secondary to slipped rib or trauma.

The symptoms of chest pain commonly associated with cardiac disease are listed in Table 25.3. Chest pain that occurs with exercise and has associated symptoms such as dizziness, syncope, pallor, or shortness of breath raises the concern for the presence of cardiac ischemia. The presence of a heart murmur or rub is an important sign of underlying cardiac disease or pericarditis. It is unusual for cardiac chest pain to change with movement, except in the case of pericarditis, when the chest discomfort is improved with the patient sitting and leaning forward and worse when the patient is in the supine position. Pericardial pain can also radiate to the left shoulder. Chest pain associated with

Table 25.2 Symptoms of noncardiac chest pain

Occurs at rest
Sharp, sudden, and short
Not associated with dizziness, syncope, and pallor
Chest pain with cough (e.g., pneumonia, reactive airway disease)
Changes with inspiration
Worse with movements of arms and chest or on palpation

Table 25.3 Symptoms of cardiac chest pain

Associated with exercise, especially at peak exercise
Associated with dizziness, syncope, pallor, or shortness of breath
Relieved following a short period of rest
Associated with a significant murmur, especially LVOT obstruction (aortic stenosis, hypertrophic cardiomyopathy)

aortic dissection is acute in onset and sharp and may radiate to the back.

Chest pain can be a presenting symptom of palpitations or tachyarrhythmia. A history of tachycardia preceding the symptoms of chest discomfort can be helpful to identify sinus tachycardia or a tachyarrhythmia as the cause of chest pain. The duration, rapidity, and mode of resolution of the tachycardia-associated chest pain are important details that can be used to separate sinus tachycardia from a tachyarrhythmia.

Family History: Patients who present with chest pain and a family history of unexplained sudden cardiac death, especially with exercise, require further evaluation if the symptoms are concerning for cardiac chest pain. Conditions such as hypertrophic cardiomyopathy and the inherited channelopathies (long QT syndrome, Brugada syndrome, catecholaminergic ventricular tachycardia) have a strong genetic component. Patients with family history of Marfan syndrome and aortic dissection or with any other phenotypic features of connective tissue disorder and worrisome chest pain require further evaluation for aortic dissection or rupture.

Past History: History of Kawasaki disease or cardiac surgery for congenital heart disease such as transposition of great arteries or anomalous origin of the coronary artery merits careful evaluation to rule out myocardial ischemia as a cause of chest pain.

Physical Examination

Vital Signs: In a patient with chest pain, the vital signs can provide important clues to the underlying cause of the chest pain. Resting tachycardia can indicate sinus tachycardia associated with anxiety, fear, pericarditis, ischemia, or heart failure. Heart rates >180 bpm in the older child and >220 bpm in the younger child in the presence of chest pain may represent a supraventricular tachycardia. The presence of respiratory distress, hypoxia, or tachypnea may indicate a pulmonary cause of the chest pain or may be a sign of pulmonary edema associated with pericarditis, ischemia, heart failure, or an arrhythmia. A fever is more commonly associated with an infectious cause of chest pain, such as pneumonia or pericarditis. The blood pressure is usually normal in a patient with chest pain, although in patients with acute pericarditis and tamponade, the pulse pressure is narrow and a pulsus paradoxus may be present.

Inspection and Palpation: Eliciting reproducible chest pain during physical examination is a reassuring sign of a musculoskeletal cause of the chest pain. The cardiac impulse may be increased with prominence of the left chest wall, a left ventricular heave, or displacement of the point of maximal impulse laterally in a patient with hypertrophic cardiomyopathy or aortic stenosis. A suprasternal notch thrill is often palpable in patients with valvar aortic stenosis. In patients with pulmonary hypertension, a right ventricular heave and displacement of the point of maximal impulse to the left or right lower sternal border may be present. The presence of the skeletal findings associated with Marfan syndrome, such as pectus excavatum or "marfanoid habitus," makes it important to look for a connective tissue disorder and possible aortic dissection as a cause of chest pain.

Auscultation: On auscultation absent or decreased breath sounds make pneumothorax or pneumonia a more likely cause of chest pain. Reactive airway disease may present as chest pain with exercise, and wheezing may be auscultated even in patients who do not have a prior diagnosis. A systolic ejection murmur of left ventricular outflow tract obstruction is an indication of hypertrophic cardiomyopathy or aortic stenosis. A holosystolic murmur of mitral insufficiency is also heard in patients with hypertrophic cardiomyopathy or in the presence of an ischemic cardiomyopathy due to infarction of the papillary muscles (as is seen in anomalous origin of coronary artery from pulmonary artery). A rub can be heard in a patient with pericarditis. In patients with pulmonary hypertension, a loud, single S2 can be audible along with a Graham Steell murmur of pulmonary insufficiency that is high pitched and sounds like aortic insufficiency.

Diagnostic Tests

Electrocardiogram: All patients undergoing assessment by a cardiologist for chest pain should have an electrocardiogram. The electrocardiogram in a patient can be diagnostic of ischemia if performed in the presence of chest pain. Coronary abnormalities that cause transient ischemia may not be detected by an electrocardiogram obtained when the chest pain has resolved. The electrocardiogram can also diagnose a prior myocardial infarction, ventricular hypertrophy, premature beats, Wolff-Parkinson-White syndrome (palpitations and chest pain), pericarditis, or pulmonary hypertension. Channelopathies associated with tachyarrhythmias such as long QT can also be diagnosed by electrocardiogram.

Echocardiogram: An echocardiogram is not indicated in all patients undergoing assessment for chest pain. The usefulness of an echocardiogram in patients with a history that is not suggestive of cardiac disease; a negative family history for hypertrophic cardiomyopathy or other inherited disorders associated with ischemia, arrhythmia, or aortic dissection; a normal physical examination; and normal electrocardiogram has not been demonstrated. In patients with a history suggestive of cardiac chest pain, a positive family history, physical examination findings, and/or an abnormal electrocardiogram, the echocardiogram can be diagnostic of structural heart disease.

In patients with exertional chest pain, it is important to demonstrate normal origin of the right and the left coronary artery. Origin of left coronary artery from the right sinus causes the coronary to travel between the aorta and pulmonary artery. This anatomical variation has been associated with symptoms of chest chain with exercise and sudden death in athletes.

Arrhythmia Monitoring: The echocardiogram is not able to diagnose the presence of tachyarrhythmias as the cause of chest pain. In patients with a history or electrocardiogram suggestive of a tachyarrhythmia, 24-h Holter monitoring, event monitoring, or loop recorders can be used to document the rhythm during an episode of chest pain. The indications for these monitoring devices depend on the frequency of the symptoms and the ability of the patient to perform the necessary technical steps to acquire and transmit a recording.

Stress Testing: Recent literature has established a role for exercise stress testing of patients with chest pain to distinguish cardiac causes from noncardiac causes such as reactive airway disease, deconditioning, and obesity [1]. In patients with chest pain with exercise and a structurally normal heart and coronary arteries by echocardiogram, there is limited utility of stress test. Stress testing in these types of patients may be used to document the presence of exercise-induced asthma, arrhythmias, or exercise-induced costochondritis. In highly competitive athletes, the AHA scientific guidelines recommend cardiopulmonary stress testing for any significant change in functional capacity or known complaints with exertion (syncope, chest pain,

dyspnea) [4]. In high-level athletes with particularly debilitating symptom of exercise-induced costochondritis, a referral to a physiotherapist is very helpful.

Cardiopulmonary stress testing is utilized to assess for ischemia or arrhythmias in the pediatric population with structural heart disease and a positive history for cardiac chest pain. The normal values of endurance for patients with structural heart disease will vary by the type of lesion present and should be used when interpreting the results of the testing. Reactive airway disease or restrictive pulmonary physiology may be the cause of chest pain, and pulmonary function can be evaluated during the testing as well [5]. A normal cardiopulmonary stress test in the presence of chest pain can provide reassurance to the patient and family and encourage increased participation in regular physical activities. Stress echocardiogram is indicated in a select group of patients with congenital or acquired coronary artery disease (Kawasaki disease) to assess for an evidence of regional myocardial ischemia.

Laboratory Testing: During an episode of acute chest pain, a cardiac troponin may be performed, even in the absence of EKG changes. The presence of elevated troponin level indicates myocardial injury and ischemia and should prompt further evaluation for possible myocarditis or other structural coronary anomalies.

Treatment

The treatment of cardiac chest pain is dictated by the underlying etiology of the pain. If there is ongoing myocardial ischemia, acute intervention is required to decrease myocardial demand, improve coronary blood flow, and support the circulation. Structural coronary anomalies are usually addressed surgically but can be treated via interventional catheterization in certain situations. The diagnosis of aortic dissection or rupture requires immediate surgical intervention. Arrhythmia treatment is determined by the mechanism of the rhythm disturbance. Pulmonary hypertension requires evaluation and treatment by an expert in the evaluation and treatment of this multifactorial disease. Patients with a known congenital or acquired heart disease and a cardiac cause of chest pain require treatment of the underlying cardiac condition.

If the assessment does not identify any cardiac causes of chest pain, the cardiovascular specialist has an important responsibility to provide the patient, family, and referring provider with convincing reassurance that the pain is not from cardiac disease. In a prospective study, Selbst et al. found psychogenic and idiopathic pain to be less common than previously thought in children presenting to the emergency room [6]. However, anxiety disorders are more common in children presenting with chest pain [7]. When providing reassurance, the specialist must address any specific concerns about the chest pain that have been identified during the history. When counseling the family, the ability of the patient to participate fully in all activities with no restrictions should be emphasized, as this can be a lingering concern if not addressed directly.

Conclusion

Chest pain remains a challenge for the pediatric cardiologist. Literature suggests that chest pain in children is most often multifactorial and non-life-threatening [2]. On the other hand, the rare cardiac causes of chest pain have significant risk for morbidity and mortality. A thorough history, physical examination, and electrocardiogram will often be sufficient to rule out a cardiac cause for chest pain. From the beginning of the consultation, it is important for the physician to establish a trusting relationship with the patient and family that establishes the groundwork for subsequent discussion. Using a systems-based approach, the management of pediatric patients with chest pain has drawn the attention of several groups who are using an iterative process to evaluate the role of testing in the assessment of the patient

with chest pain. This effort is being undertaken with the goal of reducing unnecessary testing and health-care utilization while promoting best practices [8].

Assessment of the Patient with Syncope

26

Christine A. Walsh and Myles S. Schiller

Abstract

Syncope is a common complaint in children and especially adolescents. The most frequent cause is neurocardiogenic which, in general, is benign. However, life-threatening etiologies, especially cardiac, must be identified. A cost-effective and efficient evaluation of syncope is based on history, physical examination, and electrocardiogram. If risk factors for sudden death are detected, further focused testing is indicated.

Keywords

Alpha-adrenergic agonist • Beta-blocker • Bezold-Jarisch reflex • Bradyarrhythmia • Breath-holding spells • Cardiomyopathy • Cardioinhibitory syncope • Channelopathy • Hypoxemia • Inflow obstruction • Myocardial dysfunction • Neurocardiogenic syncope • Orthostatic hypotension • Outflow obstruction • Presyncope • Seizure • Selective serotonin reuptake inhibitor (SSRI) • Syncope • Tachyarrhythmia • Vasovagal syncope • Vasodepressor syncope

Introduction

Syncope or fainting is the sudden transient loss of consciousness and postural tone due to cerebral hypoperfusion, which usually resolves spontaneously. Many of these patients also have episodes of presyncope consisting of light-headedness, dizziness, diaphoresis, pallor, nausea, and visual disturbances without loss of consciousness. Syncope in children is a cause of anxiety and great concern to physicians, parents, teachers, and coaches, resulting in a large number of emergency department visits and hospital admissions [1–3]. Since syncope is quite common, with an incidence of up to 50 % of children experiencing a syncopal episode before the end of adolescence [2, 3], in addition to the above mentioned anxiety, the resources and financial costs to society are important as well [4]. Fortunately, most syncopal episodes in children are benign; however, a life-threatening event, usually cardiac, must be ruled out. The reported incidence of sudden death in the pediatric population is 1–8 per 100,000 patient years [5]. In a review of 515 death certificates of

people between the ages of 1 and 22 years, it was found that syncope or presyncope had occurred in 3 (25 %) of 12 who experienced sudden cardiac death [6]. It is quite clear that the real dilemma is to find that very small group of patients at risk for sudden cardiac death from the large number of pediatric patients with syncope.

Epidemiology

Syncope is very common in the pediatric population with a variable reported incidence of anywhere from 15 % to 50 % [2, 3, 7]. Most episodes occur in adolescence, with a peak incidence at 15–19 years of age, and are more frequently seen in girls [8, 9]. Data have shown an incidence of 15.5 % in a group of male college and postgraduate students and a 22.3 % incidence in a group of basic trainees in the US Air Force [5]. A large pediatric emergency department reported that 2 % of all visits are for syncope [10]. The exception to these data are breath-holding spells which cause syncope in young children between the ages of 2 months and 8 years, with a peak incidence seen at 2–3 years of age [1].

Etiology

The causes of syncope can be classified into three main categories: *cardiac*, *noncardiac*, and *neurocardiogenic* (Table 26.1). Cardiac causes can be subdivided into three large categories which include obstruction to blood flow, myocardial dysfunction, and arrhythmias. Noncardiac causes include neurologic, metabolic, psychogenic, and behavioral. Neurocardiogenic (also known as vasovagal, vasodepressor, or cardioinhibitory) syncope is the most common cause of syncopal events in adolescence [11].

Cardiac Causes of Syncope

Syncope due to a cardiac etiology results from decreased cardiac output, especially during exercise, resulting in decreased oxygen delivery to the brain. This usually occurs suddenly and without warning [5, 12]. An athlete who is dehydrated may exhibit similar symptoms. The hypovolemia in the presence of peripheral vasodilatation associated with exercise may result in the development of hypotension and syncope.

Obstruction to blood flow can result from either inflow or outflow obstruction. Inflow obstruction may be due to cardiac tamponade, constrictive pericarditis, restrictive cardiomyopathy, tumors compressing the venae cavae, or intracardiac tumors such as an atrial myxoma. Intracardiac tumors are frequently associated with positional changes [12]. Outflow obstruction may occur from aortic or pulmonary stenosis, hypertrophic cardiomyopathy, or pulmonary vascular disease (primary pulmonary hypertension or Eisenmenger syndrome). Cyanotic congenital heart disease may also cause syncope or sudden death due to an abrupt drop in systemic oxygen saturation.

Severe myocardial dysfunction associated with poor cardiac contractility resulting in reduced cardiac output is another cause of syncope. This may be due to a primary dilated cardiomyopathy, neuromuscular disorders (various muscular dystrophies), inflammation (myocarditis), or ischemic causes (congenital coronary abnormalities, Kawasaki disease, post-cardiac transplant arteriopathy, or homozygous familial hypercholesterolemia). Very often, cardiac arrhythmias are associated with these conditions and are commonly the cause of the syncope.

Isolated cardiac arrhythmias are the third cause of syncope. This is seen less frequently in children than in the adult population. Syncope may be due to either marked bradycardia or tachycardia resulting in low cardiac output. Many of these children have had prior cardiac surgery [13–15]. Bradyarrhythmias may be due to heart block or sinus node dysfunction. Congenital complete heart block is rare and is mostly seen in infants of mothers with systemic lupus erythematosus. Acquired heart block can occur with Lyme disease, acute rheumatic fever, diphtheria, bacterial endocarditis, viral myocarditis, Rocky Mountain spotted fever, and some muscular dystrophies. Tachyarrhythmias are due to

Classic vasovagal, vasodepressor, or cardioinhibitory
Breath-holding
Situational (hair combing, micturition, cough, swallow)

either atrial or ventricular pathology. Ventricular arrhythmias are generally more dangerous than atrial arrhythmias and have a higher incidence of sudden death. Atrial arrhythmias include atrial flutter/fibrillation, ectopic atrial tachycardia, and reentrant tachycardias (e.g., Wolff-Parkinson-White syndrome). Ventricular arrhythmias may be isolated ventricular tachycardia or fibrillation or be associated with long QT syndrome, arrhythmogenic right ventricular dysplasia, catecholaminergic polymorphic ventricular tachycardia, or Brugada syndrome. Cardiac arrhythmias associated with structural or functional cardiac disease have a higher incidence of sudden death.

Noncardiac Causes of Syncope

There are many noncardiac causes of syncope which include neurologic, metabolic,

psychogenic, and behavioral etiologies. The neurologic causes of syncope include seizures, brain tumors, increased intracranial pressure, migraines, vertigo, and narcolepsy. Autonomic dysfunction, either inherited (familial dysautonomia) or acquired (Guillain-Barre syndrome), causes syncope due to inappropriate heart rate and blood pressure responses to stress or postural changes. Metabolic causes include hypoglycemia, severe electrolyte disturbances, anemia, or hypoxemia due to either pulmonary or cardiac disease. Hyperventilation, hysteria, and conversion reaction are well-known psychogenic causes of syncope. Behavioral factors causing syncope include drug and alcohol ingestion and overuse of prescribed medications. Severe electrolyte abnormalities often result from eating disorders such as anorexia nervosa. Miscellaneous noncardiac causes of syncope include carotid sinus hypersensitivity, orthostatic hypotension (especially when dehydrated), and subclavian steal syndrome.

Neurocardiogenic Causes of Syncope

Neurocardiogenic syncope is the most common cause of syncope in children and adolescents. As previously mentioned, it has also been most commonly referred to as vasovagal, vasodepressor, or cardioinhibitory syncope. These events are usually associated with prolonged standing or sitting; a change in position from sitting to standing; sudden cessation from vigorous physical activity, especially with associated anemia or dehydration; emotional stress or fear; and pain. Neurocardiogenic syncope also includes what is termed situational causes, which include hair combing, micturition, defecation, coughing, or swallowing. The syncopal episode may occur suddenly or be associated with a prodrome of symptoms which usually consist of pallor, dizziness, nausea, diaphoresis, palpitations, and visual changes. The loss of consciousness is brief, lasting less than 1 min, and then resolves spontaneously. The episode may be followed by a period of pallor, fatigue, and sweating. There may also be associated seizure-like activity, usually occurring after the patient loses consciousness as opposed to a true seizure which usually occurs at the onset of the syncopal episode. Seizure-like activity is often seen in breath-holding spells [16, 17].

The physiologic mechanism causing neurocardiogenic syncope remains controversial. A current theory postulates that with standing, there is pooling of blood in the lower extremities resulting in decreased venous return to the heart, leading to decreased ventricular filling pressures and decreased blood pressure. An increase in catecholamine release results in hypercontractility of a relatively empty ventricle. Mechanoreceptors in the cardiac muscle, C-fibers, are activated, sending afferent signals to the brainstem via the vagus nerve. This leads to sympathetic withdrawal and increased parasympathetic activity resulting in vasodilation, hypotension, and bradycardia [18–21]. Unfortunately, this hypothesis does not fully explain the physiology of neurocardiogenic syncope, since patients who have undergone cardiac transplant, with an obviously denervated heart, also experience similar episodes. Central nervous system mechanisms, which are not fully understood, must also be considered.

Evaluation

Evaluation is aimed at identifying the very small number of children and adolescents at risk for sudden death among the very large group with syncope. Figure 26.1 depicts an algorithmic approach to the evaluation of syncope based on the findings of the history, physical examination, and electrocardiogram, and in selected cases, basic laboratory studies [18, 22]. A cardiac cause of syncope is particularly important to diagnose since this can be life-threatening.

History

Just as the most important factors in real estate are “location, location, location,” the most

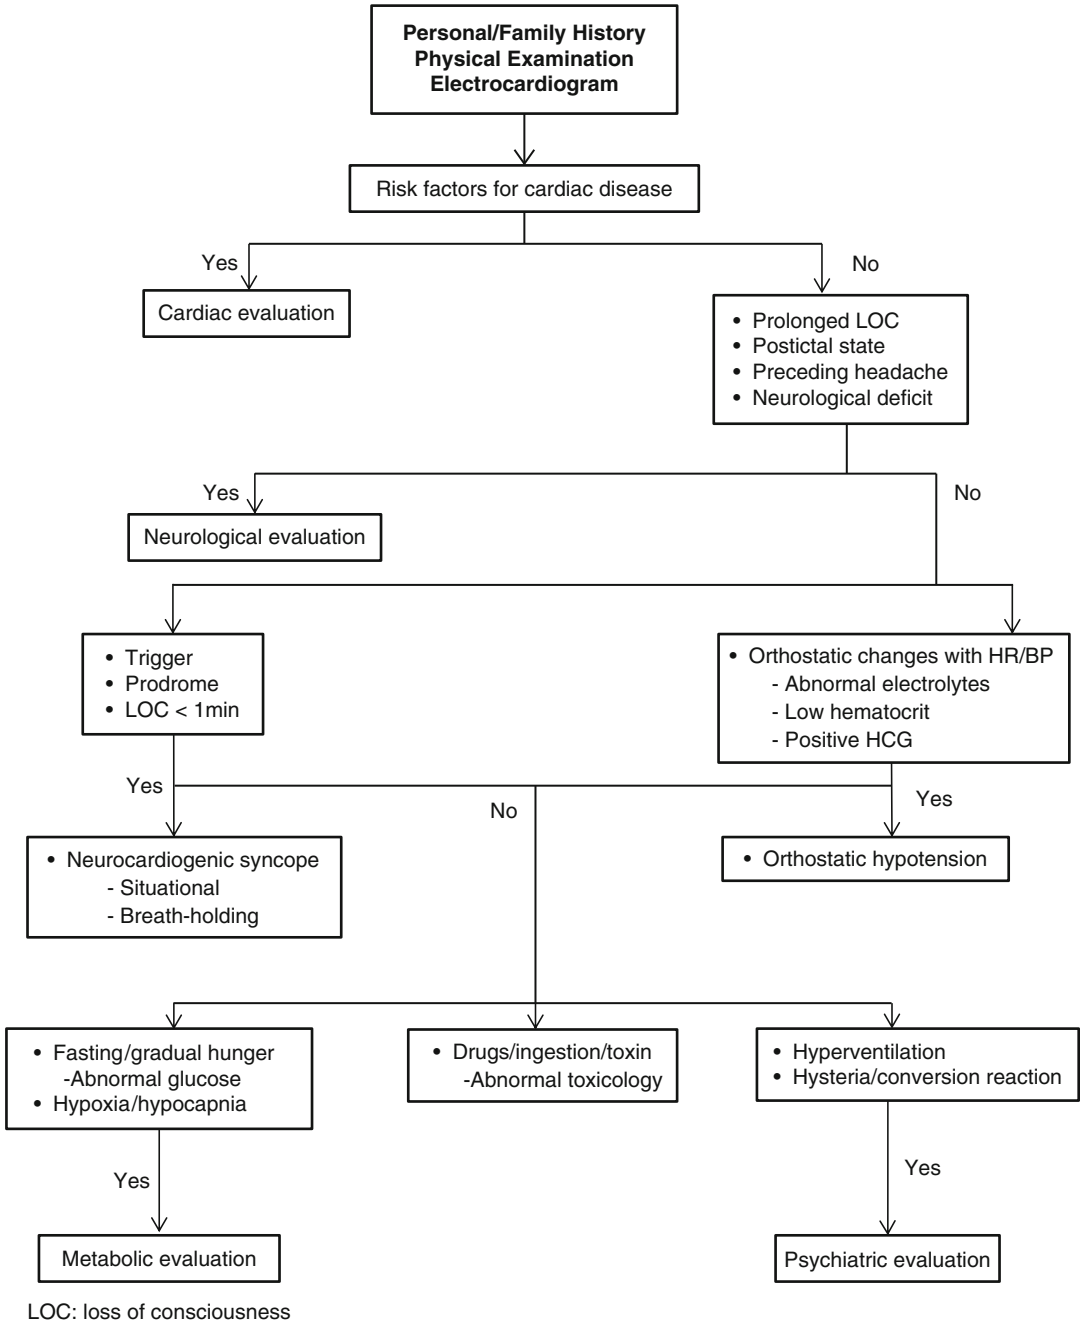

Fig. 26.1 Evaluation of syncope in children and adolescents

important aspects of evaluation of syncope are "history, history, history." The etiology of syncope can often be ascertained by a thorough and focused personal history, event history, and family history [9]. A complete medical history must be taken for cardiac, neurologic, endocrinologic, pulmonary, and psychiatric disorders. Specifically, the existence of previous syncopal episodes, anxiety, eating disorder, alcohol abuse, and prescription, over-the-counter, herbal, and

illicit drug use must be sought. Does the patient become light-headed when standing from sitting (orthostatic) or when seeing blood or having blood drawn (neurocardiogenic)?

Details are extremely important. A complete description of events before, during, and after *each* syncopal episode must be obtained. Determine the location (e.g., gym, church, waiting on line), atmosphere (e.g., crowded, hot), position (e.g., getting out of bed [orthostatic], recumbent [not neurocardiogenic], sitting, standing), trigger (e.g., pain [neurocardiogenic]; fear, surprise, anger, loud noise [long QT syndrome]); and situation (e.g., urinating, defecating, coughing, swallowing, stretching, having hair combed [all situational]; hyperventilating; standing for a long period of time [orthostatic], during exercise [arrhythmia, ischemia]; or immediately after exercise [neurocardiogenic]). Was the individual dehydrated (vomiting, diarrhea, fever, exercise), hungry/fasting, recently ill, or menstruating? Was there a characteristic neurocardiogenic prodrome of light-headedness, diaphoresis, nausea, warmth, and visual or auditory changes, or a migraine headache with a visual or auditory aura, or no warning, suggested by an injury? A witness is required for a description of color change (e.g., cyanosis [non-neurocardiogenic], pallor [neurocardiogenic]), tonic or clonic movements before/at the onset of loss of consciousness [seizure] or after loss of consciousness (neurocardiogenic), eye deviation, facial expression, incontinence, how forcefully and suddenly the person fell, and duration of loss of consciousness [not neurocardiogenic if >1 min]. Unfortunately, observers often exaggerate the length of time a person was unconscious because of anxiety and because they include recovery. In addition to duration, recovery should be described in terms of mental orientation and the presence of headache, fatigue, weakness, nausea, diaphoresis, and neurologic symptoms and signs [postictal]. The patient's affect while describing the event should be noted [psychogenic if indifferent].

An important risk factor is a family history of sudden death in a person less than 40 years of age (including sudden infant death syndrome, apparent life-threatening event [ALTE]), arrhythmias, seizures (possibly due to an arrhythmia), congenital deafness (associated with long QT syndrome), syncope, early cardiovascular disease, or known long QT syndrome, Brugada syndrome, catecholaminergic polymorphic ventricular tachycardia, Wolff-Parkinson-White syndrome, arrhythmogenic right ventricular cardiomyopathy, hypertrophic cardiomyopathy, dilated cardiomyopathy, hyperlipidemia, or Marfan syndrome. When a young family member is described as dying suddenly from a "heart attack," more detailed information should be sought, including hospital records or an autopsy report, because sudden death is often described with this term. Unexplained accidents involving swimming or a single motor vehicle may indicate sudden death. On the other hand, many patients with neurocardiogenic and migraine syncope have a strong family history of these disorders.

A careful history can reveal risk factors that are listed in Table 26.2. Syncope that is exercise induced, recurrent, not neurocardiogenic in character, and/or associated with anginal chest pain, palpitations, or dyspnea may be ominous. A trigger of emotional stress or auditory stimulus could indicate long QT syndrome. Structural heart disease, either with or without surgery, is a crucial risk factor.

Physical Examination

A complete physical examination must be performed, including a comprehensive cardiac and neurologic assessment, weight, height, BMI, and vital signs. Heart rate and blood pressure should be taken in the supine position and immediately on standing and after 2–10 min of standing, respectively. In a standing adolescent, a systolic blood pressure of less than 80 mmHg, a decrease in blood pressure of greater than 20 mmHg, or an increase in heart rate of greater than 20 BPM indicates orthostasis. When hyperventilation is suspected, the patient should be instructed to hyperventilate for 30–40 s to see if symptoms can be reproduced. Body habitus (e.g., compatible with Marfan syndrome) should be

Table 26.2 Risk factors

1. During exercise
(a) Arrhythmia, ischemia (immediately after exercise more likely neurocardiogenic)
2. Associated anginal chest pain, palpitations, dyspnea
(a) Hypertrophic cardiomyopathy, anomalous coronary
(b) Arrhythmia
(c) Pulmonary hypertension
3. Non-neurocardiogenic in character (injury, no prodrome)
(a) Arrhythmia
4. Triggered by auditory stimulus or fright
(a) Long QT syndrome
5. Tonic posturing/clonic jerks *after* loss of consciousness
(a) Arrhythmia, neurocardiogenic
6. Recurrent
(a) Cardiac, psychogenic, neurocardiogenic
7. Positive family history for sudden death, seizures, congenital deafness, accidents
(a) Channelopathy, cardiomyopathy
8. Cardiac disease

3. Neurologic
(a) Computerized tomography/magnetic resonance imaging
(b) Electroencephalogram
(c) Vestibular testing

noted. Focal neurological deficits must be detected.

Cardiac auscultation should be focused on rhythm, quality of heart sounds, murmurs, gallops, clicks, and rubs. Hypertrophic cardiomyopathy is indicated by a systolic ejection murmur at the left lower sternal border that increases with standing and decreases with squatting. A dilated cardiomyopathy is suggested by muffled heart sounds, a quiet precordium, and a gallop rhythm. A low-pitched systolic ejection murmur and a systolic ejection click are heard with aortic stenosis. Mitral valve prolapse is diagnosed by an apical midsystolic click and late systolic murmur. A loud, narrowly split second heart sound and a parasternal right ventricular heave are associated with pulmonary hypertension.

Diagnostic Tests

Diagnostic tests that may be useful in the evaluation of syncope are listed in Table 26.3 [23]. Findings on the history and physical examination should guide which tests should be performed (Fig. 26.1).

Table 26.4 Significant ECG findings

1. Bradycardia/tachycardia/significant pauses
2. Atrioventricular block
3. Ectopy
4. Prolonged QTc/short QTc ($\leq$0.30 s)
5. Brugada pattern
6. Epsilon waves (arrhythmogenic right ventricular cardiomyopathy)
7. Preexcitation (Wolff-Parkinson-White Syndrome)
8. ST-T abnormalities (anomalous coronary, cocaine)
9. Hypertrophy/strain (hypertrophic cardiomyopathy, aortic stenosis)

Electrocardiogram (ECG). The electrocardiogram is considered to be a standard part of a syncope evaluation, but its yield is relatively low [4]. Significant ECG findings are listed in Table 26.4. It is useful as a screen for long or short QT syndrome, Brugada syndrome, Wolff-Parkinson-White syndrome, arrhythmogenic right ventricular cardiomyopathy, hypertrophic

or dilated cardiomyopathy, and ischemia or infarction as may be found with an anomalous coronary artery or cocaine use. However, a normal electrocardiogram does not rule out these or other significant heart disease and arrhythmias. Moreover, certain electrocardiographic changes, such as left ventricular hypertrophy, first-degree atrioventricular block, sinus bradycardia, and pauses may be seen in some trained athletes.

Laboratory Tests. Laboratory testing is rarely helpful in an asymptomatic patient who presents hours or days after a syncopal event [9]. Particular tests should be guided by the history and physical examination (Fig. 26.1). A hematocrit can disclose anemia that can exacerbate a predisposition to neurocardiogenic syncope. A white blood count can suggest an infectious or inflammatory process, as in myocarditis. Abnormal electrolytes may be associated with dehydration and can cause arrhythmias. A low blood glucose level necessitates further metabolic investigation. A pregnancy test, toxicology screen, and drug levels are useful in selected cases.

Echocardiogram. An echocardiogram is necessary for the evaluation of structural heart disease, unoperated and operated. The degree of pulmonary hypertension can usually be estimated by echocardiogram. It may be difficult to differentiate an "athlete's heart" from hypertrophic cardiomyopathy. A normal echocardiogram does not rule out arrhythmogenic right ventricular cardiomyopathy, some coronary anomalies, and very small cardiac tumors that may be the focus of arrhythmias. Malignant arrhythmias can occur in a heart that is normal by echocardiography. An echocardiogram should not be used as a screen (Fig. 26.1) but should be performed in patients with suspected heart disease by history, physical examination, or electrocardiogram (Table 26.4) or with risk factors for sudden death (Table 26.2).

Holter Monitor/Event Recorder. If the history suggests an arrhythmia that is recurrent but not on a daily basis, an event recorder is more useful than twenty-four-hour Holter monitoring. When the patient or a witness places the small device on the body and presses the symptom button, the electrocardiogram tracing is stored. If a loop device is worn continuously, the electrocardiogram is recorded for a period of time before and after activation. In either case, the tracing can be transmitted over the phone at a later time. A device with auto-trigger will transmit the electrocardiogram automatically if high- or low-rate parameters are met, which is particularly helpful if the patient has fainted without activating the device. Twenty-four-hour Holter monitoring is useful for detecting and quantifying symptomatic and asymptomatic arrhythmias, intermittent manifestation of Wolff-Parkinson-White syndrome, and intermittent prolonged QTc, with or without typical T wave changes.

Exercise Stress Test. An exercise stress test is valuable in patients with syncope, presyncope, palpitations, chest pain, and/or dyspnea associated with exercise. It is useful in determining whether syncope or presyncope occurs during exercise which may indicate an arrhythmia or ischemia or immediately after exertion which is more likely to be neurocardiogenic. Exercise testing is especially worthwhile when catecholaminergic polymorphic ventricular tachycardia is suspected because it can induce premature ventricular contractions, followed by couplets and non-sustained polymorphic or bidirectional ventricular tachycardia in these patients [24]. Treadmill stress testing may identify patients with concealed long QT syndrome, particularly type 1 [25]. In general, benign ventricular ectopy is suppressed during exercise, whereas dangerous arrhythmias are exacerbated during exercise or early in recovery.

Tilt Table Test. Head-up tilt table testing is a method of monitoring heart rate and blood pressure with the patient supine and then in an upright posture at 60–70° for 20–45 min, sometimes with the addition of a drug such as isoproterenol. It can be performed to differentiate neurocardiogenic syncope (reflex hypotension/bradycardia with syncope) from orthostatic hypotension (progressive hypotension with or without symptoms) [26] and from postural orthostatic tachycardia syndrome (POTS) (sustained heart rate increase >30 BPM or a sustained rate of

120 BPM in the first 10 min) [27]. It may also be useful in differentiating convulsive syncope from epilepsy and for diagnosing psychogenic syncope. It is limited by variable sensitivity and specificity, poor reproducibility, and the lack of a uniform protocol in the literature. It can be helpful in patients who do not have a completely typical history for neurocardiogenic syncope in an attempt to reproduce symptoms. However, if syncope is atypical or any risk factors (Table 26.2) are present, a more life-threatening etiology must be first ruled out by specialized testing (Table 26.3) before the results of a tilt table test are relied on. Tilt table testing is not recommended for the assessment of treatment.

Magnetic Resonance Imaging (MRI). MRI may be necessary to diagnose arrhythmogenic right ventricular cardiomyopathy, cardiac tumors, or certain coronary anomalies.

Cardiac Catheterization. Cardiac catheterization is rarely needed to determine the cause of syncope but may be helpful for diagnosing coronary anomalies or evaluating pulmonary hypertension. If myocarditis is suspected, a biopsy may be useful.

Electrophysiology Study. Invasive electrophysiologic study is employed for patients with a strong suspicion of an arrhythmia because of history, cardiac disease, or findings on the electrocardiogram (e.g., Wolff-Parkinson-White syndrome), event recording, or Holter monitoring (e.g., complex ventricular ectopy). Radiofrequency ablation or cryoablation is attempted if an arrhythmia is documented and amenable.

Table 26.5 Treatment of neurocardiogenic syncope

1. Prevention
(a) Avoid triggers
(b) Increase fluid and salt intake – urine should be clear
(c) Avoid diuretics (caffeine, alcohol)
(d) Lie down or sit with head down at onset of symptoms
(e) Biofeedback in selected cases
2. Drugs
(a) Indications
(i) Frequent recurrence
(ii) No prodrome
(iii) Injury
(iv) Prolonged episode
(v) Associated with exercise
(vi) Significant asystole
(b) Mineralocorticoid (fludrocortisone)
(i) Volume expansion
(ii) Alpha-receptor sensitization
(c) Alpha-agonist (midodrine)
(i) Arteriolar vasoconstriction/venoconstriction
(d) Selective serotonin reuptake inhibitor (fluoxetine, sertraline)
(i) Increase intrasynaptic serotonin concentration/down regulation in postsynaptic serotonin receptor density
(e) Disopyramide
(i) Negative inotropic and anticholinergic effects
(ii) Peripheral vasoconstriction
(f) Theophylline
(i) Blocks uptake of adenosine, causing presynaptic inhibition of peripheral adrenergic neural transmitter release
(g) Beta-blocker (atenolol, metoprolol)
(i) Negative inotropic/chronotropic effects
3. Dual-chamber pacemaker
(a) "Malignant" neurocardiogenic syncope
(i) Prolonged asystole unresponsive to medical management

Treatment of Neurocardiogenic Syncope

Treatment of only neurocardiogenic syncope (Table 26.5) will be presented here since the management of other causes of syncope is addressed in other chapters. The management of neurocardiogenic syncope is somewhat different for children and adolescents from adults.

Prevention

Reassurance of the benign nature of neurocardiogenic syncope is needed. Triggers must be identified and avoided. Biofeedback can be helpful in "desensitization." Patients must be advised against putting themselves in potentially dangerous situations, such as leaning over a subway

platform. Diuretics such as caffeine and alcohol should be avoided.

Increased fluid intake is important, especially during exercise and when it is hot. An adolescent should drink at least eight 8-oz. glasses of non-caffeinated liquid a day, and urine should be clear. Increased salt intake is advisable, if the patient is not hypertensive.

Patients must recognize prodromal symptoms and lie down with legs raised or sit down with the head down until full recovery. Physical isometric counterpressure maneuvers should be taught, such as tensing the arms with clenched fists, leg pumping, and leg crossing, to abort or delay a syncopal episode. Patients should build strength in their lower extremities to enhance the skeletal muscle pump.

Drugs

Pharmacotherapy should be reserved for patients with frequent recurrence, no warning prodrome resulting in injury, and in whom conservative measures have failed. Syncope associated with exercise and significant asystole may need drug treatment. Unfortunately, no drug has been proven to be absolutely effective.

Fludrocortisone, often used as a first-line medication, is a mineralocorticoid which produces volume expansion and sensitizes blood vessels to the vasoconstrictive effects of norepinephrine. Hypokalemia and hypomagnesemia may require supplementation, and hypertension, bloating, and headaches may be side effects.

Midodrine, a direct-acting alpha-adrenergic agonist, increases peripheral vascular tone and decreases peripheral pooling of blood. It is used alone or in addition to fludrocortisone. It may cause hypertension, nausea, and scalp pruritis.

Selective serotonin reuptake inhibitors (SSRI), such as *fluoxetine* and *sertraline*, produce downregulation of postsynaptic serotonin receptor density. If patients are intolerant of or refractory to *fludrocortisone* and/or *midodrine*, an SSRI can be added. All three drugs have different mechanisms and may be tolerated at lower doses in combination [28].

Disopyramide has negative inotropic, anticholinergic, and direct peripheral vasoconstrictive effects, but has not proven to be effective compared to placebo and is poorly tolerated. *Theophylline* blocks the uptake of adenosine and also has frequent side effects.

Beta-blockers, such as *atenolol* and *metoprolol*, were felt to be effective through their negative chronotropic and inotropic effects, which were thought to decrease cardiac mechanoreceptor activation, and through central serotonin-blocking activity. However, several controlled trials have failed to show benefit and beta-blockers may occasionally worsen the propensity toward syncope.

Pacemaker

A dual-chamber pacemaker is very rarely needed for children with prolonged asystole who are unresponsive to preventive and pharmacologic therapy. If hypotension occurs alone or precedes bradycardia, pacing would not be effective.

Conclusion

Syncope occurs commonly in the pediatric population, especially in adolescents. The most frequent etiology is neurocardiogenic. However, the uncommon, life-threatening causes must not be missed. An efficient and cost-effective evaluation of syncope is based on history, physical examination, and electrocardiogram. If risk factors for sudden death are identified, further directed testing is indicated.

Promoting Cardiovascular Health

27

Stephen R. Daniels

Abstract

Cardiovascular disease, including myocardial infarction and stroke, is the most common cause of mortality in the United States and other developed countries. It is now clear that the atherosclerotic process that results in adverse cardiovascular outcomes begins in childhood and is progressive. It is also clear that the traditional cardiovascular disease risk factors, including hypertension, hypercholesterolemia, cigarette smoking, diabetes, and obesity, are operative at an early age to promote the development of atherosclerosis. The best approach to prevention of cardiovascular disease involves both a population and an individual, high-risk approach. The population approach focuses on improving lifestyle across the population to prevent risk factors from developing. The individual approach includes identification of those at high risk through screening and amelioration of risk factors, primarily via changes in diet and physical activity. Pharmacologic treatment is available for those with several elevated risk factors. Monitoring optimum risk status throughout childhood and young adulthood results in an important reduction of risk for cardiovascular disease.

Introduction

Cardiovascular disease (CVD) remains the number 1 cause of morbidity and mortality in the United States [1]. This is also true in many other countries around the world. There has been progress as there has been a decline in coronary heart disease, particularly in men, since the 1950s (Fig. 27.1). Improvement in risk factors such as cholesterol, blood pressure, and cigarette smoking accounts for about half of the observed decline [2]. Other factors that are responsible for the decline include more effective treatment in the intensive care setting and wider use of treatments shown to be effective for management of chronic cardiovascular disease. However, despite over 40 years of progress in understanding the pathophysiology of atherosclerosis, improvement in risk factors and improved intensive care, the burden of cardiovascular disease in terms of years of life lost, loss of productivity due to chronic disease, and diminished quality of life are substantial [1]. In addition, medical costs related to treatment of cardiovascular disease are quite high [1].

While the overall trends in cardiovascular disease mortality have been good, more recent increases in the prevalence of obesity and diabetes have threatened to reverse this progress. For example, recent trends in death due to coronary heart disease suggest a slowing of the rate of reduction seen in the past [3]. This could mean a flattening of the decline or even the beginning of a reversal in the decline, ultimately leading to future increases in cardiovascular disease morbidity and mortality.

Because the outcomes of atherosclerotic cardiovascular disease occur in adulthood, these issues have historically been the focus of internal medicine and adult cardiology. However, as more has been learned about the pathophysiology of this disease process, it has become clear that atherosclerosis begins in childhood and is progressive throughout life. This places an important emphasis on opportunities for prevention, perhaps beginning even in utero and progressing over the life course through childhood, adolescence, and into adulthood.

The evidence supporting this life-course development of atherosclerosis comes from many sources. The first source is the pathology studies. These studies have been of critical importance because there have been few methods for evaluation of the atherosclerotic process noninvasively. The first autopsy study was performed by Enos et al. during the Korean War [4]. They found that young, seemingly healthy soldiers killed in combat had atherosclerotic lesions in their coronary arteries. These findings were confirmed by McNamara et al. during the war in Vietnam [5]. While these studies identified the presence of a range of lesions from the early fatty streaks to the more advanced fibrous plaques, they did not add to the understanding of factors that increased risk for the development of these abnormalities.

Two subsequent studies, the Bogalusa Study and the Pathobiological Determinants of Atherosclerosis in Youth (PDAY) Study, demonstrated that traditional cardiovascular disease risk factors identified in adults were also important in the early stages of atherosclerosis [6–9]. These cardiovascular disease risk factors include dyslipidemia (elevated LDL cholesterol and low HDL cholesterol), hypertension, diabetes, cigarette smoking, and obesity. It is interesting to note that knowledge of these risk factors has only emerged over the last 40 years, largely due to epidemiologic studies, such as the Framingham Heart Study [10]. For example, in 1955, Paul Dudley White reported what was known about risk factors for cardiovascular disease in the aftermath of President Dwight D. Eisenhower's myocardial infarction a month earlier [11]. He identified the most important risk factors as older age, male sex, muscular body build, an ambitious personality, and heredity. He also pointed out potential environmental factors that he indicated were less important, such as stress, diet, and exercise. He included the use of tobacco as a factor that needed further study. Results from the Framingham Study have dramatically increased understanding of CVD risk factors, and subsequent studies have identified potential novel risk factors related to inflammation, endothelial dysfunction, and thrombosis [12].

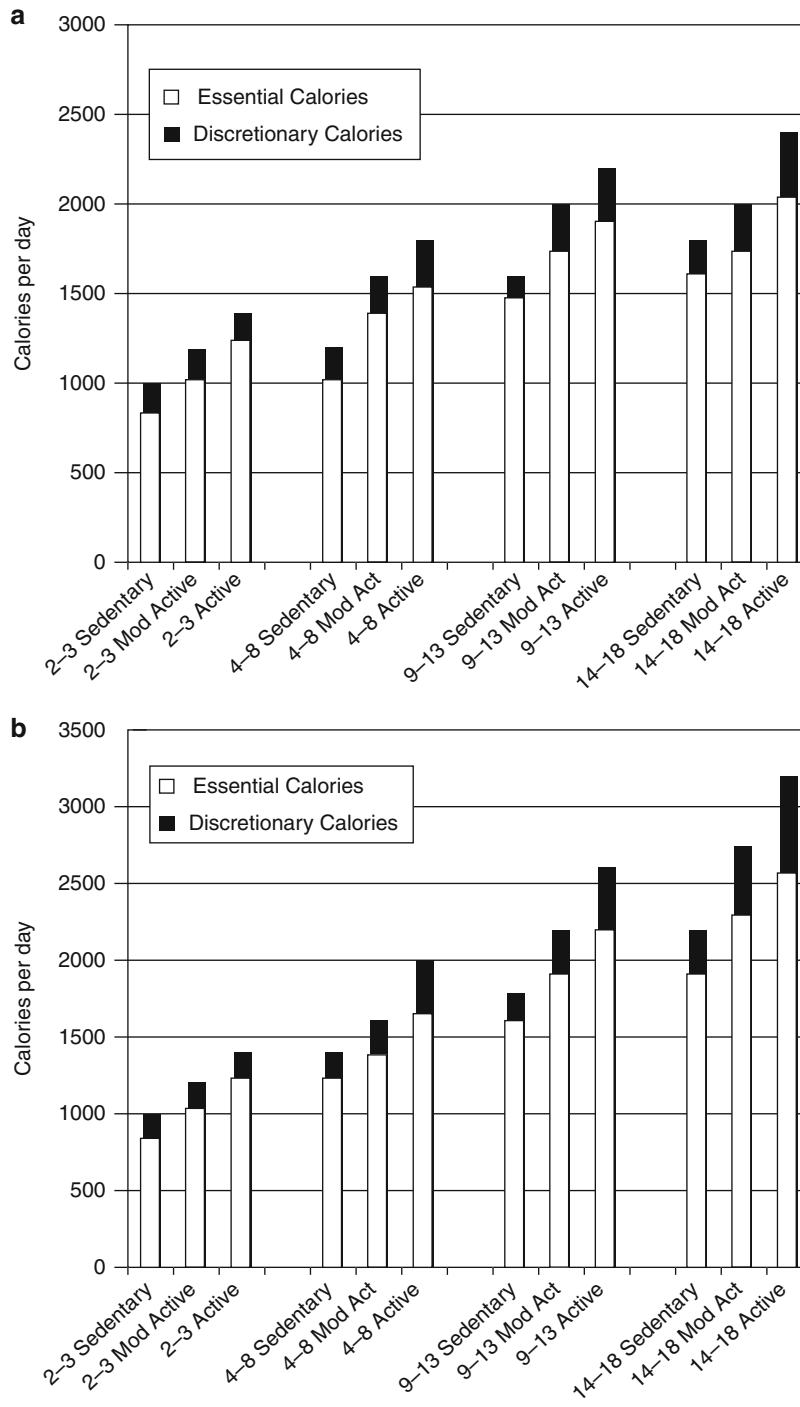

Fig. 27.1 Discretionary Calories by Gender. Graph **A** refers to females; graph **B** to males. Discretionary calories for children aged 4–8 years are based on two servings of dairy per day. Mod Act indicates moderately active. Based on estimated calorie requirements and discretionary calories published in the United States Department of Agriculture's *Dietary Guidelines for Americans* (2005)

More recent studies have identified risk-factor status in childhood and followed individuals over time with noninvasive measures of cardiovascular disease in young adulthood. The Muscatine Study used computed tomography to assess coronary artery calcium in participants under age 35 years [13]. They found that the prevalence of coronary artery calcium,

a marker for more advanced atherosclerotic lesions, was 31 % in men and 10 % in women. They found that increased body weight was the strongest predictor from childhood, but as the subjects increased in age, other factors, such as hypertension and dyslipidemia, became important.

Ultrasound can be used to evaluate the carotid intima-media thickness (IMT), which has been found to be associated with increased risk of cardiovascular disease endpoints in adults [14]. In another analysis of the Muscatine cohort, Davis et al. found that, in males, childhood total cholesterol and triglycerides were higher in those with increased carotid IMT in adulthood [15]. In females, childhood BMI, total cholesterol, and triglycerides were higher in those with higher adult carotid IMT. More recently, Juonala et al. combined data from four cohorts, the Muscatine Study, the Bogalusa Study, the Cardiovascular Risk in Young Finns Study, and the Childhood Determinants of Adult Health Study [16]. They found that the number of childhood risk factors including total cholesterol, triglycerides, blood pressure, and body mass index measured during childhood was predictive of elevated carotid IMT in adulthood. These results emphasize the importance of multiple risk factors early in life. They also identified that these risk factors were more important at or after age 9 years [16].

Thus, the process that ultimately leads to adverse cardiovascular disease outcomes in adults, such as myocardial infarction or stroke, begins in childhood. It is also clear that this process depends on the presence and severity of risk factors in children and adolescents. This leads to strategies that can be used for prevention.

Prevention of CVD

Epidemiologists refer to different kinds of prevention. For example, prevention of mortality after a patient already has evidence of advanced coronary heart disease is referred to as secondary prevention. In pediatrics, there is strong interest in primordial and primary prevention. Primordial prevention involves the prevention of risk factors developing. This is often seen as a population-based prevention, which would apply to all children and adolescents. Primary prevention is the attempt to prevent the development of atherosclerotic lesions once risk factors are demonstrated to be present. This is more of a higher risk strategy in which patients with risk factors must be identified and then appropriate intervention strategies are applied.

Geoffrey Rose has written about both kinds of prevention and shown that both are important as they can have an impact on ultimate outcomes [17]. However, each of the approaches requires different actions to implement.

The population approach to prevention is focused on shifting the distribution of a risk factor in a more favorable direction across the entire population. This approach can have a dramatic effect. For example, data from the Framingham Study indicate that a lowering of the population blood pressure distribution by 10 mmHg would lower mortality from CVD by about 30 % [17]. In order to implement a population-based approach, public health measures must be taken that can have a beneficial effect across the population. Attempts to change diet, reduce the initiation of cigarette smoking or to increase the overall level of physical activity would be examples of population-based approaches to promote primordial prevention.

The high-risk approach to prevention includes the identification of those at high risk, usually through a screening program. Once high-risk individuals are identified, treatment can be instituted. The high-risk approach usually is accomplished in the health-care setting. Depending on the level and complexity of risk-factor management, it can occur in the primary care physician's office or in a referral setting. The goal of the high-risk primary prevention approach is to reduce risk-factor burden and to retard progression of the atherosclerotic process.

The population and high-risk strategies for prevention are complementary. When both are used together, the optimal outcome can be achieved [17].

Assessment of Risk

The most widely used approach to assessment of risk for CVD in adults is the Framingham Risk Score [18, 19]. This score was derived from longitudinal data from the Framingham Study and provides an assessment of the risk of a CVD event in the subsequent 10 years. While this has been a very useful tool to stratify risk and determine the need for intervention, the Framingham Risk Score has multiple limitations [20, 21]. One important concern has been the issue of whether using a 10-year span correctly assigns longer-term risk or how best to manage patients who are in the lower to intermediate risk range, but ultimately accrue the majority of coronary heart disease events over time.

These concerns have led to the concept of lifetime risk [22]. This is important for younger adults who are often in the low 10-year risk category just because of their age but may have meaningful risk factors for CVD. This is even more important for children and adolescents, who have exceedingly low risk of a cardiac event over 10 years but, as the pathology studies have demonstrated, may have risk factors for CVD present and may be developing atherosclerotic lesions. This means that the Framingham Risk Score may give young adults a false sense of security and is essentially useless for children and adolescents.

Unfortunately, at present, there is no available lifetime risk score for use in pediatrics. The data needed to develop such a score have not been collected. Nevertheless, the concept of lifetime risk remains important. Berry et al. have demonstrated that it is possible to identify young adults who are at low 10-year risk, but a high lifetime risk, based on imaging for subclinical atherosclerosis [23]. Data from the National Health and Nutrition Examination Survey have shown that 56 % of adults in the USA have a low 10-year risk, but high lifetime predicted risk for CVD [24]. Pencina et al. have published a quantitative method for estimating the 30-year risk of cardiovascular disease in adults based on data from the Framingham Study, which take into account competing risks from other disease processes [25]. Ultimately, these principles need to be applied to long-term risk of CVD in children and adolescents.

Maintenance of Low Risk

Numerous studies support the importance of risk factors for cardiovascular disease. Research has also focused on outcomes related to maintenance of low-risk status. For example, Stamler et al. evaluated outcomes in individuals with total cholesterol <200 mg/dL, blood pressure $\leq 120/80$ mmHg, no diabetes, and no cigarette smoking [26]. They found 70–85 % lower cardiovascular mortality over 16–22 years of follow-up and 6–9 years greater life expectancy for individuals with all of those health factors compared to individuals who had one or more risk factors. The Framingham Study has shown that for men and women at age 50 years with optimum levels of four risk factors, including total cholesterol, <180 mg/dL, blood pressure $<120/80$ mmHg, nonsmoking, and absence of diabetes, had a risk of atherosclerotic CVD of only 5 % throughout the remainder of their life [22]. Those with two or more risk factors present at age 50 had lifetime risk of CVD of 50 % for women and 69 % for men. Those with optimum risk-factor status had median survival of over 40 years (age 90) compared to approximately 30 years (age 80) experienced by those with two or more risk factors.

Low risk for CVD is also associated with better quality of life, including social function, mental health, ability to work, and perception of health status [27]. Low risk for CVD maintained over a lifetime is also associated with lower all-cause mortality and lower risk of cancer, diabetes, chronic pulmonary, and chronic renal disease [28].

These results all point to the importance of the development of low-risk status early in life and the maintenance of that low-risk status throughout childhood, adolescence, and young adulthood. Unfortunately, the prevalence of individuals in the population who maintain low-risk status is quite low. Numerous studies have determined that the prevalence is about 5 % when multiple risk factors are considered [29].

There are fewer data on when risk for cardiovascular disease develops during the life course, but it is clear that it can occur in children and adolescents. Unfortunately, with the increased prevalence of obesity in children and adolescents, it is clear that certain risk factors, such as hypertension [30] and type 2 diabetes [31], are becoming more prevalent in young individuals.

It is clear that some risk factors have an important genetic component. However, it is also clear that each risk factor for CVD has a major environmental and lifestyle component. There is a strong correlation between behaviors related to diet and physical activity and CVD risk factors [32]. Numerous epidemiologic studies have also linked healthy behaviors with lower risk of cardiovascular disease. For example, in Japanese men followed in the Honolulu Heart Program, avoidance of overweight through appropriate diet and physical activity and avoidance of smoking and heavy alcohol use were all associated with substantially lower risk of death from cardiovascular disease [33].

Promotion of Cardiovascular Health

The opportunity for promotion of cardiovascular health in children and adolescents is primarily through optimum health behaviors. These healthy behaviors begin early in life and are substantially influenced by the family environment. This offers both great opportunity and great challenges to establish healthy behaviors.

One of the biggest challenges from a pediatric perspective is to tailor optimum health behaviors to the appropriate age and developmental stage. For example, there are numerous benefits to breastfeeding which have been well documented [34]. Among these effects are potential benefit for appropriate weight gain and avoidance of risk factors, such as hypertension. Breastfeeding for at least the first 6 months of life should be encouraged. In addition, physical activity should be appropriate for age and developmental stage. This requires understanding of the energy needs and physical capabilities of children at different ages. Numerous studies have supported the concept that nutrition and growth in utero have important implications for future obesity and cardiovascular health [35]. This means that risk status may actually begin at the time of conception when the mother's prepregnancy weight and health status are important for the growth and health of the fetus. Other concerns develop during pregnancy to ensure that the fetus is getting optimum nutrition and is growing appropriately.

Physical Activity

Appropriate levels of physical activity are an important aspect of lifelong promotion of cardiovascular health for a variety of reasons. First, vigorous physical activity improves energy balance and helps to prevent obesity. Second, there is evidence that physical activity can improve elevated blood pressure [36], raise HDL cholesterol [37], and improve endothelial function [38]. It also appears that reduced sedentary time is important. Increased sedentary time is associated with increased risk of obesity [39]. Unfortunately, sedentary time has been increasing for children and adolescents. This is especially true of "screen" time, that is, time spent watching television, on the computer, or playing video games. Sedentary time may be problematic for several reasons. First, it displaces time that could be spent on physical activity. Second, it appears to be independently associated with diminished cardiovascular fitness and risk factors for CVD [40, 41]. Third, exposure to advertising and other media during sedentary time may have deleterious effects on diet and excess weight gain.

Besides its beneficial impact on risk of cardiovascular disease, increased physical activity has also been associated with increased bone mineral density and improved psychological well-being [36, 37]. Children and adolescents (and their families) who engage in regular moderate-to-vigorous physical activity are more likely to engage in a variety of health-promoting behaviors than less physically active peers [42].

The appropriate amount of physical activity required for optimum cardiovascular health is less easy to define, either in terms of time spent

being active or the level of intensity of the activity. A number of studies have demonstrated that both aerobic activity, such as running, swimming, and biking and resistance activity, such as weight lifting, can have beneficial effects on cardiovascular health [36].

Recommendations for physical activity have been developed based on the available evidence [43]. These recommendations are presented by age group in Table 27.1. They include at least 60 min of moderate-to-vigorous intensity physical activity per day and additional muscle and bone strengthening activities at least three times per week [43]. Moderate intensity is defined as 3–6 metabolic equivalents (METs). This is equivalent to 3.5–7.0 Kcal/min of energy expenditure. Vigorous physical activity is defined as >6METs with >7.0 Kcal/min expended.

There are also recommendations to limit sedentary time. The American Academy of Pediatrics and others have recommended that sedentary time be limited to no more than 2 h/day [44].

While these recommendations are in place, it is clear that many children and adolescents are not achieving them. The Study of Early Child Care and Youth Development includes children and adolescents from 9 to 15 years of age [45]. They reported that moderate and vigorous physical activity declines from childhood through adolescence. By age 15, adolescents were engaged in an average of only 49 min of physical activity on weekdays and only 35 min/day on weekend days. They also found that, in general, boys were more active than girls. Kimm et al. reported that leisure-time physical activity drops to near zero for African American female adolescents [46]. Leek et al. evaluated the level of physical activity achieved during youth sports practices [47]. They found that the overall mean moderate and vigorous physical activity was 45 min, with only 24 % of participants meeting the recommended 60 min of physical activity. So, even the most active children may not be routinely getting the required amount of physical activity [47]. When physical activity levels are very low, there is tremendous pressure on diet to reduce caloric intake. The USDA dietary guidelines have developed the concept of discretionary

Table 27.1 Activity recommendations for cardiovascular health in children and adolescents

Recommendations
Newborn to 12 months
Parents should create an environment that promotes and models physical activity and limits sedentary time
1 to 4 years
Allow unlimited active playtime in safe, supportive environments
Limit sedentary time, especially TV/video
Supportive actions:
No TV in child's bedroom
Encourage family activity at least once per week
Counsel routine activity for parents as role models for children
5–10 years
Moderate-to-vigorous physical activity everyday[a]
Limit daily leisure screen time (TV/video/computer)
Supportive actions:
Prescribe moderate-to-vigorous activity 1 h/day[a] with vigorous intensity physical activity 3 day/week[b]
No TV in child's bedroom
Take activity and screen-time history from child once per year
Match physical activity recommendations with energy intake
Recommend appropriate safety equipment relative to each sport
11–17 years
Moderate-to-vigorous physical activity everyday[a]
Limit leisure time TV/video/computer use
Supportive actions:
Encourage adolescents to aim for 1 h/day of moderate-to-vigorous daily activity[a] with vigorous intense physical activity[b] 3 day/week
Encourage no TV in bedroom
Match activity recommendations with energy intake
Take activity and screen-time history from adolescent at health supervision visits
Encourage involvement in year-round physical activities
Support continued family activity once per week and/or family support of adolescent's physical activity program
Endorse appropriate safety equipment relative to each sport
18–21 years
Moderate-to-vigorous physical activity everyday[a]
Limit leisure time TV/video/computer
Supportive actions:
Support goal of 1 h/day of moderate-to-vigorous activity with vigorous intense physical activity 3 day/week

(*continued*)

Table 27.1 (continued)

Recommendations
Recommend that combined leisure screen time not exceed 2 h/day
Activity and screen-time history at health supervision visits
Encourage involvement in year-round, lifelong physical activities

[a]Examples of moderate-to-vigorous physical activities are jogging and playing baseball
[b]Examples of vigorous physical activities are running, playing singles tennis, and playing soccer

calories [48]. Discretionary calories, based on activity level and gender, are presented in Fig. 27.1. These are the extra calories available to be consumed after a nutritious diet is consumed to maintain energy balance and reduce abnormal weight gain. In sedentary children and adolescents, the discretionary calories are only about 150 Kcal/day. In the current food environment, this is very difficult to accomplish. Current studies have shown that approximately 30–40 % of the diet of children comes from energy-dense, nutrient-poor foods, such as snacks [49]. This increases intake of calories, saturated fat, and carbohydrates while decreasing protein, fiber, calcium, magnesium, iron, zinc, and vitamins.

Pediatric health-care providers should routinely assess the level of physical activity in their patients. In primary care, this should occur at every health maintenance visit. For pediatric cardiologists, this can be more targeted but should still be performed to reinforce its importance. Patients and their parents should be asked about the amount of time spent on various activities, such as walking, running, biking, and swimming. They should also be asked about general playtime and time spent in organized sports. In addition, families should be questioned about sedentary time, including time spent on homework, computer, video games, television, and phone conversations. Parents should also be queried about perceived barriers to increasing the level of physical activity.

The information obtained about physical activity and sedentary time can be used to develop age and developmental stage-appropriate recommendations to increase the level of physical activity. The child's preferred activities should be a determinant, but it is also important to recommend that the family explores new opportunities for activity and that these can be accomplished as a family unit. For preschool children, health-care providers should encourage unlimited active playtime in a safe environment as often as possible. For older children, more organized activities are appropriate. However, it should be emphasized that a wide variety of activities and settings are appropriate.

Screen time should be zero for children from birth to age 2 years. After age 2, television and other "screen" time should be monitored and limited to no more than 2 h/day. Television and other media should not be permitted in the child's bedroom.

It is most helpful when parents and other caregivers are role models for physical activity in children. This can often have multiple benefits as frequently other family members will also have issues with overweight and obesity.

Sleep

Sleep has been an increasingly recognized aspect of cardiovascular health promotion. Studies have shown that a longer duration of sleep is associated with a lower risk of obesity and cardiovascular disease [50]. Lumeng et al. have shown that the duration of sleep in third grade is associated with weight status 3 years later [51]. The mechanism of this relationship is not known. However, it is known that a shorter duration of sleep disrupts hormone release, which may have an impact on growth hormone and cortisol levels [52]. When sleep duration is shorter, cortisol levels, which are usually low during sleep, remain high. Normally, parasympathetic nervous system activity is typically more active during sleep; however, it is lowered with shorter duration of sleep and sleep deprivation [52]. Sleep deprivation is also

associated with increased appetite [53]. This may be mediated by alteration in hormones, such as ghrelin [53, 54].

Obesity may also have an adverse impact on sleep. Patients with obesity may have obstructive sleep apnea. Obstructive sleep apnea is associated with poor-quality sleep and cardiovascular changes, including pulmonary hypertension, systemic hypertension, and left ventricular hypertrophy [55, 56].

The frequency of problems with sleep in children and adolescents is not clear. It is reported that more than one half of adolescents felt sleepy during the day [57]. In addition, only 20 % of adolescents report getting 9 h of sleep on school nights. There may be multiple reasons for the poor sleep habits of children and adolescents, but the presence of television and other electronic media in the bedroom is associated with later bedtime and less sleep compared to children without a television in the bedroom [58].

Pediatric health-care providers should take a sleep history from patients. Patients with obesity and either daytime hyperactivity or excessive sleepiness and snoring should be referred for a sleep evaluation and possibly a sleep study. Health-care providers should counsel parents on appropriate sleep hygiene.

Diet

Diet is probably the most important lifestyle factor in cardiovascular health promotion. However, it is a complex constellation of multiple factors. Diet is ultimately composed of a variety of foods and drinks. These foods add up to macronutrients and micronutrients, minerals, and vitamins. Overall calorie consumption is a critical aspect of energy balance. The diet composition with respect to saturated fat and cholesterol content is an important determinant of plasma cholesterol concentrations, and for individuals who are sensitive to salt, dietary sodium is associated with the level of blood pressure [59]. However, because of its complexity and the fact that nutritional needs change with growth and development, constructing the optimum diet is difficult.

There is good evidence that increased consumption of fruits and vegetables is beneficial for cardiovascular health. Increased consumption of fruits and vegetables has been associated with improvement in several risk factors, including blood pressure, lipid levels, insulin resistance, markers of inflammation, endothelial function, and body mass index [60]. Of importance is that the same impact cannot be achieved with similar amounts of fiber, minerals, or other components given as supplements [61].

Whole grains are made up of bran, germ, and endosperm from grains. Bran contains fiber, B vitamins, minerals, flavonoids, and tocopherols. Germ contains fatty acids, antioxidants, and phytochemicals; endosperm includes starch and proteins [62].

Consumption of whole grains improves insulin levels and endothelial function [63]. Whole grains may also be beneficial in weight management. Whole grain oats have been shown to lower LDL cholesterol without raising triglycerides or lowering HDL cholesterol [64]. In adults, increased whole grain consumption is associated with lower risk of coronary heart disease, stroke, and diabetes [65].

Intake of low-fat dairy products has been associated with improved insulin resistance, endothelial function, and lower blood pressure and lipid levels [66–69]. Dairy is an important source of calcium, vitamin D, protein, potassium, and magnesium. So, in addition to promoting cardiovascular health, low-fat dairy also is important for bone health and growth.

Fish can be high in fat, but the predominant fats in fish are long-chain omega-3 polyunsaturated fatty acids. These include eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). In humans, EPA and DHA tissue concentrations are directly related to consumption of those fatty acids in the diet [70]. Fatty fish, such as salmon, trout, and white tuna, have the highest concentrations.

Fish oil has a number of effects which improve cardiovascular health. Fish oil lowers plasma triglyceride levels [71], blood pressure [72], and resting heart rate [73]. Fish oil also appears to reduce cardiac arrhythmias [74]. Consumption of

Table 27.2 Evidence-based recommendations for diet and nutrition: CHILD-I[a]

Recommendations
Birth to 6 months
Infants should be exclusively breastfed (no supplemental formula or other foods) until the age of 6 months[b]
6–12 months
Continue breastfeeding until at least 12 months of age while gradually adding solids
Transition to iron-fortified formula until 12 months if reducing breastfeeding[c]
Fat intake in infants <12 months of age should not be restricted without medical indication
Limit other drinks to 100 % fruit juice (≤4 oz/day)
No sweetened beverages; encourage water
12–24 months
Transition to reduced-fat (2 % to fat-free) unflavored cow's milk
Limit/avoid sugar-sweetened beverage intake; encourage water
Transition to table food with:
Total fat 30 % of daily kcal/EER[d]
Saturated fat 8–10 % of daily kcal/EER
Avoid trans fat as much as possible
Monounsaturated and polyunsaturated fat up to 20 % of daily kcal/EER
Cholesterol <300 mg/day
Supportive actions:
The fat content of cow's milk to be introduced at 12–24 months of age should be decided together by parents and health-care providers on the basis of the child's growth, appetite, intake of other nutrient-dense foods, intake of other sources of fat, and potential risk for obesity and CVD
100 % fruit juice (from a cup), not more than 4 oz/day
Limit sodium intake
Consider DASH-type diet rich in fruits, vegetables, whole grains, and low-fat/fat-free milk and milk products and lower in sugar
2–10 years
Primary beverage: fat-free unflavored milk[e]
Limit/avoid sugar-sweetened beverages; encourage water
Fat content:
Total fat 25–30 % of daily kcal/EER[f]
Saturated fat 8–10 % of daily kcal/EER
Avoid trans fats as much as possible
Monounsaturated and polyunsaturated fat up to 20 % of daily kcal/EER
Cholesterol <300 mg/day
Encourage high dietary fiber intake from foods
Supportive actions:
Teach portions based on EER for age/gender/age
Encourage moderately increased energy intake during periods of rapid growth and/or regular moderate-to-vigorous physical activity
Encourage dietary fiber from foods: age + 5 g/day[g]
Limit naturally sweetened juice (no added sugar) to 4 oz/day
Limit sodium intake
Support DASH-style eating plan
11–21 years
Primary beverage: fat-free unflavored milk
Limit/avoid sugar-sweetened beverages; encourage water
Fat content:
Total fat 25–30 % of daily kcal/EER
Saturated fat 8–10 % of daily kcal/EER
Avoid trans fat as much as possible
Monounsaturated and polyunsaturated fat up to 20 % of daily kcal/EER
Cholesterol <300 mg/day
Encourage high dietary fiber intake from foods
Supportive actions:
Teach portions based on EER for age/gender/activity
Encourage moderately increased energy intake during periods of rapid growth and/or regular moderate-to-vigorous physical activity
Advocate dietary fiber: goal of 14 g/1000 kcal
Limit naturally sweetened juice (no added sugar) to 4–6 oz/day
Limit sodium intake
Encourage healthy eating habits, breakfast every day, eating meals as a family, limiting fast-food meals
Support DASH-style eating plan

[a]CHILD-I is the recommended first-step diet for all children and adolescents at elevated cardiovascular risk for any reason
[b]Infants who cannot be fed directly at the breast should be fed with expressed milk. Infants for whom expressed milk is not available should be fed with iron-fortified infant formula
[c]Continued breastfeeding is still appropriate and nutritionally superior to cow's milk
[d]EER indicates estimated energy requirement
[e]For toddlers 12 to 24 months of age with a family history of obesity, heart disease, or high cholesterol, parents should discuss transition to reduced-fat milk with pediatric care provider after 12 months of age
[f]Reduced-fat milk should be used only in the context of an overall diet that supplies 30 % of calories from fat
[g]Naturally fiber-rich foods are recommended (fruits, vegetables, whole grains); fiber supplements are not advised. Limit refined carbohydrates (sugars, white rice, and white bread).
Pediatrics 2011;128:Suppl 6

fish oil is also associated with improved endothelial function, lower inflammation, and improved cardiac function [75]. In epidemiologic studies in adults, greater consumption of fish is associated with lower incidence of cardiovascular mortality, coronary heart disease, and ischemic stroke [76]. It is not known if the use of fish oil supplements is equivalent to having fish in the diet. Fried fish has lower EPA and DHA content and its consumption has not been associated with improved cardiovascular health [77, 78].

Some foods and beverages have been associated with poorer cardiovascular health. One example of this is the consumption of beverages with added sugar. Increased consumption of sugar-sweetened beverages has been associated with increased prevalence and severity of obesity in children [79]. From 1965 to 2002, the proportion of dietary calories consumed from beverages increased from 11.8 % to 21 % per person [80]. This is equivalent to an increase of approximately 220 cal/day. This increase comes mainly from soft drinks and fruit juices and was predominantly consumed in the home [81]. Sugar-sweetened beverages, such as soft drinks and fruit juice, displace more energy-dense beverages, such as low-fat milk [82].

Studies have shown that reducing the intake of sugar-sweetened beverages is helpful in improving weight loss or reducing abnormal weight gain [83, 84]. In adults, higher consumption of sugar-sweetened beverages has been associated with a high incidence of diabetes and the metabolic syndrome [85]. Another study showed a relationship of intake of sugar-sweetened beverage and incident coronary heart disease [86].

In general, the intake of sodium in the diet is far above the actual requirements. In the United States, approximately 75 % of sodium intake comes from packaged, pre-prepared, or restaurant foods. Some of the remaining sodium is derived from natural sources and the rest is added in preparation or at the table.

Bibbins-Domingo et al. have estimated the overall impact of reducing sodium in the diet in the United States [87]. They found that reducing dietary salt by 3 g/day is projected to reduce the number of new cases of coronary heart disease by 60,000–120,000; stroke by 32,000–66,000; and myocardial infarction by 54,000–92,000 per year. These results are similar to or greater than the reductions projected for interventions that would

Table 27.3 Evidence-based recommendations for dietary management of elevated LDL cholesterol, non-HDL cholesterol, and triglyceride levels

Recommendations
2–21 years elevated LDL cholesterol CHILD-2—LDL
Refer to a registered dietitian for family medical nutrition therapy
25–30 % of calories from fat, ≤7 % from saturated fat, and ~10 % from monounsaturated fat; <200 mg/day of cholesterol[a]
Avoid trans fats as much as possible
Supportive actions:
Plant sterol esters and/or plant stanol esters[b] up to 2 g/day as replacement for usual fat sources can be used after 2 years of age in children with familial hypercholesterolemia
Plant stanol esters as part of a regular diet are marketed directly to the public; short-term studies have found no harmful effects in healthy children
The water-soluble fiber psyllium can be added to a low-fat, low-saturated-fat diet as cereal enriched with psyllium at a dose of 6 g/day for children 2–12 years of age and 12 g/day for those ≥12 years of age
As for all children, 1 h/day of moderate-to-vigorous physical activity and <2 h/day of sedentary screen time are recommended
Elevated triglycerides or non-HDL cholesterol: CHILD-2—TG
Refer to a registered dietitian for family medical nutrition therapy[c]
25–30 % of calories from fat. ≤7 % from saturated fat, ~10 % from monounsaturated fat; <200 mg/day of cholesterol; avoid trans fats as much as possible
Decrease sugar intake:
Replace simple with complex carbohydrates
No sugar-sweetened beverages
Increase dietary fish to increase omega-3 fatty acids

[a]Values given are in mg/dL. To convert to SI units, divide the results for TC, LDL cholesterol, HDL cholesterol, and non-HDL cholesterol by 38.6; for triglycerides, divide by 88.6

[b]Can be found added to some foods, such as some margarines

[c]If the child is obese, nutrition therapy should include calorie restriction, and increased activity (beyond that recommended for all children) should be prescribed

Table 27.4 DASH eating plan: Servings per day according to food group and total energy intake

Food group	Number of servings						Serving size	Examples and notes	Significance of each food group to DASH eating plan
	1,200 cal	1,400 cal	1,600 cal	1,800 cal	2,000 cal	2,600 cal			
Grains[a]	4–5/day	5–6/day	6/day	6/day	6–8/day	10–11/day	1 slice bread; 1 oz dry cereal; ½ cup cooked rice, pasta or cereal	Whole-wheat bread and rolls, whole-wheat pasta, English muffin, pita bread, bagel, cereals, grits, oatmeal, brown rice, unsalted pretzels, and popcorn[b]	Major sources of energy and fiber
Vegetables	3–4/day	3–4/day	3–4/day	4–5/day	4–5/day	5–6/day	1 cup raw leafy vegetable; ½ cup cutup raw or cooked vegetables; ½ cup vegetable juice	Broccoli, carrots, collards green beans, green peas, potassium, cut-up raw or kale, lima beans, potatoes, spinach, squash, sweet potatoes, tomatoes	Rich sources of potassium magnesium and fiber
Fruits	3–4/day	4/day	4/day	4–5/day	4–5/day	5–6/day	1 medium fruit; ¼ cup dried fruit; ½ cup fresh, frozen or canned fruit	Apples, apricots, bananas, dates, grapes, oranges, grapefruit, grapefruit juice, mangoes, melons, peaches, pineapples, raisins, strawberries, tangerines	Important sources of potassium magnesium and fiber
Fat-free or low-fat milk and milk products	2–3/day	2–3/day	2–3/day	2–3/day	2–3/day	3/day	1 cup milk or yogurt; 1½ oz cheese	Fat-free milk or buttermilk, fat-free, low-fat, or reduced-fat cheese; fat-free/low-fat regular or frozen yogurt	Major sources of calcium and protein

Lean meats, poultry, or fish	≤3/day	≤3–4/ day	≤3–4/ day	≤6/day	≤6/day	≤6/day	1 oz cooked meats, poultry or fish, 1 egg[c]	Select only lean; trim away visible fats; broil, roast, or poach; remove skin from poultry	Rich sources of protein and magnesium
Nuts, seeds, and legumes	3/week	3/week	3–4/ week	4/week	4–5/ week	1/day	1/3 cup or 1½ oz nuts; 2 tbsp peanut butter; 2 tbsp or ½ oz seeds; cooked legumes(dry beans and peas)	Almonds, filberts, mixed nuts, peanuts, walnuts, sunflower seeds, peanut butter, kidney beans, lentils, split peas	Rich sources of energy, magnesium, protein, and fiber
Fats and oils[d]	1/day	1/day	2/day	2–3/day	2–3/day	3/day	1 tsp soft margarine; 1 tsp vegetable oil; 1 tbsp mayonnaise; 2 tbsp salad dressing	Soft margarine, vegetable oil (such as canola, corn, olive, or safflower), low-fat mayonnaise, light salad dressing	The DASH (Dietary Approaches to Stop Hypertension) study had 27 % of calories as fat including fat in or added to foods
Sweets and added sugars	≤3/week	≤3/week	≤3/week	≤5/week	≤5/week	≤2/day	1 tbsp sugar; 1 tbsp jelly or jam; ½ cup sorbet, gelatin; 1 cup lemonade	Fruit-flavored gelatin, fruit punch, hard candy, jelly, maple syrup, sorbet and ices, sugar	Sweets should be low in fat

Table 27.3 provides estimated energy requirements according to age, gender, and activity level:
[a]Whole grains are recommended for most grain servings as a good source of fiber and nutrients
[b]Serving sizes vary between ½ and 1 cup, depending on cereal type. Check the product's nutrition-facts label
[c]Because eggs are high in cholesterol, limit egg yolk intake to no more than 4/week; 2 egg whites have the same protein content as 1 oz of meat
[d]Fat content changes serving amount for fats and oils. For example, 1 tbsp of regular salad dressing = 1 serving, 1 tbsp of low-fat dressing = ½ serving, and 1 tbsp fat-free dressing = 0 servings

reduce cigarette smoking in the population by 50 %. The reduction of salt by 3 g/day is in a range that can be accomplished and similar to interventions already adopted in other countries.

Diet Patterns

Mozaffarian et al. reviewed the components of cardioprotective diet [60]. They concluded that a focus on foods and dietary patterns is especially beneficial. Several diet patterns have been associated with improved cardiovascular health. From research of different diet patterns, some beneficial common elements have emerged. This includes an emphasis on fruits and vegetables, beans, and nuts along with whole grains, low-fat dairy, and fish. In addition, foods to be reduced in the diet include red meats, processed meats, refined carbohydrates, and other processed, low-nutrient-density foods.

The dietary patterns that support these principles include the DASH (Dietary Approaches to Stop Hypertension) diet [88], the Mediterranean diet [89], and a Japanese diet pattern [90]. It is possible that in the future, it will be possible to customize diet to individual genetics, metabolism, and risk factors to ensure optimum cardiovascular health. However, at the moment, this is an area for additional research.

An important question concerning diet from a pediatric perspective is the diet early in life. The STRIP study has demonstrated that a diet lower in total and saturated fat can be instituted early in life (at weaning) and can result in improved cardiovascular risk status [91]. These results support the concept that reduced-fat milk can be initiated at 12 months of age without adverse effect in the context of a nutrient-dense overall diet. Diet preferences, habits, and patterns begin early in life and are reinforced as the child grows and develops. This presents an opportunity for early intervention to produce a healthful diet. Pediatric health-care providers should provide guidance about a healthful diet. The 2010 Dietary Guidelines for Americans from the USDA provide a population-based approach to diet [48]. The NHLBI Guidelines for Cardiovascular Risk Reduction in Children and Adolescents present approaches to diet for children who are deemed to be at somewhat higher risk for development of risk factors for cardiovascular disease (CHILD-1 diet) [92]. For children who already have lipid risk factors for cardiovascular disease, the CHILD-2 diet is recommended. For children with hypertension, the DASH diet is recommended [92]. The overarching principles of the CHILD-1 and CHILD-2 diets and the DASH diet are presented in Tables 27.2, 27.3, and 27.4. This shows a progressively aggressive approach to diet based on risk-factor status. When a child is at high-risk status, the assistance of a dietitian can be quite beneficial.

Similar to physical activity, pediatric health-care providers should question patients and parents about dietary patterns. Problem diet areas and settings for eating should be identified and suggestions for improvement made. Barriers to changes should also be identified and plans developed in conjunction with the family to institute changes in the food environment and the child's eating behaviors. Parents should take charge of the home food environment to make it more healthful. In general, for behavior change, it is helpful to make small incremental changes. Successful changes should be rewarded and serve as the basis for further change.

Conclusion

The promotion of cardiovascular health in children and adolescents depends on establishing optimum health behaviors early in life and maintaining them over time. In the current environment, this can be a difficult task, but the long-term payoff is great. The focus on prevention of cardiovascular disease and promotion of cardiovascular health emphasizes population-based primordial prevention, which is based on long-term optimum health behaviors across the population.

Subsequent chapters will focus on specific risk factors and imaging methods for evaluating the process of atherosclerotic cardiovascular disease. It will become apparent that optimum health behaviors underlie all risk-factor management.

Arterial Hypertension: Evaluation and Management

28

Joseph T. Flynn

Abstract

Hypertension, particularly obesity-related primary hypertension, has become increasingly common in children and adolescents. It is important to understand the epidemiology and key features of childhood hypertension, so that appropriate diagnostic evaluation can be undertaken. Diagnosis should begin by verifying the presence of hypertension, and then appropriate studies should be obtained to identify possible secondary causes. Once the cause and severity of hypertension have been determined, a treatment plan should be developed that incorporates lifestyle measures in all affected children and pharmacologic treatment in those who meet specific criteria.

Introduction

Elevated blood pressure (BP) can be observed at any time during childhood, from the newborn period through adolescence. Recent screening studies have demonstrated that hypertension may affect up to 3.5 % of children and adolescents [1, 2], which is an increase compared to studies conducted years ago [3]. This increase is largely attributable to the childhood obesity epidemic, which has resulted in an increase in the number of children with primary hypertension. Given this increase, and given the known association between hypertension and the development of target-organ damage [4], hypertension should be considered a common chronic health issue in childhood with significant long-term implications for cardiovascular health.

Evaluation of the Child or Adolescent with Elevated BP

Evaluation of the hypertensive child or adolescent begins with confirmation that the blood pressure (BP) is truly elevated and then proceeds through a thorough history and physical exam and focused laboratory and imaging studies. Since secondary causes of hypertension are more common in the pediatric age group than in adults, attention should be paid to detecting underlying conditions that may be causing the elevated BP. The initial evaluation should also include an assessment for hypertensive target-organ damage, the presence or absence of which will help guide therapy [5].

Definitions of Hypertension

Since cardiovascular sequelae of hypertension such as myocardial infarction and stroke do not occur in the young, the definition of elevated BP in childhood is a statistical one, based upon the distribution of BP values in normal children [5, 6]. The level of BP that should be considered elevated in a child varies depending on age and body size. Normal BP is defined as systolic and diastolic BP less than the 90th percentile for age, gender, and height. Hypertension is defined as an average systolic and/or diastolic BP that is $\geq$95th percentile for age, gender, and height on three or more occasions [5]. Reference BP levels for children aged 1–17 years are provided in Table 28.1 for boys and in Table 28.2 for girls. In the older adolescent $\geq$18 years, recommendations of the Joint National Committee on Prevention, Detection, Evaluation and Treatment of High Blood Pressure [7] should be followed, which defines hypertension as a BP reading >140/90 on two or more office visits. See below for a separate discussion of BP values in neonates.

Prehypertension in children is defined as average systolic and/or diastolic BP $\geq$90th percentile and <95th percentile for age, gender, and height. The definition of prehypertension is the same in adolescents as in adults, namely, a BP reading >120/80 [5, 7]. This is because by age 12 years, in both boys and girls, the 90th percentile for systolic and diastolic BP is above 120/80 mmHg. For all children and adolescents, the severity of hypertension should be staged once an individual is diagnosed with hypertension (Table 28.3). Staging the severity of hypertension is helpful in guiding subsequent evaluation and management.

What has emerged since publication of the most recent pediatric blood pressure guidelines [5] is that significant numbers of children and adolescents whose BP levels would qualify as having hypertension are not being appropriately identified as such [8]. This is perhaps related to the complexity of the normative BP data displayed in Tables 28.1 and 28.2. Several authors have proposed simplified versions of the BP tables that could be used in the office setting to screen for children with possible hypertension [9, 10]. Until such simplified tables are validated, however, practitioners should still utilize the definitions and BP values discussed above.

BP blood pressure

Diagnosis: Confirmation of Elevated Blood Pressure

BP in childhood is more labile than in adults. Even children with secondary causes of hypertension have been shown to demonstrate significant variability in office BP readings. In addition, the phenomenon of regression to the mean is commonly observed. Thus, it is crucial to confirm that the child's BP is truly elevated before making the diagnosis of hypertension and embarking on a diagnostic evaluation.

A first step in the diagnosis of hypertension is to ensure that BP is being measured correctly. The National High Blood Pressure Education Program Working Group recommended auscultation as the preferred method of BP measurement in the pediatric age group and specifically stated that elevated readings obtained using oscillometric devices should be repeated by auscultation [5]. Recent data from pediatric hypertension clinics demonstrate that BP readings obtained using oscillometric devices frequently differ significantly from BP measurements obtained by auscultation [11], thereby confirming the recommendations of the Working Group.

Attention also needs to be paid to the size of the cuff utilized in measuring BP in both children and adolescents. The bladder of the cuff should encircle 80–100 % of the arm circumference (Fig. 28.1) or else the reading may be falsely elevated. Studies have demonstrated substantial variability in "standard" cuff sizes between manufacturers [12], so it is best to first measure the arm circumference with a tape measure and then choose an appropriately sized cuff. Recent data

BP blood pressure

from the National Health and Nutrition Examination Survey (NHANES) have shown that in conjunction with the childhood obesity epidemic, arm sizes of children have increased, meaning that more adolescents will require use of a "large adult" or even "thigh" cuff to obtain an accurate BP reading [13].

With these issues in mind, it is usually recommended that for pediatric patients referred for evaluation of suspected hypertension, additional office BP measurements should be obtained to verify the diagnosis of hypertension [14]. This can be done over a period of time, depending on the severity of the BP elevation and the presence or absence of symptoms.

Optimally, ambulatory BP monitoring (ABPM) should be performed for further confirmation of hypertension and to identify patients with white coat hypertension [15]. White coat hypertension has been shown to be present in up to 30–40 % of children and adolescents referred for evaluation of suspected hypertension, depending on the diagnostic criteria used [16]. ABPM can also identify patients with masked hypertension (Table 28.4) who may have similarly increased cardiovascular risk as those with confirmed ambulatory hypertension. Home BP measurement has also been proposed to uncover white coat hypertension in pediatric patients, but uncertainty over normal values in the young makes this a less reliable method than ABPM.

Diagnosis: Differential Diagnosis

Before embarking on extensive diagnostic testing, one should try to develop a potential differential diagnosis for the child's hypertension.

Table 28.3 Classification of hypertension in pediatric patients

Blood pressure classification	Children and adolescents <18 years of age	Adolescents ≥18 years of age
Normal	SBP and DBP <90th percentile	SBP <120 mmHg and DBP <80 mmHg
Prehypertension	SBP or DBP 90–95th percentile; or if BP is >120/80 even if <90th percentile	SBP 120–139 mmHg or DBP 80–89 mmHg
Stage 1 hypertension	SBP or DBP ≥95th to 99th percentile plus 5 mmHg	SBP 140–159 mmHg or DBP 90–99 mmHg
Stage 2 hypertension	SBP or DBP >99th percentile plus 5 mmHg	SBP ≥160 mmHg or DBP ≥100 mmHg

Adapted from Refs. [5] and [7]

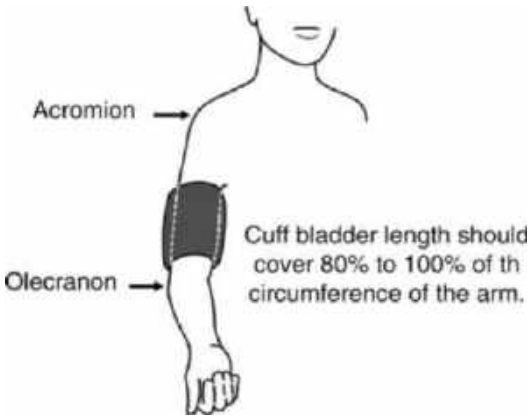

Fig. 28.1 Proper BP cuff size in children and adolescents

Young children are more likely to have secondary hypertension, whereas in adolescents, primary hypertension accounts for the majority of cases [17]. Frequent causes of secondary hypertension in childhood are listed in Table 28.5. Parenchymal kidney disease and other renal conditions are the most frequent underlying causes of secondary hypertension to consider in planning an evaluation for hypertension in otherwise asymptomatic children.

Table 28.4 Classification of BP patterns according to office and ambulatory BP values

BP pattern	Office BP	Ambulatory BP
Normotensive	Normal	Normal
White coat hypertension	Elevated	Normal
Ambulatory hypertension	Elevated	Elevated
Masked hypertension	Normal	Elevated

A positive family history of hypertension and obesity increase the likelihood of primary hypertension in children and adolescents. Offspring of hypertensive parents have been found to have higher BPs and an increased prevalence of other cardiovascular risk factors. The prevalence of a positive family history of hypertension in children and adolescents with primary hypertension has been reported to be greater than 80 % [17]. Thus, a family history of hypertension (or of other cardiovascular disease such as stroke) increases the likelihood of a diagnosis of primary hypertension, especially when the results of initial diagnostic studies are normal. Obesity is more common among pediatric patients with primary hypertension than those with secondary hypertension and is associated with an earlier age of onset of hypertension, independent of family history [18].

Diagnosis: History and Physical Examination

Evaluation of the hypertensive child or adolescent should begin with a complete medical history and physical examination. Recent research has shown that hypertensive children are frequently symptomatic [19], so the history should begin by determining whether symptoms suggestive of hypertension are present, such as headaches, dizziness, diplopia, vomiting, or sleep disturbances. The interview should then focus on uncovering symptoms of other underlying disorders, including symptoms of possible renal disease, heart disease, or diseases affecting other

Table 28.5 Differential diagnosis of secondary hypertension in children and adolescents

Renal	Endocrine
Obstructive lesions (UPJ, UVJ)	Diabetes (type 1 or type 2)
Glomerulonephritis (acute or chronic)	Cushing's syndrome
Other acquired renal parenchymal disease (pyelonephritis, reflux nephropathy, infarction)	Primary aldosteronism
Renovascular disease	Hyperparathyroidism
Intrinsic: fibromuscular hyperplasia, arterial or venous thrombosis	Congenital adrenal hyperplasia
Extrinsic: compression	Hyperthyroidism
Congenital defects (hypoplasia/dysplasia, autosomal dominant or recessive PKD)	Genetic
Hemolytic-uremic syndrome	Turner's syndrome
Vascular	Williams syndrome
Thoracic aortic coarctation	Neurofibromatosis
Mid-aortic syndrome	Tuberous sclerosis
Vasculitis (Takayasu's, polyarteritis nodosa)	Single-gene defects (Liddle's syndrome, AME, GRA)
Neurologic	Neoplastic
Increased intracranial pressure	Renal tumors (renal cell carcinoma, Wilms tumor)
Guillain-Barré syndrome	Pheochromocytoma
Cervical and leg traction	Neuroblastoma
Pain	Miscellaneous
	Drug-induced (see Table 28.7)
	Stress
	Organ transplantation

AME apparent mineralocorticoid excess, *GRA* glucocorticoid-remediable aldosteronism, *PKD* polycystic kidney disease, *UPJ* ureteropelvic junction, *UVJ* ureterovesical junction

Table 28.6 History and physical exam findings suggestive of secondary hypertension

Present in history	*Suggests*
Known UTI/UTI symptoms	Reflux nephropathy
Joint pains, rash, fever	Vasculitis, SLE
Acute onset of gross hematuria	Glomerulonephritis, renal venous thrombosis
Renal trauma	Renal infarct, RAS
Abdominal radiation	Radiation nephritis, RAS
Renal transplant	Transplant RAS
Precocious puberty	Adrenal disorder
Muscle cramping, constipation	Hyperaldosteronism
Excessive sweating, headache, pallor, and/or flushing	Pheochromocytoma
Illicit drug use	Drug-induced hypertension
Present on examination	*Suggests*
BP >140/100 at any age	Secondary hypertension
Leg BP < arm BP	Aortic coarctation
Poor growth, pallor	Chronic renal disease
Turner syndrome	Aortic coarctation
Cafe-au-lait spots	Renal artery stenosis
Delayed leg pulses	Aortic coarctation
Precocious puberty	Adrenal disorder
Bruits over upper abdomen	Renal artery stenosis
Edema	Renal disease
Excessive sweating	Pheochromocytoma
Excessive pigmentation	Adrenal disorder
Striae in a male	Drug-induced HTN

BP blood pressure, *HTN* hypertension, *RAS* renal artery stenosis, *SLE* systemic lupus erythematosus, *UTI* urinary tract infection

organ systems. Table 28.6 lists history and physical exam findings suggestive of secondary hypertension in children. The past medical history should include questions about recent as well as chronic illnesses, prior hospitalizations or episodes of trauma, recurrent urinary tract infections, or unexplained fevers, as well as the neonatal history. Family history of hypertension, diabetes, renal disease, and other cardiovascular disease (hyperlipidemia, myocardial infarction at an early age) should be elicited. Finally, it is important to ask about over-the-counter, prescription and illicit drug use, as many commonly used substances can either cause or exacerbate hypertension (Table 28.7).

Physical examination should begin with measurement of the child's weight and height so that growth percentiles can be plotted and body mass index calculated. BPs should be obtained in both upper extremities in the seated position and in at

Table 28.7 Substances that may elevate blood pressure in childhood

Prescription medications	Nonprescription medications	Others
Calcineurin inhibitors (cyclosporine, tacrolimus)	Caffeine	Cocaine
COX-2 inhibitors (celecoxib, others)	Ephedrine	DHEA (dehydroepiandrosterone)
Erythropoietin	Nonsteroidal anti-inflammatory drugs[a]	Ethanol
Glucocorticoids	Pseudoephedrine	Heavy metals (lead, mercury)
Migraine medications (ergotamine, sumatriptan)		Herbal preparations (*Ephedra, Glycyrrhiza*)
Oral contraceptives		MDMA ("Ecstasy")
Phenylpropanolamine		Tobacco
Pseudoephedrine		
Stimulant medications[a] (dexedrine, methylphenidate, amphetamine derivatives)		
Tricyclic antidepressants[a]		

[a]These cause elevated blood pressure relatively infrequently compared with the other agents in the table

least one arm and one leg in the supine position in order to rule out aortic coarctation. As with the history, the rest of the physical examination should focus on uncovering signs of specific underlying disorders that may be causing the child's hypertension (Table 28.6). In obese adolescents, there may be signs of insulin resistance such as acanthosis nigricans, or in females, findings suggestive of polycystic ovary syndrome (PCOS) such as hirsutism. The physical examination may also provide clues as to the severity/chronicity of the patient's hypertension, such as left ventricular hypertrophy (signified by an apical heave) or hypertensive retinopathy.

Diagnosis: Laboratory Testing and Imaging

Patients with confirmed hypertension should undergo a tailored diagnostic evaluation, to confirm or exclude secondary causes, and also should be assessed for the presence of other cardiovascular risk factors [5]. It is typical to obtain a basic set of screening studies in all patients, including a urinalysis, serum chemistries (electrolytes, BUN/creatinine, and calcium), fasting lipid panel, and fasting glucose.

Recent reports confirm the frequent presence of dyslipidemia in children and adolescents with high BP, especially among those who are obese [20, 21]. The typical pattern is normal to slightly elevated total cholesterol with low HDL cholesterol and elevated triglycerides. This pattern is similar to the dyslipidemia that occurs in type 2 diabetes and likely reflects underlying insulin resistance, even in non-obese hypertensives. Obese adolescents with hypertension may also have impaired glucose tolerance, which in conjunction with elevated BP and dyslipidemia would be consistent with the metabolic syndrome [21]. Identification of multiple cardiovascular risk factors in children or adolescents should be considered indicative of an increased risk of premature cardiovascular disease and would call for more intensive management.

Plasma renin activity (PRA) and aldosterone are sometimes also included in the initial set of diagnostic studies, especially when the patient's hypertension is severe, or if both systolic and diastolic hypertension are present. Suppressed PRA is suggestive of one of the monogenetic forms of hypertension, in which there is altered renal sodium handling, leading to volume overload. These have been reviewed elsewhere [22].

Given the high likelihood of primary hypertension in adolescence, a renal ultrasound, which is routinely obtained in younger hypertensive patients, may be omitted in some adolescents

with stage 1 hypertension if the screening studies are normal and if other features of primary hypertension are present, including obesity, a positive family history, and isolated systolic hypertension. Those with stage 2 hypertension, with abnormal screening laboratory studies, or with diastolic or sleep hypertension on ABPM [23] should have a renal ultrasound. Additional imaging studies, including renal angiography, nuclear renal scans, and voiding cystourethrograms should be obtained only in selected children and adolescents based upon the results of the history, physical examination, and initial imaging studies.

Diagnosis: Assessment for Hypertensive Target-Organ Damage

An important component in the evaluation of a hypertensive child or adolescent is to determine whether there is hypertensive target-organ damage, which would then be an indication for use of antihypertensive medications [5]. Left ventricular hypertrophy (LVH) is the most easily detectable target-organ effect of hypertension, with prevalence in hypertensive children and adolescents as high as 30–40 % [24, 25]. Although the adverse effects of LVH seen in adults, such as heart failure and sudden cardiac death, have not been proven to occur in hypertensive children, LVH should still be considered an indicator of increased cardiovascular risk.

Given the high prevalence of LVH, consensus organizations recommend that 2-D and m-mode echocardiography should be obtained to assess hypertensive target-organ damage [5, 26]. In children, echocardiography rather than electrocardiography is the preferred method to detect LVH. Left ventricular mass should be indexed to height to correct for age and the effect of obesity. Age- and gender-specific normative data have recently been published that should be used to interpret the left ventricular mass index [27].

Other target-organ effects of high BP are also being detected in children and adolescents. When examined systematically, retinal changes can be detected in some hypertensive children and adolescents. A recent study in large samples of school children detected a correlation of retinal arteriolar dimension with BP level, suggesting that subtle changes in retinal vascular structure could develop even prior to confirmed hypertension [28]. Ophthalmologic exams, if obtained, should be performed by an experienced pediatric ophthalmologist as hypertensive retinal changes will likely be quite subtle in children. An increase in carotid intimal-medial thickness (cIMT) is associated with atherosclerosis and increased cardiovascular risk in adults. Recent reports describe greater cIMT in hypertensive children and adolescents when compared to age and BMI matched normotensive children [29, 30]. As in hypertensive adults, increased cIMT in the young is associated with obesity and left ventricular hypertrophy [29].

With respect to other effects of hypertension in children and adolescents, Assadi [31] recently demonstrated that treating microalbuminuria in children with primary hypertension with renoprotective therapy was associated with LVH regression. Lubrano and coworkers [32] detected an association of urinary protein excretion and glomerular filtration rate with BP load on ABPM in children with prehypertension. Recent reports also describe subtle neurocognitive deficits, particularly in the domain of executive function, in hypertensive children compared to normotensive children [33, 34]. However, carotid imaging, urine microalbumin testing, and neurocognitive assessment remain research tools for now, as more data are needed before these studies can be recommended for routine clinical use.

Approach to Therapy

Treatment of hypertension in children and adolescents is still largely empiric, because no long-term studies of either dietary intervention or drug therapy have been conducted [35]. Even though more data are now available on safety and effectiveness of drug therapy than in the past [36], the decision as to whether a specific child or adolescent should receive medication must be individualized.

Treatment: Non-pharmacologic Measures

Weight loss, exercise, and dietary modifications have all been shown to reduce BP in children and adolescents and are therefore considered primary treatment, especially in those with obesity-related hypertension [5]. Studies in obese children have demonstrated that modest weight loss will not only reduce BP but can also improve other cardiovascular risk factors such as dyslipidemia and insulin resistance [37, 38]. Unfortunately, weight loss is difficult and frequently unsuccessful. However, identifying a medical complication of obesity such as hypertension can sometimes provide the necessary motivation for patients and families to make the appropriate lifestyle changes. In this context, family-based interventions should be considered, as they have been shown to be reasonably successful long term [39].

Aerobic forms of exercise are generally recommended in management of hypertension in the young. Many children and adolescents may already be participating in one or more appropriate activities and may only need to increase the frequency and/or intensity of these. Increased physical activity has clear benefit in contributing to weight control and can also lead to improvements in insulin resistance, endothelial function, and other atherogenic risk factors [40, 41]. The combination of increased physical activity and improved fitness along with decreases in body fat may also forestall the development of type 2 diabetes in at risk individuals. At the very least, the amount of time spent in sedentary activities such as video game playing should be restricted to <2 h/day [37].

Dietary modification in the management of hypertension in children and adolescents has been studied both as treatment for hypertension and as a strategy for primary prevention of hypertension. Nutrients that have been examined include the obvious, such as sodium, potassium, and calcium, as well as folate, caffeine, and other substances. Given the usual intake of processed and "fast" foods by many children and adolescents, their typical dietary sodium intakes far exceed nutritional requirements. While individual studies of reduced sodium intake in children have not demonstrated consistent effects on BP, a meta-analysis of 10 studies found that a 54 % reduction in sodium intake was associated with a 2.47 mmHg reduction in systolic BP [42]. A high salt intake increases thirst, and high dietary sodium intakes of children have been linked to the obesity epidemic through increased consumption of sweetened drinks [43, 44]. These findings indicate that limitation of dietary sodium intake could have an additional beneficial effect in the treatment of obese adolescents with hypertension.

Other nutrients that have been examined in patients with hypertension include potassium and calcium, both of which have been shown to have antihypertensive effects. A 2-year trial of potassium and calcium supplementation in hypertensive, salt-sensitive Chinese children demonstrated that this combination significantly reduced systolic BP [45]. Therefore, a low-sodium diet that is also enriched in potassium and calcium content may be more effective in treatment of hypertension than a diet that restricts sodium intake only. An example of such a diet is the "DASH" diet, which is high in fruits, vegetables, and low-fat dairy foods, and has been shown to lower BP in adults with hypertension, even in those receiving antihypertensive medication [46]. A recent pilot study demonstrated that the DASH eating plan can also reduce BP in children and adolescents with modestly elevated BP [47].

Non-pharmacologic measures need to be implemented in a systematic manner, with a great deal of family involvement and long-term support, in order to be most effective. They should be instituted even if there is an established indication for initiation of antihypertensive medications, as successful lifestyle intervention will complement the efficacy of pharmacologic treatment.

Treatment: Antihypertensive Medications

Some hypertensive children and adolescents will need antihypertensive medications in order to

achieve the desired BP. An important fact to recognize when contemplating the use of antihypertensive medications is that the long-term consequences of untreated hypertension in the young remain unknown. At the same time, long-term data on the risks and benefits of antihypertensive drug therapy in the pediatric age group are limited, adding further difficulty to decision making about drug treatment.

For these reasons, treatment recommendations by consensus organizations [5, 26] have been conservative, stressing that a definite indication for initiating pharmacologic therapy should be present before antihypertensive medication is prescribed in a child or adolescent. Appropriate indications are the following:

- Stage 2 hypertension
- Symptomatic hypertension
- Secondary hypertension
- Hypertensive target-organ damage
- Diabetes (types 1 and 2)
- Persistent hypertension despite non-pharmacologic measures

Most of the above indications represent situations in which BP reduction is likely to be of benefit in treatment of another condition: for example, reduction of BP in patients with chronic kidney disease has been shown to slow the rate of progression toward end-stage renal disease [48]. Only the final indication is somewhat unclear, as it is difficult to know how much of time is needed to see an effect of lifestyle changes. Based upon recent data by Litwin et al. [49], a period of up to 12 months of non-pharmacologic measures is probably sufficient to see a reduction in BP, so those patients whose BP does not fall by then should probably be considered for antihypertensive medications due to the risk of development of hypertensive target-organ damage. Repeat assessment for LVH and other cardiovascular risk factors may be helpful in determining how long to continue lifestyle measures alone.

Currently, little guidance exists as to what class of antihypertensive medication should be chosen as the initial agent in the pediatric age group. While adult clinical practice guidelines have clear recommendations based upon clinical trial evidence, a similar evidence base is lacking for pediatric patients. Clinical trials designed to compare different classes of antihypertensive agents have not yet been conducted in children. Until data are available to differentiate the advantages and disadvantages of different classes of antihypertensive medications in the young, several classes of agents, including diuretics, beta blocking agents, angiotensin-converting enzyme inhibitors (ACEi), angiotensin receptor blocker agents (ARB), and calcium channel blockers (CCB), may be considered as acceptable first-line agents. Medications from all of these classes have been recently studied in pediatric clinical trials [36], so there is some evidence available to guide dosing (Table 28.8).

There are some clinical situations in which specific classes of antihypertensive agents are indicated or possibly contraindicated. ACEi or ARBs are preferred in children with chronic kidney disease due to the beneficial effects of these drugs on slowing deterioration in renal function [48]. In hypertensive patients with the metabolic syndrome, the potential adverse effects of thiazide diuretics and some beta blocking agents on glucose metabolism should be kept in mind and alternatives considered as first-choice medication [50].

Adherence to drug therapy is important to consider in choosing an antihypertensive medication because most hypertensive children and adolescents are asymptomatic or have nonspecific symptoms that may not be ascribed to their elevated BP [19]. In adolescents, this is particularly difficult because they often do not remember to take their medications and do not like to be perceived as different from their peers. The likelihood of adherence will improve if BP control can be achieved with a single, once-daily agent. Adverse effects of the chosen drug should also be considered. Available combination preparations may improve compliance when more than one agent is needed to achieve the desired goal BP.

The "stepped-care" approach (Fig. 28.2) to use of antihypertensive medications in the young has been a recommended strategy for use of antihypertensive drugs in management of hypertension in children and adolescents [5].

Table 28.8 Suggested doses of antihypertensive medications for use in children

Class	Drug	Starting dose	Interval	Maximum dose[a]
Aldosterone receptor antagonists (ARAs)	Eplerenone	25 mg/day	QD–BID	100 mg/day
	Spironolactone[b]	1 mg/kg/day	QD–BID	3.3 mg/kg/day up to 100 mg/day
Angiotensin-converting enzyme (ACE) inhibitors	Benazepril[b]	0.2 mg/kg/day up to 10 mg/day	QD	0.6 mg/kg/day up to 40 mg/day
	Captopril[b]	0.3–0.5 mg/kg/dose	BID–TID	6 mg/kg/day up to 450 mg/day
	Enalapril[b]	0.08 mg/kg/day	QD	0.6 mg/kg/day up to 40 mg/day
	Fosinopril	0.1 mg/kg/day up to 10 mg/day	QD	0.6 mg/kg/d up to 40 mg/day
	Lisinopril[b]	0.07 mg/kg/day up to 5 mg/day	QD	0.6 mg/kg/d up to 40 mg/day
	Quinapril	5–10 mg/day	QD	80 mg/day
Angiotensin receptor blockers (ARBs)	Candesartan	1–6 years, 0.2 mg/kg/day; 6–17 years, < 50 kg 4–8 mg once daily > 50 kg 8–16 mg once daily	QD	1–6 years, 0.4 mg/kg; 6–17 years, < 50 kg 16 mg once daily, > 50 kg 32 mg once daily
	Losartan[b]	0.75 mg/kg/day up to 50 mg/day	QD	1.4 mg/kg/day up to 100 mg/day
	Olmesartan	20 to <35 kg 10 mg once daily; ≥35 kg 20 mg once daily	QD	20 to <35 kg 20 mg once daily ≥35 kg 40 mg once daily
	Valsartan[b]	6–17 years, 1.3 mg/kg/day up to 40 mg/day; <6 years, 5–10 mg/d	QD	6–17 years, 2.7 mg/kg/day up to 160 mg/day; <6 years, 80 mg/day
α- and β-adrenergic antagonists	Labetalol[b]	2–3 mg/kg/day	BID	10–12 mg/kg/day up to 1.2 g/day
	Carvedilol	0.1 mg/kg/dose up to 12.5 mg BID	BID	0.5 mg/kg/dose up to 25 mg BID
β-adrenergic antagonists	Atenolol[b]	0.5–1 mg/kg/day	QD–BID	2 mg/kg/day up to 100 mg/day
	Bisoprolol/ HCTZ	0.04 mg/kg/day up to 2.5/6.25 mg/day	QD	10/6.25 mg/day
	Metoprolol	1–2 mg/kg/day	BID	6 mg/kg/day up to 200 mg/day
	Propranolol	1 mg/kg/day	BID–TID	16 mg/kg/day up to 640 mg/day
Calcium channel blockers	Amlodipine[b]	0.06 mg/kg/day	QD	0.3 mg/kg/day up to 10 mg/day
	Felodipine	2.5 mg/day	QD	10 mg/day
	Isradipine[b]	0.05–0.15 mg/kg/dose	TID–QID	0.8 mg/kg/day up to 20 mg/day
	Extended-release nifedipine	0.25–0.5 mg/kg/day	QD–BID	3 mg/kg/day up to 120 mg/day
Central α-agonist	Clonidine[b]	5–10 mcg/kg/day	BID–TID	25 mcg/kg/day up to 0.9 mg/day
Diuretics	Amiloride	5–10 mg/day	QD	20 mg/day
	Chlorthalidone	0.3 mg/kg/day	QD	2 mg/kg/day up to 50 mg/day
	Furosemide	0.5–2.0 mg/kg/dose	QD–BID	6 mg/kg/day
	HCTZ	0.5–1 mg/kg/day	QD	3 mg/kg/day up to 50 mg/day
Vasodilators	Hydralazine	0.25 mg/kg/dose	TID–QID	7.5 mg/kg/day up to 200 mg/day
	Minoxidil	0.1–0.2 mg/kg/day	BID–TID	1 mg/kg/day up to 50 mg/day

BID twice daily, *HCTZ* hydrochlorothiazide, *QD* once daily, *QID* four times daily, *TID* three times daily
[a]The maximum recommended adult dose should never be exceeded
[b]Information on preparation of a stable extemporaneous suspension is available for these agents

Stepped care allows individualization of therapy and ongoing assessment of efficacy and adverse effects. Given the new FDA-approved pediatric labeling for many antihypertensive agents, most clinicians should be able to prescribe agents that are labeled for pediatric use.

Treatment goals for hypertensive children and adolescents should take into consideration the

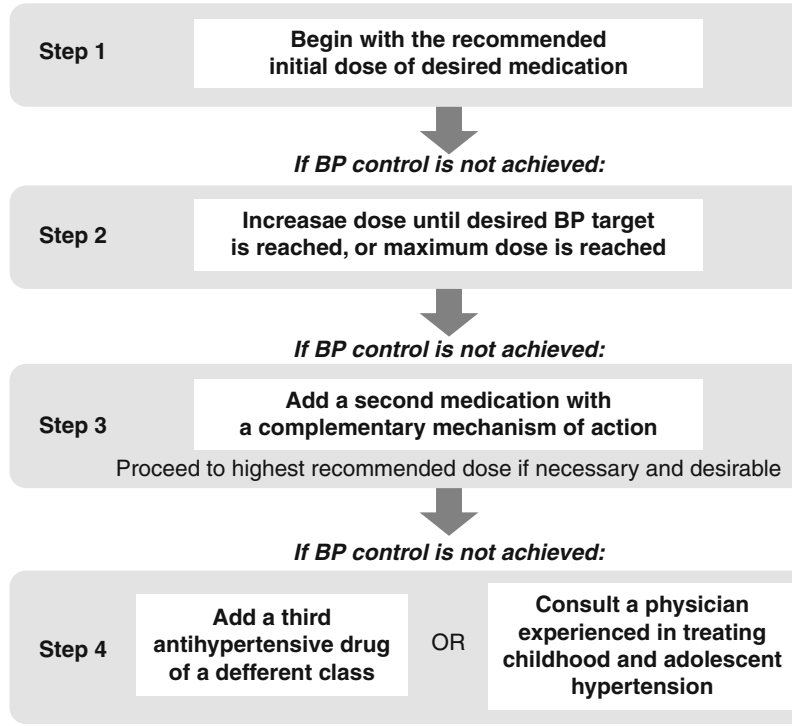

Fig. 28.2 Stepped-care approach to pharmacologic management of hypertension in adolescents

presence of concomitant disease [5]. For patients with uncomplicated primary hypertension and no hypertensive target-organ damage, goal BP should be <95th percentile for age, gender, and height, whereas for those with secondary hypertension, diabetes, or hypertensive target-organ damage, goal BP should be <90th percentile for age, gender, and height. These goals are consistent with current recommendations for therapy of hypertension in adults that recommend treatment to a lower BP goal in patients with complicated hypertension, such as those with diabetes or renal disease [7]. The European Society of Hypertension has recently issued updated guidelines for management of childhood hypertension that recommend an even lower goal of <75th percentile for patients with chronic kidney disease [26].

Treatment of hypertension requires follow-up at regular intervals to ensure that the desired BP goal has been reached, to assess adherence to therapy, and to monitor for medication-related adverse effects. Hypertensive children and adolescents can be encouraged to monitor their BP at home using an appropriate device in order to increase their involvement in treatment and hopefully improve compliance. Similarly, continuation of non-pharmacologic measures should be encouraged, as these will help to achieve and maintain BP control.

Selected laboratory studies should be obtained periodically, especially fasting lipids and glucose in obese adolescents, and electrolytes/BUN/creatinine in those treated with diuretics, ACEi, or ARBs. Adolescent girls receiving ACEi or ARBs should receive ongoing counseling to avoid pregnancy and to use effective contraception if sexually active, due to the risks for fetal damage associated with these drugs [51].

Hypertension in Infancy

BP in infancy varies according to body size, gestational age, and postconceptual age, among other factors, and few studies have been conducted to develop normative BP data, so there is no generally accepted BP level to define hypertension, especially in neonates.

Dionne et al. [52] have recently summarized the scant available data and have proposed BP levels that could be used to define hypertension in this age group. There are also some normative data available from the Second Task Force Report [53] that should be useful for infants from 1 to 12 months of age, although these older BP values differ somewhat from those for 1-year-olds in the more recent Fourth Report [5], further emphasizing the need for additional studies in this age group.

The actual incidence of hypertension in neonates is very low, ranging from 0.2 % in healthy newborns to between 0.7 % and 2.5 % in high-risk newborns [52]. Certain categories of infants are at significantly higher risk, however, including neonates with a history of umbilical artery catheterization, those who suffered acute renal failure in the neonatal intensive care unit (NICU), or those with chronic lung disease [54]. Generally, those infants with more difficult NICU courses, and those with persistent pulmonary problems, will be more likely to develop hypertension requiring intervention.

The differential diagnosis of hypertension in neonates and older infants is wide ranging (Table 28.9) and has been reviewed in detail by Dionne et al. [52]. The most important categories include renovascular disease (most commonly umbilical-artery-related aortic or renal thromboembolism) renal parenchymal disease, and bronchopulmonary dysplasia. The most common cardiac cause is coarctation of the thoracic aorta, in which hypertension may persist or recur after surgical repair [55].

Investigation of hypertensive infants should proceed in a similar fashion to evaluation of older children with hypertension. There is some variability between upper and lower limb BPs in neonates, so it is important to be consistent in choice of extremity for BP measurement. A thorough review of the infant's history and a focused physical examination should point to the underlying cause in most cases. Selected laboratory studies should be obtained as indicated. Renal ultrasonography is particularly useful and should always be obtained given the preponderance of renal causes (Table 28.9).

Table 28.9 Differential diagnosis of hypertension in infancy

Renovascular	*Medications/ intoxications*
Thromboembolism	Infant
Renal artery stenosis	Dexamethasone
Mid-aortic coarctation	Adrenergic agents
Renal venous thrombosis	Vitamin D intoxication
Renal artery compression	Theophylline
Abdominal aortic aneurysm	Caffeine
Idiopathic arterial calcification	Pancuronium
Congenital rubella syndrome	Phenylephrine
	Maternal
Renal parenchymal disease	Cocaine
Congenital	Heroin
Polycystic kidney disease	*Neoplasia*
Multicystic-dysplastic kidney disease	Wilms tumor
Tuberous sclerosis	Mesoblastic nephroma
Ureteropelvic junction obstruction	Neuroblastoma
Unilateral renal hypoplasia	Pheochromocytoma
Primary megaureter	*Neurologic*
Congenital nephrotic syndrome	Pain
Acquired	Intracranial hypertension
Acute tubular necrosis	Seizures
Cortical necrosis	Familial dysautonomia
Interstitial nephritis	Subdural hematoma
Hemolytic-uremic syndrome	*Miscellaneous*
Obstruction (stones, tumors)	Total parenteral nutrition
Pulmonary	Closure of abdominal wall defect
Bronchopulmonary dysplasia	Adrenal hemorrhage
Pneumothorax	Hypercalcemia
Cardiac	Traction
Aortic coarctation	ECMO
Endocrine	Birth asphyxia
Congenital adrenal hyperplasia	
Hyperaldosteronism	
Hyperthyroidism	
Pseudohypoaldosteronism type II (Gordon syndrome)	

Therapy of neonatal hypertension should be tailored to the severity of the hypertension and the infant's overall clinical status. For example, critically ill infants with severe hypertension should be treated with an intravenous agent administered by continuous infusion in order to control the rate and magnitude of BP reduction. On the other hand, relatively well infants with mild hypertension may be treated with oral antihypertensive agents. In the latter group, it can be quite difficult to decide when to initiate drug treatment [52].

The legislative initiatives that have increased data on pediatric drug efficacy and safety have not resulted in trials conducted in infants, so the choice of antihypertensive medications for use in neonates relies even more heavily on the experience of the individual practitioner than in older children. This is highlighted by a recent study demonstrating that although relatively few neonates receive antihypertensive medications, a wide variety of agents are employed in NICUs [56]. Suggested medication dosing and more detailed guidance on use of antihypertensive medications in infancy have recently been published [52, 57].

Conclusions

Hypertension and prehypertension together represent a common childhood health problem. The prevalence of childhood hypertension has increased in recent years, primarily as a consequence of the childhood obesity epidemic. Key steps in the management of children and adolescents with hypertension include first verifying the hypertension and then conducting an evaluation to distinguish primary from secondary hypertension. The medical evaluation also includes an evaluation for other cardiovascular risk factors and for evidence of target-organ damage. Lifestyle changes in diet, physical activity, and weight control are appropriate for all children and adolescents with high BP. Selected hypertensive children and adolescents may benefit from drug treatment, although additional data are needed on the long-term benefits and risks of antihypertensive medications in the young.

Obesity, Metabolic Syndrome and Type 2 Diabetes

29

Julia Steinberger and Aaron S. Kelly

Abstract

Atherosclerotic cardiovascular disease (ASCVD) begins within the first two decades of life, and the process is accelerated in the presence of risk factors. Obesity, metabolic syndrome (MetS), and type 2 diabetes mellitus (T2DM) are among the most prominent risk factors associated with ASCVD in childhood and adolescence. The dramatic increase in pediatric obesity over the last 40 years has been accompanied by more frequent reports of the MetS and its component cardiometabolic risk factors in children. Moreover, the increased prevalence of T2DM has occurred in parallel with the rapid rise in the prevalence of childhood obesity rates, suggesting that adiposity may be a primary culprit. The strong association of childhood obesity with cardiometabolic risk factor clustering and its tracking into adulthood is among the reasons that the current obesity epidemic with its relationship to future ASCVD and T2DM is considered to be one of the most important public health challenges in modern-day society. Emerging evidence suggests that the proper identification of at-risk youth and appropriate intervention early in life may reduce the risk of developing premature ASCVD and T2DM. Although the field of pediatric preventive medicine is still in its infancy, research in this area will be critically important to the future health of generations to come.

Introduction

It is now well known that the process of ASCVD begins early in life and is accelerated in the presence of risk factors such as hypertension, dyslipidemia, obesity, and insulin resistance. Since childhood adiposity is associated with multiple ASCVD risk factors, current obesity trends suggest a grim outlook for the future cardiovascular health of the current generation of youth. In particular, a shift toward severe obesity may greatly increase the risk of adverse cardiovascular outcomes earlier in life than would normally be expected. In parallel with the rapid rise in the prevalence of pediatric obesity rates, the prevalence of MetS and T2DM also has increased steadily, threatening to undo the progress that has been made in reducing cardiovascular morbidity and mortality over the last few decades. Obesity, a condition that tracks strongly from childhood to adulthood, predisposes individuals to developing the MetS and T2DM. The MetS is a clustering of risk factors including obesity, hypertension, dyslipidemia, and hyperglycemia/insulin resistance. Although MetS has been well established in adults and there is general agreement about the construct of MetS in childhood, there is currently no consensus definition for children and adolescents. T2DM, traditionally considered a disease of adult onset, has become much more prevalent in children and adolescents. Youth with T2DM are more likely to have subclinical atherosclerosis compared to healthy peers, and although no long-term data currently exist, a diagnosis of T2DM in childhood is likely to greatly increase the risk for premature ASCVD. In this chapter, the epidemiology and pathophysiology of obesity, MetS, and T2DM will be reviewed. Particular emphasis is given to the association of these conditions with early development of ASCVD.

Obesity

Obesity is arguably the most pressing public health problem in industrialized societies. Of great concern is the threat that obesity poses to the future health of the current generation of children since the pediatric population is not immune to its effects. Indeed, over the last 30 years, the prevalence of childhood obesity has dramatically increased. Current estimates suggest that 32 % of children and adolescents in the United States are overweight and 16 % are obese [1]. Overweight and obesity in youth is defined by sex- and age-adjusted percentiles for body mass index (BMI), a ratio of weight to height (kg/m^2). BMI $\geq$85th–$<$95th percentile is considered overweight and BMI $\geq$95th percentile is considered obesity [2]. The BMI percentiles for these classifications were derived from decades-old normative pediatric height/weight data when the distribution of BMI values was relatively static [3]. Online BMI calculators, such as the one offered by the Centers for Disease Control and Prevention, provide a convenient way to determine BMI values and the associated percentiles in children and adolescents (http://apps.nccd.cdc.gov/dnpabmi/Calculator.aspx). BMI Z-score is also used to define pediatric overweight and obesity. The BMI Z-score reflects the distance from the mean BMI of the population in terms of standard deviation units and is considered a good way to compare the relative BMI rank across a wide range of ages throughout childhood and adolescence.

Most children do not outgrow their excess adiposity, and robust longitudinal evidence has shown that obesity tracks strongly from childhood into adulthood [4, 5]. The public health and economic implications of childhood obesity are serious, especially considering that the rise in prevalence of childhood obesity has

paralleled the increase in pediatric T2DM and the fact that obesity in childhood predicts T2DM and premature ASCVD in adulthood. Largely due to obesity, the lifespan of the current generation of children may be shorter than previous generations [6], and the costs associated with obesity and its comorbidities will place significant strains on healthcare and economic systems [7].

Pediatric obesity is associated with ASCVD [8–10], T2DM [11, 12], and premature death [13, 14]. As further described in the section on MetS, overweight and obese youth have higher levels of blood pressure, triglycerides, insulin resistance, and inflammation, as well as lower levels of HDL cholesterol compared to normal weight children and adolescents [15, 16]. Evidence suggests that the process of ASCVD begins in childhood. Subclinical pathological arterial changes have been shown to begin within the first two decades of life. Obese children and adolescents have impaired endothelial function, higher levels of arterial stiffness, and thicker carotid arteries compared to normal weight controls [17–19]. Autopsy studies have shown early signs of atherosclerosis in the aorta and coronary arteries in adolescents and young adults. Furthermore, fatty streaks and advanced atherosclerotic plaque lesions have been shown to be associated with dyslipidemia, hypertension, and obesity during childhood and adolescence [20–22]. Moreover, longitudinal data uniformly implicate obesity in childhood as a strong predictor of future risk factor clustering and vascular abnormalities in adulthood (e.g., increased carotid artery intima-media thickening) [23, 24]. Childhood BMI has been shown to predict adult ASCVD and T2DM at least as strongly as childhood MetS [25].

Although childhood obesity rates appear to have reached a plateau in the last 5–10 years, recent data suggest that severe pediatric obesity, defined as an age- and gender-specific body mass index (BMI) $\geq$1.2 times the 95th percentile or BMI $\geq$ 35 kg/m^2, is an emerging problem [26]. Severe obesity is the fastest growing category of obesity in youth – the prevalence has increased 300 % since 1976 and over 70 % since 1994. Recent estimates suggest that up to 7 % of children and adolescents (ages 2–19 years old) are afflicted with severe obesity [27]. The number and levels of ASCVD risk factors are considerably higher in severe pediatric obesity compared with milder forms of obesity [5]. The percentage of severely obese youth with MetS has been reported to be over two times higher (31 %) than moderately obese (12 %) children and adolescents. Severe pediatric obesity is associated with endothelial activation and damage [28] and with elevated levels of inflammation and oxidative stress [29]. In fact, subclinical atherosclerosis and arterial stiffening in the carotid artery is present in severely obese youth at levels similar to peers with T2DM [30]. Severe obesity in childhood is strongly associated with the future development of T2DM [11, 12, 31–33], and tracking of obesity is particularly strong in this group as approximately 90 % of severely obese youth will have a BMI $\geq$ 35 kg/m^2 in adulthood [5].

Metabolic Syndrome

ASCVD, the number one cause of death in the adult population of Western societies [34], is strongly associated with the MetS. The term metabolic syndrome (MetS) has been proposed to describe the association among obesity, insulin resistance, hypertension, dyslipidemia, T2DM, and ASCVD (Fig. 29.1). In adults, the definition of MetS varies in terms of the indicators featured and the cut points used [35, 36]. Most commonly used in adults are the criteria proposed by the Third Report of the National Cholesterol Education Program Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III [ATP III]) [35] and a more recent consensus report of multiple international organizations [37], based on central obesity (waist circumference), high blood pressure, high triglycerides, high glucose and low HDL cholesterol. Nonetheless, the clinical utility of MetS above and beyond its individual components continues to be the subject of vigorous debate [38, 39]. A recent meta-analysis of prospective studies concluded that the MetS

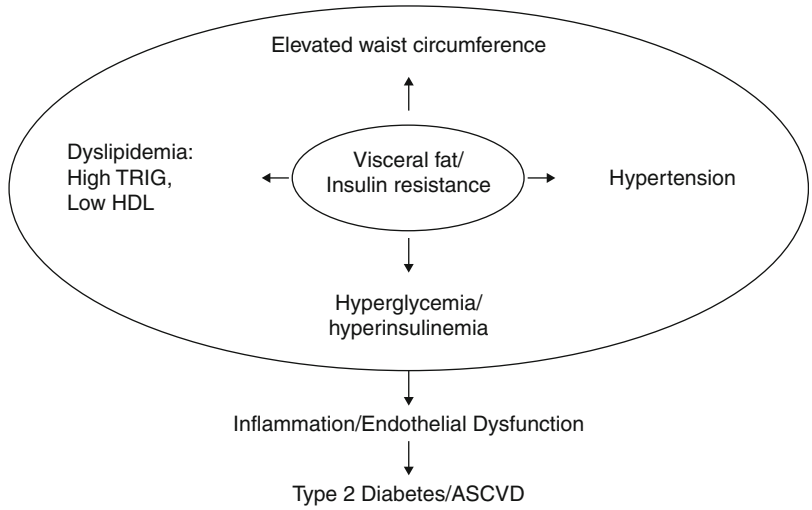

Fig. 29.1 A model of metabolic syndrome and its presumed precursors and consequences

does indeed increase the risk of developing ASCVD and that the MetS was a predictor of cardiovascular events even after adjustment for the individual components of the syndrome [40]. However, other studies suggest that the Framingham Risk Score is a better predictor of incident ASCVD than the MetS [41, 42].

The increasing prevalence of pediatric obesity has led to an intensive effort to identify youth at risk for development of ASCVD and T2DM. In the pediatric literature, a number of attempts have been made to characterize the MetS or related constructs with a meaning similar to the adult MetS [43–45]. Barriers to a consistent, accepted definition for children and adolescents include the use of adult cut points or a single set of cut points for all ages throughout childhood, the fact that disturbances seen in the metabolic indicators in most children are quantitatively moderate, the lack of a normal range for insulin concentration across childhood, the physiological insulin resistance of puberty, the lack of central obesity (waist) cut points linked to obesity morbidity or MetS for children, the differences in baseline lipid levels among various races, and the lack of stability over time for the different proposed definitions [46]. Despite lack of agreement on a formal definition, the link between childhood obesity, abnormal lipids, hypertension, insulin resistance, and adult ASCVD risk is well known. Moreover, there is ample evidence from cross-sectional and longitudinal studies that the clustering of these obesity-related risk factors continues into adulthood [25, 47–49].

An important epidemiologic aspect of cardiovascular risk in children is the tracking of risk factors. Tracking indicates the likelihood that children will maintain their percentile ranking for specific risk factors over time. Most components of the MetS track relatively modestly from childhood into adulthood. Of all the MetS components, childhood obesity is the strongest predictor of subsequent obesity, insulin resistance [6], and abnormal lipids in adulthood [5]. Moreover, the rate of increase in adiposity during childhood has been significantly related to the development of components of the MetS risk in young adults [10], whereas the decline of adiposity between childhood and adulthood significantly improved these factors [50]. Tracking has also been demonstrated for lipid and lipoprotein concentration in a number of studies, most notably the Muscatine Study [51, 52] and the Bogalusa Heart Study [53]. In the Muscatine Study, 75 % of school-aged children who had total cholesterol concentrations greater than the 90th percentile at baseline had total cholesterol concentrations of >200 mg/dL in their early 20s. In the Bogalusa Heart Study, approximately 70 % of the children with elevated cholesterol levels continued to have cholesterol elevations in young adulthood. Because of the strong correlation

between weight and blood pressure, excessive weight gain is likely to be associated with elevated blood pressure over time. Therefore, maintenance of normal weight gain in childhood should lead to less hypertension in adulthood. Blood pressure levels also have been shown to track from childhood through adolescence and into adulthood [54, 55] in association with weight [56, 57], and weight loss in overweight adolescents is associated with a decrease in blood pressure [58, 59] and other cardiovascular risk factors such as dyslipidemia and insulin resistance [60]. There is strong clinical and epidemiologic evidence that childhood obesity is associated with ASCVD risk factors and is at the core of the adult MetS, and that weight loss can improve all the components of the cardiovascular risk profile.

Type 2 Diabetes Mellitus

Although T2DM in childhood and adolescence is relatively rare (extremely rare in children <10 years old and only 0.18/1,000 in youth ages 10–19) [61], the consequences are profound. Traditionally viewed as a disease of adult onset, it has become apparent that the foundation of T2DM is laid in childhood and that obesity and physical inactivity increase the risk. Indeed, the rising prevalence of overweight and obesity in youth has coincided with the increasing prevalence of T2DM [62]. Current projections are that approximately 1/3 of children born today will develop T2DM in their lifetime [63]. Evidence also suggests that the risk of developing this disease greatly increases with increasing BMI [64]. In adults, T2DM is considered a coronary risk equivalent, meaning that individuals with T2DM are at similar risk for adverse ASCVD events as those with preexisting ASCVD [65]. The precise long-term implications for youth who develop T2DM are not fully known. However, it stands to reason that the higher cumulative lifetime exposure to the disease and associated comorbidities, compared to those who develop T2DM in adulthood, portends very poor outcomes. Moreover, the economic strain of pediatric T2DM will become more prominent in the decades to come since T2DM is one of the most expensive chronic diseases to manage.

Most youth with T2DM are obese and have an elevated waist circumference, suggesting a strong association between adiposity and development of the disease [61]. In addition, genetic predisposition is a strong predictor since approximately 80 % of youth with T2DM have a family history of the disease [61]. Although multifactorial and complex, the pathophysiology of T2DM is primarily characterized by peripheral insulin resistance (primarily in skeletal muscle and to a lesser extent in adipocytes) and pancreatic β-cell dysfunction/failure. In combination, these core defects lead to progressive hyperglycemia. In healthy individuals, insulin suppresses hepatic glucose production and promotes the uptake, utilization, and storage of glucose by the liver and peripheral tissues [66]. However, defects in insulin signaling can lead to insulin resistance and eventual compensatory hyperinsulinemia, which can take the form of insulin hypersecretion or reduced insulin clearance. If the pancreas can adequately compensate for insulin resistance by increasing insulin levels, blood glucose concentrations remain normal. However, in some individuals, the capacity of the β-cell erodes over time [67], leading to eventual β-cell failure and subsequent T2DM. Alarmingly, some evidence suggests that the transition from prediabetes to T2DM may be accelerated during adolescence due to the naturally occurring increase in insulin resistance midway through pubertal development (i.e., Tanner stage 3) [32, 68]. Prior to the development of frank T2DM, some children and adolescents exhibit impaired glucose tolerance (IGT), a condition characterized by postprandial hyperglycemia and/or impaired fasting glucose (fasting glucose levels ≥100–<126 mg/dL).

Evidence suggests that insulin resistance may be independently associated with cardiovascular risk in children and adolescents. Fasting insulin levels in 6- to 9-year-old children predicted blood pressure at age 9–15 years [69], and in 5- to 9-year-old Pima Indian children, fasting insulin was associated with the level of weight gain during the subsequent 9 years of childhood [70].

The Bogalusa Heart Study has shown strong associations between persistently high fasting insulin levels and the development of cardiovascular risk factors in children and young adults [71]. In studies of insulin resistance in childhood using the hyperinsulinemic euglycemic clamp (the gold standard technique for measurement of insulin sensitivity), an important independent association of both adiposity and insulin resistance with increased cardiovascular risk factors was shown, as well as an interaction between adiposity and insulin resistance, so that the presence of both was associated with a level of cardiovascular risk greater than that expected with either adiposity or insulin resistance alone [16].

The most commonly reported ASCVD risk factors in pediatric T2DM include elevated blood pressure, triglycerides, and low levels of HDL cholesterol [61], all components of the MetS. The fact that the risk factor profile in pediatric T2DM is similar to that found in obesity and MetS is not surprising considering that most children and adolescents with T2DM are obese and insulin resistant. Beyond increased levels of traditional ASCVD risk factors, youth with T2DM demonstrate myocardial and vascular abnormalities compared to healthy controls. In particular, pediatric T2DM is associated with reduced brachial artery endothelial function [72], increased peripheral and regional arterial stiffness (measured by pulse wave velocity and carotid/brachial artery distensibility) [73], intima-media thickening in the carotid artery [30, 72], and abnormal cardiac geometry and diastolic dysfunction [74]. Together, these findings suggest that the atherosclerotic process is well underway in youth with T2DM and that aggressive management of ASCVD risk factors is likely to be warranted to minimize the potential for profound cumulative arterial damage over time. A major ongoing intervention study, the "treatment options for type 2 diabetes in adolescents and youth" trial, will soon be completed. This trial is evaluating whether aggressive reduction in insulin resistance early in the clinical course of T2DM will lead to better glycemic control and an improvement in the cardiovascular risk profile in youth with T2DM [75, 76]. Treatment arms include a family-based comprehensive lifestyle modification program and two pharmacologic therapies: metformin and rosiglitazone. Although this study will provide important and useful information, more research will be needed to evaluate the effect of various ASCVD risk factor treatment strategies on vascular structure and function since prevention of adverse cardiovascular outcomes should be a primary goal in these youth.

Hypercholesterolemia and Dyslipidemia

30

Elizabeth Yeung and Robert Eckel

Abstract

Cardiovascular disease (CVD) is a process that begins in children and is a major cause of morbidity and mortality in adults. The pathologic findings include lipid deposits and inflammation in the arterial wall. Strong correlations between CVD risk factors, including dyslipidemias in childhood, have been made with atherosclerosis. The recent obesity epidemic and increased prevalence of metabolic syndrome in children and adolescents reflect the prevailing pattern of high triglycerides and low HDL seen in this population. Appropriate identification of dyslipidemias in children and treatment may help reduce their CVD risk as adults.

Introduction

Ischemic CVD, including heart disease and stroke, is the most common cause of mortality in the world [1]. Premature CVD is considered an event prior to the age of 55 in men and before age 65 in women. Although the presentation of disease is typically in late adulthood, it is believed that this process starts at a young age, possibly even in utero.

A number of risk factors can contribute to the development of atherosclerosis, many of which can be affected by lifestyle. Some of these risk factors include age, gender, family history, obesity, hypertension, metabolic syndrome, and lipid levels. There is tremendous potential to intervene as early as childhood to alter some of these risk factors and, hopefully, offset CVD later on in life. Some elements, such as family history, cannot be altered. Familial hypercholesterolemia (FH) is a monogenic form of dyslipidemia that is associated with increased risk of cardiovascular disease. The most striking example is seen in individuals with homozygous hypercholesterolemia. In these patients, LDL cholesterol (LDL-C) levels are extremely elevated and coronary events begin as early as the first decade. Patients with FH typically experience abbreviated life spans. Other dyslipidemias may be primarily related to diet and lifestyle, but most will be multifactorial in nature, influenced by genetic makeup as well as environment. Understanding these complex disorders is paramount for early recognition, intervention, and pharmacologic treatment, if necessary, with the goal of reducing CVD risk in adulthood.

Atherosclerosis

Early studies include autopsy examination of young soldiers killed in the Korean and the Vietnam War [2, 3]. The mean age of these men at death was 22 years in both series. The results were surprising in that 45–77% of the men were found to have early atherosclerotic disease, without clinical symptoms. Since then, there has been evolution in identifying coronary artery disease prevalence, progression, and risk factors. One of the early pathologic findings of atherosclerosis, fatty streaks, has been demonstrated in fetal life [4]. Based on an autopsy study, Napoli et al. were able to demonstrate aortic fatty streaks in developing fetuses. They showed a high prevalence of lesions, upwards of 63% in the normocholesterolemic mothers. Larger plaques correlated with a long-standing history of hypercholesterolemia in the mothers and an intermediate correlation with mothers who had high cholesterol only during the pregnancy. There are some data to suggest that these individuals have a higher rate of progression of atherosclerotic disease later in life, despite having a normal cholesterol level [5].

There have been a number of community-based longitudinal studies that have helped to clarify the atherosclerotic process and identify risk factors for early CVD in children and young adults. These include the Pathological Determinants of Atherosclerosis in Youth (PDAY), Bogalusa Heart Study, and Muscatine Study, many of which involve autopsy studies from young people dying from accidents or homicide (See Table 30.1). Fatty streaks in the aorta have been found in a large percentage of children, increasing throughout puberty and into early adulthood [6]. Early lesions also occur within the coronary vessels around the time of puberty, again increasing in extent with age.

Pathology of Atherosclerosis

The earliest histologic changes in the development of atherosclerosis have been characterized into types I, II, and III lesions [16]. These are the precursors to more advanced lesions, which predispose to ischemic events. Type I consists of macrophage foam cells (macrophages with lipid droplets), in the intima without intimal disruption. These typically cannot be seen with the naked eye. Type II includes fatty streaks. These lesions not only have lipid droplets in macrophages, but they also appear in the surrounding smooth muscle cells. Foam cells are seen in adjacent layers, as well as an increased number of macrophages.

Table 30.1 Historical studies identifying cardiovascular risk factors in young people

DAY – Pathological Determinants of Atherosclerosis in Youth [7–10]	*Age 15–34, death from accidental causes*	*Presence of fatty streaks and fibrous plaques associated with elevated cholesterol levels and BP*
		VLDL-C and LDL-C are associated with fatty streaks and raised lesions
		HDL-C is negatively associated with fatty streaks and raised lesions
		Smoking was associated with a threefold increase in presence of lesions
		BMI in men was associated with an increase in lesions
		High BP, hyperglycemia, and age increased risk
Bogalusa Heart Study [11, 12]	Ongoing since 1972 in Bogalusa, LA, biracial, semirural community, from birth now up to age 45	Atherosclerosis, HTN, and CAD begins in childhood
		Extent of fatty streaks and fibrous plaques increases with age. Present as early as 2 y.o.
		Prevalence of fatty streaks in aorta near 70 % in childhood
		Increase in aortic fatty streaks with high LDL-C and high cholesterol; increase fatty streaks in coronaries with high VLDL-C
		Smoking correlates with increase in fibrous plaques
		Severity increased with presence of multiple risk factors (obesity, BP, cholesterol, TG, LDL-C, HDL-C, cigarette smoking)
		http://tulane.edu/som/cardiohealth/index.cfm
Cardiovascular Risk in Young Finns Study [13]	>4,000 Finnish children in 1980 with follow-up studies every 3 years with ~65 % f/u rate after 21 years	CVD risk status (obesity, BP, LDL-C, HDL-C, smoking) in young adults is predictive of increased carotid artery intima media thickness in adulthood, independent of risk factors for CVD present in adulthood (*only seen in 12–18 age group; in age 3–9, there was a weak association in males only)
Muscatine Study [14, 15]	Muscatine, Iowa	Coronary calcification found in age 29–37-year-old males, related to increased weight, BMI, and TG in childhood
	School survey 1971–1981 (age range 8–18), with young adult f/u surveys (age 20–34)	Increased carotid IMT in 33–42-year-olds correlated with elevated BP, cholesterol during childhood
Framingham Study	1948, Started in adult population up to third and fourth generation f/u	Identification of major CVD risk factors, primarily in adults
		http://www.framinghamheartstudy.org/about/milestones.html

In type III lesions, the collection of lipid droplets begins to disrupt the intimal smooth muscle layer. The first advanced stage, type IV, is the atheroma and consists of a lipid core, intimal disruption, and deformation of the arterial wall.

The initiation of plaque formation is a complex process. The mechanisms responsible for the injury include (1) inflammatory response to injury. Injury to the endothelial tissue may occur from oxidized LDL (see LDL section), free radicals,

or infectious agents. The inflammatory response causes smooth muscle migration and proliferation from the media to the intimal layer, causing smooth muscle cell accumulation. If the inflammation is an ongoing process, this may lead to thickening of the artery wall followed by dilatation. Activation of macrophages and lymphocytes can start a cascade of hydrolytic enzymes, ultimately leading to necrosis of the area; (2) platelet/fibrin deposits on the intima which release mitogens; and (3) high concentrations of atherogenic lipoproteins and mechanical forces that keep the particles in the area for a longer period of time. Lipoproteins become trapped in the intima, where they are then modified. The Korean/Vietnam War studies which showed a predilection for lesions to occur at branching points of the coronary artery vessels, suggesting that turbulence of blood flow may be an important etiologic factor.

Lipid Metabolism

Lipids are important biochemical molecules involved in cellular membrane content, stability, and permeability in all cell types, steroid synthesis, biliary function, and in neuronal development. Most of the cholesterol is synthesized at the cellular level, but cholesterol in the diet can also be utilized. The recommended dietary intake is about 200–300 mg a day, with the body producing about 1,000 mg daily. There are biofeedback mechanisms that help regulate the cholesterol synthesis according to intake. The bulk of cholesterol synthesis occurs in the liver but can also take place in the adrenal glands, intestines, and reproductive organs. Cholesterol is produced de novo from acetyl coA within the cell cytoplasm. The rate-limiting step in the biochemical pathway of cholesterol synthesis is HMG-CoA reductase (see Fig. 30.1). The mechanisms that contribute to the cholesterol pool within the liver include de novo synthesis; receptors for LDL, VLDL, and chylomicron remnants; as well as receptors for HDL. There is constant efflux of cholesterol from tissues to the liver for excretion, with about 70% of LDL clearance occurring within the liver. Once internalized into the intrahepatic cholesterol pool size that includes cholesteryl esters, cholesterol can then be converted to bile acids, directly excreted into the bile or be secreted in lipoproteins, i.e., VLDL and nascent HDL. Any alteration in the cholesterol pool can affect the above processes (see Fig. 30.2).

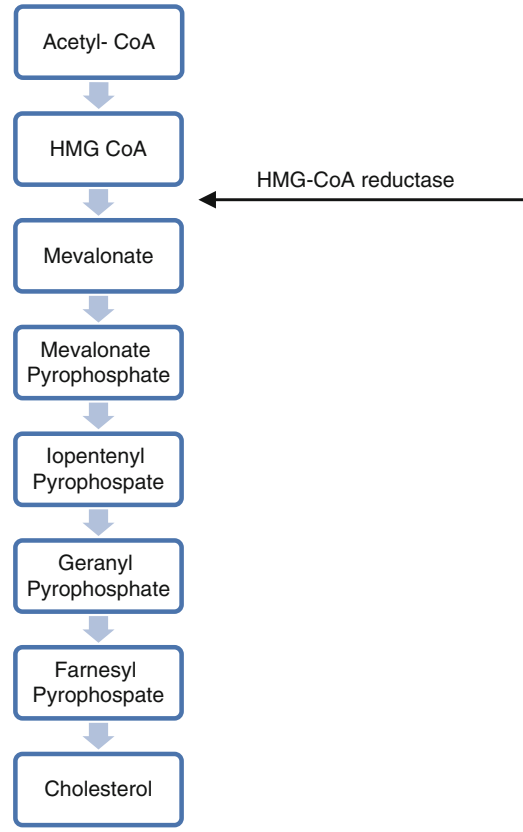

Fig. 30.1 Biochemical pathway of cholesterol synthesis

Dietary cholesterol is transported from the intestines to the systemic circulation in the form of chylomicrons. Excess cholesterol and triacylgylcerols in the liver from exogenous and endogenous sources are packaged into VLDL and secreted from the liver. VLDL is converted to LDL after the release of fatty acids by lipoprotein lipase. Fatty acids can then be used as an energy source. LDL can bind to peripheral tissues to be used intracellularly or return to the liver via the LDL receptor. Excess cholesterol in

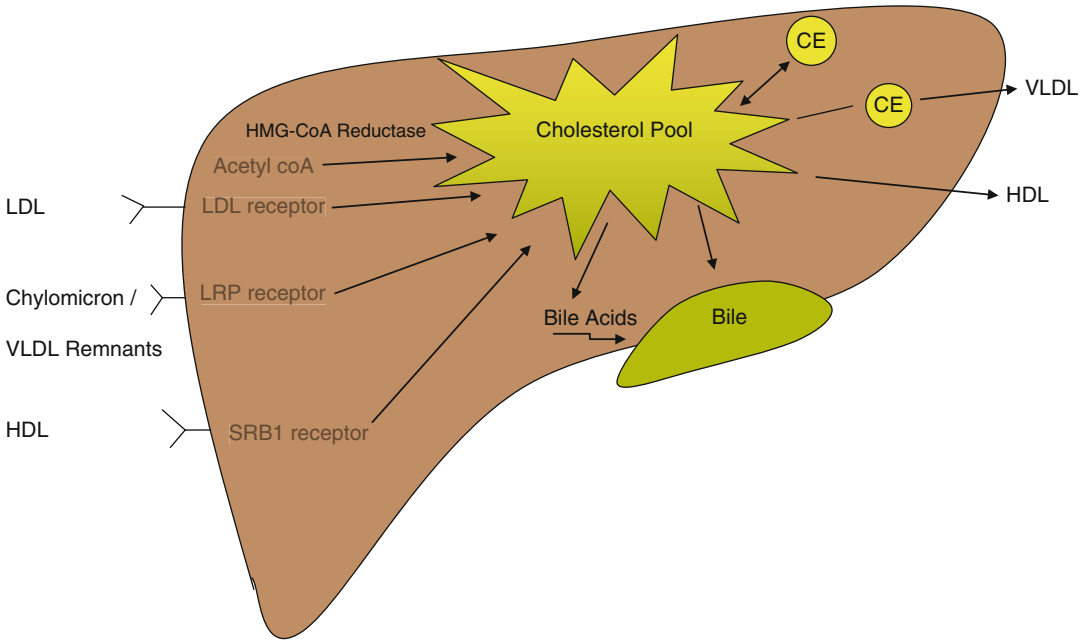

Fig. 30.2 Cholesterol homeostasis. The cholesterol pool within the liver is in a constant state of flux. The elements that contribute to the pool include de novo synthesis from acetate of which HMG-CoA reductase is the limiting step, return via LDL, chylomicron and VLDL remnants, and HDL through their respective receptors. Cholesterol in the liver can then be converted to bile salts and/or excreted in bile unchanged. 95 % of bile will be reabsorbed in the intestines to aid in digestion and will ultimately return to the liver. This is called the enterohepatic circulation. Cholesterol esters (long-chain fatty acids linked to the hydroxyl group) are much less polar than free cholesterol and is the preferred form of transport in the plasma. Free cholesterol also leaves the liver in the form of primitive HDL. *LRP* LDL-related protein, *SRB1* scavenger receptor B1, *CE* cholesterol ester

peripheral tissues can be reverse transported by HDL and transferred back to LDL/VLDL via CETP (cholesterol esterase transfer protein). As already noted, cholesterol returning to the liver can then be excreted in bile or transformed to bile salts (see Figs. 30.3 and 30.4)

Clinical Recommendations and Screening

In 2011, new guidelines were released from the Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents [17]. The expert review continued to support a population approach to treat adult CVD. This is largely based on the aforementioned longitudinal studies that collectively demonstrated CVD risk factors present in the pediatric population, namely, obesity, tobacco use, elevated total cholesterol, systolic hypertension, and low HDL-C levels. As these risk factors track into adulthood, it is reasonable to utilize primary prevention, starting in childhood.

New dietary guidelines released in 2010 (Dietary Guidelines for Americans) [18] replace the 1992 National Cholesterol Education Program (NCEP) report. The guidelines are based on nutrient and energy requirements, targeting obesity and CVD risk reduction. These guidelines are for children aged 2 years and older. Given the safety and efficacy in reducing cholesterol with a 30% upper limit, the expert panel recommends the "CHILD-1," diet summarized below:

- Total caloric intake should be sufficient to support normal growth and development and maintain a desirable body weight.
- Total fat should provide 25–30% of calories for children aged 2–18.

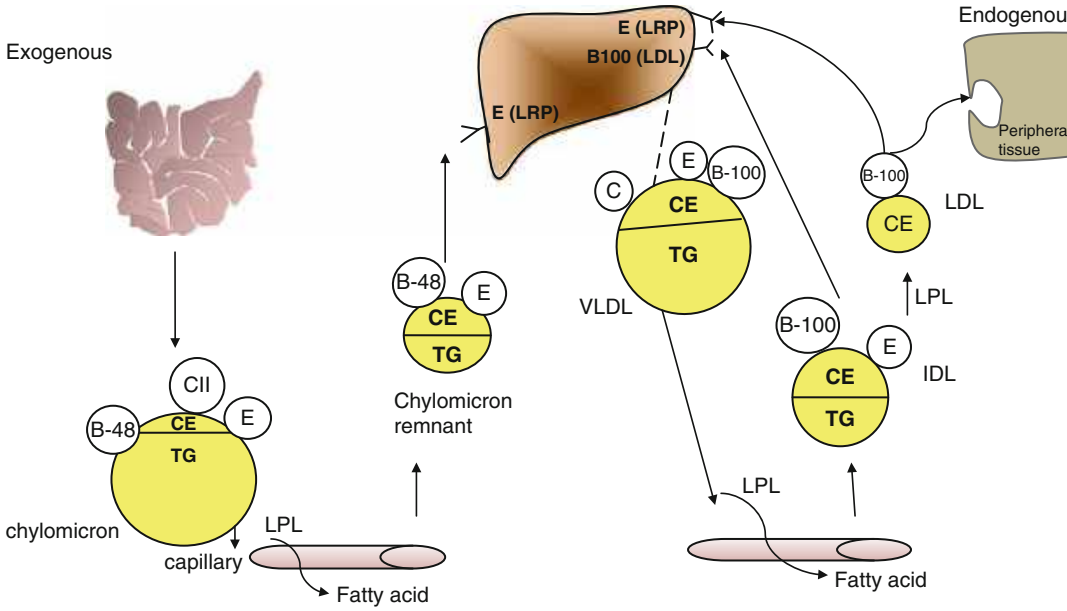

Fig. 30.3 B48 is the primary apolipoprotein associated with chylomicrons. ApoB48 is truncated ApoB100 (48 % of ApoB100, controlled by an editing enzyme in the intestine). Dietary TG are modified in the intestinal cells and packaged into chylomicrons. In peripheral tissue, they are hydrolyzed by lipoprotein lipase (LPL), releasing free fatty acids and yielding chylomicron remnants. Chylomicrons are not recognized by the LDL receptor. Instead, the remnants are taken up by the liver by the LDL-related protein (LRP), which recognizes ApoE. Excess triglycerides in the liver are packaged into VLDL. Apolipoprotein B100 is associated with VLDL and LDL. VLDL is also hydrolyzed in peripheral tissues, releasing fatty acids, yielding remnant particles. These particles can further be degraded to LDL. Both LDL and VLDL are taken up by the liver when the LDL receptor recognizes B100. Alternatively, LDL particles may be endocytosed into peripheral cells for use

- Saturated fats should provide 8–10% of calories.
- Cholesterol should be limited to less than 300 mg/day.
- Limit sodium.
- Limit sugar-sweetened beverages and 100% fruit juice.
- 15–20% of calories from protein and 50–55% from carbohydrates.
- Encourage high fiber, fruits, vegetables, and whole grains.

In addition, at least 1 h of moderate to vigorous physical activity daily is recommended for children over the age of 5 with limitation in TV/computer (screen) time to under 2 h/day.

The most striking change in recommendations for the general population involves universal screening at age 9–11 with a lipid profile (non-fasting non-HDL level or a fasting lipid profile) and again at age 18–21. Previous National Cholesterol Education Program (NECP) guidelines from 1992 supported universal screening starting at age 20, with an individualized selective screening approach in childhood [19]. The individualized approach recommends using family history of CVD or elevated cholesterol to identify patients at risk. However, it has been estimated that this approach may miss 30–60% of pediatric patients with elevated cholesterol [20, 21], largely in part due to incomplete or inaccurate family histories. In addition to primary prevention and universal screening, the expert panel continues to recommend screening by family history starting at age one. A fasting lipid profile is recommended for positive family history of CVD in males before the age of 55 and in females before the age of 65. This includes myocardial infarction, coronary artery bypass surgery or intervention, stroke, treated

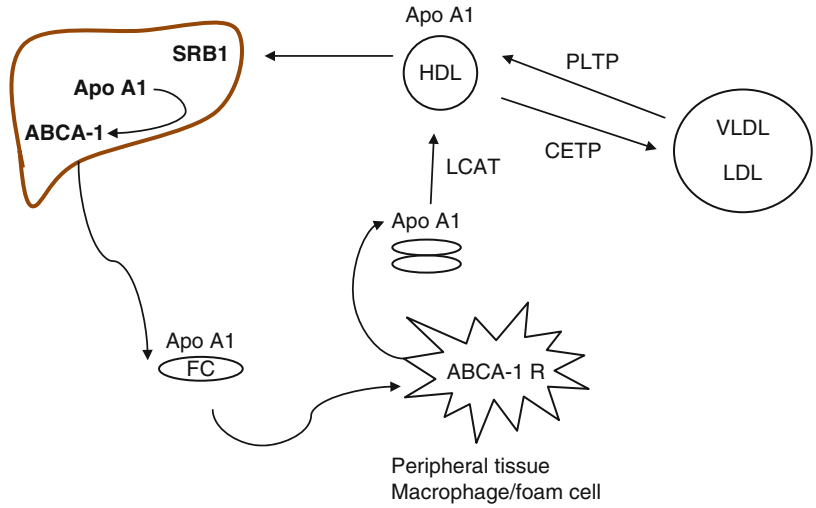

Fig. 30.4 ApoA1 is produced in the liver and the intestine. This is exclusively associated with HDL. Interaction with ABCA-1 which mediates the efflux of cholesterol and phospholipids to ApoA1 and ApoE, yields a primitive HDL molecule. These nascent HDL particles can then pick up more free cholesterol from peripheral tissues, again via the ABCA-1 receptor. LCAT then mediates conversion of free cholesterol into cholesterol esters. Because cholesteryl esters are more hydrophobic, this alters the shape of the molecule into a sphere, burying the cholesterol esters in the center. This is the mature HDL. At this point, HDL can return to the liver via SRB1 where HDL-delivered cholesterol may preferentially be a precursor for bile acid synthesis. The alternate pathway is mediated by CETP, in which cholesterol ester from HDL is exchanged with triglycerides from LDL or VLDL and the small HDL particle returns to the liver to repeat the process. PLTP transfers phospholipids to HDL from the triglyceride-rich lipoproteins VLDL and LDL. *FC* free cholesterol, *ABCA-1* *ATP*-binding cassette transporter A1, *LCAT* lecithin-cholesterol acyltransferase, *SRB1* scavenger receptor B1, *CETP* cholesterol ester transfer protein, *PLTP* phospholipid transfer protein

angina, and sudden cardiac death. As family history changes over time, ongoing evaluation is crucial. In addition to a positive family history, the panel recommends obtaining a lipid profile in children with other risk factors. Risk factors include HTN, cigarette smoking, BMI $\geq$ 95%, HDL $\leq$ 40 mg/dl, and diabetes mellitus.

Special Considerations

Much of the pediatric population with other primary illnesses, such as chronic renal disease and systemic lupus erythematosus, will be at risk for CVD. These conditions place them in a moderate- or high-risk category.

CVD accounts for a majority of deaths in adults with ESRD and one fourth of pediatric patients with ESRD [22, 23]. In adults, the pathogenesis has been identified as vascular or myocardial injury related to renal failure, including hypertension, elevated homocysteine levels, increased calcium burden, and elevated cholesterol levels. A large majority of patients undergoing peritoneal dialysis or who have ESRD have high LDL-C. In ESRD, TG levels are consistently elevated, with low levels of HDL-C. Additionally, although Lp(a) is genetically regulated, higher levels are typically found in patients with renal disease, which seem to improve with improvement in their renal status [24]. Dyslipidemias found in patients with renal disease should be treated.

CVD is a major cause of morbidity and mortality in adults with types I and II diabetes mellitus. Elevated triglycerides are commonly seen in patients with type II diabetes. About a third of patients with T2DM will have TG $>$ 200 mg/dl, low HDL-C, and small dense LDL particles. A similar pattern is seen in poorly

controlled T1DM. In T2DM, insulin resistance results in increased production and secretion of hepatic VLDL [25].

Patients with Kawasaki syndrome are also at higher risk for CVD. Much of this is related to arterial wall stiffness with the presence of aneurysm, as well as in those without detectable aneurysms. Low HDL-C is a prevalent finding among patients with resolved Kawasaki disease [26]. North American children with that history have also been found to have higher blood pressure with higher BMI and triglyceride levels compared to controls [27].

Patients who have received orthotopic heart transplants are at particularly high risk for coronary vascular disease. It has been found to be the primary cause of later mortality in 20–30% of cases, with as many as 75% demonstrating evidence of transplant CAD with ongoing surveillance [28]. While there is a component of vascular rejection in this disorder, their risk is compounded by other comorbidities often seen in transplant patients such as hypertension, renal failure, and obesity, along with the use of immunosuppressive drugs.

Lipid Markers

The traditional lipid profile includes total cholesterol, LDL-C, HDL-C, and triglycerides. LDL-C is estimated using the Friedewald equation (LDL-C = TC-HDL-C-TG/5). This requires a fasting state of at least 12 h and is not accurate with TG levels above 400 mg/dl [29]. The LDL-C estimation also does not account for the LDL particle number nor does it account for the density of LDL particles, which appear in two types. Some consider smaller dense particles to be more atherogenic. The LDL-C value also includes intermediate density lipoproteins and lipoprotein (a). Given the above limitations, there has been a shift towards other markers to assess atherogenic risk. In patients with high triglycerides, non-HDL-C or ApoB may better assess CVD risk than the triglyceride level. Non-HDL-C is simply the total cholesterol minus HDL-C. This value encompasses both cholesterol-rich and triglyceride-rich apolipoprotein B-containing particles, VLDL, IDL, LDL, and Lp(a). It does not require overnight fasting. ApoB measures the aggregate of atherogenic particles, as each one has one ApoB100 particle. In the PDAY study assessing postmortem young adults aged 15–34, non-HDL-C had a stronger association with preclinical disease (presence of fatty streaks, raised lesions) than ApoB [30]. The Bogalusa Study also demonstrated a strong relationship between non-HDL-C and subclinical disease measured by carotid IMT. However, it was similar to the relationship with LDL-C, HDL-C, total cholesterol/HDL-C ratio, and ApoB/ApoA1 ratio, but better than TG, ApoB, or ApoA1 alone [31].

Non-HDL-C is a secondary target of therapy according to the NCEP ATP III guidelines for adults. However, in children, the expert panel now recommends non-HDL-C or fasting lipid profile for screening. Evidence has not demonstrated any superiority of ApoB measurements. The panel does suggest that Lp(a) measurement may be useful in children with hemorrhagic or ischemic stroke. In clinical practice, Lp(a) may also be useful to measure in children of parents with premature CVD with no other identifiable risk factors.

Normal Lipid Values

The distribution of lipids in normal children is presented in Tables 30.2 and 30.3 below. There are some small differences between males and females with total cholesterol and LDL-C, which is typically lower in males than in females. There is a transient decrease in both sexes during adolescence as well. In males, the decrease seems to primarily be of HDL-C [32]. Despite the obesity epidemic, there does not seem to have been a significant increase in mean cholesterol levels in children over time [33].

When an abnormal value is obtained during screening, the average of two fasting lipid profiles should be taken between 2 weeks and

3 months apart. When the average value is elevated, consideration should be made for additional laboratory evaluation including liver function tests, creatinine, blood urea nitrogen, urinalysis, thyroid stimulating hormone, and screening in the parents.

Lipid Abnormalities

The predominant pattern in dyslipidemia in childhood is a mild to modest elevation in triglycerides (less than 400 mg/dl), normal to mild elevation in LDL-C, and a reduced HDL-C. This may be related to the rise in childhood obesity and the prevalence of the metabolic syndrome. The result is an increased burden of free fatty acid load on the liver with downregulation of lipoprotein lipase, resulting in increased VLDL and hence a higher triglyceride level [35]. Dyslipidemias are complex. Some disorders are inherited in a monogenic fashion, while others that are polygenic in nature are often influenced by environmental factors. It is easiest to consider each component individually.

Table 30.2 Lipid distributions in children aged 5–19, based on lipid research prevalence studies [32, 34]

	<5 %	<75 %	75–95 %	>95 %
Total cholesterol		<170 mg/dl	170–199	≥200
LDL-C		<110	110–129	≥130
Triglycerides				
0–9 y.o.		<75	75–99	≥100
10–19 y.o.		<90	90–129	≥130
HDL-C	≤35	>45		
Non-HDL-C		<120	120–144	≥145

Elevated LDL-C

LDL is thought to be atherogenic in its oxidized form. It seems to have longer residence time at specific lesion specific sites [36], which increases its potential to become modified. Oxidized LDL has many properties which may be pro-atherogenic. It is chemotactic for monocytes, which after differentiation into macrophages may cause more oxidation. Oxidized LDL inhibits macrophage mobility, thus trapping cholesterol in the intima. Scavenger receptor pathways load the cells with

Table 30.3 Mean lipid levels differentiated by sex and age. Based on NHANES data, Ford et al. [33]

cholesterol and contribute to foam cell formation. The endothelium is damaged. Oxidized LDL can also elicit antibody formation, alter coagulation pathways, and adversely affect the vasomotor properties of the coronary arteries [37, 38].

The majority of patients with isolated high LDL-C have some genetic form of hypercholesterolemia.

Familial hypercholesterolemia (FH) is autosomal dominant in transmission. It is fairly common in the heterozygous form, with a prevalence of about 1/500. The homozygous form is extremely rare, about one in a million, and presents with very early manifestations of hypercholesterolemia. Only half the number LDL receptors are present in the heterozygous form where the LDL-C is typically in the range of 175–350 mg/dl, while in the homozygous form, LDL-C will be above 400 mg/dl, with a range up to 1,200 mg/dl. The heterozygous form will likely have elevated cholesterol at birth. Patients often develop arcus corneae and xanthomas (deposits of cholesterol in the tendons and skin) by the third decade. CVD events appear in the fourth decade. Homozygotes will have very high cholesterol early in life with xanthoma by age 4, arcus corneae by age 10, and coronary disease beginning in the second decade of life [39]. Aortic stenosis may develop as well due to cholesterol deposition on the valve [40]. Myocardial infarction is common before age 30 (see Figs. 30.5, 30.6, 30.7, 30.8, 30.9, 30.10, 30.11, 30.12, 30.13, 30.14)*.

The FH defect is in the LDL receptor gene. In the 1970s, Goldstein and Brown isolated the biofeedback mechanism by which plasma levels of cholesterol are controlled. If there is too much cholesterol in the intrahepatic cholesterol pool, there will be downregulation of cholesterol synthesis (reduced HMG-CoA reductase), an increase in ACAT (acyl-CoA cholesterol acyltransferase) which esterifies cholesterol, and a downregulation of LDL receptor synthesis. When there is not enough exogenous cholesterol, synthesis of cholesterol increases along with an upregulation of LDL receptors. In the heterozygous form, LDL receptors do exist, with only about half the number of LDL receptors [41]. These cells then compensate for their lack of intracellular cholesterol delivery by increasing cholesterol synthesis. Homozygotes have no functioning LDL receptors or very few. In patients homozygous for FH, diet and pharmacologic treatment have limited impact. LDL apheresis is the treatment often needed.

Hypercholesterolemia with a modest increase in LDL-C can be due to familial ligand defective apolipoprotein B100 (FLDB). This is due to a defect in the binding of LDL via the LDL receptor. It is transmitted in an autosomal dominant fashion [42]. FLDB is the result of a single point mutation in the apoB gene. The mutation is carried among persons of European descent with a prevalence of about 1/500 [43]. LDL levels can range from normal, about 100 mg/dl, to upwards of 450 mg/dl. It is hypothesized that this defect does not affect VLDL metabolism as VLDL uptake by the liver is primarily through the ApoE receptor [39]. There are no clinical differences between FLDB and the heterozygous form of familial hypercholesterolemia except that patients with FLDB may have lesser degrees of LDL-C elevation.

Other rare causes of familial forms of hypercholesterolemia include phytosterolemia (sitosterolemia), LDLRAP1 (LDL receptor adaptor protein 1) mutation, and PCSK9 mutation. Phytosterolemia is a result of a gene mutation in ABCG5/8, which disrupts the active transport of passively absorbed plant sterol back into the intestines. 25–60% of plant sterols may be absorbed, whereas normal absorption is about 5%. Treatment consists of dietary restriction of plant sterols. Ezetimibe, a cholesterol absorption inhibitor, is a pharmacologic option. Loss-of-function mutations in LDLRAP1 are a cause of autosomal recessive FH. This gene encodes a protein required for clathrin-mediated internalization of the LDL receptor by liver cells [44]. PCSK9 downregulates the LDL receptor in hepatic and extrahepatic tissues. Loss-of-function mutations cause lower LDL and decreased CVD risk. Conversely, gain-of-function mutations result in an increased clearance of LDL receptors, decreased availability of LDL receptors, and an increase in plasma LDL, which can be severe [45].

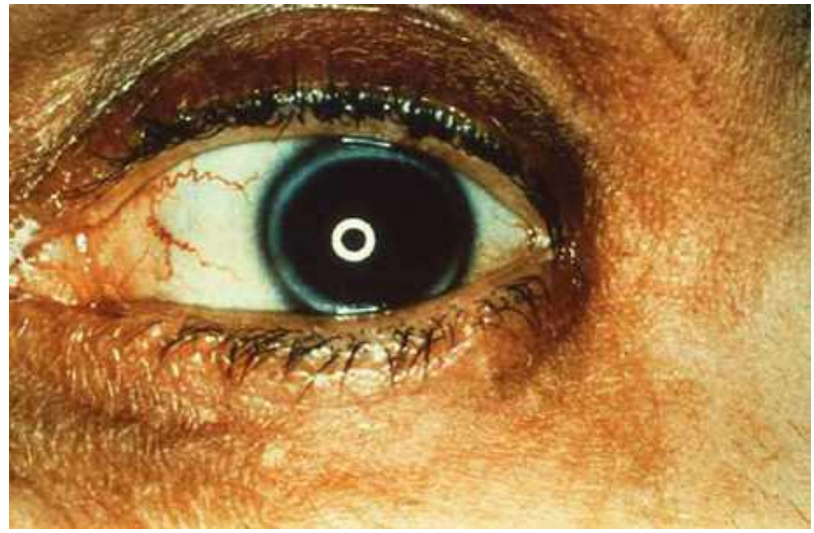

Fig. 30.5 Clinical images in dyslipidemia: arcus corneae

Fig. 30.6 Clinical images in dyslipidemia: xanthoma

Elevated Triglycerides

Most patients with very high triglyceride levels (>500 mg/dl) will have a genetic form of hypertriglyceridemia compounded by a secondary cause of hypertriglyceridemia [46]. These secondary causes may include diabetes, hypothyroidism, alcohol, oral estrogens, renal disease, diuretics and B blockers, retinoic acid drugs, and atypical antipsychotics [47]. The genetics behind hypertriglyceridemia are complex. Recent genome-wide association studies have found as many as 95 loci associated with lipid abnormalities in the general population. Additive effects of common variants likely result in the clinical abnormalities. It is also unclear whether the genes themselves are responsible or if it is the association with predisposing factors, such as insulin resistance [48]. This likely accounts for what was previously described as familial hypertriglyceridemia and familial combined

hyperlipidemia. In the pediatric population, mild to moderate elevations in triglyceride levels are often seen. This may be related to the increase in obesity in this population and a TG level above 150 mg/dl is often considered a criterion for metabolic syndrome in pediatric patients. About 10–20% of obese children have elevations in TG [49, 50]. In a recent review of pediatric patients with severe elevations in triglycerides (greater than 350 mg/dl), about 17% were related to excess adiposity; 43% had a mixed hyperlipidemia with elevations in LDL/VLDL; 33% had high VLDL levels, but normal cholesterol levels; and less than 7% were associated with severe hypertriglyceridemia (>500 mg/dl) and due to rare, usually genetic, conditions such as lipoprotein lipase deficiency [51].

Fig. 30.7 Clinical images in dyslipidemia: tuberoeruptive xanthoma

Defects in lipoprotein lipase (LPL) or its cofactor, CII, result in chylomicronemia. Lipoprotein lipase is an important enzyme involved in triglyceride hydrolysis. The process releases fatty acids to be used as an energy source or to be stored in adipose tissue. Without effective clearance of triglycerides, buildup of chylomicrons and VLDL can occur (Refer to Fig. 30.3). Both of these disorders are autosomal recessive in inheritance, with an incidence of about one/million. Gene testing is available. LPL deficiency typically presents in childhood with failure to thrive, colicky abdominal pain, hepatomegaly, and with increased risk for pancreatitis. Patients with triglyceride levels above 1,000 mg/dl are more likely to present with xanthomas, and those with levels above 4,000 mg/dl may present with lipemia retinalis (pale pink color to the retinal arterioles and venules due to light scattering of the large chylomicrons) (see Figs. 30.5, 30.6, 30.7, 30.8,

Fig. 30.8 Clinical images in dyslipidemia: tendinous xanthomas present with very thick ankles

Fig. 30.9 Clinical images in dyslipidemia: lipemic serum: the normal is on the left and the very lipemic serum is on the right

Fig. 30.10 Clinical images in dyslipidemia: xanthelasma, lipid deposits in the eyelids

30.9, 30.10, 30.11, 30.12, 30.13, 30.14). Blood serum is lipemic. ApoCII deficiency typically has a later onset of symptoms and is often milder in appearance. The degree of hypertriglyceridemia is related to the amount of dietary long-chain fatty acids ingested. Treatment, therefore, is targeted at restricting dietary fat intake to keep plasma levels below 1,000 mg/dl, at which point, most of the symptoms have resolved and triglyceride lowering drug therapy is effective. Restricting fat to less than 5% of caloric intake is recommended; medium-chain fatty acids can be ingested as they are absorbed through the portal system. HDL-C and LDL-C levels are typically very low in these two diseases.

ApoA5 carriers have mutations in the apoA5 gene. These rare mutations can result in disruption in the lipid binding domain of the protein. Homozygous carriers can have very high serum TGs, with levels above

1,000 mg/dl, and may be difficult to treat [52]. GPIHBP1 (glycosylphosphatidylinositol-anchored high-density lipoprotein-binding protein 1) is another very rare syndrome due to a genetic mutation. These mutations affect binding to LPL and the hydrolysis of chylomicron triglycerides. TG levels are typically above 500 mg/dl [53].

Combined hyperlipidemia describes a condition where there are increased levels of LDL-C, TG, or a combination of the two. TG levels are typically above 200 mg/dl. ApoB plasma levels are also elevated as the disease process is due to overproduction of ApoB lipoproteins, which in turn increases VLDL, LDL, and IDL [54]. Presentation may occur in childhood but usually will not reach full expression until the third decade. However, with the rise of obesity in children, there has been an increase in cases in young adulthood because increased ApoB secretion is associated with higher adipose tissue mass [55].

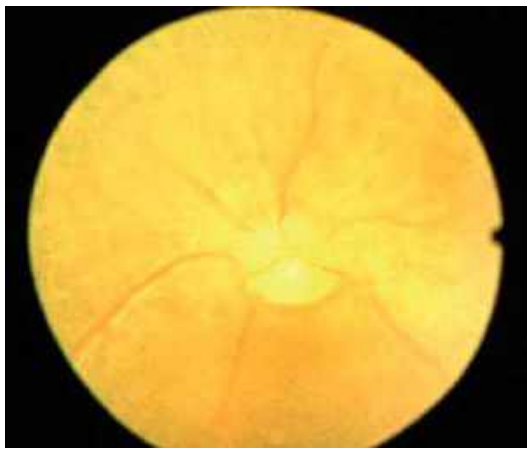

Fig. 30.11 Clinical images in dyslipidemia: lipemia retinalis

A much less common manifestation of moderately severe triglyceride elevation in infancy is the autosomal dominant form of dysbetalipoproteinemia (type III dysbetalipoproteinemia). This involves a mutation in ApoE, an important ligand for the LDL receptor, resulting in poor binding to lipoprotein receptors (see Fig. 30.3). ApoE is the primary apolipoprotein responsible for mediating hepatic uptake of chylomicron and VLDL remnants from circulation. Patients with this disorder accumulate these particles in the plasma, collectively termed β-VLDL. β-VLDL has shown a propensity to be taken up by macrophages, resulting in accumulation of cholesterol in these cells [56]. The most common form is the presence of the mutant apoE2, as a result of a single amino acid substitution at residue 158,

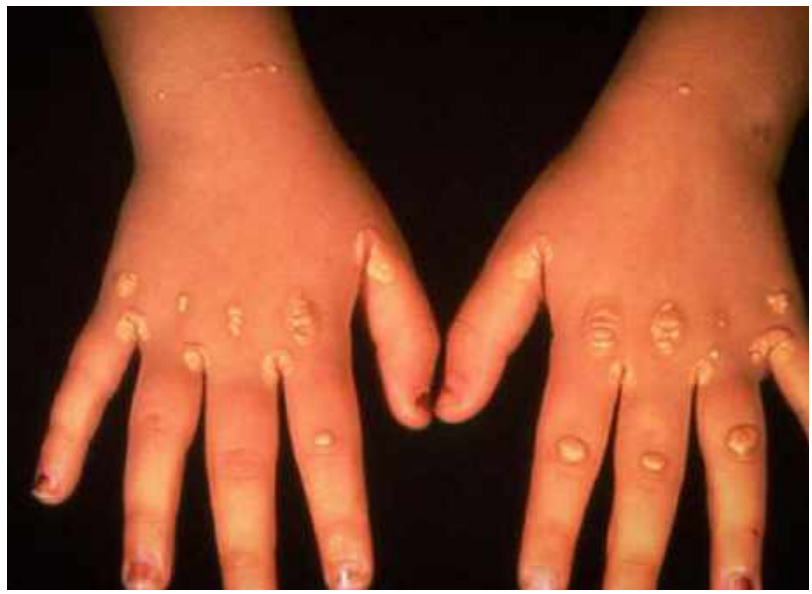

Fig. 30.12 Clinical images in dyslipidemia: 12-year-old girl with FH, pre treatment

Fig. 30.13 Clinical images in dyslipidemia: 12-year-old girl with FH, post treatment

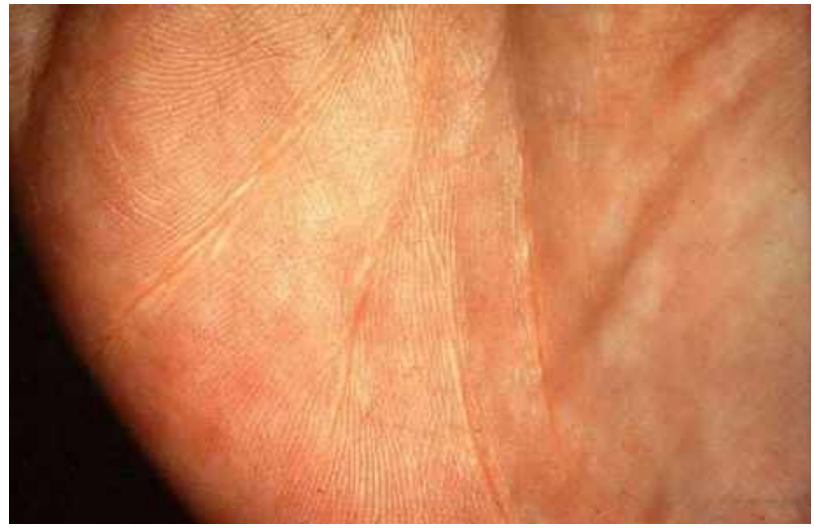

Fig. 30.14 Clinical images in dyslipidemia: planar xanthomas

and is inherited in a recessive pattern (1% of North American and Northern Europeans). Patients with ApoE2 do not have β VLDL and have normal lipid levels until superimposed secondary causes of hypertriglyceridemia ensue, i.e., hypothyroidism, alcohol, drugs, obesity, and diabetes. Those patients who manifest elevated plasma lipid levels may present with xanthomas. Planar xanthomas, lipid deposits in the palmar creases, seem to only appear with this condition. Other common xanthomas include tuberous and tuberoeruptive xanthomas of the elbows and knees (See Figs. 30.5, 30.6, 30.7, 30.8, 30.9, 30.10, 30.11, 30.12, 30.13, 30.14). This condition can be suspected when TG and cholesterol levels are approximately the same, in the range of 250–400 mg/dl. Patients are at risk for premature CVD and it has been associated with peripheral vascular disease. Dietary modification is usually effective, along with treating secondary insults [55]. Fish oil, niacin, fibric acid derivatives, and statins are often helpful.

Low HDL-C

Low HDL-C is a risk factor for CVD. Although it has been found to be an independent risk factor, it is usually associated with high triglycerides or some other lipoprotein abnormality [57]. The risk of a CVD event rises by 2% for every 1% decrease in HDL-C in the general population. HDL participates in reverse transport of cholesterol, moving cholesterol from peripheral tissues back to the liver (refer to Fig. 30.4). HDL particles have other actions that may contribute to its protective effects: they can inhibit the oxidation of LDL, felt to be the pathologic process in atherosclerosis, promote vasodilatation by prolonging the half life of prostacyclin [58], and bind to LPS, protecting the blood vessel from injury due to bacterial endotoxin [59].

Rare mutations in the apoAI gene can affect HDL-C levels. ApoA1 is transcribed in the liver and intestines and produces the major HDL structural protein. Patients with no detectable levels of ApoA1 protein have extremely low HDL-C levels, 0–4 mg/dl [60]. Interestingly, one subset of patients from Italy was found to have an ApoAI mutation, termed ApoA1 Milano, that caused a structural variation in the protein. Despite having low HDL-C levels, these individuals do not seem to have an increased risk for CVD.

Other causes of low HDL-C include LPL and CII deficiency (see above). These patients have very high triglyceride levels and have low LDL-C and HDL-C levels. Much of HDL is derived from the constituents of VLDL and chylomicrons released in the lipolytic process. Reduced LPL activity will result in reduced production of HDL.

Lecithin-cholesterol acyltransferase deficiency (LCAT) and fish-eye disease are two other syndromes that can result in low levels of circulating HDL. The mutations are isolated to chromosome 16. LCAT deficiency results in complete inability to esterify free cholesterol. The lipoproteins are structurally and functionally abnormal. Patients will present with corneal opacification, normochromic anemia, proteinuria, and glomerulosclerosis and are at risk for renal insufficiency later on in life along with increased risk of premature CVD. Partial LCAT deficiency (fish-eye disease) impairs the esterification of free cholesterol in HDL only. These patients have severe corneal opacities, very low HDL-C with high triglcyerides, and LDL-C levels in the upper range of normal [60].

A very dramatic presentation of low HDL-C is Tangier disease. Tangier disease is characterized by severe deficiency of HDL and the accumulation of cholesterol esters within the body with involvement in multiple organ systems. Patients have high or normal TG with low total cholesterol and neglible HDL-C. They have characteristic yellow-orange tonsils and adenoids and may have splenomegaly, peripheral neuropathy, hepatomegaly, coroneal opacities, hemolytic anemia, and thrombocytopenia [60]. Tangier disease is due to a mutation in the ATP-binding cassette 1 (ABC1) gene on chromosome 9q31 [61]. It is extremely rare, inherited in an autosomal recessive fashion. Other disorders to include in the differential diagnosis are the aforementioned disorders, storage diseases such as Wolman disease and Niemann-Pick disease, obstructive liver disease, severe malnutrition, and hepatic parenchymal diseases. There is no specific treatment for Tangier disease.

High HDL-C levels as a result of a mutation in CETP have been described in the Japanese population [62]. Homozygotes can have very high levels of HDL-C in the range of 100–250 mg/dl. Congruently, heterozygotes may have a 25–50% increase in their HDL-C levels above normal values.

While there are genetic causes for low HDL-C, those with genetic mutations are only a small fraction of the people seen with low HDL-C. Exogenous estrogens increase HDL-C, while androgens decrease HDL-C. Alcohol, exercise, and dietary saturated fat increase HDL-C, while weight gain and cigarette smoking decrease the lipoprotein.

Lipoprotein (a)

Lp(a) is a form of LDL that has been associated with premature CVD. Lp(a) levels have been

studied in children and may predict CVD risk. In the Bogalusa Heart Study, children whose parents had myocardial infarctions were found to have higher Lp(a) levels when compared to children whose parents did not have myocardial infarction. This association was only found in white children as opposed to black children [63]. An association of higher levels of Lp(a) with higher risk of CVD is well established in adults [64–66]. A meta-analysis of over 36 prospective studies in adults from 2009 demonstrated an independent but modest risk between Lp(a) and CVD [67] adjusted for age and sex. The risk ratio for CHD was 1.16. When taking into consideration total cholesterol, diabetes, smoking, and systolic BP, the risk ratio was similar at 1.13. Notably, the association between Lp(a) and CHD, as well as stroke, was continuous, with higher levels correlating to higher incidence of disease.

The structure of Lp(a) consists of a LDL particle linked to apolipoprotein A, a large glycoprotein consisting of multiple domains, known as kringles. ApoB100 of the LDL is linked to the ApoA via a disulfide bridge. Kringle IV has strong homology to plasminogen [68] and is repeated many times within Lp(a). No major physiologic role has been identified for Lp(a) [69]. The atherogenic association with Lp(a) is felt to be due to its interference with clotting and fibrinolysis by competing with plasminogen for binding sites [70] and interfering with plasminogen activation. Transport of Lp(a) cholesterol to damaged sites may trigger cholesterol deposition in growing atherosclerotic plaque as well as become trapped in due to glycosaminoglycan cross-reactivity [71]. It may also be taken up in macrophages via the VLDL receptor contributing to lipid accumulation within the cell.

Serum Lp(a) levels are genetically determined. There is large variation within and across populations. For example, African populations have been found to have much higher Lp(a) levels than Caucasians (which correlates much less to increased CVD risk). Lp(a) levels may be affected by diseases such as end-stage renal disease, but are otherwise not affected by environment, diet, or exercise. Screening for Lp(a) levels is not routine. It is only recommended for patients with CHD with no other dyslipidemia, patients with a strong family history of CHD with no other dyslipidemia, and patients with hypercholesterolemia refractory to therapy with LDL lowering meds.

Treatment

As mentioned above, the population approach to improve cardiovascular health is strongly recommended. Lipid and lipoprotein levels above the 95 percentile (below the 5th percentile for HDL-C) will require intervention and follow-up. Pharmacologic therapy is typically reserved for patients aged 10 or older, but severe abnormalities in younger individuals may warrant earlier treatment [17, 34] (See Tables 30.4 and 30.5). Patients homozygous for FH are at very high risk for early CAD. They may need frequent plasmapheresis (LDL apheresis when available) and may benefit from a high-dose statin with a cholesterol absorption inhibitor and low-dose anticoagulation. Patients with heterozygous FH should be treated initially with lifestyle modification and often will not require statin therapy until age 10 [72]. These patients should be followed by a lipid specialist.

CHILD 2 diet involves more restriction of saturated fats to 7% of total calories and dietary cholesterol to 200 mg/day with avoidance of *trans* fats, which has not changed from previous guidelines. The new guidelines do, however, suggest benefit of replacing usual fat sources with plant sterol/stanol esters, such as those found in margarine, and adding water soluble fiber psyllium to the diet. In adults, plant sterols can reduce cholesterol from 5% to 10%. The dose of fiber recommended is 6 g/day for children aged 2–12 and 12 g/day for older children. Fiber is thought to bind to bile acids, partially removing them from the enterohepatic circulation. One hour of moderate daily activity and restriction to less than 2 h of TV time continues to be recommended. For those with elevated triglycerides, the same dietary recommendations are made with the addition of decreasing sugar intake and replacing simple carbohydrates with complex carbohydrates as well as increasing dietary fish intake [17].

Table 30.4 Indication for treatment of high LDL-C in children ≥10 y.o. In children as young as 8, they may consider statin therapy if LDL-C persists >190 mg/dl, and there is a positive family history, 1 high-risk factor, or 2 moderate-risk factors [17, 34]

In children ≥10 y.o.	LDL-C ≥130 mg/dl	LDL-C ≥160 mg/dl	LDL-C ≥190 mg/dl	LDL-C ≥250 mg/dl
First 6 months	CHILD 1 first 3 months. Advance to CHILD 2 diet if needed			Seek expert opinion
If hyperlipidemia persists after 3–6 month trial of diet/exercise				
			Statin therapy	
Positive family history		Statin therapy		
1 high-risk factor or 2+ moderate-risk factors		Statin therapy		
2 high-risk factors or 1 high-risk factor and 2+ moderate-risk factors	Statin therapy			

Table 30.5 Indication to treat elevated triglycerides in children ≥10 y.o. [17, 34]

In children ≥ 10 y.o.	TG ≥100 mg/dl (<10 y.o)	TG ≥130 mg/dl (10–19 y.o)	TG >200 mg/dl	TG >500 mg/dl
First 6 months	CHILD 1 first 3 months. Advance to CHILD 2 diet if needed			CHILD 2 diet: consider fish oil/drug therapy. See expert opinion
If dyslipidemia persists after 6 months				
	Intensify diet and emphasize weight loss	Intensify diet and emphasize weight loss	Consider omega-3 fish oils	
	Increase dietary fish	Increase dietary fish	Consider drug therapy if LDL-C target is achieved and non-HDL-C ≥145	
	Repeat 6 months	Repeat 6 months		
	Non-HDL-C goal <145 mg/dl	Non-HDL-C goal <145 mg/dl		

Pharmacologic Therapy

Statins

HMG-CoA reductase inhibitors block the rate-limiting step in cholesterol biosynthesis (See Figs. 30.1 and 30.2). This class of medication has proven to be safe and effective in adults and children. It is typically the first-line pharmacologic therapy in pediatrics and adults. When initiating therapy, it should be started at low dose with an increase every 3 months of compliant use to target. An adjunctive therapy should be considered if the target is not reached. The most significant side effects include elevations in liver transaminases, as well as myopathy. Patients should have AST/ALT and CK measured at baseline, every 3–4 months for the first year, followed by every 6 months if the target LDL-C is achieved. CK should be measured if there are symptoms of muscle pain, cramps, or weakness. The CK threshold is 10 times upper limit of normal; the threshold for AST/ALT is 3 times normal. If labs are abnormal and/or there are clinical symptoms, medications should be withheld for 2 weeks. After 2 weeks, restart at lower doses when abnormalities resolve with close monitoring. Growth and development should also be followed. Statins are contraindicated in pregnancy. Adolescent females should be counseled regarding prevention of pregnancy. Rhabdomyolysis as a result of statins is extremely rare, but patients should be hospitalized to preserve renal function and treat symptoms if this occurs.

Bile Acid-Binding Resins

Bile acid-binding resins bind bile acids in the intestinal lumen, removing a percentage from the enterohepatic circulation, which drives more conversion of intrahepatic cholesterol to bile acids. Therapy has been found to lower total cholesterol and LDL-C from about 10–20% with a slight increase in HDL-C and triglyceride levels. These are considered safe in children since colesevelam has been approved in the pediatric population for single or adjunctive therapy. The major problem includes side effects of GI bloating, constipation, and cramping. Adherence may be a problem because these medications are difficult to take in either the granulated powder or large tablet form.

Fish Oils

In adults, omega-3 fish oils have been shown to lower TG by 30–40% and raise HDL-C by 6–17% dependent on the extent of TG lowering. Presently, there have been no randomized controlled studies performed on children. Lovaza is the only FDA-approved formulation of omega-3 fish oil.

Niacin

Niacin has been used since the 1950s for lowering cholesterol. It can lower TG and LDL-C, while raising HDL-C, and has been the only pharmacologic agent that decreases Lp(a). The primary mechanisms include (a) decreasing fatty acid mobilization from adipose tissue triglyceride stores, (b) inhibiting hepatocyte diacylglycerol acyltransferase and triglyceride synthesis leading to increased intracellular ApoB degradation and subsequent decreased secretion of VLDL and LDL particles, (c) decreasing the fractional catabolic rate of HDL-ApoA1 without affecting the synthetic rates and increasing plasma levels of ApoA1 thereby raising HDL-C, and (d) selectively inhibiting the uptake/removal of HDL-ApoA1 (but not HDL-cholesterol ester) by hepatocytes, thereby increasing the capacity of retained HDL-ApoA1 to augment cholesterol efflux through reverse cholesterol transport pathway [73]. Although it can be effective, flushing is a very common side effect and an elevation in liver transaminases can be seen in about a one fourth of patients. Niacin is not routinely recommended in the pediatric population.

Fibrates

Peroxisome proliferator-activated receptor agonists (PPAR-α) upregulate lipoprotein lipase and downregulate ApoCIII. This increases the clearance of VLDL ApoB and triglycerides, inhibits synthesis of VLDL production, and decreases hepatic extraction of free fatty acids, which reduces TG production. Fibrates are mainly used to decrease TG (reported up to 40% change) with increases in HDL-C, with limited impact on LDL-C. The major side effects include myopathy (rarely rhabdomyolysis) especially when used with statins or in patients with renal insufficiency. Fibrates have not been systematically evaluated in pediatric patients.

Cholesterol Absorption Inhibitors

Ezetimibe and phytosterols inhibit intestinal absorption of cholesterol and plant sterols. There is therefore reduced delivery of cholesterol to the liver, as well as upregulation of LDL receptors. These agents lower LDL-C (approximately 10–20%) but can also have lesser impact on TG and ApoB, as well as increasing HDL-C. They may be used as monotherapy but are used primarily in adults as combination therapy with statins. Ezetimibe is not currently approved for use in the pediatric population; however, it is indicated to treat phytosterolemia. Side effects include fatigue, dizziness, diarrhea, myopathy, and an elevation in transaminases.

Cholesterol Ester Transfer Protein (CETP) Inhibitors

These are the newest class of drugs for favorably modifying lipid and lipoprotein levels. CETP mediates transfer of cholesterol from HDL to

ApoB-containing particles (see Figs. 30.3 and 30.4). Reduced activity of CETP has been associated with higher HDL-C and lower CVD events in some populations. There have been four such drugs, the earliest being torcetrapib, then anacetrapib, dalcetrapib, and evacetrapib. Torcetrapib was the first to reach stage III trials, and although associated with a substantial increase in HDL-C and reduction in LDL-C, it was not pursued further due to high mortality [74]. Torcetrapib was associated with elevations in aldosterone with a modest increase in BP. Anacetrapib recently entered phase III development. The other two are currently in phase II trials. Both anacetrapib and evacetrapib also reduce LDL-C and double HDL-C levels without elevations in aldosterone or BP. When used in combination with statins, the reduction in LDL-C was even greater [75, 76]. Dalcetrapib has also been effective, but to a lesser degree.

Non-invasive Assessment of Arterial Structure and Function

31

Michael R. Skilton and David S. Celermajer

Abstract

Atherosclerotic cardiovascular disease is a leading cause of mortality worldwide. Structural and functional evidence of early vascular disease is present in children and adolescents and can be assessed noninvasively. This chapter details the noninvasive techniques commonly used to assess arterial structure and function and their research and clinical application in children and adolescents. The use of these techniques in describing the "at-risk" individual and the potential for assessing early prevention strategies are also discussed.

Keywords

Adventitia • Arterial stiffness • Arteriosclerosis • Artery • Atherosclerosis • Cardiovascular disease • Cerebrovascular disease • CT • Endothelium • Flow-mediated dilatation • MRI • Noninvasive detection • Plethysmography • Risk factors • Ultrasound

Introduction

Cardiovascular and cerebrovascular diseases are common and related diseases that affect the heart and blood vessels. They have differing presentations – including ischemic stroke, angina, and myocardial infarction – but a common pathogenesis. Together they are the leading cause of morbidity and mortality in both developed and developing nations.

Cardiovascular events occur almost uniquely in adults, with approximately 95 % of first myocardial infarctions occurring in those over 40 years of age [1]. Cardiovascular events often occur suddenly, without prior symptoms or clinical signs. This frequent lack of identifiable prior symptoms belies the chronic nature of the diseases of the blood vessels that account for the majority of these events. These vascular diseases can be categorized loosely as atherosclerosis and arteriosclerosis, the former being characterized by low level inflammation and lipid deposition

in the arterial wall and the latter being defined as a hardening of the arteries. Indeed, the structural and functional antecedents of atherosclerosis and arteriosclerosis may begin in the first decade of life [2–4]. Logically, early detection is valuable to identify high-risk subjects and to maximize chances of disease reversibility by early prevention strategies.

Atherosclerosis

Atherosclerosis is an inflammatory disease of the blood vessels, involving the formation of plaque-like lesions through a process of adaptive thickening of the intima, foam cell formation with subsequent appearance of lipid pools, and fibrous thickening of the arterial wall over the lesion. Of importance to the non-invasive detection of atherosclerosis, the disease process results in arterial wall thickening, calcium deposition in or near arterial atheromatous lesions, and dysregulation of the functional properties of the vasculature. These occur at varying stages of disease progression; however, the earliest structural changes to the arterial wall seem to be ubiquitous and can appear in the first decade of life [3, 4]. The earliest structural evidences consistent with the atherosclerotic disease process are lipid deposits in the aortic wall, present in all individuals, but the extent and severity of which are influenced by putative risk factors, especially hyperlipidemia [3]. By late childhood, the influence of risk factors on disease progression becomes more pronounced, especially in "at-risk" parts of the vasculature, resulting in widespread fatty streaks and the development of aortic fibrofatty lesions in some individuals (Fig. 31.1) [4]. More advanced atheromatous and complex lesions follow, often in early adult life, but these are rare in children and adolescents. Despite structural evidence of the atherosclerotic disease process being present in some form in all individuals, the extent and severity of the disease differs greatly among adults.

There is now a large body of literature, however, indicating that the functional properties of the arterial wall are important contributors to the initiation, progression, and clinical risk of atherosclerosis. The endothelial layer is the most well-characterized functionally active layer of the arterial vasculature. The healthy endothelium generally has an atheroprotective influence on the vasculature; however, in the presence of risk factors or other pro-atherosclerotic stimuli, it can promote or favor the initiation and progression of atherosclerosis [5].

Functional properties of the arterial adventitia and periadventitial tissues may also contribute to the progression of atherosclerosis. While less well understood, there is evidence that the adventitia and periadventitia may be involved in cross talk with the other arterial layers, including via the release vasoactive substances [6], and as such may be important mediators of vascular health and disease.

Risk Factors for Cardiovascular Disease: Relevance in Childhood

There are a number of risk factors that are considered to be established independent risk factors for cardiovascular disease, including hypertension, hypercholesterolemia, diabetes, smoking (active or passive), male gender, aging, and a family history of premature cardiovascular disease. Many of these can be relevant in children and adolescents. While these are considered risk factors for cardiovascular disease as a whole, the strength of risk associated with each factor differs for each specific type of cardiovascular disease and hence may also differ for each specific measure of arterial health. These associations may also be population dependent.

More recently, obesity has emerged as a risk factor of considerable interest, although whether it is an independent risk factor remains contentious, as much of the risk of atherosclerotic cardiovascular disease associated with obesity is mediated at least in part by other established

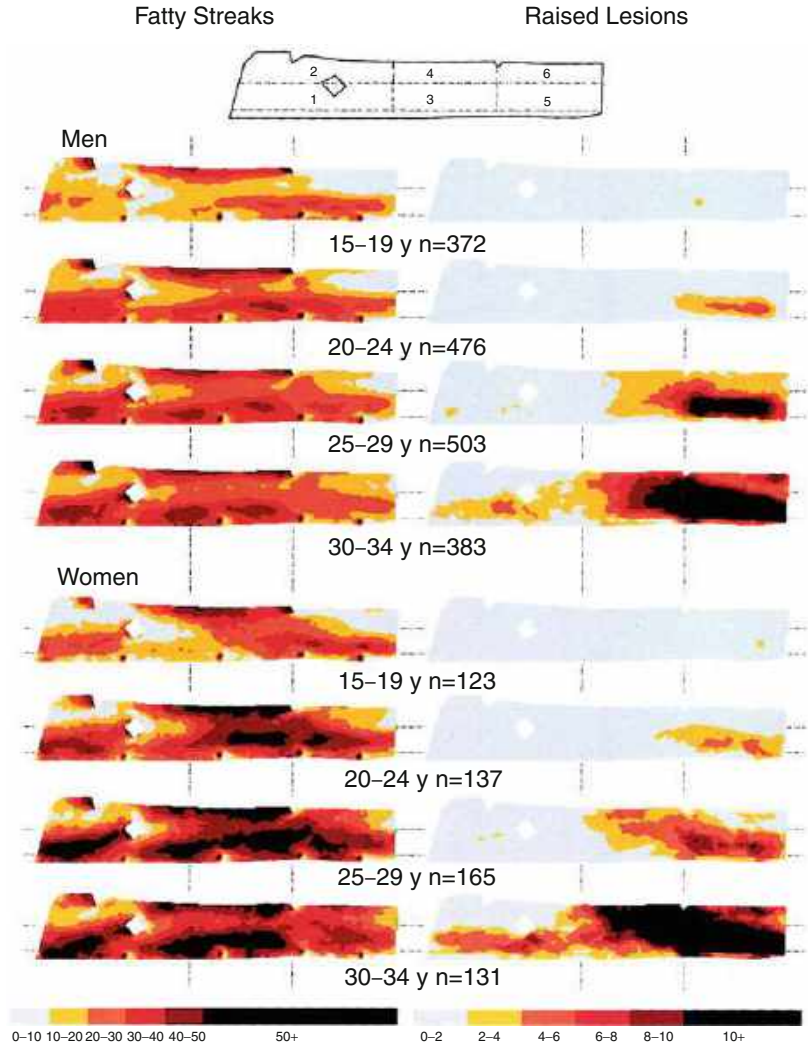

Fig. 31.1 Prevalence of fatty streaks and raised lesions in the abdominal aorta stratified by age and sex [4]. Proximal portion at *left*; distal, *right*; dorsal, lower edge. *Bottom*, color intensity scales for prevalence of fatty streaks and raised lesions (Reprinted from McGill et al. [4]., Lippincott Williams & Wilkins)

coexisting risk factors, such as hypertension and diabetes. There is a variety of other emerging risk factors, including sleep apnea, periodontal disease, and sedentary lifestyle.

Noninvasive measures of arterial health reflect only specific aspects of cardiovascular risk and do not fully capture an individual's risk of cardiovascular events. As with specific risk factors, the association of different measures of arterial health with different cardiovascular disease endpoints differs [7]. Accordingly, while noninvasive measures of arterial health provide some indication of the impact of risk factors and disease prevention strategies, they are inherently a surrogate measure for cardiovascular events. Nonetheless, they provide an excellent means by which to assess vascular health in asymptomatic individuals, including children, and provide insight into potential risk factors and prevention strategies.

Early abnormalities can be structural (e.g., arterial wall thickening) or functional (e.g., impaired vascular reactivity). These aspects are reviewed in the next section.

Noninvasive Assessment of Arterial Structure

Carotid Intima–Media Thickness (IMT)

Carotid IMT is the most widely used noninvasive test for the assessment of preclinical atherosclerosis in adults. The test uses high-resolution external ultrasound to obtain a longitudinal scan of the carotid artery, near the bifurcation into the internal and external carotid arteries. There are a number of different scanning and measurement protocols for the assessment of carotid IMT, specifically differing by site (common carotid, carotid "bulb," internal carotid, or a combination) and the type of measurement (mean, maximum, or the average of the maximum thickness from multiple sites).

There are numerous factors that enable the assessment IMT of the carotid artery and the relevance thereof. It is a large conduit artery that is sufficiently superficial to allow for detailed imaging using high-resolution ultrasound. The carotid IMT is measured near a major bifurcation, which allows for more marked intimal–medial thickening than that from a straight nonbranching arterial segment.

In adults, increased carotid IMT is associated with multiple cardiovascular risk factors, including male gender, systolic blood pressure, type 2 diabetes, LDL cholesterol, cigarette smoking, obesity, and the metabolic syndrome [8–11]. Risk factors present during childhood and adolescence are also associated with increased carotid IMT and progression of carotid IMT in later adulthood [12, 13], independent of risk factors assessed during adulthood. Beyond being reflective of risk factor levels alone, carotid IMT is predictive of future cardiovascular events, even after taking into account the effect of established cardiovascular risk factors [7, 14]. These associations with incident cardiovascular events are similar, irrespective of measurement site or type of measurement [7], although a recent study indicates that in adults this association may be more pronounced for the single thickest measure derived from the internal carotid artery [14], a site prone to plaque development, rather than measuring the mean carotid IMT over a long segment of the common carotid.

Carotid IMT is readily obtained in older children and adolescents. In these groups carotid IMT is associated with cardiovascular risk factors, including obesity, familial hypercholesterolemia, low HDL cholesterol, type 1 diabetes, and increased blood pressure [15–19], and can be influenced by intervention strategies, most notably with weight loss and exercise [20]. Carotid IMT tracks well through adult life [21], but it is unknown whether or not it tracks well specifically from childhood to adolescence to adulthood.

Aortic IMT

While the carotid artery is the most common site for IMT assessment in adults and children alike, the earliest structural changes consistent with the atherosclerotic process and the first arterial lesions appear in the abdominal aorta [4]. Assessment of aortic wall structure is possible in adults using MRI; however, due to the depth of penetration required to scan the abdominal aorta in adults, the use of high-frequency, high-resolution ultrasound is potentially limited. In contrast, in infants and children it is possible to assess the IMT of the abdominal aorta [18, 22]. As with carotid IMT, aortic IMT is derived from a longitudinal ultrasound scan, typically obtained using a high-resolution linear array transducer (7–15 MHz). The abdominal aorta is routinely scanned in a non-branching segment, frequently localized near a specific landmark, such as the aortic bifurcation [18].

Aortic IMT may be a more sensitive marker of subclinical atherosclerosis during childhood than is carotid IMT, with respect to ascertaining the effects of risk factors on arterial structure [18]. For example, aortic IMT is significantly increased in newborns with impaired fetal growth (Fig. 31.2) [22], an emerging cardiovascular risk factor [23]. This observation provides potential mechanistic insight into the link between fetal growth and adult cardiovascular disease and

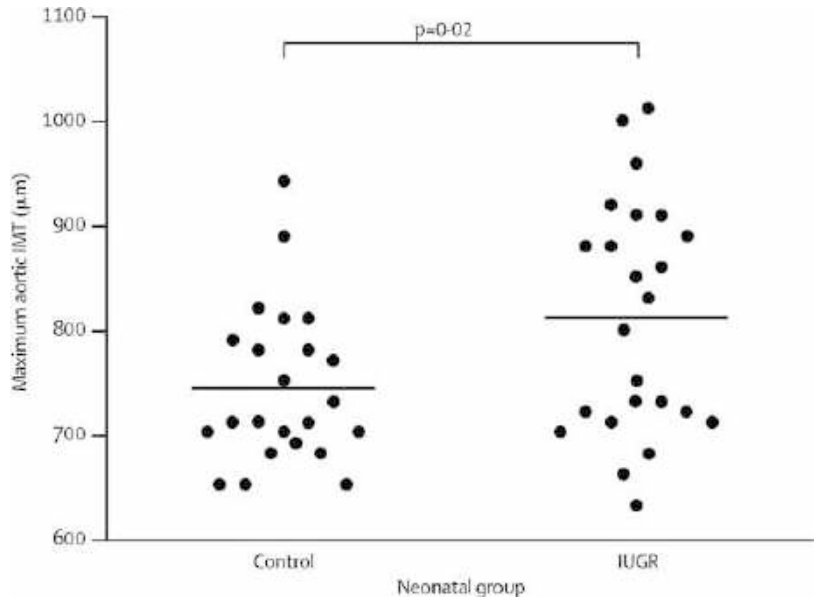

Fig. 31.2 Impaired fetal growth (intrauterine growth restriction; *IUGR*) and aortic intima–media thickness in newborns [22]. *Horizontal lines*, group means (Reprinted from Skilton et al. [22], copyright (2005), with permission from Elsevier)

suggests that measures of arterial structure may be a useful means by which to assess the putative benefits of early life interventions aimed at improving vascular health, in those with intrauterine or other early life risk factors [23].

Adventitial Thickness

Beyond IMT, recently developed noninvasive techniques allow for the assessment of arterial adventitial structure. A major constraint in the assessment of carotid adventitial structure is the poor differentiation by ultrasound of the outer interface of the adventitia. Emerging techniques directly, or indirectly, overcome this constraint through a variety of means.

Contrast-enhanced imaging allows for a quantitative measure of the carotid artery vasa vasorum, an important and major component of the adventitia, as opposed to the adventitia per se. The widespread application of this technique in children is restricted, however, by the requirement for contrast-enhanced imaging.

Very high-resolution ultrasound, using a much higher frequency transducer (25–55 MHz) than that used for traditional vascular scans, clearly delineates the outer edge of the adventitia [24]. The trade-off between frequency and depth of penetration means that this technique is only applicable in the most superficial, muscular arteries, such as the brachial and radial, and not the carotid artery or other central arteries, even in a pediatric population [24].

Carotid extra-medial thickness uses high-resolution longitudinal ultrasound of the carotid–jugular complex approximately 1.5–2 cm proximal to the bifurcation, where the jugular and carotid rest side by side [25], and avoids the need to delineate the outer edge of the artery by including the carotid wall from the media–adventitia interface through the jugular lumen–intima interface in the measure. For this technique the trade-off is the incorporation into the measure of the entire venous wall and any interstitial tissue that lies between the two vessels. Importantly though, these non-arterial components do not appear to be altered by cardiovascular risk factors [25], and while obviously being important contributors to the absolute thickness, they appear to be only minor contributors to variance in thickness [26]. As the carotid extra-medial thickness technique has only recently been described, there is currently limited evidence concerning associations with risk factors. A cross-sectional study indicated that

carotid extra-medial thickness may be more closely related to modifiable risk factors than is carotid IMT and that these associations are independent of carotid IMT [25]. There are currently no published reports of the use of this technique in children. The similarity between this technique and carotid IMT in terms of acquisition methodology indicates that the measurement of carotid extra-medial thickness is most likely feasible in children, and indeed it has recently been successfully assessed in children aged 8 years of age (Skilton and Celermajer, unpublished results).

These techniques do not allow for the differentiation between different tissue types and cell populations within the adventitia, such as resident fibrocyte populations or progenitor cells, with the exception of imaging of the vasa vasorum.

Carotid and Aortic Wall Thickness by Magnetic Resonance Imaging (MRI)

Carotid and aortic wall thickness can be assessed noninvasively by MRI without the use of contrast agents. The artery is routinely imaged in cross section with MRI, in keeping with the slice direction of the acquisition sequence, which is in contrast to the ultrasound-based techniques described above. This allows for a circumferential measure of thickness, which may capture greater heterogeneity of arterial wall structure including areas that are prone to lesion development [27]. The arterial wall when imaged with MRI appears as a single layer, so differentiation between the intima, media, and adventitia is not possible. Whether arterial wall thickness derived by MRI includes all three layers or only the intima and media is open to conjecture [26–28]. This may be dependent upon the spatial resolution, which is greater for larger 3T MRI, when compared with 1.5T MRI. The spatial resolution limitations of 1.5T MRI are also likely to limit the accuracy of MRI in children, as a means by which to serially monitor arterial wall thickness or to determine the associations of wall thickness with risk factors. Despite this limitation, MRI may provide a useful means by which to diagnose and monitor diseases that involve aortic wall thickening and vascular inflammation, such as Takayasu's arteritis [29].

Coronary Artery Calcium by Computed Tomography (CT)

As noted earlier, calcium deposits form in advanced atherosclerotic lesions. These are detectable in the coronary arteries by CT. In adults, the extent of coronary artery calcium is associated with cardiovascular risk factors [30] and is inversely associated with coronary vasoreactivity; independent of such risk factors [31], coronary calcium also appears to be predictive of future cardiovascular events [32].

There are two underlying limitations for the use of CT for detecting coronary artery calcium in children and adolescents. The first is that CT scanning involves some radiation exposure, so coronary artery calcium CT is not recommended for clinical use or clinical research in children. Accordingly, there have only been a few studies detailing the use of CT for coronary artery calcium in children and adolescents, and in general the application of the technique is restricted to high-risk groups in which the perceived benefit outweighs the known risks [33].

Published reports indicate that in asymptomatic adolescents and young adults, aged 14–29 years, the prevalence with any measurable coronary artery calcium is 11 % for males and 6 % for females, although the latter was derived from a single individual with detectable coronary calcium (from 17 individuals assessed) [34]. While asymptomatic, the majority of patients described in this chapter were referred because of known cardiovascular risk factors or self-referred, so the population prevalence of detectable coronary calcium in this age group is likely to be lower. At the other end of the risk spectrum are those with familial hypercholesterolemia, a major risk factor for premature cardiovascular events. In patients with familial hypercholesterolemia, one third of individuals aged 11–23 years have no detectable evidence of coronary calcium [35]. "High" coronary calcium scores were found

in 24 % of these patients, suggesting that CT for coronary artery calcium may potentially allow further risk discrimination for adolescents and young adults with a high-risk profile. These studies underline the second limitation of CT for detection of coronary artery calcium in children and adolescents, that it measures a level of disease that is generally more advanced than that seen in children and adolescents.

Arterial Function: Endothelial and Smooth Muscle

Conduit Artery Flow-Mediated Dilatation (FMD)

As noted earlier, the arterial endothelium is an active cell layer that forms the interface with the blood. Of importance, a healthy functional arterial endothelium has a host of antiatherogenic properties, many mediated by the release of nitric oxide. Nitric oxide plays a key role in maintaining vascular homeostasis, in addition to other anti-atherosclerotic properties such as reducing coagulation and leukocyte adhesion to the endothelium [5]. Nitric oxide is difficult to assess in the circulation; however, its dilatory effects on the arterial vasculature in response to various stimuli can be assessed in the coronary arteries by invasive techniques and in the peripheral vasculature by noninvasive techniques.

The gold-standard research methodology for the noninvasive determination of conduit artery endothelial function is arterial FMD assessed by high-resolution ultrasound. The technique evaluates arterial endothelial function as the ability of the artery to dilate in response to a hyperemic stimulus, most commonly initiated by a period of arterial occlusion. Protocols differ on whether this occlusion is upstream or downstream from the site of assessment, and this choice may alter the proportion of the subsequent dilatation resulting from endothelial release of nitric oxide [36] and therefore endothelial function. Nonetheless, the technique itself has changed little since its initial description [2]. In adults, the brachial or radial arteries are most frequently imaged; however, in children the femoral is also utilized (see subsequent discussion below for further details). Importantly, the FMD of peripheral conduit vessels correlates with coronary endothelial function [37].

A high-resolution, longitudinal B-mode ultrasound of the artery is acquired while the participant lies at rest. An occlusion cuff situated either proximal or distal to the site of assessment (see below for further details) is then inflated to suprasystolic pressure, typically 50 mm Hg above systolic blood pressure. After approximately 5-min occlusion, the cuff is rapidly deflated. The artery dilates in response to the ensuing hyperemia, typically reaching peak dilatation at around 45–60 s post cuff release in healthy young subjects; however, this may be markedly delayed in subjects with poor vascular health [38]. Protocols differ, however, and the FMD is most commonly taken as the percentage dilatation from the resting diameter at either a particular point in time (e.g., 45–60 s) or the peak dilatation within 3 min of cuff deflation, the latter of which appears to better discriminate between healthy and at-risk individuals [39]. Furthermore, the peak dilatation has been demonstrated to be largely due to endothelial release of nitric oxide [40]. After the arterial diameter has returned to baseline levels (approximately 10 min), endothelium-independent dilatation is assessed to ensure the smooth muscle dilatory capacity. This is typically tested using sublingual glyceryl trinitrate.

In addition to the timing of FMD measurement post-occlusion, there are a number of critical elements in the protocol that can introduce variance to the FMD measure if not standardized, including the duration of occlusion and the site of the occlusion cuff. These seemingly slight variations may have important implications [36], including altering the proportion of the dilatation due to endothelial nitric oxide release; however, they do not appear to alter the association of FMD with cardiovascular events [41].

This technique was originally described in a pediatric population and is thus readily applicable in children. There are, however, some minor changes to the protocol that are often

introduced for use in children. These include the assessment of a larger conduit artery, such as the femoral, instead of the brachial artery as interrogated in adults. This is primarily a means by which to limit the excessively high FMD observed in arteries with small diameters [2] but also for ease of data acquisition. Another common alteration to the protocol is the removal of the endothelium-independent dilatation component of the protocol, involving administration of the smooth muscle vasodilator glyceryl trinitrate.

Arterial FMD has been demonstrated to be inversely associated with individual cardiovascular risk factors, including systolic blood pressure, male sex, smoking, age, and body mass index [42, 43], and independently with the total burden of cardiovascular risk, as determined by the number of risk factors [44]. The use of arterial FMD as a surrogate has also aided in the description of emerging risk factors, such as fetal growth, allowing for greater refinement of the "at-risk" individual, in addition to more complete mechanistic insight [45, 46].

Beyond associations with risk factors, arterial FMD is associated with carotid IMT in cross-sectional examinations [47], and also with progression of carotid IMT [48], and is predictive of cardiovascular events [41]; however, this has not been the case in all studies. The majority of studies showing this association with incident cardiovascular events suggest that the association is independent of established risk factors and is similar in those with preexisting cardiovascular disease and asymptomatic individuals [41].

In childhood, FMD is associated with risk factors, and putative risk factors, including hyperlipidemia (especially familial hypercholesterolemia; Fig. 31.3), low HDL cholesterol, type 1 diabetes, obesity, passive smoking, and impaired fetal growth [2, 15, 19, 45, 49, 50].

FMD is a dynamic measure of arterial endothelial function and is thus well suited as a means to determine the efficacy on arterial health of putative prevention strategies and treatments. A limitation, however, is that it may be transiently impaired, for example, during a flu-like illness [51]. Reversibility studies with arterial FMD have included demonstrations of improvement in endothelial function with oral L-arginine supplementation in young adults with familial hypercholesterolemia (Fig. 31.4) [52], weight loss and exercise in obese children (Fig. 31.5) [20], and "cessation" of passive smoking [53].

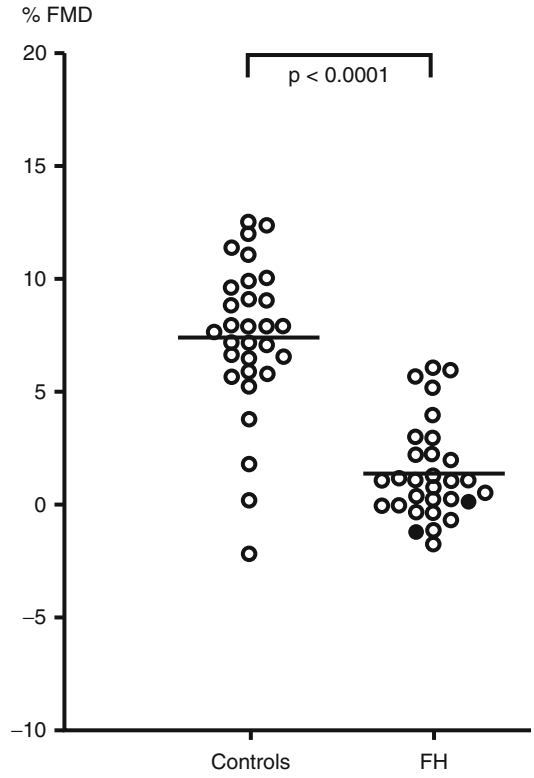

Fig. 31.3 Children with familial hypercholesterolemia (*FH*) have impaired endothelium-dependent dilatation, as assessed by flow-mediated dilatation (*FMD*) [50]. *Horizontal lines*, group means; *open circles*, subjects with heterozygous FH; *solid circles*, subjects with homozygous FH (Reprinted from Sorensen et al. [50], with permission from The American Society for Clinical Investigation, Inc.)

Small-Vessel Function

There are a number of techniques that allow for the study of small-vessel function. The gold-standard measure of resistance vessel endothelial function is the forearm blood flow response to acetylcholine infusions, assessed by venous-occlusion strain-gauge plethysmography. This technique is not routinely used in pediatric

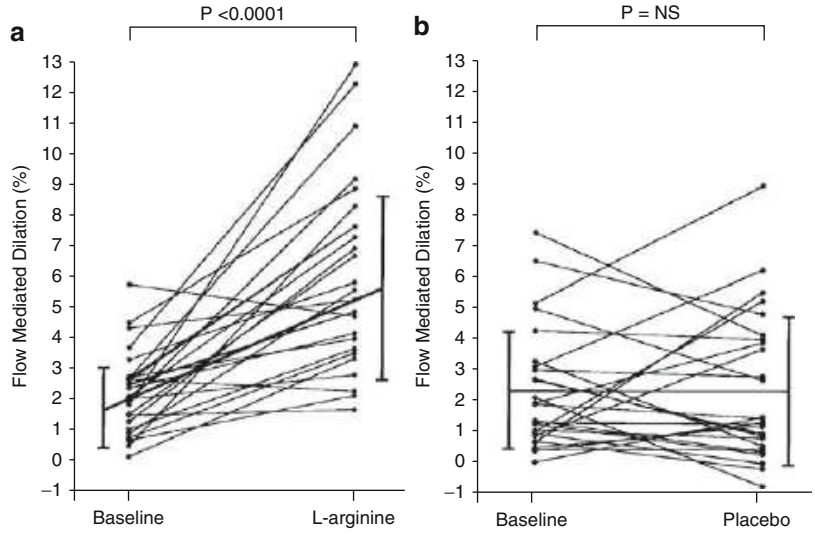

Fig. 31.4 Reversal of endothelial impairment with oral L-arginine in hypercholesterolemic young adults – a randomized placebo-controlled crossover trial of 4-week L-arginine supplementation on flow-mediated dilatation [52]. Results of $P < 0.001$ for comparison of L-arginine with placebo. *Bold lines* represent group means and standard deviation (Reprinted from Clarkson et al. [52], with permission from The American Society for Clinical Investigation, Inc.)

research due to the need for an arterial line; however, like arterial FMD, plethysmography can also be used to quantify the vascular response to a hyperemia.

Two distinct plethysmographs are commonly used – strain-gauge plethysmography and fingertip plethysmography. With the former, the measuring device – a mercury in Silastic strain gauge – is placed around the forearm at the point of greatest circumference and is able to assess the pulsatile changes in forearm circumference. Periodic upper arm venous occlusion allows for the quantification of forearm blood flow, either at rest or during post-occlusion hyperemia.

The fingertip method has recently become popular, with devices such as the EndoPAT (Itamar Medical Ltd, Israel), an FDA-approved device for the noninvasive assessment of endothelial function, streamlining and simplifying the assessment of arterial function and providing good reproducibility, including in adolescents [54].

With these two techniques, the site of measurement is distal to the occlusion site, as it is with the upper arm cuff position used in some FMD protocols. Accordingly, the proportion of the measure due to endothelial-derived nitric oxide may be lower, with ischemic metabolites potentially having a larger influence. This may be more pronounced for strain-gauge plethysmography around the forearm, as this measures a larger, more muscular body of tissue, as opposed to the fingertip-derived EndoPAT. Indeed, nitric oxide is only a minor contributor to the hyperemic response of the forearm [55], whereas the EndoPAT-assessed response has been reported to be ~50 % due to endothelial nitric oxide release [56]. Both methods correlate with more established measures of endothelial function; forearm plethysmography with acetylcholine-induced dilatation of the same vascular bed [57], and EndoPAT with both brachial FMD from the same hyperemic stimulus [58], and coronary microcirculatory function [59]. Similarly, there is evidence that both techniques may predict cardiovascular events independent of established risk factors [60, 61].

Both techniques are applicable in adolescents, with the response to hyperemia measured by EndoPAT being impaired in adolescents with type 1 diabetes [62] and the forearm hyperemic response being impaired in African American adolescents [63].

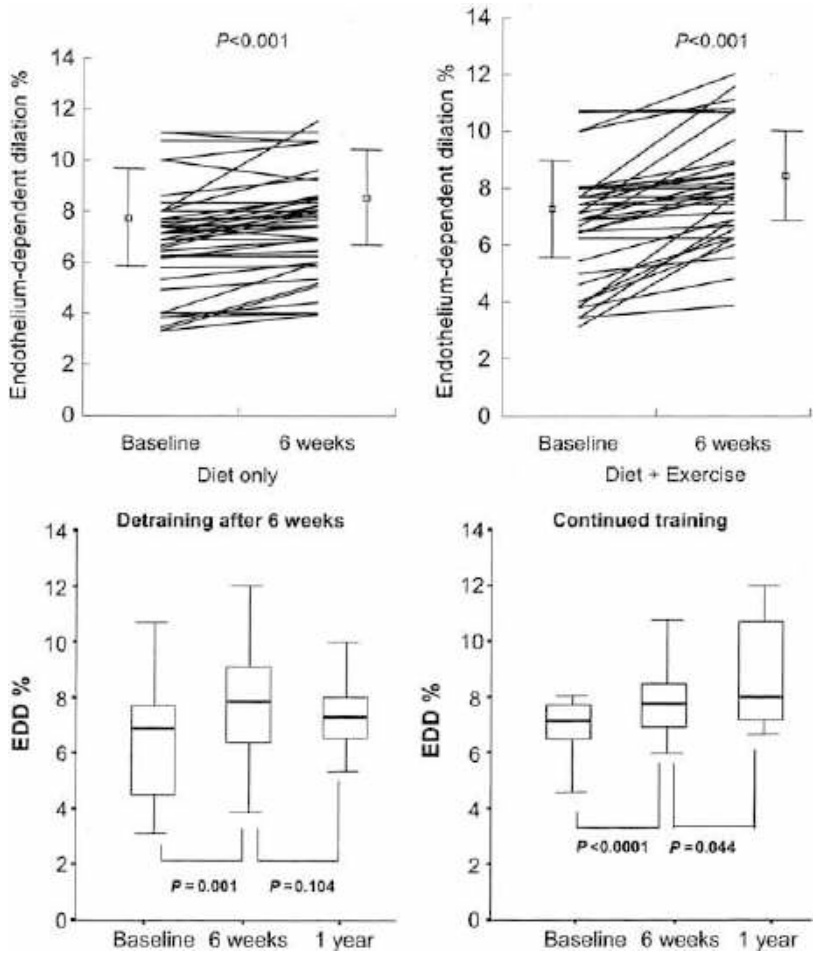

Fig. 31.5 Reversal of endothelial impairment with weight loss and exercise in overweight children – a randomized trial of dietary modification and supervised exercise versus dietary modification alone [20]. *Top panel* shows improvement in flow-mediated dilatation in both groups; however, this improvement was greater in the diet and exercise group ($P = 0.01$). Group data are means and standard deviation. *Bottom panel* shows the continued improvement in flow-mediated dilatation in those who maintained exercise training through 1 year, whereas the endothelial function in those who "detrained" and reverting to dietary modification alone returned toward baseline levels ($P = 0.035$ for comparison at 1 year). *Box, line*, and *error bars* represent 2.5th, 25th, 50th (median), 75th, and 97.5th percentiles (Reprinted from Woo et al. [20], Lippincott Williams & Wilkins)

Arterial Stiffness

Pulse Wave Velocity (PWV)

PWV can be noninvasively assessed through the comparison of the timing of pulse waves at two peripheral arterial sites. The most common techniques involve the use of (a) two tonometers recording simultaneously or (b) a single tonometer used to assess two sites sequentially, with concurrent ECG reading. With both techniques, the distance between the sites is required to calculate the velocity. There are three different measurement methods – total distance between sites, subtracting the carotid to sternal notch distance from the total distance, or subtracting the carotid to sternal notch distance from the sternal notch to femoral distance. These differing methods introduce variance to the absolute PWV values reported in the literature. This stresses the importance of consistency of methods for

Table 31.1 Noninvasive techniques for presymptomatic assessment of arterial structure and function in children or young adults

Technique	Guidelines, consensus statements, or method description	Site	CVD prediction (when assessed in adulthood)	Relevance – children/adolescents

cross-sectional studies or when undertaking serial measures [64].

With the "two tonometer" technique, the PWV (in m/s) is calculated as the distance between the two sites divided by the difference in time between the arrival of the pulse wave (as indicated by the upstroke of the pulse waveform) at the two sites of assessment.

With the "single tonometer" technique, each pulse wave is assessed independently, and the transit time from the heart to the site is derived from a comparison with the ECG.

In adults, the two sites most frequently assessed are the carotid artery and the femoral artery, and the carotid–femoral PWV is considered the gold-standard noninvasive test of arterial stiffness [64]. Importantly, using these two sites provides a measure of PWV principally due to aortic arterial stiffness.

Subject acceptability potentially limits the use of the femoral artery site as a component of a noninvasive research methodology in otherwise healthy children. One alternative is to use other more readily accessible distal sites, such as carotid–radial PWV, carotid–dorsalis pedis PWV, or brachial–ankle PWV. There is limited evidence available to support the use of one site over the other; however, carotid–dorsalis pedis PWV and brachial–ankle PWV will at least partially reflect central (aortic) stiffness. Furthermore, there are distinct structural differences between muscular arteries, such as the brachial

and radial arteries, and the central arteries, which are predominantly elastic in nature, and as such the PWV along these distinct segments may differ.

In adults, aortic PWV is an independent predictor of cardiovascular events in both asymptomatic and "at-risk" populations [65, 66]. For children, the available evidence indicates that age, sex, type 1 diabetes, blood pressure, and obesity may be important childhood risk factors for increased PWV [67–69].

Cross-Sectional Distensibility

Site-specific measures of arterial stiffness can be assessed in the aorta, carotid, or brachial artery using ultrasound or MRI. The ultrasound techniques can be added to an IMT or FMD protocol using standard equipment or undertaken using dedicated echo-tracking equipment. Ideally, a simultaneous pressure measurement is required to allow calculation of stiffness indices, such as distensibility and compliance, likely more meaningful for cardiovascular risk than measuring the change in diameter alone. Regional measures of carotid stiffness may not be as relevant as aortic stiffness derived by PWV, with regard to their prediction of incident cardiovascular events [70], possibly related to inherent differences in the determinants of carotid and aortic stiffness [71]. In children and adolescents, carotid stiffness is associated with LDL-cholesterol levels, obesity, and insulin resistance [72, 73]. Aortic stiffness can be assessed in newborns by ultrasound and is increased in those born with impaired fetal growth [74].

Conclusion

Atherosclerosis begins in childhood and is detectable using noninvasive techniques to assess structural and functional changes in the arterial vasculature (Table 31.1). At this early stage, such changes are potentially reversible. Accordingly, noninvasive detection of atherosclerosis provides important insights into the pathogenesis and prevention of atherosclerosis. These techniques are not currently recommended for clinical use, however, and there remain important gaps in the current knowledge, especially concerning the relevance of these measures in children, as surrogates for cardiovascular risk.

Specifically, do measures of arterial structure and function assessed in childhood and adolescence predict future cardiovascular events?

The long time period that separates childhood from the typical age of onset of cardiovascular events will make this difficult to determine, but the latter may be inferred through a combination of tracking from childhood to early adulthood and studies that will soon report on whether or not measures of arterial structure and function assessed in early adulthood predict early cardiovascular events. While an important issue, the lack of this evidence need not distract from the consistency of association of these measures with the extent and severity of atherosclerosis in childhood and adolescence and their relevance in describing risk factors for, and designing preventive strategies to slow the progression of, early atherosclerosis. Further research will show whether early identification and reversibility studies can influence the natural history of cardiovascular events secondary to atherosclerosis.

Echocardiography in the Assessment of Cardiovascular Disease Risk

32

Thomas R. Kimball

Abstract

Echocardiography is a powerful tool in the assessment of cardiovascular risk. It is perhaps most useful in the measurement of left ventricular mass which is an independent risk factor for future adverse cardiovascular events. In addition, risk can be further stratified by combining mass measurements with evaluation of relative wall thickness to determine left ventricular geometry and type of hypertrophy (eccentric vs. concentric). Doppler echocardiography and Doppler tissue imaging provide valuable data on left ventricular diastolic function. Left atrial size is an important index which when elevated indicates long-standing diastolic dysfunction.

Studies have shown that with pediatric obesity, hypertension, and type II diabetes, left ventricular mass and diastolic function become abnormal. Encouraging results demonstrate that in obese pediatric patients, weight loss (albeit profound) can produce reversal of these abnormalities.

Newer echocardiographic techniques such as ventricular strain may prove useful in evaluating cardiovascular risk in the future.

Introduction

Echocardiography is a powerful tool in determining cardiovascular risk. Cardiac ultrasound is readily available, painless, and harmless, making it an ideal modality for serial and large-scale monitoring of patients even in the pediatric age group. The assessment of left ventricular mass (LVM) by echocardiography has been a particularly robust measure. Detection of elevated LVM, i.e., left ventricular hypertrophy (LVH), is a powerful and independent predictor of future cardiovascular events. In patients with hypertension, LVH is the most prominent evidence of target organ damage.

Echocardiographic evaluation of left ventricular diastolic function can also be useful. Doppler echocardiographic measurement of blood flow velocities across the mitral valve allows assessment of LV relaxation properties. Likewise, Doppler tissue imaging provides measures of LV wall motion velocities which are even more useful for evaluating LV diastolic function. As left ventricular relaxation becomes impaired, the left atrium enlarges, which can be an indicator of chronic left ventricular diastolic abnormalities.

In this chapter, these principal echocardiographic measures will be discussed. Focus will be on their measurement and utility in assessing the young patient at risk for adverse cardiovascular events.

Left Ventricular Mass

It is well established that left ventricular hypertrophy as assessed by M-mode echocardiography is a powerful independent predictor for mortality and morbidity in adults [1–3]. For example, in a 4-year follow-up of 1,141 Framingham subjects (mean age of 69 years) who were free of coronary artery disease, Levy et al. [4] showed that after adjusting for age, blood pressure, smoking, obesity, and cholesterol, increased LV mass conferred a relative risk of 7.8 in men and 3.4 in women for a cardiovascular event such as myocardial infarction, cerebrovascular accident, or congestive heart failure. Since there is a paucity of such end points in children, echocardiographic identification of LVH has been particularly useful as a marker to identify children and younger patients at risk for cardiovascular complications later in life with LVH itself becoming the end point of interest.

CARDIA (Coronary Artery Risk Development in Young Adults) is an epidemiologic prospective multicenter study of young adults (23–35 years old at the time of initial echocardiogram). Echocardiograms were performed in 4,243 subjects (874 African-American men, 1,034 Caucasian men, 1,176 African-American women, and 1,159 Caucasian women) [5]. In young adults (23–35 years old) participating in the CARDIA study, African-American race, male gender, weight, systolic blood pressure, subscapular skinfold thickness, and both fatness and lean body mass were associated with increased LV mass. Importantly, after adjustment for previously described covariates and weight, LV mass was higher in men than in women [6]. Other investigators have also found that LV mass is higher in males. The relationship remains true in children and adolescents. For instance, Daniels et al. [7] showed that LV mass correlated significantly with male sex in children age 6–23 years. These results have also been shown in children and adolescents participating in the Bogalusa Heart Study [8]. Interestingly, neither of these two studies demonstrated a relationship between LV mass and race/ethnicity.

Left ventricular mass is derived from two-dimensionally guided M-mode echocardiograms (Fig. 32.1). M-mode measurements are made according to conventions established by the American Society of Echocardiography [9]. Specifically, the left ventricular minor axis dimension, septal thickness, and posterior wall thickness are measured in centimeters at end-diastole. Traditionally, multiple (at least three) cardiac cycles are measured. LV mass is derived from the formula described by Devereux et al. [10]: LVM (g) = 0.8 [1.04 (interventricular septal thickness + posterior wall thickness + LV end-diastolic internal dimension)^3 – (LV end-diastolic internal dimension)^3] + 0.6.

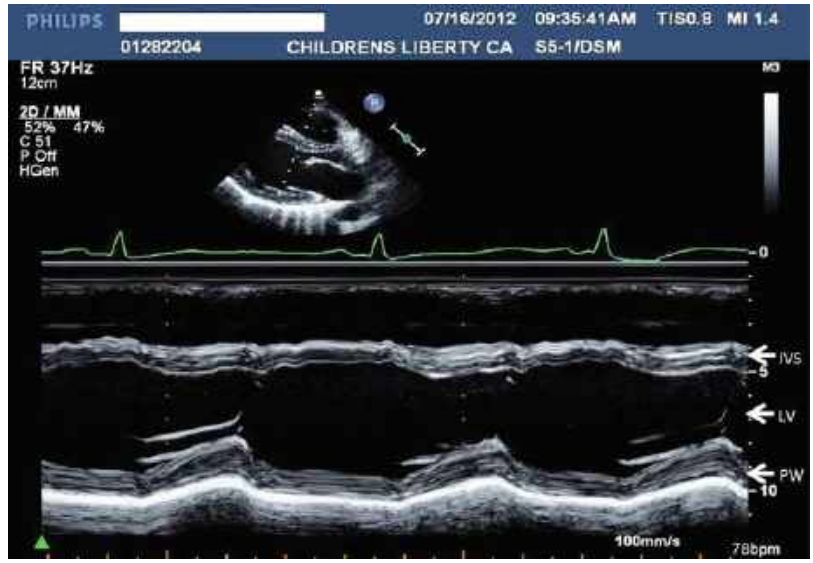

Fig. 32.1 Two-dimensionally guided M-mode echocardiogram of the left ventricle just inferior to the mitral valve leaflet tips. LV mass is calculated from measurement of the interventricular septum (*IVS*), the left ventricular posterior wall (*PW*), and the left ventricular cavity dimension (*LV*) at end-diastole

Echocardiography image quality is usually adequate enough to reliably measure left ventricular mass. For example, Gardin et al. [6] have shown that 90.5 % of subjects in the CARDIA study had echocardiograms from which LV mass could be measured accurately.

Alternatively, LV mass can be measured from two-dimensional echocardiography alone [11]. Since this technique uses measurements from orthogonal views of the heart, it may provide a more comprehensive view of LV mass than the M-mode technique which provides an "ice-pick" view of only one portion of the left ventricle. However, the technique is more time consuming, and the measurements are a bit more complex potentially leading to more variation in the LV mass calculation. For these reasons, measurement of LV mass by the M-mode technique remains the reference standard [12].

Relative wall thickness (RWT) is an adjunct echocardiographic index to LV mass. It is calculated using the formula: (interventricular septal thickness + posterior wall thickness)/LV end-diastolic internal dimension [7]. It is considered abnormal for values >0.41. Combining LV mass and RWT measurements allows classification of a patient's LV geometry (Fig. 32.2). Concentric hypertrophy, thickening toward the central axis of the LV, is commonly a result of pressure overload (e.g., systemic hypertension) and is defined as elevated LV mass with increased RWT. Eccentric hypertrophy, increasing mass away from the central axis of the LV, is commonly a result of volume overload (e.g., obesity) and is defined as hypertrophy with a normal RWT. Elevated relative wall thickness with normal LV mass indicates concentric remodeling – a possible precursor to LV hypertrophy. Each geometric type carries variable cardiac risk with concentric LVH having a poorer prognosis than eccentric hypertrophy. Concentric remodeling carries an intermediate prognosis between normal geometry and eccentric hypertrophy. De Simone et al. [13] have pointed out that RWT may have age-related variation which, when not accounted for, can lead to an underclassification of concentric and overclassification of eccentric hypertrophy types. They suggest using age-adjusted equations for RWT (= RWT−0.005 × (age-10)).

LV mass increases during childhood growth, and therefore, normal values must be defined in the context of body size. Mahoney et al. [14] reported that in children aged 6–15 years in the Muscatine Study, age was strongly correlated with unadjusted LV mass. Burke et al. [8] found a similar strong correlation between age and unadjusted LV mass. However, after adjusting

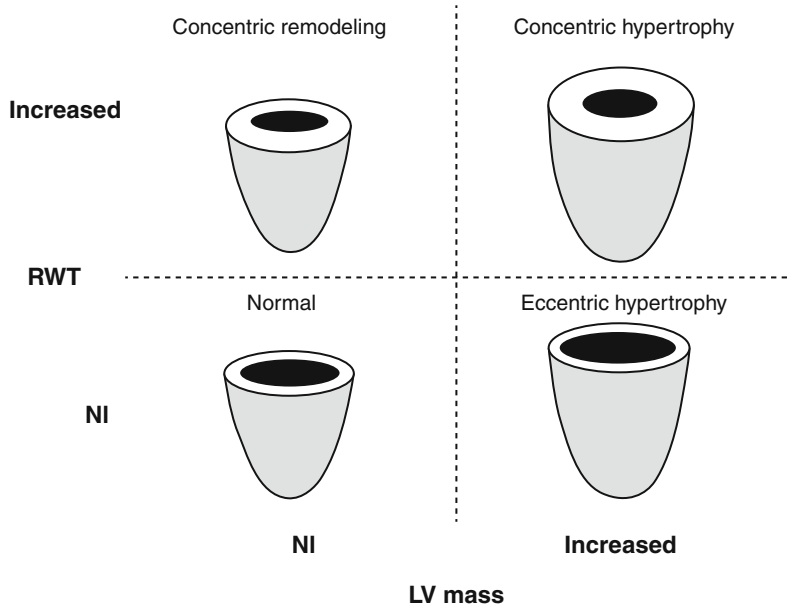

Fig. 32.2 Left ventricular geometry can be classified into risk categories based on LV mass and relative wall thickness (*RWT*) values. Normal (*NI*) LV mass and RWT indicates normal LV geometry. Elevated LV mass, by definition, indicates LV hypertrophy and can be further classified as eccentric hypertrophy (normal RWT) or concentric hypertrophy (elevated RWT). Concentric remodeling is a LV geometry type associated with increased RWT and normal LV mass. Patients with concentric hypertrophy carry the highest CV risk followed by eccentric hypertrophy. Concentric remodeling is associated with a lesser risk

for ponderosity and BSA, the correlation with age was lost. These studies demonstrate that LV mass is proportional to body size and that LV mass must be indexed in order to determine appropriateness of LV mass relative to body size. The topic of normalization of LV mass is actively discussed in the literature [15, 16]. There are several methods for correcting LV mass for body size which have included height, BSA, weight, and various exponential powers of height. The most ideal method for normalization of LV mass would account for a patient's growth and ideal body weight without discounting (or overinflating) the effect of overweight, or adiposity, on LV mass. The accuracy of any indexing method has become more critical with the increasing prevalence of obesity in children. Body weight is not an ideal indexing method since it represents a composite of fat and lean body mass. Likewise, since BSA is dependent on weight, it is not considered an ideal indexing variable – because adipose tissue represents a greater proportion of the weight in overweight than in non-overweight individuals, scaling LV mass to BSA can result in underestimation of the relative LV mass in overweight individuals.

Ideally, to account for growth and differences in body size, it is necessary to separate out the effects of lean body mass alone. Many studies have shown that LV mass is strongly predicted by a patient's lean body mass (LBM). In fact, lean body mass explains more variability in LV mass than either height or weight [17, 18]. Although lean body mass is the best index for normalization of LV mass for body size, it is difficult to measure.

Body composition consists of two main components – the fat mass and the fat-free mass. The latter consists of water, protein, and bone. Lean body mass is the fat-free mass which does not include bone. Body composition can be measured by a variety of techniques. Predictive methods include skinfold measurements, body circumferences, and bioelectric impedance. Although these methods are relatively easy, they may be inaccurate and are based on two

compartment models of body composition (fat-free mass and fat mass), in which the fat-free measurement includes not only lean body mass but also bone mass. Reference methods, methods by which a component of the body is directly measured and the body fat percent is then determined, include underwater weighing, air displacement plethysmography, and dual-energy X-ray absorptiometry (DXA). Underwater weighing is cumbersome and does not include measurement of the bone mass. Availability of air displacement plethysmography is limited. Only DXA provides a measurement of bone density, thereby allowing a calculation of lean body mass. Although radiation exposure is low and the test is easy, DXA is costly and has limited availability.

Therefore, investigators have attempted to find easily measurable surrogates for lean body mass. Most of these inquiries have focused on using height or exponential powers of height as surrogates of lean body mass. Height (expressed in meters) raised to an exponential power of 2.7 has been found to be an accurate surrogate for lean body mass in adults [18, 19]. This method closely approximates the equivalent effect of LBM and excludes the effect of obesity on LV mass.

Although indexing LV mass by height$^{2.7}$ is the most ideal method for accounting for body size, it has limitations. The method has been shown to be extremely useful for adults, adolescents, and older children. It is the indexing method recommended for children and adolescents by the Fourth Report on hypertension [12]. However, in younger children (i.e., <9 years old), LV mass/ht$^{2.7}$ varies significantly, and percentile curves are double what they are for older children. For example, while the 95th percentile is approximately 40 g/m$^{2.7}$ for older children, it is 80 g/m$^{2.7}$ for newborns [16]. Clearly, a different indexing method is needed for younger children and infants. In these patients, indexing by height alone better accounts for body size.

Ultimately, it would be most ideal if LBM could be measured (or approximated) directly. Recognizing the limitations of using BSA and other simple body size measurements as surrogates for LBM, Foster et al. [20] derived gender- and race-specific predictive equations of LBM based on weight and height. The predicted values correlated closely with LBM measures from DXA with a mean difference (measured – predicted) of just over −0.1 %. Validation of the equations in two independent samples demonstrated that LBM was predicted within 4 % of DXA measurements.

The criteria used to define LV hypertrophy depend on the method for normalizing LV mass for body size. One adult criterion for LVH is indexed LV mass >51 g/m$^{2.7}$ [21]. Indeed, this threshold has proven useful as hypertensive adults with LV mass greater than 51 g/m$^{2.7}$ have a fourfold greater risk of adverse cardiovascular outcomes. The 95th percentile for LV mass in pediatric patients is 36.88 g/m$^{2.7}$ for girls and 39.36 g/m$^{2.7}$ for boys [22]. When LV mass is indexed by height alone, the threshold values are >80 g/m for girls and >100 g/m for boys.

Another method for defining LVH and proposed by many investigators is to use percentile curves [15, 16]. With these methods, a patient's absolute or indexed LV mass is plotted against percentiles derived from normative data to arrive at a LV mass z score.

With appropriate measurement and indexing and application of accurate thresholds for defining LVH, indexed LV mass becomes a powerful index since it is an independent risk factor for development of cardiovascular morbidity and mortality. Separating out the effects of growth allows study of the impact of other factors such as obesity, sexual maturation, and blood pressure on LV mass and, therefore, cardiovascular risk. Daniels et al. [23] showed that lean body mass, fat mass, blood pressure, and sexual maturation stage have statistically significant relationships with LV mass suggesting that all play a biological role in determining LV mass. By taking into account the various body compartments, it is possible to determine which component has the greatest impact on cardiovascular health. In a later study, Daniels et al. [24] showed that the distribution of fat, specifically greater deposition of central fat (android pattern), is more important in predicting LVM index than total percent body fat.

Left Ventricular Diastolic Function

Doppler Echocardiography

Doppler echocardiography allows regional measurement of blood flow velocities anywhere through the heart. In the evaluation of LV diastolic function, the velocities across the mitral valve are used. Two distinct waveforms occur across the mitral valve during LV filling. The first wave (E) occurs during early diastole just after the mitral valve opens and is due to passive filling of the LV from the left atrium. The second wave (A) occurs later in diastole and is due to filling because of left atrial contraction. The ratio of E/A is used as an index of diastolic function. Normally, the E velocity is higher than the A velocity, and the ratio is >1. With early diastolic dysfunction, ventricular filling becomes more dependent on atrial contraction so the E wave velocity decreases and the A wave velocity increases with the E/A ratio eventually becoming <1. As left atrial pressure increases in the face of increasing LV stiffness, there may be period of diastolic dysfunction when the E wave becomes more dominant again – the pseudonormalization phase. However, as left atrial pressure increases even further, the last phase of diastolic dysfunction is evident when the E wave is very dominant and there is little or no A wave. This stage of diastolic dysfunction is known as restrictive physiology and is due to such a stiff left ventricle and high atrial pressure that the left atrium empties into the LV immediately and completely upon mitral valve opening.

Doppler Tissue Imaging

Mitral inflow is dependent on LV relaxation and left atrial pressure [25]. Therefore, confounding effects of changes in loading conditions can alter LV filling velocities. Doppler tissue imaging measures the velocities of the myocardium (usually at the mitral valve annulus) where the velocity profile, as with transmitral flow velocities, consists of a wave due to early filling (E′) and a wave due to left atrial contraction (A′) (Fig. 32.3). The E′ wave is relatively preload independent, and the ratios of both E′/A′ and E/E′ are useful measures of LV diastolic function. The latter index has been shown to correlate with LV end-diastolic pressure – a catheter-derived measure that is considered the reference standard for LV diastolic function [26]. In addition, the E′/A′ ratio is more useful than transmitral E/A velocity ratio because it does not pseudonormalize in the face of increasing left atrial pressure.

Left Atrial Size

Left atrial size is perhaps one of the more valuable tools in evaluating diastolic function. As the left ventricle becomes stiffer, its filling is impaired leading to increased left atrial pressure and left atrial dilatation. Increased left atrial size is considered an index of diastolic dysfunction chronicity. Although left atrial size can be assessed with a simple M-mode measurement through its anterior-posterior diameter, the reference standard is left atrial volume using orthogonal echocardiographic imaging planes.

Applications

Hypertension

Hypertension is an established risk factor for target organ damage which is known to predict hard cardiovascular events. LV hypertrophy is the most prominent evidence of target organ damage. The International Pediatric Hypertension Association has studied the effects of hypertension on LV mass in children [27]. LV hypertrophy occurs commonly in this population (41 % of patients) and is related to BMI, emphasizing the need for obesity prevention in hypertensive children. Although LVH occurs more frequently in hypertensive adults of African-American race/ethnicity, these investigators showed that LVH was most frequent in Hispanic children. Further, the Hispanic children had the

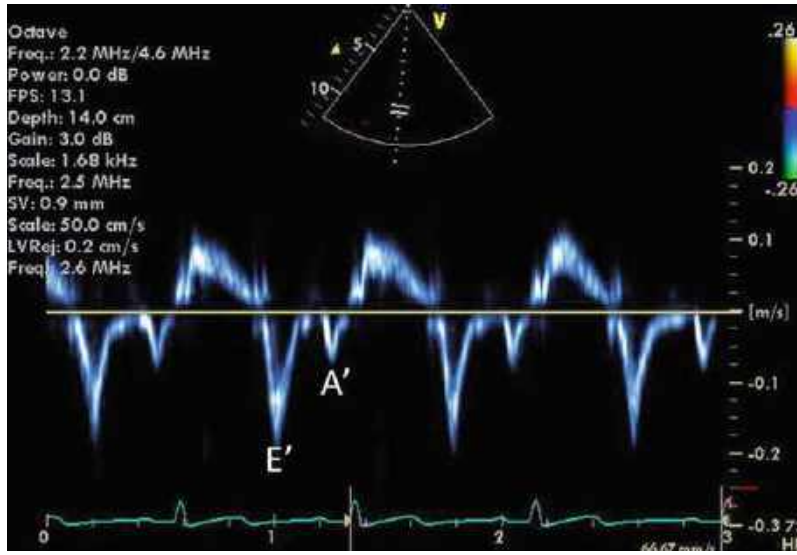

Fig. 32.3 Tissue Doppler imaging is an echocardiographic method which measures the velocity of wall motion at the mitral valve annulus. Just as with transmitral Doppler blood flow velocities, mitral valve annular motion during diastole consists of two waveforms. The first occurs from motion due to rapid, early ventricular filling (E′). The second occurs from motion due to filling from atrial contraction (A′). As with transmitral blood flow velocities, normal annular motion is associated with a higher passive filling wave than the wave due to filling during atrial contraction as shown here. As ventricular relaxation becomes impaired, the A′ wave becomes more prominent and exceeds the E′ wave. With very impaired ventricular relaxation, left atrial pressure becomes so high that the left atrium begins and completes filling of the left ventricle immediately upon opening of the mitral valve with little or no further filling due to atrial contraction

highest prevalence of concentric geometry possibly conferring an even worse prognosis. However, other investigators have shown that hypertensive African-American children, like their adult counterparts, have a higher prevalence of LV hypertrophy [28].

Studies suggest that no safe BP threshold exists because "prehypertension" (i.e., BP between the 90th and 95th percentile in children or between 120/80 and 140/90 mmHg in adults) may progress to hypertension. Indeed, even in these children with prehypertension, LVH is already apparent [29].

Echocardiography to identify LV hypertrophy and other signs of cardiac involvement has now become part of the standard work-up of confirmed hypertension [12]. The presence of LV hypertrophy on echocardiography is an indication to begin or up-titrate antihypertensive treatment.

Border et al. [30] found a 36 % prevalence rate of diastolic abnormalities in children with hypertension. Elevated LVM index was the most significant predictor of diastolic abnormalities, and patients with concentric hypertrophy pattern were most affected.

Obesity

Long-standing obesity can induce LV structural and functional abnormalities, which manifest by volume overload, a hyperdynamic state, eccentric LVH, diastolic dysfunction, and at times systolic dysfunction and overt heart failure [31]. Many of these abnormalities begin in childhood and adolescence [32]. LVH is associated with obesity independent of the effects of other comorbidities such as hypertension [27, 33, 34]. The Fels Longitudinal Study is a longitudinal study designed to study child growth and development. Today it focuses on body composition and risk factors for cardiovascular disease and obesity. Investigators have shown that as adults get older they tend to

get fatter, and this fatness is reflected in an increase in BMI, reflecting total body fatness, and increased abdominal circumference, reflecting central adiposity. Left ventricular mass correlates not only with BMI but also abdominal circumference possibly reflecting a significant role for central adiposity [35]. Crowley et al. [36] showed a generational increase in LVM index in today's youth compared to youth in the late 1980s. This change was related to a corresponding increase in BMI.

Studying covariates of LV mass in this population can be difficult because of the problem of accounting for patient growth. For example, body weight is a composite of lean body mass and fat and therefore correlates strongly with LV mass. Weight explains the variance due to lean body mass, but a portion of the positive relation is also due to subscapular skinfold thickness for instance. Because body weight "overcompensates" for this positive relation of skinfold thickness with LV mass, a negative partial correlation coefficient for skinfold thickness results when it enters a multiple-regression model.

Investigators have shown that it is possible to decrease LV mass with weight management. For example, weight reduction in overweight patients in the Bogalusa study resulted in 20 % decrease in LV mass [8]. Ippisch et al. [37] demonstrated that with profound weight loss due to bariatric surgery (average weight loss 59 kg), LVM decreases. More importantly, the prevalence of concentric LVH decreased (from 28 % preoperatively to 3 % postoperatively), the prevalence of normal LV geometry increased (from 36 % to 79 %), and diastolic abnormalities improved.

Many studies [33, 38] have shown that obese children have abnormal diastolic function as assessed by Doppler tissue imaging indices and left atrial size. In some, these abnormalities are related to LV mass, but in others, they are independent from LV mass suggesting that the mechanism of diastolic dysfunction is not related to LVH.

Cardiac abnormalities can impact aerobic fitness which has been shown to be related to increased LV mass, relative wall thickness, and left atrial size in obese children [39].

Type 2 Diabetes

Shah et al. [40] have studied cardiovascular changes with echocardiography in lean youth and obese youth with and without type 2 diabetes. Not surprisingly, LVM index was higher in the obese groups vs. lean control subjects. However, there were progressive diastolic abnormalities in patients who were lean to obese without diabetes and even higher in those who were obese with diabetes. These data suggest that in youth, type 2 diabetes confers an even greater cardiovascular risk beyond that due to obesity alone. Diastolic abnormalities are independent of blood pressure and are strongly related to degree of insulin resistance and abdominal obesity [41].

Future Directions

Newer echocardiographic tools include assessment of regional and ventricular strain using either Doppler technology or two-dimensional speckle tracking [42–45]. Strain and strain rate are proving to be robust measures of systolic and diastolic atrial and ventricular function. For instance, obese, non-hypertensive children have abnormal strain mechanics of the left atrium and LV which correlate to insulin resistance, obesity, and LV mass [44, 45]. Three-dimensional echocardiographic analysis of myocardial deformation may also prove useful in the assessment of cardiovascular risk [46]. Finally, with the development of sophisticated tools capable of assessing the arterial vasculature, it is now possible to combine echocardiography to investigate ventriculo-arterial coupling [47]. As echocardiographic techniques such as these become more sophisticated, adverse cardiac changes could be detected earlier and intervention could begin sooner in a patient's disease course.

Anesthetic Agents and Their Cardiovascular Effects

33

Dean B. Andropoulos

Abstract

A myriad of anesthetic approaches can be used for patients with congenital heart disease (CHD) undergoing cardiac or noncardiac surgery, procedures in the cardiac catheterization laboratory, or other diagnostic procedures such as magnetic resonance imaging. Any regimen must be designed with the goal of producing general anesthesia or adequate sedation, while preserving systemic cardiac output and oxygen delivery. These patients often have limited cardiac reserve and deranged cardiac pathophysiology, and if cardiac compromise from the anesthetic regimen occurs, resuscitation has a lower success rate than in patients with normal hearts [1–3]. This means that carefully considered selection of anesthetic regimen and drug dosage, with the patient's unique pathophysiology in mind, along with anesthetic requirements for the particular procedure they are undergoing, is essential. Another chapter in this section addresses techniques for specific cardiac pathologies. This chapter will review the effects of anesthetic agents on hemodynamics and myocardial contractility in patients with congenital heart disease.

Volatile Agents

Infants from the neonatal period up to an age of approximately 6 months exhibit an exaggerated depression of myocardial contractility and blood pressure with all volatile anesthetic agents, but especially halothane, which is now rarely available or used in developed countries [4]. Greater myocardial depression is due to the immaturity of the calcium release and reuptake system in the cytosol, necessitating higher levels of free cytosolic calcium to be available to bind to the troponin-actin-myosin complex to produce myocyte contraction [5]. Sevoflurane and, to a greater extent, halothane interfere with both L-type calcium channel and Na^{+}-Ca^{++} exchanger calcium flux at the plasmalemmal membrane. This effect is greater in neonatal than adult rat myocytes [6]. This effect, along with immature calcium release and resequestration in the underdeveloped sarcoplasmic reticulum in the neonate, provides a pathophysiologic explanation for the effects observed clinically.

Using transthoracic echocardiography in 54 children with two-ventricle congenital heart disease, Rivenes et al. reported that 1 and 1.5 MAC halothane caused significant myocardial depression, resulting in a decline in mean arterial pressure of 22 % and 35 %, ejection fraction of 15 % and 20 %, and cardiac output of 17 % and 21 % [7] (Fig. 33.1). Sevoflurane maintained both cardiac output and heart rate and had less profound hypotensive and negative inotropic effects compared with halothane. Isoflurane, in concentrations as high as 1.5 MAC, preserved cardiac output and ejection fraction, had less suppression of mean arterial pressure (22 % and 25 %) than halothane, increased heart rate (17 % and 20 %), and decreased systemic vascular resistance (20 % and 22 %).

Desflurane commonly produces tachycardia and hypertension in normal children during the induction phase, followed by a slight reduction in heart rate and systolic blood pressure during steady state at 1 MAC anesthetic level [8, 9]. Hemodynamic responses to desflurane have not been reported patients with congenital heart disease.

Studies of volatile anesthetic effects in patients with a single functional ventricle are limited. Ikemba et al. [10] assessed 29 infants with a single functional ventricle before their bidirectional cavopulmonary connection, randomized to receive sevoflurane at 1 and 1.5 MAC or fentanyl/midazolam at equivalent doses. Myocardial performance index (MPI), an echocardiographic measurement of ventricular function, was not changed with any of these regimens when compared to baseline, indicating that either sevoflurane or fentanyl/midazolam in the usual anesthetic doses can be used in this population to maintain hemodynamic stability (Fig. 33.2).

The effects of volatile agents on pulmonary (Qp) and systemic (Qs) blood flow ratio in 30 biventricular patients and left-to-right shunts have also been assessed. Halothane, isoflurane, and sevoflurane did not change Qp:Qs as measured by echocardiography [11]. Russell et al. [12] compared halothane with sevoflurane in the pre-bypass period in 180 children with a variety of cardiac diagnoses. The incidence of significant hypotension, bradycardia, and arrhythmia requiring drug treatment with atropine, phenylephrine, epinephrine, or ephedrine was higher with halothane (two events per patient vs. one). Serum lactate also increased slightly with halothane.

Few studies to date have addressed the effects of the different anesthetics on an important group of pediatric patients with heart disease: patients with cardiomyopathy or significantly decreased systolic ventricular function. Isolated case reports of cardiovascular collapse during dental surgery with sevoflurane induction limited to 3–5 % inhaled concentration in a child with severe dilated cardiomyopathy and ejection fraction <20 % and another child with left ventricular non-compaction cardiomyopathy highlight the potential for myocardial depression with abnormal myocardium [13, 14].

Patients receiving sevoflurane have a 6–12 % incidence of arrhythmias, mostly atrial or junctional [15, 16]. Sevoflurane induction caused a 20 % incidence of junctional bradycardia (less than 80 beats/min) during high-dose induction in a group of infants, average age 7 months. There are case reports of sevoflurane causing torsade de

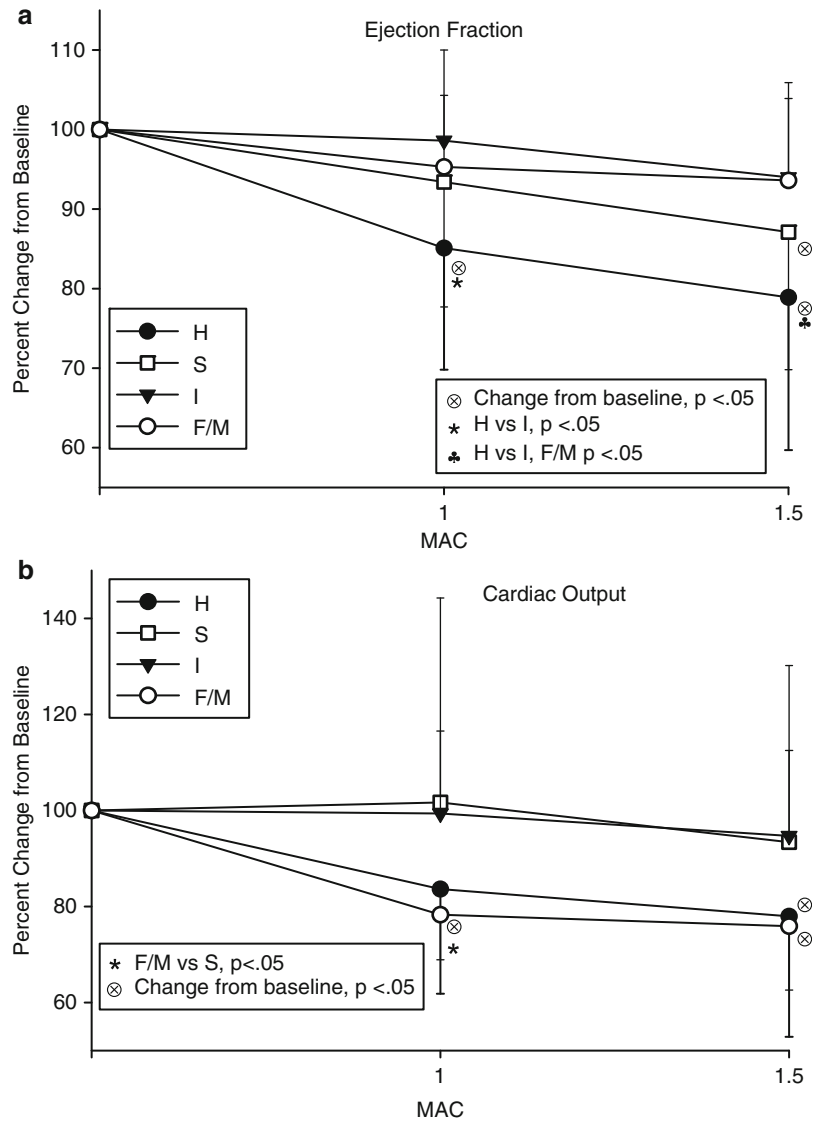

Fig. 33.1 (**a**) Ejection fraction responses to halothane (*H*), sevoflurane (*S*), isoflurane (*I*), or fentanyl/midazolam (*F*/*M*) at baseline and 1 and 1.5 MAC concentrations, or equivalent for fentanyl/midazolam, in 54 two-ventricle patients, assessed by transthoracic echocardiography. (**b**) Cardiac output responses measured by echocardiography

pointes in children with congenital long QT syndrome; this effect may be due to the increase in heart rate often seen with induction of anesthesia with this agent [17]. Bradycardia with sevoflurane induction was 50 times more prevalent in patients with Trisomy 21, when compared to patients with normal chromosomes, even in the absence of heart disease [18]. Isoflurane, when utilized in children for electrophysiological studies and radiofrequency ablation for supraventricular tachycardia, does not affect sinoatrial or atrioventricular node conduction, and all arrhythmias are easily induced [19]. Electrophysiological properties of desflurane were reported in a study of 47 children undergoing electrophysiological study for supraventricular tachycardia (SVT). Desflurane allowed induction of the SVT in all patients and demonstrated no clinically important differences in any electrophysiological parameter, compared to fentanyl [20]. Desflurane and isoflurane have similar very low arrhythmogenic potential [21].

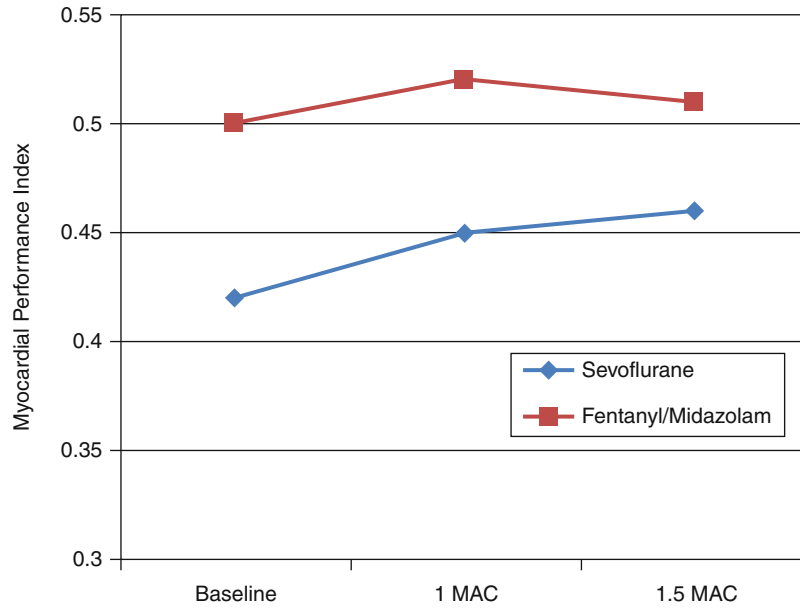

Fig. 33.2 Myocardial performance index (*MPI*) measured by transthoracic echocardiography in 29 infants with a functional single ventricle, with sevoflurane at baseline, and 1 and 1.5 MAC, or equivalent doses with fentanyl/midazolam. Higher MPI values signify worse myocardial function

Nitrous Oxide

There is limited data on the hemodynamic effects of nitrous oxide despite its ubiquitous use as an adjunct to anesthetic induction and maintenance in patients with congenital heart disease. Nitrous oxide is relatively contraindicated where increased FiO_2 is needed or where enlargement of enclosed air collections is possible, such as in any intracardiac or intrathoracic surgery. Most anesthesiologists limit N_2O use to the immediate induction period for congenital heart surgery.

Hickey et al. [22] studied the effects of 50 % N_2O in 14 patients recovering from congenital heart surgery and observed a decrease of 9 % in heart rate, 12 % in mean arterial pressure, and 13 % in systemic cardiac index. Mean pulmonary artery pressure and pulmonary vascular resistance (PVR) were not significantly changed, even in patients with elevated pulmonary vascular resistance at baseline, as long as oxygenation and ventilation were maintained. This single report represents the total number of patients with congenital heart disease in which N_2O administration has been carefully studied.

Opioids and Benzodiazepines

The synthetic opioids fentanyl and sufentanil have been studied as a single anesthetic agent in infants with congenital heart disease. Hickey and Hansen et al. [23–26] performed a series of studies in infants less than 1 year of age undergoing complex repairs ranging from the Norwood operation to complete repair of biventricular lesions. Fentanyl doses of 50–75 mcg/kg, and sufentanil doses of 5–40 mcg/kg administered with pancuronium at 0.1–0.15 mg/kg, provided excellent hemodynamic stability with minimal changes in heart rate and blood pressure. Fentanyl 25 mcg/kg prevents the increase in pulmonary artery pressure and resistance in response to suctioning in infants with pulmonary hypertension recovering from cardiac surgery. Sufentanil at a dose of 5, 10, or 20 mcg/kg had no effect on ejection fraction as measured by echocardiography, in patients undergoing repair of biventricular lesions [27]. Larger doses of fentanyl (at 100 mcg/kg) or sufentanil (at 20 mcg/kg) in children 6 months to 9 years of age decreased both ejection fraction and shortening fraction

after induction, but they returned to or above baseline after intubation [28].

Fentanyl is often utilized with midazolam with the latter providing sedation and amnesia, in lieu of low-dose volatile anesthetic agent, especially in hemodynamically unstable patients and young infants, where the myocardial depressant effects of volatile agents are more pronounced. Fentanyl and midazolam together have been studied in two different clinically utilized dose regimens to simulate 1 and 1.5 MAC of volatile agents. This included fentanyl 8–18 mcg bolus followed by 1.7–4.3 mcg/kg/h infusion; then repeat bolus at 50 % of the original doses followed by increase of infusion by 50 %, depending on age. Midazolam dose was 0.29 mg/kg bolus followed by 139 mcg/kg/h infusion, then repeat bolus 50 % of the original dose, followed by increase in infusion of 50 % in congenital heart surgery in biventricular patients [7]. Measurements of cardiac output and contractility were made by echocardiography. Fentanyl/midazolam caused a significant decrease (22 %) in cardiac output despite preservation of contractility by echocardiography, due to a decrease in heart rate.

Remifentanil is a synthetic ultra-short-acting narcotic agent metabolized by plasma esterases with half-life less than 5 min independent of the duration of infusion [29]. Remifentanil may be useful for short noncardiac procedures with intense stimulation where opioid anesthesia with hemodynamic stability is desirable, yet where rapid emergence is also important. In 55 children undergoing cardiac catheterization with a remifentanil infusion of 0.1 mcg/kg/min, Donmez et al. reported excellent cardiovascular stability, with minimal changes in heart rate, blood pressure, or oxygen saturation [30, 31]. Remifentanil has been reported as a component of fast track protocols for atrial septal defect repair, where patients are extubated in the operating room [32]. Friesen et al. compared remifentanil 0.3–0.7 mcg/kg/min to fentanyl 15 mcg/kg, both with isoflurane and pancuronium, in fast track pediatric cardiac operations (atrial and ventricular septal defect repairs). They reported that heart rate was significantly slower in the remifentanil group, but there was no difference in time to extubation, analgesic requirements in the intensive care unit (ICU), nausea/vomiting or hypertension in ICU, or ICU length of stay [33] (Table 6.2). Akpek et al. compared higher-dose remifentanil, 2 mcg/kg load and 2 mcg/kg/min maintenance infusion, with fentanyl 20 mcg/kg load and 20 mcg/kg hour infusion in 33 infants with pulmonary hypertension undergoing surgery for repair of left-to-right shunting defects. There were no clinically important differences in hemodynamic, respiratory, or oxygen saturation parameters between groups and no difference in clinical outcomes [34].

Propofol

In a study of 31 patients 3 months to 12 years old undergoing cardiac catheterization, Williams et al. [35] studied the hemodynamic effects of propofol at a dose of 50–200 mcg/kg/min (Fig. 33.3). Propofol significantly decreased mean arterial pressure and systemic vascular resistance; but systemic cardiac output, heart rate, and mean pulmonary artery pressure, as well as pulmonary vascular resistance, did not change. In patients with intracardiac shunts, there was a significant increase in the right-to-left shunt, a decrease in the left-to-right shunt, and decreased Qp:Qs, resulting in a statistically significant decrease in PaO_2 and SaO_2. In two acyanotic tetralogy of Fallot patients, there was reversal of the shunt from left to right to right to left in two patients. In another study of patients undergoing cardiac catheterization, Lebovic et al. [36] demonstrated that patients could experience a 20 % decrease in heart rate or mean arterial pressure.

Propofol has no significant effect on sinoatrial or atrioventricular node conduction, or on the ability to induce supraventricular tachycardia, and therefore is desirable as a primary agent during electrophysiological studies and radiofrequency ablation [18, 37]. However, ectopic atrial tachycardia may be suppressed by propofol [38].

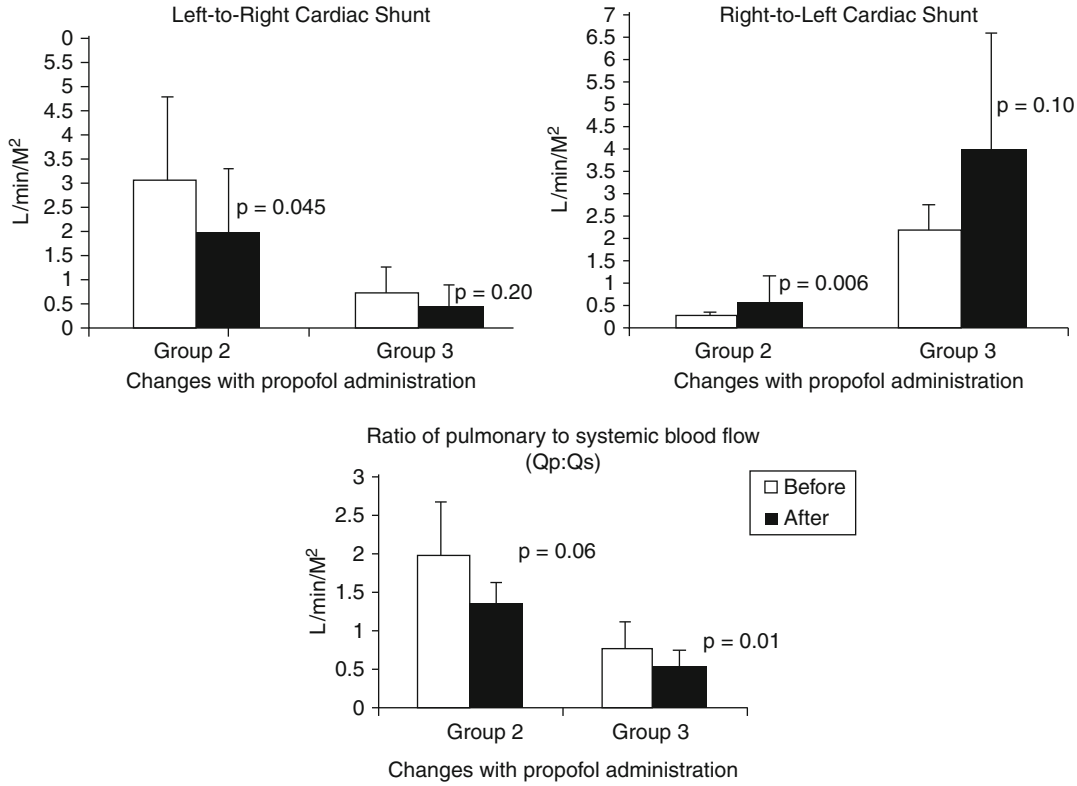

Fig. 33.3 Changes in intracardiac shunting in response to propofol induction and infusion in children undergoing cardiac catheterization. Group 2: patients with net l*eft-to-right* cardiac shunting. Group 3: patients with net *right-to-left* cardiac shunting. Qp:Qs decreased significantly in both groups (Reproduced with permission from Reference [35])

In summary, propofol can be utilized in patients with adequate cardiovascular reserve who can tolerate a mild decrease in contractility and heart rate and a decrease in preload and systemic vascular resistance. This agent should be used with caution, if at all, in patients who are significantly preload and afterload dependent, i.e., dilated cardiomyopathy patients. Propofol may cause an increased intracardiac right-to-left shunt and reversal of shunt in some patients, and thus hemodynamic data obtained in the cardiac catheterization laboratory should be interpreted accordingly.

Ketamine

The general anesthetic and analgesic effects of ketamine are mediated by binding N-methyl D-aspartate receptors in the brain [39]. Ketamine increases heart rate, blood pressure, and cardiac output via central nervous system-mediated sympathomimetic stimulation and inhibition of the reuptake of catecholamines. Ketamine is a direct myocardial depressant when studied in isolated myocyte preparations [40] and in adult human failing atrial and ventricular muscle trabeculae [41]. This direct myocardial depression may be unmasked when administered to patients whose own endogenous sympathetic responses are maximized. In addition, patients receiving ß-adrenergic agonists may have downregulation of adrenergic receptors in the myocardium, resulting in a diminished response to endogenously generated catecholamines, which allows the myocardial depressant effects of ketamine to predominate.

Myocardial depression by ketamine is by inhibition of L-type voltage-dependent calcium

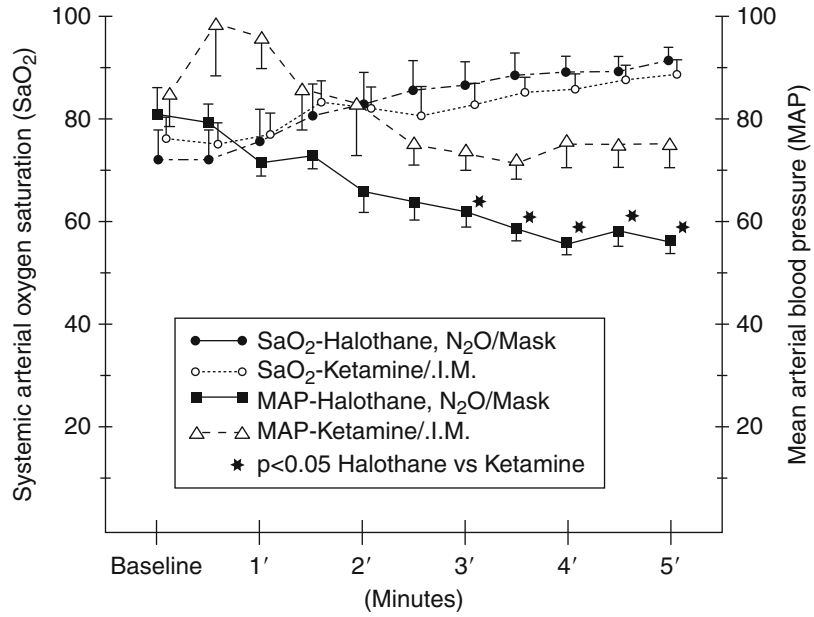

Fig. 33.4 Oxygen saturation and MAP in response to induction with intramuscular ketamine versus halothane in patients with right-to-left cardiac shunting, most of whom had tetralogy of Fallot (Reproduced with permission from Reference [47])

channels in the sarcolemmal membrane. An increased extracellular calcium concentration may enhance this effect [40]. Ketamine causes greater direct myocardial depression than etomidate [42]. A case report of a patient with end-stage cardiomyopathy suffering hemodynamic collapse with induction of anesthesia with ketamine underscores this potential effect [43]. Murphy et al. reported a series of 28 general anesthetics in children with severe heart failure; 89 % of anesthetics included ketamine. Although the majority did well, the two patients who suffered cardiac arrest had ketamine induction, in combination with a small dose of opioid and less than 0.5 MAC volatile anesthetic [44].

Despite potential adverse effects of ketamine to cause direct myocardial depression, this drug has been a mainstay of induction of general anesthesia in patients with congenital heart disease and adequate ventricular function, even with severe cyanosis [45, 46]. Ketamine can be administered intravenously or intramuscularly for induction and will reliably maintain heart rate, blood pressure, and systemic cardiac output at an induction dose of 1–2 mg/kg IV or 5–10 mg/kg IM and a maintenance dose of 1–5 mg/kg/h in patients with a variety of congenital heart diseases, including tetralogy of Fallot [47, 48] (Fig. 33.4). Ketamine has been reported to exacerbate pulmonary hypertension in adults, but this is not the case in pediatric studies. Morray et al. [49] demonstrated that in cardiac catheterization patients, 2 mg/kg ketamine caused a minimal (<10 %) increase in mean pulmonary artery pressure and ratio of pulmonary to systemic vascular resistance, with no change in direction of shunting or Qp:Qs. Hickey et al. [23] studied postoperative cardiac surgery patients with normal $PaCO_2$ and reported that ketamine 2 mg/kg had no effect on pulmonary artery pressure or pulmonary vascular resistance (PVR) in patients with normal or elevated baseline PVR. Williams et al. reported that ketamine 2 mg/kg load followed by an infusion of 10 mcg/kg/min did not change PVR at all in 15 children with severe pulmonary hypertension, when breathing spontaneously with a baseline of 0.5 MAC sevoflurane [50]. Ketamine administration as a component of general anesthesia in a group of 68 children with pulmonary hypertension undergoing major or minor noncardiac surgery, cardiac catheterization, or other procedures was not associated

with a higher complication rate than in patients not receiving ketamine [51].

Intramuscular induction of anesthesia may be achieved with ketamine 5 mg/kg, succinylcholine 4 mg/kg, and atropine 20 mcg/kg mixed in the same syringe. This regimen is useful for small patients who present without intravenous access in whom the inhalational induction of anesthesia may produce undesirable hemodynamic effects. Endotracheal intubation can usually be achieved in 3–5 min, and attention can be turned to establishing intravenous access with the airway secure and a stable hemodynamic state.

Etomidate

Etomidate is an imidazole derivative introduced into clinical practice in 1972. It produces its hypnotic effects by binding to gamma-aminobutyric acid receptors [39]. Etomidate consistently demonstrates the smallest amount of direct myocardial depression of all intravenous induction agents in several in vitro models. Two studies using adult human atrial and ventricular tissue demonstrated no effect of etomidate on myocardial contractility in concentrations seen in clinical use.

Data reporting the hemodynamic effects of etomidate in children with congenital heart disease are limited. In a study of 20 patients with a variety of congenital defects in the cardiac catheterization laboratory, Nguyen et al. found that etomidate at 0.3 mg/kg bolus followed by an infusion of 26 mcg/kg/min had similar effects as ketamine 4 mg/kg followed by an infusion of 83 mcg/kg/min. Both caused a slight increase in heart rate but no change in mean arterial pressure during induction or the 60 min infusion [52]. Sarkhar et al. [53] administered etomidate bolus 0.3 mg/kg in 12 children undergoing cardiac catheterization for device closure of atrial septal defect, or radiofrequency ablation of atrial arrhythmias. Hemodynamic parameters did not change, including heart rate, mean arterial pressure, filling pressures, vascular resistances, Qp:Qs, or mixed venous oxygen saturation. A case report of stable hemodynamics in a pediatric patient with end-stage cardiomyopathy receiving a second anesthetic 4 weeks after cardiovascular collapse with ketamine induction (see above) demonstrates the utility of the drug in this population [43]. In a study of 30 children under age 12 undergoing cardiac catheterization for left-to-right ($n = 15$) or right-to-left ($n = 15$) intracardiac shunting, 0.3 mg/kg bolus of etomidate was administered after basal sedation with morphine and midazolam, while breathing room air. Even though a number of patients had significant pulmonary hypertension, or cyanosis from right-to-left shunting, there was no change in systemic or pulmonary hemodynamics, including Qp:Qs and pulmonary vascular resistance [54].

Dexmedetomidine

Dexmedetomidine is an imidazole derivative highly selective α-2 adrenergic receptor agonist (1,620:1 α-2 to α-1 activity, vs. 220:1 for clonidine). Dexmedetomidine is a centrally acting agent which produces sedation at the level of the locus ceruleus and a dose-dependent decrease in heart rate and MAP by decreasing CNS sympathetic nervous system activity. It also potentiates opioid effects with binding to α-2 adrenergic receptors in the spinal cord. Dexmedetomidine is suitable for use during and after cardiac surgery, as a component of a general anesthetic and as a sedative /analgesic agent in the intensive care unit. Usual dose for sedation is 0.2–0.7 mcg/kg/h; a loading dose of 0.5–1 mcg/kg given over 10 min can be utilized if desired. Dexmedetomidine has minimal effect on respiration, making this agent attractive for use in fast-tracking protocols.

Dexmedetomidine was studied by Muktar et al., as an adjunct agent in general anesthesia for pediatric cardiac surgery. A loading dose of 0.5 mcg/kg was followed by 0.5 mcg/kg/h infusion, along with an isoflurane-fentanyl-midazolam anesthetic. Dexmedetomidine significantly reduced heart rate, mean arterial pressure, and cortisol, blood glucose, and serum catecholamine response in children aged 1–6 years undergoing cardiac surgery with bypass, when compared to the baseline anesthetic without dexmedetomidine [55].

Chrysostomu et al. studied dexmedetomidine sedation for 38 pediatric patients after two-ventricle repair with cardiopulmonary bypass. Thirty-three of 38 were extubated, and average age was 8 years; dexmedetomidine infusion rate varied from 0.1 to 0.75 mcg/kg/h (mean 0.3), and desired sedation was achieved in 93 %, and analgesia in 83 % of patients, respectively. There was no respiratory depression, but hypotension was observed in 15 % of patients [56]. Dexmedetomidine as a sole sedative agent for pediatric cardiac catheterization was studied by Munro et al. in 20 children [57]. A loading dose of 1 mcg/kg was followed by an infusion of 1 mcg/kg/h. Dexmedetomidine caused a slight decrease in mean arterial pressure but not heart rate.

Dexmedetomidine frequently causes bradycardia and thus may not be suitable as a sedative for electrophysiological studies. In 12 children undergoing electrophysiological studies, Hammer et al. reported that dexmedetomidine 1 mcg/kg load, followed by 0.7 mcg/kg/h infusion for 20 min, decreased heart rate by 15–20 %. More importantly, dexmedetomidine depressed sinus node recovery times and sinus node automaticity and increased atrioventricular nodal block cycle lengths and PR interval [58]. In the setting of pediatric cardiac surgery, however, dexmedetomidine has some desirable effects, suppressing both atrial and ventricular dysrhythmias and controlling hypertensive episodes. Chrysostomu et al. [59] studied 32 patients undergoing complex cardiac surgery; 20 received dexmedetomidine load and infusion from the start of the anesthetic through the initial ICU admission, and 12 received standard anesthesia. The incidence of tachyarrhythmia was much less in the dexmedetomidine group (6 % vs. 50 %, $p = 0.001$), including 0 % versus 25 % incidence of ventricular tachycardia and 6 % versus 25 % incidence of supraventricular arrhythmia (both $p < 0.05$). In addition, control patients had higher heart rate and more episodes of sinus tachycardia and required both sedation/analgesia and vasodilator therapy more often for hypertension. Transient complete heart block was only seen in three patients: one in the dexmedetomidine group and two in the control group.

A rapid bolus or large doses of dexmedetomidine can cause a biphasic response, with hypertension from binding to peripheral arteriolar α-2b adrenoceptors, followed by hypotension as the sympatholytic responses predominate over time from binding the central α-2a receptors. In a study of 29 infants and children receiving dexmedetomidine loading dose of 1–4 mcg/kg over 10 min following corrective 2 ventricle cardiac surgery, plasma dexmedetomidine concentrations above 1.0 mcg/L were associated with a 20 % increase in mean arterial pressure. Doses above 1 mcg/kg load were more likely to produce this degree of hypertension [60]. Su et al. determined that at dosing ranges corresponding to the package insert of 0.35–1 mcg/kg over 10 min, followed by continuous infusion of 0.25–0.75 mcg/kg/h in 36 infants aged 1–36 months in the ICU following cardiac surgery, hemodynamic status was stable without major change. A pharmacokinetic model was developed which included a clearance of 29.1 ml/min/kg, intercompartmental clearance of 93.4 ml/min/kg, central volume of distribution of 1.2 L/kg, and peripheral volume of distribution of 1.5 L/kg [61].

There is limited data on dexmedetomidine's effects on pulmonary artery pressure and resistance. Twenty-two patients without preexisting pulmonary hypertension were studied with transthoracic echocardiography to estimate pulmonary artery pressure after corrective cardiac surgery by Lazol and colleagues. A dexmedetomidine loading dose of 0.62 mcg/kg, followed by infusion of 0.5 mcg/kg/h and then increased to 0.65 mcg/kg/h, was administered. By echocardiographic estimate of tricuspid regurgitation peak velocity, PA pressure decreased slightly and the PAP/systemic pressure ratio decreased slightly, and left ventricular function was unchanged [62]. In a study of 12 patients undergoing surveillance cardiac catheterization after cardiac transplant, a rapid bolus of 0.25 or 0.5 mcg/kg dexmedetomidine over 5 s, Jooste et al. reported a 10 % and 40 % increase in PVR and a 14–17 % increase in systolic PAP; these returned to below baseline by 5 min, and systemic pressures and resistances also increased; cardiac output was not changed [63].

Table 33.1 Expected hemodynamic effects of anesthetic drugs in congenital heart disease

Drug class	Drug	Heart rate	Systemic ventricle contractility	Systemic vascular resistance	Pulmonary vascular resistance	Systemic cardiac output	Arrhythmogenic potential
Anesthetic gas	Isoflurane	↑	→	↓↓	↓	→	→
	Sevoflurane	↑	↓	↓	↓	→	↑
	Desflurane	↑↑	→	↓	↓	→	→
	Halothane	↓↓	↓↓	↓↓	↓	↓↓	↑↑
	N_2O	↓	→	↓	→	↓	→
Intravenous	Fentanyl/ midazolam	↓↓	→	→	↓	↓	→
	Ketamine	↑↑	↑ or ↓[a]	↑↑	→	↑ or ↓[a]	↑
	Etomidate	→	→	→	→	→	→
	Dexmedetomidine	↓↓	→	↓ or ↑[b]	↓ or ↑[b]	↓	↑
	Propofol	↓↓	↓	↓↓	→	↓↓	→

Expected hemodynamic effects of anesthetic agents in congenital heart disease at usual clinical doses for induction and/or maintenance. ↑, small increase; ↑↑, moderate increase; ↓, small decrease; ↓↓, moderate decrease; →, no appreciable change

[a]Ketamine is a direct myocardial depressant and may decrease contractility and cardiac output in patients with compromised baseline ventricular function

[b]Dexmedetomidine will cause hypertension with rapid or large loading doses. This table is a general guide only, and each individual patient must be assessed carefully for response to any anesthetic regimen. Any anesthetic regimen may result in hemodynamic compromise in patients with marginal cardiovascular reserve

Dexmedetomidine is thus a potentially useful agent as an adjunct to general anesthesia, a postoperative sedative, and an adjunct sedative for cardiac catheterization (non-electrophysiological studies) in pediatric cardiac surgery patients. The patient must be able to tolerate the predictable decrease in heart rate and frequent decrease in arterial blood pressure associated with dexmedetomidine. Hemodynamic effects in neonates have not been reported, and this drug should be used with caution in this age group.

A summary of the hemodynamic effects of the inhaled and intravenous anesthetics is presented in Table 33.1.

Intracardiac Shunts

Right-to-left intracardiac shunting decreases the rate of rise of the concentration of inhaled anesthetic in the arterial blood because a portion of the systemic cardiac output bypasses the lungs, diluting the anesthetic concentration in the systemic arterial blood. The anesthetic concentration in the blood thus never equals the exhaled concentration. Huntington et al. [64] studied six children with right-to-left shunts from a fenestrated Fontan operation whose average pulmonary to systemic blood flow ratio was 0.58. These patients achieved an arterial anesthetic concentration (Fa) of only 55 % of inspired halothane concentration (Fi) after 15 min during washin of 0.8 % halothane. After occlusion of Fontan fenestration in the cardiac catheterization laboratory, the arterial concentration of halothane equaled the inspired concentration. This difference between Fa and Fi is greater during induction or washout and greater with less soluble drugs such as sevoflurane, desflurane, and nitrous oxide than with more soluble drugs such as isoflurane and halothane. The corollary of slower induction with right-to-left shunting is slower decrease in Fa during emergence or, when a lower concentration is desired quickly, i.e., during periods of hypotension.

Right-to-left intracardiac shunting will cause intravenous agents given by bolus to pass directly into the left side of the heart with less dilution by systemic venous blood and passage through the

pulmonary vascular system. Intravenous induction agents and muscle relaxants may also achieve sufficient arterial and brain concentrations more rapidly with right-to-left intracardiac shunts [65].

Left-to-right intracardiac shunts have little effect on the speed of induction with inhaled anesthetic agents [66]. The recirculation of blood through the lungs results in increased uptake of anesthetic and in a higher blood anesthetic concentration in the pulmonary capillaries, which in capillary blood, reducing anesthetic uptake. The two effects cancel each other. Only with severe congestive heart failure, with significant interstitial and alveolar edema, would left-to-right intracardiac shunting be expected to slow inhalation induction, from the combined effects of diffusion limitation and ventilation-perfusion mismatch resulting in alveolar dead space ventilation in which no new anesthetic agent is taken up.

Conclusion

The congenital cardiovascular anesthesiologist's central role is to design an anesthetic strategy for the individual patient who often has limited cardiovascular reserve. Understanding of the expected hemodynamic effects of inhaled and intravenous anesthetic agents, as well as continuous monitoring and assessment of cardiovascular responses, is essential for optimal care of these complex patients. Despite a paucity of controlled studies comprehensively evaluating the hemodynamic effects of anesthetic agents in congenital heart disease, there is sufficient data and extensive clinical experience to intelligently plan the anesthetic for each patient.

Operative Preparation of the Patient for Heart Surgery: Airway and Ventilation, Vascular Access and Monitoring

34

Sana Ullah and Luis M. Zabala

Abstract

Airway and ventilation management are key components in the perioperative management of patients with congenital heart disease. Diverse cardiovascular pathophysiology mandates individualized management, as ventilatory strategy can significantly influence cardiorespiratory interactions. Many patients with congenital heart disease have associated airway anomalies. Airway and respiratory complications are an important cause of morbidity after cardiac surgery. Inhaled nitric oxide has become a valuable treatment in the perioperative management of certain groups of patients. Establishing vascular access and invasive hemodynamic monitoring are also essential components during the perioperative period. The use of real-time ultrasound imaging has greatly increased the safety and efficiency of line placement. Other monitoring modalities such as near-infrared spectroscopy may provide additional useful information about vital organ function.

Airway and Ventilation Management

Expert airway and ventilatory management is critical in the perioperative care of patients with congenital heart disease (CHD). Patient size can vary from tiny premature neonates to morbidly obese adults. Many patients are chronically hypoxemic with a reduced margin of safety during anesthesia induction and securing the airway. Ventilatory management will alter the cardiorespiratory interactions which will have a direct impact on hemodynamics. Many patients with CHD will have preexisting airway anomalies or will develop airway complications after surgery which can have a significant impact on morbidity and mortality. The combination of a difficult airway with CHD will require advanced planning in terms of equipment and personnel. Single lung ventilation for surgeries involving a thoracotomy presents additional challenges in small children due to cardiorespiratory compromise and the limited availability of appropriately sized airway equipment.

Airway Management

Introduction

Management of the airway in patients with CHD presents special challenges for the anesthesiologist. These include ventricular dysfunction, cyanosis with diminished reserve once apnea occurs, and pulmonary hypertension (PHTN). Patients with balanced circulatory physiology, where pulmonary flow (Qp) and systemic flow (Qs) will change secondary to alterations in $PaCO_2$, PaO_2, and pH, can be particularly difficult to manage. Patients with large left-to-right shunts such as ventricular septal defect (VSD), patent ductus arteriosus (PDA), or atrioventricular (AV) canal defects will have increased pulmonary blood flow (PBF) in response to increased FiO_2 and/or hyperventilation due to a decrease in pulmonary vascular resistance (PVR). This will worsen congestive heart failure at the expense of systemic blood flow. Conditions in which there is decreased PBF, such as tetralogy of Fallot (TOF), will respond favorably to high FiO_2 and hyperventilation, as will patients with PHTN. In unpalliated hypoplastic left heart syndrome (HLHS), it is absolutely critical to maintain the fragile balance between Qp and Qs preoperatively. These patients have ductal-dependent systemic blood flow due to hypoplasia or atresia of the left heart structures. As the PVR decreases rapidly after birth, this leads to a large increase in PBF at the expense of systemic perfusion, which places these patients at increased risk of circulatory shock with compromised organ perfusion including the heart, brain, gut, and kidneys. Preoperatively, these patients are frequently maintained on 21 % oxygen and hypercarbia (through mechanical ventilation and using inspired CO_2) to maintain a higher PVR [1]. The anesthesiologist needs to be extremely vigilant not to use high FiO_2 and a tendency to hyperventilate these patients during anesthesia induction or transport to the operating room or other sites as this could lead to a catastrophic and irreversible decrease in systemic cardiac output.

Management of the Normal Airway

A detailed anesthetic history and airway examination is essential in all patients presenting for anesthesia. It is helpful to know about previous intubations, endotracheal tube (ETT) sizes, and any problems encountered. The main purpose of evaluating the airway is to predict whether intubation will be difficult or require special preparation and equipment. However, the usual method of airway assessment in adults, the Mallampati classification [2], has not been validated in neonates, infants, and young children less than 6–8 years of age due to the age-related differences between children and adults and the need for cooperation with making the assessment. Therefore, every child may be regarded as a potential difficult airway, and the anesthesiologist must be prepared to deal with such an eventuality. Concurrent CHD adds to the risk by reducing cardiorespiratory reserve.

Anesthesia induction can be a risky time in children with complex CHD. Most children presenting for elective surgery will not have an intravenous catheter placed preoperatively.

Inhalational induction with sevoflurane in a mixture of nitrous oxide and oxygen is usually smooth and well tolerated by most patients with CHD. Once anesthetic-induced respiratory depression sets in, it is important not to assist ventilation with high concentrations of the inhaled agent, as this may lead to rapid cardiovascular depression. A tendency to hyperventilate must also be avoided, particularly in patients with large left-to-right shunts or those with a balanced circulation, as this can lead to increases in PBF. If peripheral venous access is difficult, then consideration must be given to using intramuscular drugs such as ketamine and rocuronium. A deltoid injection of rocuronium, 1 mg/kg in infants and 1.8 mg/kg in older children, provides satisfactory intubation conditions in less than 3 min [3]. This will allow a reduction in the inhaled agents which are potent cardiovascular depressants. If rapid access to the circulation is required, the external jugular vein, which is very superficial and visible in most patients, or the intraosseous route is a good alternative.

Endotracheal Tube Size Selection

The correct size tube (internal diameter, ID) is based on patient age and size (Table 34.1). These are a guide only, and ETT sizes one-half size smaller and larger than predicted should be available.

When the correct sized tube is appropriately placed, it should allow for a gas leak around the tube at 20–25 cm H_2O of peak inspiratory pressure. A leak at 30–35 cm H_2O may be acceptable for procedures of short duration. However, with a tight-fitting tube, the risk of submucosal edema and subsequent subglottic stenosis is increased. Before securing the tube, the correct depth of insertion must be confirmed, that is, midway between the vocal cords and the carina. This step is even more critical in patients having repair of congenital cardiac defects, especially those who have low baseline oxygen saturations, and who may be having the procedure done via a thoracotomy. For example, in a neonate having an aortopulmonary shunt placed via a thoracotomy, a lower than expected oxygen saturation may be mistakenly misattributed to an undersized shunt rather than endobronchial intubation of the nondependent lung. In the operating room, the correct depth of tube placement is usually confirmed by auscultation of bilateral equal breath sounds in both axillae. Some practitioners deliberately advance the tube into a main stem bronchus (usually the right) while simultaneously listening for the loss of breath sounds in the left axilla. Patients with heterotaxy syndromes have abnormal bronchial anatomy. Asplenia (bilateral right-sidedness) is associated with bilateral *right* bronchial morphology, whereas polysplenia (bilateral left-sidedness) is associated with bilateral *left* bronchial morphology. Endobronchial intubation is likely to occur on either side in these patients. Once breath sounds are lost on one side, the ETT is pulled back 2 cm above the carina and secured. An alternative technique is to place the ETT with the cuff just below the vocal cords. The use of x-rays or a fiber-optic bronchoscope to confirm correct depth is not routinely used in the operating room. It is important to emphasize that even with correct initial placement, the ETT may move with flexion or extension of the head which might occur during final patient positioning. Flexion of the head advances the tube, and extension withdraws the tube (*ex*tension = *ex*tubation) [4]. Manipulations of the transesophageal echocardiography (TEE) probe can also lead to ETT movements and even inadvertent extubation, in addition to airway compression. The ventilatory parameters should be closely monitored during probe insertion to

Table 34.1 Endotracheal tube sizes for infants and children

Endotracheal tube sizes for infants and children[a]	
Age	Size (mm ID)
Preterm	
1,000 g	2.5
1,000–2,500 g	3.0
Neonates–6 months	3.0–3.5
6 months–1 year	3.5–4.0
1–2 years	4.0–4.5
Over 2 years	(Age in years + 16)/4

ID internal diameter
[a]Uncuffed. For cuffed ETT, use one-half size smaller

ensure there is no airway compression. If there is any doubt, the TEE probe should be removed, and epicardial imaging used if necessary. Before separation from cardiopulmonary bypass, it is useful to suction the ETT and also visually confirm that both lungs are being ventilated.

Nasal Versus Oral Intubation

In infants and small children, the nasal route is preferred by most practitioners because it is more stable and less prone to movement with TEE probe manipulations during surgery. It is also better tolerated by awake patients and avoids being obstructed by the patient biting on the tube. Prior to nasal intubation, a few drops of a topical vasoconstrictor such as oxymetazoline are instilled into both nares, and nasal patency is confirmed by passing a small soft suction catheter into the appropriate naris. Nasal intubation is slightly more difficult than oral intubation, and advancing the tube through the cords can be facilitated with a Magills forceps, taking care not to damage the cuff. Due to the natural curve of the ETT, it has a tendency to hang up anteriorly at the cords. This may be overcome by flexing the neck as the tube is advanced or by rotating the tube as it is advanced. Common problems with nasal intubation include trauma and bleeding from the nose, sinusitis, potential for transferring nasal organisms into the lower respiratory tract, and damage to the nares from pressure necrosis. Nasal intubation should not be used in patients who are anticoagulated, have a bleeding tendency, or who are immunocompromised (heart transplant recipients).

Cuffed Versus Uncuffed Tracheal Tubes

Traditional practice has been to use uncuffed ETTs in children less than about 8 years of age because of the risk of causing subglottic stenosis due to excessive pressure from the cuff. However, subglottic stenosis still existed in the predominantly "uncuffed" era, presumably due to the multifactorial etiology of this complication. A recent MRI study of pediatric airway anatomy [5, 6] might explain why even an uncuffed ETT may cause airway trauma, producing subglottic stenosis. The narrowest portion of the pediatric airway is considered to be the rigid cricoid cartilage which was thought to be a circular structure. An uncuffed tube seals the airway at the cricoid ring. However, the MRI study showed that the cricoid ring is actually slightly oval, with a larger anteroposterior diameter and a smaller transverse diameter. So, even an appropriately sized uncuffed tube with an acceptable leak, which occurs at the anterior and posterior segments of the cricoid, could potentially be exerting enough pressure on the lateral walls to produce ischemic injury to the mucosa. A well-designed, properly positioned cuffed tube seals the airway at the tracheal level below the cricoid ring, where the posterior mucosal portion of the trachea allows for some expansion and reduces the potential for ischemic injury. The use of uncuffed tubes has many disadvantages: The need for multiple tube changes to obtain the correct leak, particularly in patients whose lung compliance changes perioperatively; too much leak leading to inadequate ventilation, inaccuracy with expired CO_2 monitoring, aspiration, and operating room pollution. Over the past 10 years, cuffed tubes have been used more frequently in the anesthesia and pediatric critical care setting. Many of the complications related to intubation were due to prolonged intubation with inappropriately sized uncuffed tubes or the use of poorly designed cuffed tubes with high pressure low-volume cuffs. There are wide variations in cuffed tube design in terms of external diameter, cuff size and shape, and length of tube distal to the cuff [7]. Recently, a new cuffed tube has become available for use in children (Fig. 34.1). The Microcuff tube (Kimberly-Clark, Healthcare, Atlanta, GA, USA) has an ultrathin, high-volume, low-pressure cuff with better seal characteristics and also a shorter length distal to the cuff to reduce the chance of endobronchial intubation.

Over the past 10 years, cuffed tubes have been used more frequently in the anesthesia and pediatric critical care setting with no differences in the complication rates [8–10]. A well-designed, prospective, randomized, multicenter trial using the newly designed Microcuff ETT showed that the incidence of postoperative stridor was similar to the use of uncuffed tubes and required fewer

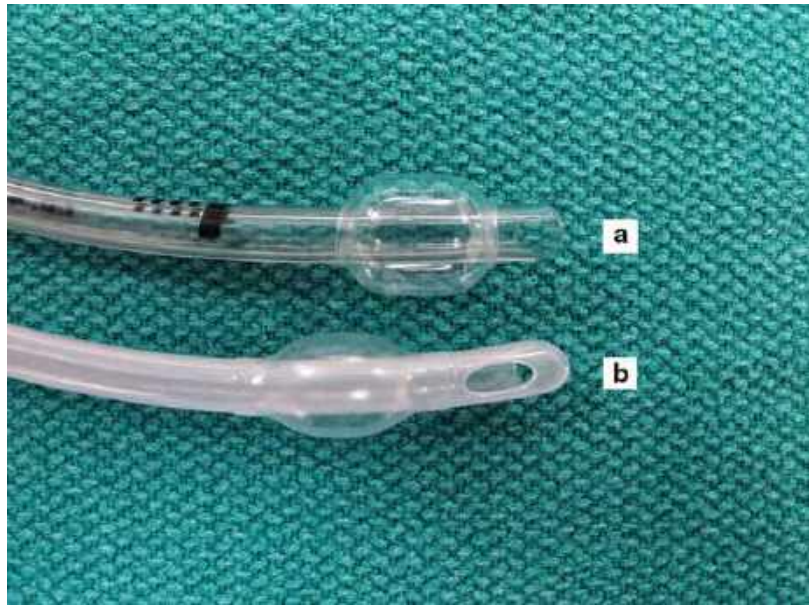

Fig. 34.1 Microcuff and standard ET tube. The Microcuff ET tube (**a**) has an ultrathin, high-volume/low-pressure cuff placed more distally near the tip that allows a better seal at the subglottic level instead of the cricoid ring. Elimination of the Murphy's eye shortens the length of the tube distal to the cuff, reducing the chance of endobronchial intubation. The anatomically based depth marker aids correct positioning. A standard cuffed ET tube of the same size (**b**) is shown for comparison (Photograph by Michael White, MD)

tube changes to find the appropriate-sized tube. However, in the cuffed tube group, cuff pressure was monitored in all patients and was kept at less than 20 cm H_2O [11]. In the pediatric cardiac surgery setting, there are several advantages of having an ETT where the air leak can be controlled because of the changing lung compliance due to the effects of cardiopulmonary bypass and postoperative changes in fluid balance and "third spacing." In patients with PHTN, it is important to be able to control blood gases and ventilation, which may not be possible with an excessively leaking uncuffed tube. Exchanging an uncuffed ETT for a cuffed one due to excess air leak can be a hazardous undertaking, particularly in small patients with unstable physiology and postoperative upper airways edema. For these reasons most institutions prefer to use cuffed ETTs from the outset. The size of the cuffed ETT is generally one-half size smaller than the appropriate uncuffed tube.

Management of the Difficult Airway

The combination of a difficult airway, whether anticipated or not, and CHD represents a significant challenge for the practitioner. Children desaturate much faster than adults due to a higher metabolic rate, higher oxygen consumption, and reduced oxygen reserves due to a much greater decrease in functional residual capacity (FRC) under anesthesia. If uncorrected, this can rapidly lead to bradycardia, cardiac arrest, and severe neurological injury or death. Patients with cyanotic heart disease are at even greater risk of such injury.

Difficult intubation is conventionally graded on the laryngoscopic view of the glottis, as described by Cormack and Lehane [12]. Grades 1 and 2 are associated with easy intubation. Grades 3 and 4 are generally associated with increasingly poor views of the glottis and difficulty with intubation. However, this grading system does not take into account the possibility of subglottic pathology, so even a grade 1 view may be associated with the inability to pass the tracheal tube below the vocal cords. A retrospective study of over 11,000 general anesthesia procedures with endotracheal intubation in children showed a 1.35 % incidence of difficult laryngoscopy (Cormack & Lehane grades 3 and 4), with a much higher incidence in infants compared with older patients (4.7 % vs. 0.7 %). Patients undergoing cardiac surgery and oromaxillofacial surgery showed the highest

rates of grade 3 and 4 findings [13]. In another retrospective analysis of 1,278 children undergoing congenital heart surgery, the incidence of difficult intubation (defined as more than one attempt or the use of special blades/aids or a grade 3 or 4 view) was 1.25 %. Anterior larynx was the most common reason (44 %) for difficult intubation, and 50 % of difficult intubations had associated syndromes or other congenital abnormalities [14]. A different study reported a much higher incidence of difficult intubation of 4.6 % in children having cardiac surgery and also an association of difficulty in patients with Down's syndrome. This higher incidence may be related to the preference for nasotracheal intubation in this study [15]. The true incidence of *unexpected* difficult intubation in patients presenting for congenital cardiac anesthesia is unknown, but an analysis of the Society of Thoracic Surgeons/Congenital Cardiac Anesthesia Society (STS/CCAS) database showed a 0.4 % incidence (23/5,757 cases) [16] (http://www.pedsanesthesia.org/ccas/newsletters/2011winter/STS-CCAS_Database_Update-2010_Data.ppt).

Being able to predict the difficult airway can be useful as it allows for adequate preparation and planning. Due to anatomical differences and the need for cooperation with airway assessment, the predictors of a difficult airway in adults have not been validated or considered useful in small children. However, there are certain factors that may be associated with a difficult laryngoscopy and intubation: restricted neck movement, retrognathia or mandibular hypoplasia, large tongue, limited mouth opening, and craniofacial dysmorphism. There are also many specific syndromes and disease processes involving cardiovascular abnormalities which are associated with potentially difficult airways that may require advance preparation and planning (Appendix Table 34.10).

Anticipated Difficult Airway

The key principles for a successful outcome are (1) having all the necessary equipment available, checked, and ready, (2) availability of experienced assistance, and (3) having plans A, B, and C, with a bailout plan for unsuccessful intubation, that is, wake the patient up or proceed to a surgical airway [17]. The availability of an individual who is proficient in performing a rigid bronchoscopy and obtaining a surgical airway (cricothyrotomy or a tracheostomy) is also necessary in the rare event that the patient cannot be intubated or ventilated.

Patient preparation includes judicious premedication and sedation titrated to effect. Choices include midazolam, opioids such as fentanyl or remifentanil, ketamine, and dexmedetomidine. Atropine or glycopyrrolate should also be given to reduce airway secretions and treat reflex bradycardia associated with airway instrumentation.

Techniques

The management of the difficult pediatric airway has been well described in several recent reviews [17, 18]. The method chosen will depend on patient characteristics, disease pathology, surgical procedure, and practitioner's expertise and experience. Whichever technique is chosen, the primary objective is to *maintain oxygenation* and ventilation. Most small children will not cooperate with an awake technique, so some form of sedation or general anesthesia is employed, in addition to topical anesthesia of the airway. *A key principle is to maintain spontaneous ventilation until the airway is secured*. Administration of muscle relaxants can lead to airway obstruction due to loss of muscle tone in the upper airways and removes the option of allowing the patient to awaken quickly. Smaller children can be anesthetized with oxygen and sevoflurane, which can be supplemented with intravenous drugs once access is established. Topical anesthesia of the airway can be achieved with nebulized 4 % lidocaine (maximum dose 5 mg/kg), "spray as you go" technique, or lidocaine paste or gel applied to a swab. Transtracheal injection of lidocaine may be used in older cooperative patients where coughing will spread the

anesthetic to the supraglottic structures as well. Another useful technique is the blind instillation (orally or nasally through an airway after the patient is anesthetized) of lidocaine into the back of the pharynx and massaging the larynx externally to spread the local anesthetic to the adjacent structures [19]. Although a wide range of techniques have been described for tracheal intubation of difficult airways, most practitioners should acquire and maintain expertise in two or three techniques, which can be used regularly. By using these techniques in elective non-difficult airways, expertise can be maintained. Three methods of difficult intubation are discussed here.

Fiber-Optic Intubation

The flexible fiber-optic bronchoscope (FOB) is considered the "gold standard" for managing difficult airways. Various sizes of FOB are available, the smallest being 2.2 mm diameter (Olympus LFP) which can accommodate a 2.5-mm internal diameter tracheal tube. However, this size of scope does not have a working channel for suctioning, administering oxygen, or instilling topical anesthetic. The keys to success are advanced planning and availability of equipment, skilled assistance, deep anesthesia while maintaining spontaneous ventilation, and topical anesthesia to prevent coughing and laryngospasm. The nasal route is a more direct path to the glottis than the oral route and is generally preferred in younger patients. Topical vasoconstrictors and generous lubrication should minimize the risk of bleeding, which is the major disadvantage of the nasal route. Inhalational anesthesia and oxygenation can be maintained by using specially designed masks or a regular facemask connected to a bronchoscopy swivel adapter. In neonates and infants, a modified nasal airway or a regular uncuffed tracheal tube can be passed through one nostril and connected to the breathing circuit to maintain anesthesia [20]. The oral route can also be used for FOB-guided intubation, but the angle of approach to the glottis is more acute than the nasal route. However, the risk of nasopharyngeal trauma and bleeding is avoided by the oral route, which can seriously impede further attempts at intubation with the FOB.

Intubation Through a Laryngeal Mask Airway

Advantages of using a laryngeal mask airway (LMA) include an almost direct approach to the glottis, as well as a means of maintaining anesthesia and oxygenation. Once the LMA has been inserted, a FOB with a proximally loaded ETT is passed through the LMA and into the trachea. The ETT can then be railroaded down the FOB, through the LMA into the trachea. The main disadvantage of this method is how to secure the ETT once it is correctly positioned. The LMA may be left in situ, but this makes it difficult to stabilize the tube in a precarious airway. The ETT may be grasped with a long endoscopy forceps as the LMA is removed. Another solution is to load the FOB with two ETTs which have been telescoped together. Once the ET tube is in place, the LMA can be easily removed over the double-length tube and the proximal ETT disconnected leaving the distal tube in place. A second problem is that the pilot balloon of the ETT will not pass through the LMA. This problem has been overcome by cutting off the pilot balloon and then "reconstructing" it by using an intravenous catheter and a stopcock with a Luer connector. The recent availability of a new LMA overcomes both these issues. The Air-Q (Mercury Medical, Clearwater, Florida) is wider and shorter than the other LMAs. It allows easy passage of the ETT and the pilot balloon, as well as easy removal, due to the shorter length.

Videolaryngoscopy

Over the past 10 years, several new devices have become available for use in neonates and infants which incorporate internal and/or external light sources and video monitor screens to facilitate laryngoscopy and intubation in normal and difficult airways [21, 22]. Most of these devices are

designed to improve the laryngoscopic view of the glottis. Experience is limited to small series and case reports. However, they are a useful addition to the equipment available for managing difficult airways in small children and may play a bigger role in the future.

Unanticipated Difficult Airway

The unexpected difficult airway in a child with CHD will challenge the most seasoned anesthesiologist. The likelihood of a successful outcome is increased if the following principles are kept in mind: *maintaining oxygenation and ventilation at all costs to prevent cardiac arrest or neurological injury*; recognizing the situation and calling for extra assistance and equipment; limiting airway instrumentation attempts to minimize trauma, bleeding, and swelling which can convert a "cannot-intubate, *can-ventilate*" situation into a "cannot-intubate, *cannot-ventilate*" scenario; and having a bailout plan – awaken the patient or proceed to a surgical airway. The latter will depend on the urgency of the surgery and the availability of extra assistance and equipment in a timely manner. If the patient can be ventilated, then one has the option of proceeding as described in the anticipated difficult airway section above.

The "cannot-intubate, cannot-ventilate" scenario is, fortunately, a very rare occurrence. Rescue options are limited to a surgical airway via a needle cricothyrotomy or a surgical cricothyrotomy. These are high-risk procedures and should only be undertaken by those with some experience in these techniques. Rigid bronchoscopy may be attempted before a surgical airway if a skilled person is immediately available [23].

Difficult Airway Algorithms and Guidelines

An algorithm is a set of unambiguous instructions performed in a prescribed sequence to achieve a goal. Algorithms for the management of a difficult airway have been published by the American Society of Anesthesiologists (ASA) [24] and the Difficult Airway Society (DAS) in the United Kingdom [25]. The DAS algorithms can be accessed and downloaded from their website, www.das.uk.com. Algorithms for use in the pediatric population have been proposed but not validated [22, 26, 27]. These should not be rigidly applied to all patients in all situations, but should be modified based on patient characteristics, the clinical situation, the practitioner's experience, and the availability of special equipment and trained personnel. They should be used to formulate a primary plan and several backup strategies in case of failure of plan A.

Extubating the Difficult Airway

A plan to extubate the difficult airway should be formulated as soon as the airway is secured. The details of this plan will depend on the difficulty of intubation, degree of airway trauma and edema, and surgical factors. Low-risk patients – easy mask ventilation, minimal airways instrumentation, and short surgery – may be extubated with minimal difficulty. High-risk airways – difficult mask ventilation, prolonged, multiple attempts at intubation, possibility of significant airway edema, and other comorbidities – need more preparation before extubation is carried out. Reintubation is likely to be more difficult than the initial attempts due to airway edema. Prophylactic administration of dexamethasone (0.5 mg/kg, maximum 10 mg) has been shown to reduce the incidence of post-extubation stridor and the rate of reintubation [28]. Airway edema may cause loss of the air leak around the ETT. However, absence of an air leak (where there was one before) is not predictive of extubation failure [29]. For the high-risk airway, extubation is best done safely in the operating room, with all the necessary equipment for reintubation and a surgeon in attendance who is capable of creating a surgical airway. Alternatively, to facilitate oxygenation and rapid reintubation, a Cook Airway Exchange Catheter (CAEC) (Cook Critical Care, Bloomington, IN, USA) may be utilized as a bridge in case of extubation failure [30].

The CAEC is a long, hollow, flexible, soft-tipped catheter which can be passed through the ETT and left in the trachea until the patient is no longer considered at risk for the loss of the airway. It is packaged with two different connectors for the proximal end – a RapiFit adapter which can be connected to a jet ventilation device and a standard 15-mm ETT connector for attachment to a breathing circuit. The smallest size available will accommodate a 3-mm internal diameter ETT. For even smaller patients, a J-tipped guidewire may be left in the trachea and used to facilitate reintubation.

Airway and Ventilation Management for Thoracic Surgery

Many cardiovascular procedures in children are performed via a thoracotomy. These include repair of aortic coarctation, ductal ligation, unifocalization procedures which can involve bilateral sequential thoracotomies, repair of vascular rings, placement of systemic to pulmonary shunts, and surgery on the distal aortic arch and proximal descending aorta. Use of single lung ventilation facilitates surgical exposure and reduces trauma to the lung. Before describing the various techniques for lung isolation, a brief discussion of the physiology of the lateral decubitus position (LDP) and single lung ventilation (SLV) is appropriate.

Physiology of the Lateral Decubitus Position

Optimal oxygenation of blood in the lung occurs when ventilation (V) is perfectly matched to perfusion (Q), a V/Q ratio of 1. In normal, healthy individuals, the V/Q ratio is typically 0.85, signifying a slight excess of perfusion over ventilation. Low V/Q (shunt) or high V/Q (dead space ventilation) ratios will both produce arterial hypoxemia. Major V/Q mismatching occurs in the LDP due to the effects of gravity, anesthesia and muscle relaxation, and the influence of hypoxic pulmonary vasoconstriction (HPV). Furthermore, the effects of LDP on oxygenation differ significantly between adults and older children and infants [31]. In adults and older children placed in the LDP, perfusion is greater in the dependent lung due to the effects of gravity and hydrostatic pressure. Ventilation is also better in the dependent lung due to the alveoli being on the more favorable, steep portion of the lung compliance curve. Even though anesthesia, muscle relaxation, and an open chest all combine to reduce the FRC of the dependent lung, these effects are still overcome by the increased perfusion and a lesser tendency toward hypoxemia. This explains why adults with unilateral lung disease have better oxygenation when they are placed in the LDP with the healthy lung in the dependent position, as there is better matching of ventilation and perfusion [32]. In infants, the picture is quite different. Because of the greater compliance of the rib cage and lungs in infants, when they are placed in the LDP, there is greater compression of the dependent lung due to the lack of a rigid thorax. This results in greater reductions in FRC, such that tidal ventilation may be close to the closing volume of the lung. Combined with the effects of anesthesia and compression of the dependent lung by the mediastinum, ventilation is more favored toward the nondependent lung. Furthermore, because of the shape of the infant thorax – more cylindrical or box-like compared with adults – the influence of hydrostatic pressure on the distribution of perfusion to the dependent lung is not as great as in adults. Therefore, infants have greater V/Q mismatching than adults and are more susceptible to hypoxemia during thoracic procedures. In contrast to adults, infants with unilateral lung pathology have better oxygenation if they are placed in the LDP with the diseased lung in the dependent position because there is more even distribution of perfusion to both lungs [31].

Single Lung Ventilation

Single lung ventilation produces an obligatory shunt due to perfusion but no ventilation of the nondependent lung. Hypoxemia is reduced by *hypoxic pulmonary vasoconstriction*, a mechanism whereby local alveolar hypoxia causes regional vasoconstriction of the pulmonary vasculature, thus diverting blood to the ventilated

parts of the lung. This protective mechanism is attenuated by volatile anesthetics (but not intravenous anesthetic agents), systemic vasodilators (nitroprusside, nitroglycerin, calcium channel blockers), and hypocapnia.

Hypoxemia is almost inevitable with SLV, and various maneuvers can be applied to mitigate against this: using 100 % inspired oxygen; ensuring correct position of the ETT or bronchial blocker; suctioning of secretions; insufflating oxygen and/or applying continuous positive airways pressure (CPAP) of 5 cm of H_2O to the nondependent lung; applying PEEP to the dependent lung, which may worsen hypoxemia by shunting blood to the nondependent lung; intermittent inflation of the operative lung if surgery allows; and finally, the surgeon may clamp the pulmonary artery on the nondependent side.

Techniques of Lung Isolation

There are four choices available for lung isolation [33].

- Single lumen endobronchial intubation
- Balloon-tipped bronchial blockers
- Univent tube
- Double lumen tubes (DLT)

Single Lumen Bronchial Intubation

This is the simplest method of using a standard ETT to selectively intubate the right or left main bronchus. This technique may be used in neonates and infants even without the use of a FOB, although this is desirable. A one-half to one size smaller cuffed ETT than indicated is used due to the smaller bronchial diameter. The cuff allows a better seal in the bronchus and trachea. Using an uncuffed ETT which provides a good endobronchial seal may have too large a leak once it is withdrawn into the trachea. A problem with this technique is that if repeated inflation of the operative lung is required by the surgeon, then the ETT has to be withdrawn and advanced, with the risk of inadvertent extubation during the procedure. The right main stem bronchus is more easily intubated due to the less acute angle from the trachea. Care must be taken not to advance the ETT too far so as to obstruct the lumen of the upper lobe bronchus.

Balloon-Tipped Bronchial Blockers

Various types of balloon-tipped catheters have been used to selectively occlude a main stem bronchus. These include Foley catheters, Fogarty embolectomy catheters, and balloon-tipped pulmonary wedge catheters. These can be positioned through the lumen of the ETT or passed alongside the tube. Final position can be confirmed with a FOB or fluoroscopically. The smallest Fogarty catheter (Edwards Lifesciences LLC, Irvine CA) available is a two French size, which is suitable for neonates and infants. Recently, a 5-Fr endobronchial blocker has become available in a kit form which includes a multiport adaptor which fits onto a standard ETT (Arndt Endobronchial Blocker Set, Cook Critical Care, Inc., Bloomington, IN). The adapter has separate channels for a FOB, the balloon-tipped blocker, and connecting to the anesthesia breathing circuit. The blocker has an adjustable wire guide loop protruding from the distal tip through which the FOB is passed into the appropriate bronchus. The wire loop is used to thread the blocker over the FOB and into the bronchus where it is inflated, and then it can be locked in place by a screw-down mechanism at the multiport adapter (Fig. 34.2). The smallest size ETT that will allow passage of the blocker and a 2.2-mm FOB is 4.5 mm ID. The catheter has a 0.7-mm internal lumen to facilitate lung deflation and suctioning. After the patient is positioned in the LDP, blocker placement should be reconfirmed using the FOB. Disadvantages of balloon blockers include dislodgement during patient positioning or surgical manipulation, leading to loss of lung separation, inadequate lung deflation, and inability to insufflate oxygen or suction secretions. Airways obstruction can occur if the balloon is dislodged into the tracheal lumen.

Univent Tube

The Univent tube (Fuji Systems Corporation, Tokyo, Japan) is a single lumen ETT which has an internal channel containing a balloon-tipped catheter that can be advanced into the appropriate bronchus under FOB visualization (Fig. 34.3). Pediatric sizes are available with 3.5 mm ID

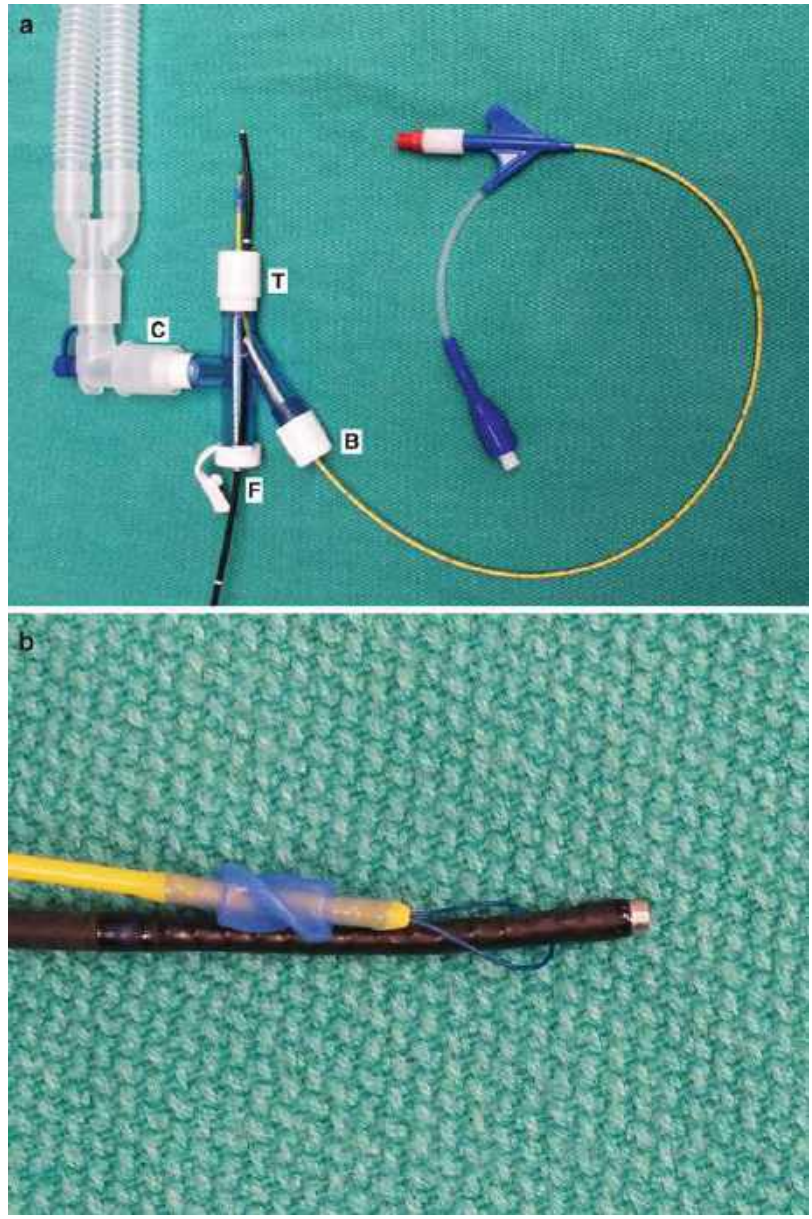

Fig. 34.2 (**a**) Cook Bronchial Blocker set up. Setup of the Cook 5-Fr endobronchial blocker (Cook Critical Care, Inc., Bloomington, IN, USA) with the multiport adaptor showing separate ports for the balloon catheter *B*, fiberscope *F*, breathing circuit *C*, and ET tube *T*. (**b**) Cook Bronchial Blocker detail. Showing detail of the fiberscope passing through the wire loop at the distal tip of the balloon catheter. Once the fiberscope is positioned within the appropriate bronchus, the catheter is threaded down the scope and inflated under fiber-optic view (Photograph by Michael White, MD)

(uncuffed) and 4.5 mm ID (cuffed). The outer diameter (OD) of these two sizes is 8 and 9 mm, respectively, which are equivalent to the OD of a 5.5 and 6.5 mm ID conventional ETTs. Hence, the smallest size Univent tube can only be used in patients over about 6 years of age. A major advantage of the Univent tube is that it can be left in place if the patient requires postoperative ventilation. The blocker is simply pulled back into the lumen of the tube after balloon deflation.

Double Lumen Tubes

Double lumen tubes (DLT) are considered the "gold standard" for lung separation. They are essentially the equivalent of two ETTs incorporated into a single device. The smallest size available for pediatric use is a 26 Fr, which can be used in patients over about 8 years of age. Advantages of a DLT include rapid inflation and deflation, application of CPAP, suctioning, and bronchoscopic visualization. Both left- and right-sided

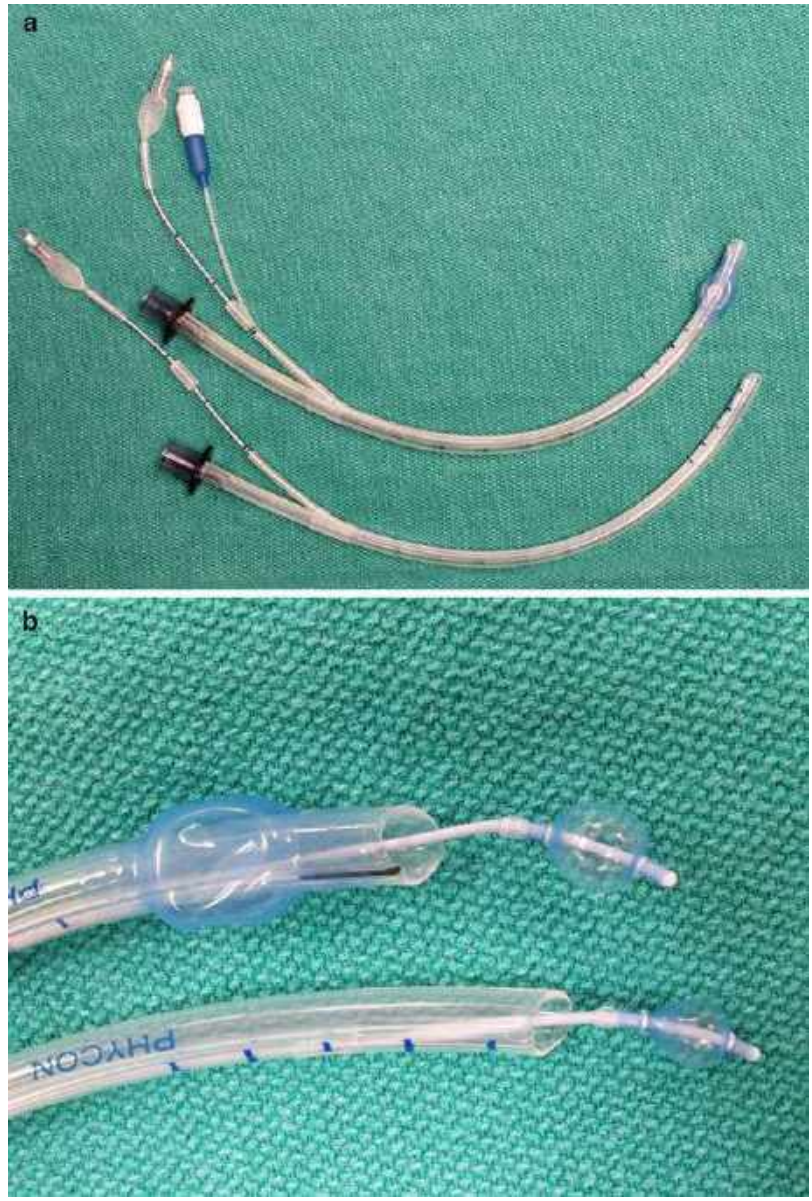

Fig. 34.3 Univent tubes. (**a**) Shows a cuffed 4.5 mm ID and an uncuffed 3.5 mm ID tube with the bronchial blockers retracted into the lumen. (**b**) Univent tubes detailAfter intubation, the blocker is advanced into the desired bronchus and inflated under fiber-optic visualization (Photograph by Michael White, MD)

versions are available, but for most situations, a left-sided tube is preferred because it is easier to place with less risk of obstructing the upper lobe bronchus. Although a DLT can be positioned "blindly" using auscultation, the use of a FOB is highly recommended. Tube placement must be confirmed after final patient positioning. If postoperative mechanical ventilation is required, it is preferable to change a DLT to a standard single lumen tube to reduce the risk of injury to the tracheobronchial tree. This can be safely done using an airway exchange catheter, if any difficulties are expected with laryngoscopy.

Choice of Technique for SLV

The most appropriate technique for SLV depends mainly on patient size. Most children over the age of 8–10 years can be managed with a Univent or DLT. Use of a balloon-tipped catheter or a standard ETT may be more suitable for younger

Table 34.2 Tube selection for single lung ventilation in children is based mainly on patient size. Univent and double lumen tubes are only suitable for patients over 6–8 years of age

Tube selection for single lung ventilation in children				
Age (yr)	ETT (ID)	BB (Fr)	Univent tube	DLT (Fr)
0.5–1	3.5–4.0	2		
1–2	4.0–4.5	3		
2–4	4.5–5.0	5		
4–6	5.0–5.5	5		
6–8	5.5–6.0	5	3.5	
8–10	6.0 cuffed	5	3.5	26
10–12	6.0 cuffed	5	4.5	26–28
12–14	6.5–7.0 cuffed	5	4.5	32
14–16	7.0 cuffed	5, 7	6.0	35
16–18	7.0–8.0 cuffed	7, 9	7.0	35–37

patients. Guidelines for selecting the appropriate tube or catheter have been published and are shown in Table 34.2.

Airway Problems Specific to Congenital Heart Disease

Patients with CHD have an increased incidence of airway-related problems which can have a significant impact on morbidity and mortality. Complex, often repeated, surgery on neonates and infants requires multiple tracheal intubations and frequently prolonged ventilatory support which increases the risk of airway complications. Airway anomalies associated with CHD significantly increase the duration of mechanical ventilation and hospital stay. Common presentations of airway complications include failed extubation, post-extubation stridor, feeding intolerance, and recurrent aspiration. Any patient who fails extubation, not due to primary cardiac or pulmonary failure, warrants an aggressive workup for airway abnormalities [34, 35]. The incidence of extubation failure (defined as a need for reintubation of the trachea within 24 h of extubation) was 10 % in one study. The most common causes were cardiac dysfunction, lung disease, and airways edema. Risk factors for failed extubation were pulmonary hypertension, Down's syndrome, and use of deep hypothermic circulatory arrest [36].

Airway problems can be divided into two groups: (1) *compression of the airway by cardiovascular structures in the thorax and* (2) *airway complications related to surgical treatment*.

Vascular Compression of the Airways

Vascular compression of the tracheobronchial tree may complicate airway management in the perioperative period [37]. Cardiovascular causes of airway compression are shown in Table 34.3 [38]. Presenting symptoms include stridor, wheezing which may be misdiagnosed as asthma, dysphagia, and recurrent respiratory infections. Accurate diagnosis is essential in planning the surgical management. Diagnosis is confirmed by chest radiography, echocardiography, multidetector-computed tomography, or magnetic resonance imaging. Fiber-optic endoscopy, with or without bronchography, may be needed to assess dynamic aspects of airway obstruction. The most common cause of airway compression is a *vascular ring*. This is an abnormal configuration of aortic arch branches, pulmonary artery, and ductus arteriosus or its remnant that encircle the trachea and esophagus producing symptoms of dysphagia or stridor. Treatment is surgical and usually requires a thoracotomy.

Table 34.3 Vascular causes of airway compression in children. The most common cause is a vascular ring, produced by abnormal branches of the aorta

Causes of vascular compression of the airway in children
Anomalies of the aorta
Double aortic arch
Interrupted aortic arch (after arch repair)
Right-sided aortic arch
With aberrant left subclavian artery
With mirror image branching and right ligamentum arteriosum
Left-sided aortic arch
With aberrant right subclavian artery and right ligamentum arteriosum
Right-sided descending aorta with right ligamentum arteriosum
Cervical aortic arch
Absent pulmonary valve syndrome
Aberrant left pulmonary artery ("pulmonary artery sling")
Acquired cardiovascular disease
Dilated cardiomyopathy
Aneurysm
Ascending aorta
Ductus arteriosus
