Subglottic stenosis (SGS) after pediatric cardiac surgery has a reported incidence of between 0.82 % and 1.08 %, with children less than 2 years having twice the incidence [39, 40]. Severity of SGS is graded based on the external diameter of the largest ETT that will pass through the lumen with a leak of less than 25 cm H_2O and comparing that to the diameter of the age-appropriate ETT size [41]. Although the etiology is multifactorial, identified risk factors are age less than 2 years and prolonged postoperative ventilation. The use of cuffed ET tubes is not a risk factor per se. In one study, 15/17 cases of SGS were in patients with uncuffed ET tubes [40]. The use of cuffed ET tubes is now widely accepted, even in neonates. It is most likely the presence of a leak around the tube which is more important than whether it is cuffed or uncuffed. The mechanism is related to ischemia of the tracheal mucosa, followed by inflammation and scar formation. In mild cases, conservative treatment may be effective and consists of systemic steroids (dexamethasone), racemic epinephrine, and antibiotics. More severe cases may need tracheal dilation, eschar removal, anterior cricoid split, tracheostomy, or laryngotracheal reconstruction.

Vocal Cord Paralysis

The right and left vocal cords receive their nerve supply from the right and left recurrent laryngeal nerves (RLN), respectively. Their convoluted intrathoracic course places them at increased risk of injury during cardiothoracic surgery. The right RLN loops around the brachiocephalic artery, while the left RLN passes around the ductus arteriosus and aortic arch. The majority of vocal cord paralyses involve the left side, with operations on the aortic arch, and ductal ligations being the predominant risk factors [39]. Manifestations include hoarseness, stridor, recurrent aspiration, and feeding intolerance which might require gastrostomy tube placement [42]. Recovery can be expected to occur in approximately a third of the cases with unilateral paralysis. If symptoms persist, especially aspiration and feeding difficulties, then earlier surgical intervention is warranted [43].

Phrenic Nerve Injury

Phrenic nerve injury causes diaphragmatic paralysis (DP) on the affected side. Etiology is usually related to surgical dissection, particularly during reoperations. It may also rarely be injured during cannulation of the internal jugular or subclavian vein. DP may be suspected after failure to wean from mechanical ventilation or appearance of a raised hemidiaphragm on a chest x-ray. The effects of DP are more apparent in neonates and infants because of their greater reliance on diaphragmatic breathing. During normal spontaneous

inspiration, the diaphragm descends, generating a negative intrathoracic pressure. This causes lung expansion and also increased venous return to the heart. However, a paralyzed hemidiaphragm moves paradoxically upward into the thoracic cavity during inspiration, due to the negative intrathoracic pressure. This leads to reduced lung expansion, atelectasis, and compromised ventilation. Single-ventricle patients are even more adversely affected by DP because PBF is mainly passive in these patients and relies greatly on a negative intrathoracic pressure. Thus, DP leads to a redistribution of pulmonary flow away from the affected side [44]. The diagnosis is confirmed by demonstrating paradoxical movement of the hemidiaphragm during *spontaneous* respiration. Treatment consists of surgical plication of the diaphragm which improves ventilatory efficiency, allowing better lung expansion on the affected side. Indications for plication include failure to wean from mechanical ventilation, age less than 6 months, and single-ventricle physiology [45]. Although a trial of conservative treatment (noninvasive ventilation) may be considered, further waiting may lead to atrophy of the diaphragm, with a suboptimal surgical result.

Tracheostomy

The reported incidence for tracheostomy after congenital cardiac surgery is 0.2–2.7 % [46–48]. The etiology is multifactorial and includes significant cardiovascular or pulmonary disease, DP, SGS, laryngotracheomalacia, vocal cord dysfunction, or neurological abnormality. The exact indications and timing vary by institution, but generally, if a patient has failed extubation after three attempts (after all treatable factors have been excluded), a need for tracheostomy should be discussed. Tracheostomy can be considered as a surrogate for severe cardiovascular or pulmonary disease and was associated with a very high mortality in the group of patients with single-ventricle physiology [47]. A patient with a tracheostomy who requires a sternotomy should be intubated by the nasal or oral route and the stoma decannulated and covered with a sterile impermeable dressing. There is a potentially increased risk of mediastinitis after tracheostomy. However, there is no data in the pediatric cardiac surgery literature to support this.

Ventilatory Management

Appropriate ventilation management plays a key role in the care of patients with CHD because of the close interactions between the heart and lungs in the thoracic cavity. An understanding of these cardiorespulmonary interactions is essential in choosing the optimal ventilation strategy for these patients with diverse pathophysiologies [49].

Heart-Lung Interactions

Because the heart and great vessels are located in the thoracic cavity, they are exposed to changes in intrathoracic pressures and volumes during spontaneous and mechanical ventilation. Changes in intrathoracic pressure are transmitted directly to the cardiac chambers and will affect their filling (preload) and emptying (afterload). During spontaneous inspiration, the intrapleural pressure becomes negative with respect to atmospheric pressure. This increases venous return to the right heart, but preload to the left heart is decreased for several heart beats due to pooling of the blood in the pulmonary vasculature and a shift of the interventricular septum to the left, impeding filling of the LV. This explains why pulse amplitude is decreased during normal inspiration. An exaggeration of this normal phenomenon is seen as "pulsus paradoxus" when right heart filling is severely impaired during conditions such as cardiac tamponade, constrictive pericarditis, and status asthmaticus. During mechanical ventilation, intrathoracic pressure is increased to above atmospheric during inspiration, which impedes venous return to the right heart and decreases cardiac output. Patients who are hypovolemic or who have restrictive physiology will have an exaggerated decrease in cardiac output with the institution of mechanical

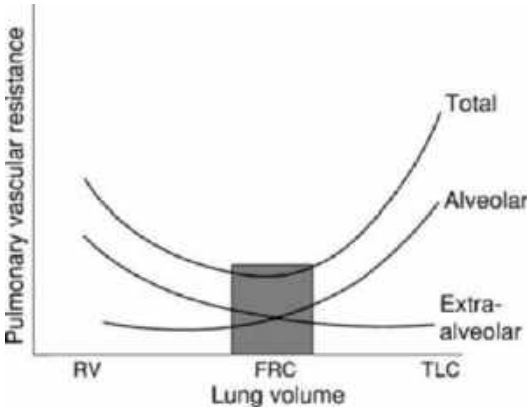

Fig. 34.4 Schematic representation of relation between lung volume and PVR. As lung volume increases from residual volume (RV) to total lung capacity (TLC), the alveolar vessels become increasingly compressed by the distending alveoli, and so their resistance increases, whereas the resistance of the extra-alveolar vessels (which become less tortuous as lung volume increases) falls. The combined effect of increasing lung volume on the pulmonary vasculature produces the typical "U-shaped" curve as shown, with its nadir or optimum, at around normal functional residual capacity (FRC) (From [158])

ventilation. This can be offset somewhat with judicious volume infusion and the use of vasoconstrictors to increase RV preload.

In addition to intrathoracic pressure influencing RV preload, changes in intrathoracic volume also affect RV afterload by altering PVR due to changes in the morphology of the alveolar and extra-alveolar vessels. The lowest PVR occurs around normal FRC (Fig. 34.4). Inflation above FRC compresses *alveolar* capillaries by alveolar distension and increases PVR. At decreasing lung volumes below FRC, the *extra-alveolar* vessels become tortuous and collapse, increasing PVR. In addition, terminal airway collapse at low lung volumes reduces regional PO_2, leading to HPV and further increases in PVR.

Changes in intrathoracic pressure also affect LV function *primarily by altering afterload*. This effect becomes more important in patients with diminished systolic function. LV afterload is not merely the systemic vascular resistance, but is more accurately defined as the force opposing left ventricular fiber shortening during ejection. This can be represented by the transmural pressure (TMP) gradient that the LV has to overcome during systole. The LV TMP is the difference between the pressure inside the ventricle minus the surrounding intrathoracic (pleural) pressure: The greater the TMP, the greater the afterload. In other words, the greater the negative pressure outside the ventricle, the greater the impedance to left ventricular emptying, and vice versa. Institution of positive pressure ventilation, by intubation or more easily by the application of CPAP, has many beneficial effects in patients with systolic LV dysfunction. It reduces the afterload by decreasing LV TMP (Fig. 34.5), preload, work of breathing, and myocardial oxygen consumption. However, intubating a patient with severe LV dysfunction can be a risky procedure due to the cardiovascular depressant effects of anesthetic agents and the reduction in preload of the RV.

Clinical Correlates

There are many situations in the management of patients with congenital heart disease (CHD) where manipulations of ventilation can have beneficial results, and these should be used in conjunction with pharmacological interventions to improve hemodynamics and oxygen delivery.

Patients with ductal-dependent systemic blood flow, such as HLHS, have a very fragile balance of pulmonary to systemic blood flow (Qp:Qs). Ideally, this should be close to 1:1, with corresponding systemic saturations of about 80 %. Due to the rapid decline in PVR after birth, PBF increases markedly at the expense of systemic flow, leading to hypoperfusion of the myocardium, brain, kidneys, liver, and bowel. If uncorrected, this can cause multiorgan dysfunction and circulatory collapse. Manipulating Qp:Qs can be accomplished by using sub-ambient oxygen (usually 17 %) or using 3 % inspired CO_2. Although both interventions maintain systemic oxygen delivery, the use of hypoxic gas mixture is associated with reduced mixed venous saturation and cerebral oxygen delivery [1]. The use of different gas mixtures usually requires

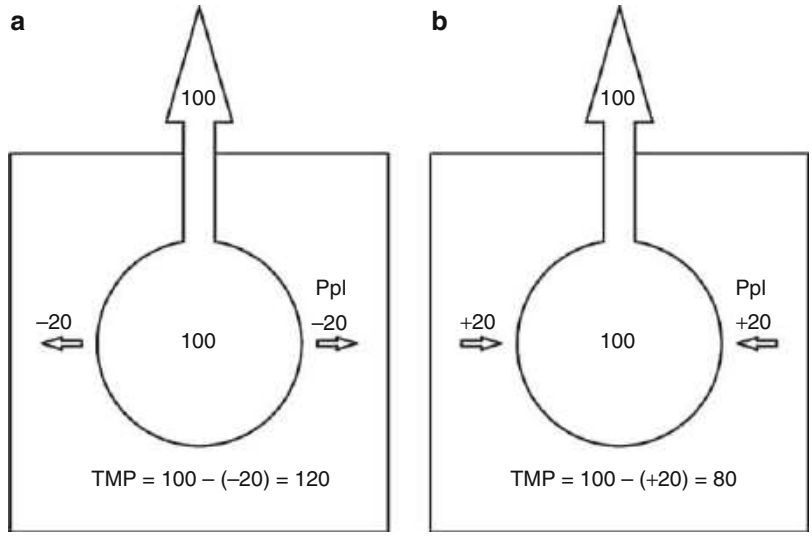

Fig. 34.5 Effect of positive pressure ventilation on LV afterload. Schematic representation of the left ventricle ejecting into the aorta, enclosed within the thoracic cavity. TMP represents the transmural pressure or tension, developed by the LV, and is equal to the difference between the pressure inside the ventricle and the pressure around the ventricle. A higher TMP equals a greater afterload. During spontaneous ventilation (**a**), the LV must develop greater tension to empty due to the surrounding negative intrathoracic pressure "opposing" emptying. With positive pressure ventilation (**b**), the LV needs to develop less tension (lower TMP) to empty, in effect, a reduction in afterload. *Ppl* pleural pressure

intubation and mechanical ventilation, and it is important to also avoid hyperventilation and alkalosis, as both of these will have detrimental effects on systemic oxygen delivery.

In patients where the PBF is passive and predominantly determined by systemic venous pressure (bidirectional cavopulmonary connection or Glenn, Fontan), the mode of ventilation can have a significant impact on hemodynamics. In Glenn physiology, the venous return from the upper body is directly connected to the pulmonary circulation. Decreases in PBF will cause significant systemic desaturation. Factors that decrease PBF include a high PVR, pulmonary venous obstruction, AV valve regurgitation, ventricular dysfunction, systemic outflow valve obstruction, and high systemic vascular resistance. High mean intrathoracic pressures, as in positive pressure ventilation, will increase PVR and impede systemic venous return, causing decreases in PBF and systemic desaturation [50]. Negative intrathoracic or extrathoracic pressure enhances PBF in Glenn and Fontan physiology [51]. An additional important factor affecting PBF in Glenn patients is the effect of arterial PCO_2. Hyperventilation reduces PVR by reducing PCO_2 and producing a respiratory alkalosis. This should, theoretically, enhance PBF. But, paradoxically, in infants with a Glenn shunt, this strategy has the opposite effect [52]. This is because in infants, cerebral blood flow is a greater proportion of upper body flow compared with older children. Hyperventilation reduces cerebral blood flow, hence, total upper body venous return, which constitutes the majority of PBF in Glenn patients. The detrimental effects of hypercarbia on PVR are outweighed by the beneficial effects of increased PBF via enhanced cerebral blood flow. This strategy has been shown to improve systemic oxygenation in the setting of Glenn physiology [53].

Spontaneous ventilation has significant benefits in patients who have passive PBF, such as Glenn or Fontan [54], and those with restrictive physiology, such as postoperative tetralogy of Fallot [55]. The negative intrathoracic pressures generated by spontaneous ventilation increase venous return, increase PBF, and improve cardiac

output in these groups of patients. Negative pressure ventilation, although not widely available, can also significantly improve hemodynamics in those patients that cannot be extubated but who would benefit from the effects of mimicking spontaneous ventilation [56, 57]. Maintaining low airway pressures and early return to spontaneous ventilation confers significant benefit postoperatively. In a small group comparison of volume-controlled ventilation with pressure-regulated volume-controlled (PRVC) ventilation, the use of PRVC resulted in a 19 % decrease in peak airway pressure but no difference in mean airway pressures, hemodynamics, or gas exchange [58]. Airway pressure release ventilation (APRV) is a relatively new mode of ventilation which applies a continuous positive airways pressure, with intermittent "release" of this pressure to allow exhalation. Spontaneous ventilation is permitted during all phases of respiration. A comparison of APRV with pressure-controlled ventilation and pressure support ventilation in a diverse group of 20 postoperative patients after repair of tetralogy of Fallot or cavopulmonary shunts showed improved PBF and oxygen delivery with APRV. However, this benefit was only seen in the presence of spontaneous ventilation. The authors concluded that APRV may be a useful modality to consider in other situations where hemodynamics are compromised by positive pressure ventilation [59]. Noninvasive ventilation (NIV) may have a limited role in the management of children after cardiac surgery as a means of avoiding intubation, which can have significant adverse hemodynamic consequences [60]. Clinical experience is limited to small series and case reports but indicates some benefit in improving hemodynamics and reducing the work of breathing [61, 62]. Another modality which is being increasingly used to provide ventilatory support is high flow nasal cannula (HFNC). This method uses humidified gas flows of up to 10 l/min, delivered via a snug-fitting nasal cannula such as Vapotherm 200i (Vapotherm, Stevenville, MD, USA). Whether this therapy is useful in reducing ventilator days or the need for reintubation is unclear at this time.

Inhaled Nitric Oxide

The scientists who discovered nitric oxide (NO) were awarded the Nobel Prize for physiology in 1998. Ironically, nitroglycerin, which is now known to act via nitric oxide, was also used to manufacture dynamite by Alfred Nobel. NO is a ubiquitous signal transduction molecule which is synthesized in the vascular endothelium by the action of nitric oxide synthase on the amino acid L-arginine. It produces vasodilation by relaxing smooth muscle cells via the guanylate cyclase pathway. NO also inhibits platelet aggregation and leukocyte adhesion to vascular walls. It only acts locally near the site of synthesis because it is rapidly deactivated by combining with hemoglobin to form methemoglobin. Inhaled NO (iNO) is only approved by the FDA for the treatment of persistent pulmonary hypertension in term or near-term neonates. However, over the past 10 years or more, it has become a mainstay in the treatment of perioperative PHTN and right ventricular failure. PHTN, defined as a mean pulmonary artery pressure of 25 mmHg or above at rest, can occur from increases in PBF or PVR, or both. In a retrospective study of postoperative pediatric cardiac surgical patients, the incidence of "severe" PHTN, defined as a pulmonary artery pressure equal or greater than systemic, was 2 %, most commonly associated with atrioventricular septal defects and Down's syndrome [63]. In the pediatric cardiac surgery setting, PHTN is usually associated with lesions causing increased PBF, pulmonary venous obstruction, cardiac transplant recipients, and single-ventricle lesions palliated with a bidirectional cavopulmonary shunt (Glenn) or a Fontan. A high PVR is also a strong predictor for right ventricular failure after cardiac transplantation [64]. Cardiopulmonary bypass increases pulmonary vascular reactivity by causing endothelial dysfunction, increasing the likelihood of postoperative pulmonary hypertensive crises [65]. Several studies have been published which show benefit of iNO in the postoperative setting [66–68]. However, they are hampered by single-center, small sample size and reporting of different outcome measures.

Nonetheless, the largest of these was a blinded study which enrolled 124 patients who were randomly assigned to iNO or placebo (nitrogen). All the patients underwent repair of unrestricted ventricular septal defects or atrioventricular septal defects, with preoperative evidence of high pulmonary artery pressures or flow. Compared with the placebo group, the iNO patients had 30 % fewer pulmonary hypertensive crises, a lower median PVR, and a shorter median time to extubation [68].

Single-ventricle patients who have undergone a bidirectional Glenn (BDG) anastomosis or a Fontan procedure depend on a low PVR and low transpulmonary gradient to maintain an adequate preload to the systemic ventricle. These patients are very susceptible to increases in PVR and, therefore, may benefit from iNO therapy. In one study, nitric oxide was administered to two groups of patients after a fenestrated Fontan procedure: One group had baseline saturations of less than 85 % and the other more than 85 %. Patients with the lower baseline saturations responded better with higher saturations and lower transpulmonary gradients, possibly due to a larger effect on reversing hypoxic pulmonary vasoconstriction [69]. The data for the beneficial effects on iNO in the BDG is not so clear-cut. Adatia et al. [70] administered 80 ppm iNO to 26 patients after a BDG for systemic saturations of less than 75 %. Although there was a significant decrease in SVC pressures, there was no improvement in oxygenation. Prior to iNO therapy, the SVC pressures were less than 20 mmHg in all their patients, but there is no data regarding PVR before surgery. In contrast, in another study, the administration of iNO to patients with Glenn pressures above 20 mmHg resulted in significant reductions in Glenn pressures and increases in systemic oxygenation, with concomitant reductions in inotropic score and fluid volume support in 11/16 patients. Patients requiring iNO also had significantly higher PVR before surgery. The 5 nonresponders were all found to have anatomic lesions which required further surgical interventions [71]. In heart transplant recipients, the presence of elevated PVR is a strong predictor of posttransplant RV failure and mortality. Preemptive use of iNO is associated with improved outcomes in this group of patients [72].

Clinical Correlates

Although iNO may be started based on the clinical picture, therapy should be guided by hemodynamic monitoring. Echocardiography and a surgical placed PA catheter can be used to follow treatment. Exactly when to begin iNO therapy is unclear, but PA pressures more than half-systemic with evidence of reduced cardiac output should prompt a trial of therapy. However, there are several pathophysiological states where the use of NO will not be helpful and may even be detrimental. These include (1) total anomalous pulmonary venous return, (2) left atrial obstructive lesions prior to relief of obstruction (mitral stenosis, supramitral ring), and (3) left ventricular dysfunction. iNO will result in an acute increase in blood flow to the left atrium or left ventricle which may not be tolerated and could precipitate pulmonary edema [73]. Nitric oxide is also not warranted in patients who have a high PVR due to pulmonary overflow from increased left-to-right shunting. In addition to using iNO, it is important to optimize PaO_2, $PaCO_2$, pH, FRC, and hematocrit, as these have a significant influence on PVR. Pulmonary hypertensive crises can be precipitated by sympathetic stimulation such as tracheal suctioning. Adequate sedation and paralysis is, therefore, important.

Administration of Nitric Oxide

Inhaled NO is administered using commercially available delivery devices (INOvent or INOmax DS, Ikaria, Inc., Hampton, NJ, USA), which allow for accurate delivery and monitoring of FiO_2, NO, and nitrogen dioxide (NO_2). The device requires two connections into the breathing circuit: an injector module for NO delivery and a sample-T connector for gas sampling. The injector module is placed in the inspiratory limb at the CO_2 absorber-end of the breathing circuit,

and the gas sample-T is placed 15 cm to 30 cm from the patient Y, on the inspiratory limb. The precise configuration will vary depending on the ventilator (whether ICU or anesthesia) and breathing circuits (anesthesia vs. transport), and it is recommended that the technical manual is consulted to ensure proper placement. This is especially important in the operating room where different types of breathing circuits are used in conjunction with a circle absorber system. The manufacturer does not recommend the use of coaxial breathing circuits with the INOmax DS delivery system (Bain Mapleson and the F-type breathing circuit) [74]. Inaccuracies in gas monitoring can occur due to rebreathing and sampling of mixed expired gases. The fresh gas flow should be set higher than the minute volume of the patient.

Toxicity of Inhaled Nitric Oxide

In routine clinical use at standard doses of less than 20 ppm, toxic effects are very rare. However, iNO is associated with several well-described adverse effects [75]. Nitric oxide is rapidly converted to *nitrogen dioxide* (NO_2) in the presence of oxygen. NO_2 can cause acute lung injury with airways inflammation and pulmonary edema. The Occupational Safety and Health Administration (OSHA) has set the exposure limit to 5 ppm. NO_2 levels are routinely monitored continuously during iNO therapy. Nitric oxide can convert hemoglobin to *methemoglobin* (metHb), which can cause tissue hypoxia. This is uncommon during routine clinical use, but metHb levels should be monitored daily. Methemoglobin is converted back to hemoglobin by the enzyme metHb reductase. The congenital absence of this enzyme is a contraindication to iNO therapy. Neonates have reduced activity of this enzyme and may be more susceptible to developing methemoglobinemia. Nitric oxide can also alter *platelet function* and may increase the risk of bleeding in high-risk patients.

Sudden discontinuation of iNO can result in *acute rebound pulmonary hypertension*. Weaning should be done slowly over the course of 12–24 h or longer, with careful monitoring of physiological variables.

Inhaled NO therapy is expensive, associated with important toxic side effects, and should only be used when strongly indicated. If a trial of iNO is started, and there is no improvement in hemodynamics and oxygenation, then it should be discontinued. *Recommendations* and *consensus guidelines* have been published for the use of NO in pediatrics [76, 77].

Vascular Access

Choice of vascular access and hemodynamic monitoring is guided by the specific condition of the child and the magnitude of the planned surgical procedure. Intravascular access and hemodynamic monitoring are crucial elements in the careful planning of a pediatric patient with CHD undergoing surgery. Secure, reliable venous and arterial access is imperative for the intraoperative management of every patient undergoing cardiac surgery.

Standard noninvasive monitoring, which includes electrocardiography (ECG), capnography, pulse oximetry, blood pressure cuff, temperature, and precordial stethoscope, is the basis of all intraoperative anesthesia care. Nevertheless, additional invasive venous or arterial monitoring requires special knowledge, understanding, and skills for successful vascular access.

Venous Access

Peripheral Venous Access (PIV): Technique

The ability to obtain secure and reliable peripheral intravenous (PIV) access is an essential skill of every anesthesiologist, more so, for a pediatric anesthesiologist caring for children with CHD. Venous access is generally performed after inhalational induction of anesthesia in the majority of the pediatric population, including CHD patients with stable hemodynamics. Exceptions to this

rule are critically ill patients in the intensive care unit and those patients with heart disease severe enough that inhalation induction of anesthesia is prohibitive. In these circumstances, peripheral venous access must be secured prior to anesthesia induction. The use of topical lidocaine-prilocaine at the access site is encouraged in this population. In either case, the number of attempts for securing a peripheral IV must be minimized and preferentially assigned to the most skilled practitioner in the operating room. Administration of 50 % nitrous oxide in selected cardiac patients prior to induction of anesthesia may represent a viable and safe alternative for securing IV access. The percentage of successful IV line procedures is reported to be higher in patients treated with 50 % nitrous oxide than in patients treated with 10 % nitrous oxide and or midazolam alone (67 %, 40 %, and 37 %, respectively; $p = 0.04$) in patients aged 5–18 years with reported anxiety or difficulties with the procedure [78]. Careful patient selection is warranted in the pediatric population with CHD. Patients with pulmonary hypertension and extreme cyanosis merit caution. Deliberate practice to improve performance in obtaining peripheral IV should be reserved for simulation laboratories and for the healthiest patients undergoing elective surgery.

Generally, peripheral cannulation is first attempted at the most peripheral site. This practice avoids leakage of infused fluid in the proximal site and should allow for more proximal attempts if the initial attempts fail.

The magnitude of the surgical procedure guides the need for fluid therapy and therefore access. The rate of fluid is proportional to the radius to the power of four and inversely proportional to length; therefore, fluids run faster on shorter peripheral IV catheters and larger diameter tube. Catheter size is a limitation for rapid rate of infusion in neonates and small infants, due to the size of their peripheral veins. Recommended sizes are 24–22 ga 1" catheters for newborns through 6 months of age and 22 ga 1"–20 ga 1.25" catheters from 6 months to 3 years. Choice of larger diameter catheters is encouraged when rapid blood transfusion or crystalloid fluid resuscitation might be expected. Rapid flow rates are achieved with increasing diameter; for example, with a 20 ga providing 39.5, and 18 ga providing 60.0, and a 16 ga providing 96.3 mL/min of PRBC [79].

Universal precautions are applicable for all PIV placements. Gloves must be worn while starting all IVs, and alcohol swab/chlorhexidine must be used prior to venipuncture. The technique used for IV access is similar and applicable to all peripheral veins.

The great saphenous vein is a large and anatomically reliable vein in patients of all ages (Fig. 34.6). It may be hard to visualize and palpate, but it is easily accessible on the medial aspect of the foot where it ascends between the medial malleolus and the medial edge of the tibia. The antecubital veins are safe and easily accessible, but caution should be used due to the close proximity of the brachial artery. The basilic (medial) vein is straighter and thus preferred. Other peripheral veins, like scalp veins, are easy sources of peripheral access to the circulation in the neonate. However, these are often friable and small vessels that pose a risk for extravasation. Once the condition allows, it is recommended that a more secure and less precarious access be obtained. Another site of peripheral access is the external jugular (EJ) vein. The technique to access the EJ is similar to that of obtaining central venous access through the internal jugular vein. It might require a slight degree of Trendelenburg position to promote venous distension; often a shoulder roll is appropriate for achieving neck extension and vein distension. The head is tilted toward the contralateral side (about 45°), and puncture follows an antiseptic technique. A syringe secured on the back chamber of the catheter allows for gentle aspiration and easy manipulation of the needle. The angle of access and thread is almost parallel to the skin; wider angles have the risk of nerve and vascular injury.

Alternatives to Difficult PIV: Difficult Venous Access (DVA)

A delay in establishing vascular access in a patient with CHD can result in a delay in the

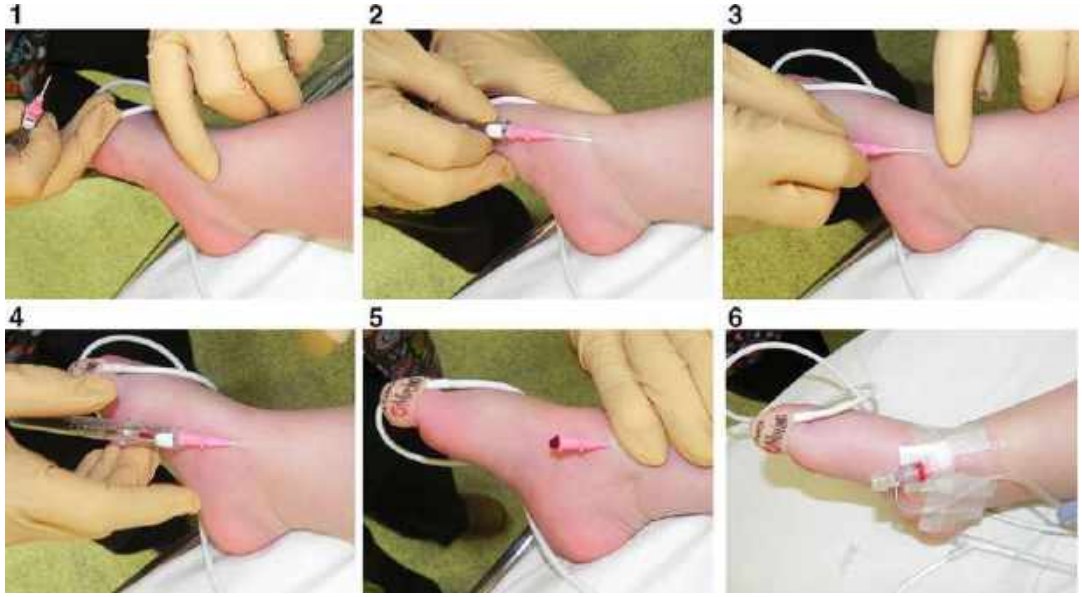

Fig. 34.6 Peripheral IV – Great Saphenous vein access. The great saphenous vein runs anteriorly to the medial malleolus. (**1**) Apply a tourniquet to the leg above the access site, visualize and palpate the vein. (**2**) Cleanse the site with chlorhexidine, stabilize the vein, and apply counter-tension with the nondominant hand. Insert the stylet through the skin and then reduce the angle as you advance. (**3**) If the vein is not cannulated on entry, palpate the vein and redirect the needle toward the vessel. (**4**) Observe for "flashback" as blood fills the back chamber of the catheter. (**5**) Pull the needle back slowly while advancing the catheter into the vein. Occlude the distal end of the catheter with the 3rd, 4th, and 5th finger of the nondominant hand and remove the needle. (**6**) Secure tubing to the catheter and protect in place

administration of fluids and/or medications critical to sustain cardiovascular and respiratory function. This delay may result in morbidity or mortality from cardiorespiratory arrest. The presence of cardiovascular disease has been identified as a risk factor for pediatric difficult venous access [80]. This is in addition to patient-related factors such as age <3 years, weight <5 kg, prematurity, and dark skin, all constant concerns for the pediatric cardiac anesthesiologist during induction of anesthesia [80–82]. Also, multiple attempts for IV placement in children with CHD and those with history of prolonged ICU course often lead to limited access sites due to central and peripheral thrombosis, hardened vessels, increased pain sensitivity, dehydration, patient distress, and problems placing IV peripheral catheters. Clinical studies have shown that 51 % of children and 83 % of toddlers experience high levels of distress during routine venipuncture and 36 % of young children experience significant pain [83, 84]. Several alternative modalities are currently available to the anesthesiologist to increase the chance of successful vascular access. These alternatives represent primary modes of access in children identified as potential DVA or needed backup resource in case of emergent need for access.

Ultrasound-Guided Peripheral Intravenous Access

Ultrasound (US) guidance for insertion of PIV catheters allows for cannulation of vessels that are neither palpable nor visible. It provides 2-D image of blood vessels that appear as compressible circular structures (transverse approach). Studies have shown that US-guided PIV catheter placement results in higher and first-pass success and very low complication rate [85, 86]. Indication for US-guided PIV access may

Fig. 34.7 Ultrasound Equipment. Cart-mounted SonoSite S-Nerve and L25× (13–6 MHz) transducer used for peripheral intravenous cannulation

include, but not limited to, overweight or obese patients, Down's syndrome infants (risk of sinus or junctional bradycardia with inhalation induction), concerns of dehydration in shunt-dependent patients, history of prior difficult IV, and failure to cannulate with traditional technique and elective primary technique.

The two-dimensional ultrasound machine commonly used for central venous cannulation and regional anesthesia techniques (SonoSite Inc. Bothell, WA, USA) is easy to use. With the attachment of a linear array probe (13–6 MHz), high-resolution images of superficial structures are depicted in rectangular format on a screen (Fig. 34.7). In preparation for US-guided PIV cannulation, a thorough investigation of the venous anatomy with ultrasound should allow for identifying the largest caliber vessel, correct depth, and gain. Preparation and equipment is critical for PIV cannulation. The upper extremity targets include the basilic, brachial, and cephalic veins. In many instances large forearm venous plexus can be identified also. The saphenous vein on the medial aspect of the foot, anterior to the medial malleolus, represents the largest caliber peripheral vein in the lower extremities and the most likely anatomical constant vein.

Technique

Once a target vein has been identified, apply a tourniquet proximal to the access site. Clean the skin with alcohol/chlorhexidine. Apply sterile gel to the transducer and skin to improve image quality. A static "no touch" technique is generally used, which involves placing a large amount of gel ridge between the transducer and the skin. This allows better superficial vein visualization by better accommodating the focal zone of the transducer and avoids contact on the skin, which inevitably collapses the underlying superficial veins. While holding the probe with the nondominant hand and the needle with the dominant hand, align the center of the probe with the center of the vessel in a transverse or short axis technique (longitudinal approach is difficult in small infants for PIV access). Insert the needle at a 45° angle aligned with the center of the transducer. The distance from the insertion site to the transducer should mirror the distance of the transducer to the depth of the vein. After initial puncture, move the probe proximal and distal from the insertion site to identify the tip of the needle. Once identified, advance the catheter toward the lumen of the vessel. Significant hand-eye coordination is required when watching the US monitor screen while advancing the needle. Constant readjustment of the probe may be needed to identify the needle and is crucial to successful cannulation of peripheral veins. Once vessel puncture is confirmed, either on the screen or by the appearance of blood in the hub of the needle, the catheter is advanced into the vein using standard technique.

Reflective Near-Infrared Technology for Peripheral IV Access

This technique relies on near-infrared light devices that emit a signal toward the skin, which is reflected back from tissues that surround the hemoglobin in the blood (all vessels). An advanced processing unit in the emitting device generates an image, which is projected back onto the surface of the skin in real life (VeinViewer, Luminetx Corporation, Memphis, TN, USA). This image delineates the course of all subcutaneous veins in the area covered by the emitting signal. A recent study reported an overall first attempt success rate of 69.4 % and 14/24 for patients with a difficult intravenous access score (DIVA) greater than 4 with the use of this device [87].

Intraosseous Access (IO)

Intraosseous access is a rapid, safe, efficient, and acceptable route for vascular access in children, and it is useful as the initial vascular access in case of cardiac arrest [88]. Recommendations from the Consortium on Intraosseous Access in Healthcare Practice (2010) state that IO access should be considered as an alternative to peripheral IV access when an increase in patient morbidity or mortality is possible [89]. In addition, for patients not requiring long-term access or hemodynamic monitoring, IO access should be the first alternative to failed peripheral venous access. The IO route is useful for the administration of medications, fluids, blood products, and blood sampling [90–92]. Multiple studies have reported first-time success rates of 80–93 % for IO access, with a time of insertion between 10 s and 1.5 min [91, 93].

The risks and complications of IO insertion are few and well defined. *Extravasation* is the most common complication, usually associated with misplacement of the needle and failure to identify fluid collection. Extravasation could potentially result in compartment syndrome and necrosis of the nearby muscle due to hypertonic or caustic medication. After failed placement of IO needle on first attempt, second attempt should follow in a different limb to avoid extravasation by proximity. *Osteomyelitis* is a rare complication and more likely to occur if aseptic technique was not followed during insertion. Other complications include *microemboli, local hematoma, and growth plate injuries*.

After initial medication delivery and fluid resuscitation, alternative access should be obtained and IO access removed to decrease the possibility of complications (may be left in place 72–96 h).

Preferred pediatric sites:

- Proximal tibia: located by palpation, flat anterior tibial surface 2 cm below the patella and 1 cm medial to the tibia tuberosity.
- Distal tibia: insertion at 3 cm proximal to the most prominent aspect of the medial malleolus.
- Distal femur.
- Proximal humerus: insertion is located at the most prominent aspect of the greater tubercle.
- Iliac crest flat surface of the anterior iliac crest.
- Sternum (used in adults, should be avoided in children because of the possibility of perforating the chest cavity).

Techniques

Following aseptic technique:

- *Manual needle with a removable stylet*

  Insert the needle through the skin and subcutaneous tissue perpendicular to the bone (90° angle). Once the solid surface of bone is identified, hold the needle with the index finger and thumb as close to the skin as possible and apply constant pressure on the needle with the palm. With a drilling motion, advance the needle through the cortex until a slight loss of resistance is achieved, indicating access to the marrow. Remove the stylet and aspirate to confirm placement. Infuse 10 ml of 0.9 % normal saline to rule out extravasation and appreciate slight resistance on injection.

Fig. 34.8 EZ-IO driver and needles. EZ-IO battery-powered driver – with 45-mm (*yellow*) length needle loaded. Other needles: 15 mm (*red*) and 25 mm (*blue*) (Image provide by Vidacare Corporation)

- *Battery-powered, driver-based technology (EZ-IO, Vidacare Corporation, Shavano Park, TX)* (Fig. 34.8).

  The technology comprises of a lithium battery-powered device that is used as a driver. It uses a beveled needle that rotates into the IO space. It follows the same technique described by manual needle placement (site selection and appropriate aseptic technique). The needle is loaded to the driver, and pressing the trigger on the driver activates the battery-operated rotor. Once the needle enters the IO space noted by loss of resistance, the stylet is withdrawn, and the metal catheter remains with a Luer lock attachment left in place. Three needle lengths of IO are available: 15 mm (children weighing <39 kg), 25 mm (patients weighing >40 kg), and large 45-mm length for obese or edema overlying the bone and the humeral sites greater than patients >40 kg for the driver device. Sites cleared by the Food and Drug Administration for the EZ-IO device are the proximal tibia, distal tibia, and proximal humerus (Fig. 34.9). *The EZ-IO has been approved for 24 h.*

- *Other devices: the Bone Injection Gun (B.I.G., WaisMed, Kansas City, MO). This is a spring-loaded device that actively penetrates the cortex when a button is pushed. The B.I.G. device is available in sizes that allow use from neonates to adults.*

Percutaneous Central Venous Access

Central Access: Site Selection, Catheter Size, and Complications

The need for central venous access is dictated by the magnitude of the surgical procedure and the adequacy of peripheral venous access. In a hemodynamically stable child, it is acceptable to proceed with cardiac surgery without central venous access. In this case, the surgeon, by means of right atrial intracardiac line, will secure reliable central venous access. In many instances a left atrial intracardiac line is also established intraoperatively for monitoring left atrial pressures.

Sites of percutaneous central venous access include the following: internal jugular vein, subclavian vein, femoral vein, and umbilical vein.

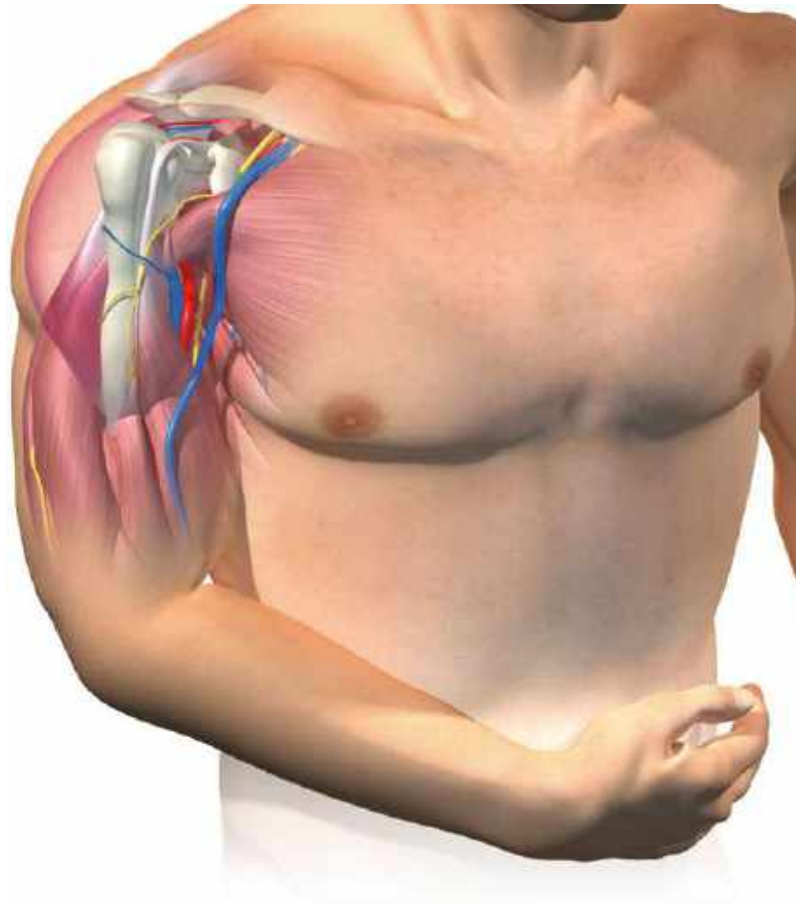

Fig. 34.9 IO sites folder – (**a**) proximal humerus (**b**) Proximal tibia. (**c**) Distal tibia. EZ-IO sites approved for access and description for identification (Images provided by Vidacare Corporation) (**a**) The proximal humerus insertion site is located directly on the most prominent aspect of the greater tubercle. Ensure that the patient's hand is resting on the abdomen and that the elbow is adducted (close to the body). Slide thumb up the anterior shaft of the humerus until you feel the greater tubercle, this is the surgical neck. Approximately 1 cm (depending on patient anatomy) above the surgical neck is the insertion site. Vidacare recommends the 45-mm needle on patients >40 kg. This is the preferred site for patients who are responsive to pain. Once the insertion is completed, secure the arm in place to prevent movement and accidental dislodgement of the IO catheter. (**b**) The proximal tibia insertion site is approximately 2 cm below the patella and approximately 2 cm medial to the tibial tuberosity (depending on patient anatomy). (**c**) The distal tibia insertion site is located approximately 3 cm proximal to the most prominent aspect of the medial malleolus (depending on patient anatomy). Place one finger directly over the medial malleolus; move approximately 3 cm proximal and palpate the anterior and posterior borders of the tibia to assure that your insertion site is on the flat center aspect of the bone

The anesthesiologist usually performs central venous access after induction of anesthesia and endotracheal intubation. Full barrier precautions should be used whenever a central line is being placed in the operating room and should include mask, hair cover, sterile gloves, gown, antiseptic solution to clean the site of access, and sterile drapes to cover the entire patient.

Appropriate catheters size and length can generally be estimated based on the patient age and weight (Table 34.4). A recent large study of central venous catheter placement in infants and children undergoing surgery for congenital heart disease developed formulas to calculate the length of superior vena cava central venous access insertion in pediatric patients on the basis

Table 34.4 Pediatric central venous catheter size and length for internal jugular/subclavian vein access site

Age/weight	Central venous catheter size and length
Neonate >2.5 kg	3 Fr 5 cm single lumen; 4 Fr 5 cm double lumen
Infant <5 kg	3 Fr 5–8 cm single lumen; 4 Fr 5–8 cm double lumen
Larger infant/ toddler <10 kg	4 Fr 8 cm double lumen
Preschool children <25 kg	4 Fr 8–12 cm double lumen; 5 Fr 12 cm double or triple lumen
Older children	5 Fr 12 cm double or triple lumen or when >50 kg 7 Fr adult triple lumen when indicated

Table 34.5 Height- and weight-based formula for length of insertion of CVC from the internal jugular vein or subclavian vein

Patients with heights less than 100 cm	Patients with heights 100 cm or greater
(Height/10) – 1 cm	(Height/10) – 2 cm

of weight when cannulation is achieved from the right-sided internal jugular or subclavian vein [94] (Table 34.5).

Meta-analysis of randomized controlled trials indicate that, compared with the anatomic landmark approach, real-time ultrasound-guided venipuncture of internal jugular vein has a higher first insertion rate, reduced access time, higher overall successful cannulation rate, and decreased rates of arterial puncture. Similar results are reported for the subclavian vein and femoral vein. The American Society of Anesthesiologist recommends the use of real-time ultrasound guidance for vessel localization and venipuncture when the internal jugular vein or femoral vein is selected for cannulation. Static ultrasound imaging for identification and patency is recommended when the internal jugular vein is selected for cannulation and may be used when subclavian or femoral vein is selected [95].

Common Complications and Precautions

The risk of bloodstream infection (BSI) is greatly increased with the presence of a central venous catheter. The risk of BSI decreases by the use of antibiotic-impregnated catheters, careful placement, and diligent continuous assessment while the line is present [96]. However, it should be kept in mind that cases of anaphylactic shock have been reported after placement of catheters coated with chlorhexidine and silver sulfadiazine [97, 98]. For immunocompromised patients and high-risk neonates, administration of antibiotic prophylaxis for central line placement should be done on a case-by-case basis. Intravenous antibiotics prophylaxis should not be administered routinely [95].

Bleeding from inadvertent arterial puncture is a common complication readily controlled with direct pressure of superficial vessels. Exceptions to this rule are the subclavian artery, proximal femoral artery, and deep arterial structures in the neck, in which direct pressure of arterial bleeding is difficult, often inefficient and potentially life threatening. Many patients with congenital heart disease have low-grade consumption of coagulation factors and in addition to being treated with aspirin and platelet receptor blocker (Plavix) to avoid shunt thrombosis, in which case the bleeding may be profuse. Careful attention to anatomical landmarks and US-guided techniques are encouraged.

Pneumothorax may result from central line placement from the subclavian and internal jugular placement. This complication is less likely to occur when real-time US-guided vascular access is performed at the internal jugular site. From the subclavian vein, the most effective precautionary measure is advancing the needle during exhalation aiming toward the suprasternal notch.

Thrombosis is a common complication and often under diagnosed. Buildup of thrombus surrounding the vessel or attached to the catheter may ultimately occlude the vessel. Despite recommendations for catheter size and length from internal jugular site and subclavian vein site in neonates, it is advisable to avoid these sites if possible, especially in single-ventricle patients due to the high risk of thrombosis, which would be potentially unfortunate for future palliative procedures.

Specific Access Sites

Internal Jugular Vein

The internal jugular (IJ) vein is the *most common* site used by pediatric anesthesiologists. Its course provides a direct route to the SVC and RA junction and allows for reliable central venous pressure monitoring. At this site the vein lies in close proximity to the carotid artery. Maneuvers used to increase the diameter of the internal jugular vein and the overall success of cannulation include slight Trendelenburg position, small roll under the shoulders to enhance cervical extension, liver compression, and <45° head rotation toward the contralateral site to be accessed. Anatomical landmark technique is ill defined in small infants, and recent recommendations support the use of ultrasound guidance to define the course of the vessel and any overlap with the carotid artery.

Cannulation from the right side ensures central venous location due to the continuity of the IJ with the superior vena cava and the right atrium. Left side cannulation carries the risk of thoracic duct injury, pneumothorax, and inadequate positioning within the central circulation.

Persistence of the left superior vena cava (LSVC) is the most common anomaly of the venous circulation, present in 0.5 % of the general population and more in the CHD population. It is clinically asymptomatic and might create difficulties when cannulating the central circulation from the left side IJ. The introduction of a dilator through the LSVC has been associated with vascular injuries and fatal outcomes. In addition, if the innominate vein is small or absent, occlusion of a persistent LSVC by a catheter during cardiopulmonary bypass may produce venous hypertension and possibly neurologic injury.

Technique

Anatomical landmark technique – Middle or low approach: Identify the apex of the triangle formed by the two bellies of the sternocleidomastoid (SCM) muscle superiorly and the clavicle inferiorly. At this point, palpate the carotid artery with the nondominant hand, feeling the pulsations in the inner aspect of the fingers toward the medial aspect of the neck or medial belly of the SCM muscle. Introduce the needle at 30° angle from the skin, lateral to the artery and aimed toward the ipsilateral nipple. Depth should not be more than 2.5 cm. If no blood is obtained during gentle aspiration, withdraw the needle gently and cautiously redirect. Once free blood is aspirated, carefully remove the syringe and insert J-tip flexible guidewire. Continuously monitor the electrocardiogram for signs of ectopy while placing the wire. With the wire in place, remove the needle; create a small surgical nick on the skin to allow for dilation over the wire and advancement of catheter into the vessel.

For the anterior approach, the needle enters the skin along the anterior margin of the SCM halfway between the mastoid process and the sternum (directed toward the ipsilateral nipple). In the posterior approach, the needle enters the skin at the posterior border of the SCM halfway between the mastoid process and the clavicle (directed toward the sternal notch) [99] (Fig. 34.10).

Ultrasound-guided technique (description in image): Ultrasound is used to guide the insertion of the needle. It clearly identifies the carotid artery, internal jugular vein, and surrounding structures (Fig. 34.11). *The technique for placement of the catheter is as described above in the anatomical landmark technique. A longitudinal US image should allow for visualization of the wire in the intraluminal position prior to dilation of skin and vascular structures.*

Subclavian Vein

The subclavian (SCV) vein and the internal jugular vein unite inside the anterior border of the superior thoracic inlet, forming the right and left brachiocephalic veins behind the manubrium. The brachiocephalic trucks unite to form the superior vena cava. Access to the subclavian vein is routinely achieved below the clavicle. The vein at this point is positioned immediately behind the medial third of the clavicle. With the patient in slight Trendelenburg position and the head turned toward the site of access (this compresses the internal jugular vein and avoids threading the guidewire cephalad), the site is prepped and draped following strict aseptic technique and full barrier precaution. Common

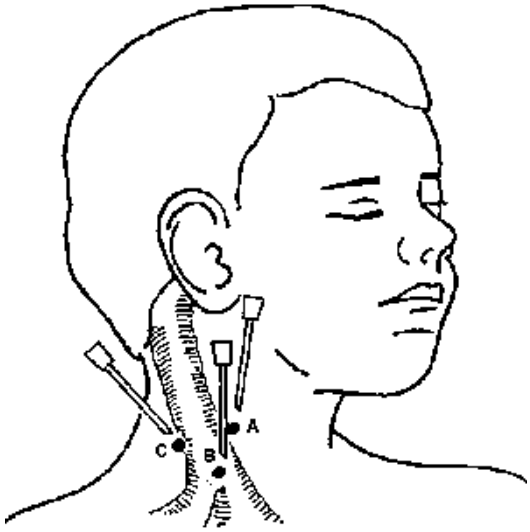

Fig. 34.10 IJ Access technique. Anatomical landmark technique: middle or low, anterior, and posterior. Three sites to access or approaches to internal jugular vein access: (**a**) Anterior – puncture site is at the anterior margin of sternocleidomastoid muscle with the needle aimed toward the ipsilateral nipple. (**b**) Middle – puncture site is at the apex of the triangle formed between the clavicle and the margins of sternocleidomastoid muscle. (**c**) Posterior – puncture site is at the posterior margin of sternocleidomastoid toward sternal notch. Reproduced with permission from Schettini, ST, Ybarra Martins de Oliveira LF, Henao HR, Lederman HM. Ultrasound evaluation of techniques for internal jugular vein puncture in children. Acta Cir. Bras. [online]. 2008, 23(5):469–72. ISSN 1678–2674

needle insertion sites include 1 cm inferior to the junction of the middle and lateral third of the clavicle or one fingerbreadth lateral to the angle of the clavicle.

The advantages of the SCV site include fixed landmarks and ease of securing the line. Disadvantages include potentially fatal pneumothorax or hemothorax.

Technique

Insert the needle at the site described above. The needle at this point follows a shallow course initially inferior to the clavicle and then slightly behind it aiming toward the sternal notch. Gently aspirate while moving toward the sternal notch. If unsuccessful, withdraw the needle slowly with continuous gentle aspiration, and once the vein is entered, advance the guidewire. Aim the J-tip wire caudally to improve successful placement into the subclavian vein and therefore superior vena cava. Advance the wire until ectopy is seen on the cardiac monitor, then retract 1–2 cm. Remove the needle and thread a dilator over the wire with a firm and gentle twisting motion while maintaining control of the guidewire (a scalpel to make a small stab incision might be necessary to enlarge the catheter entry site). At this point pass the catheter to the desired depth using the recommended length. Suture and apply a sterile dressing.

Femoral Vein

The femoral vein is the *preferred method* of central circulation in pediatric patients, with no greater complication or infection rate when compared with other sites [100]. In patients with profound respiratory failure or cyanosis, the femoral access precludes the risk of development of hemothorax or pneumothorax, both of which are potential complications of upper circulation access. In addition, it preserves the integrity of the upper body circulation in patients with single-ventricle physiology in which the SVC will provide over half of their pulmonary blood flow (cavopulmonary anastomosis). The femoral site allows cannulation with the patient supine, without Trendelenburg position, shoulder roll, or forced rotation of the cervical spine. It also allows for intravenous sedation for line placement and easy access to airway manipulation by a second practitioner. The catheter must pass into the thorax to provide accurate cardiac filling pressure measurements. The femoral vein is the preferred site for hemodynamic right heart catheterization in patients with congenital heart disease, and as such, it is common to find in the pediatric congenital heart population that one or both femoral veins have thrombosed due to prior prolonged venous cannulation. Known or suspected thrombosis of the femoral or iliac veins on the proposed side of venous cannulation is an absolute contraindication.

The femoral vein is a branch of the external iliac vein, and it crosses deep in the medial third of the inguinal ligament, medial to the femoral artery. Distally in the leg, the femoral vein lies

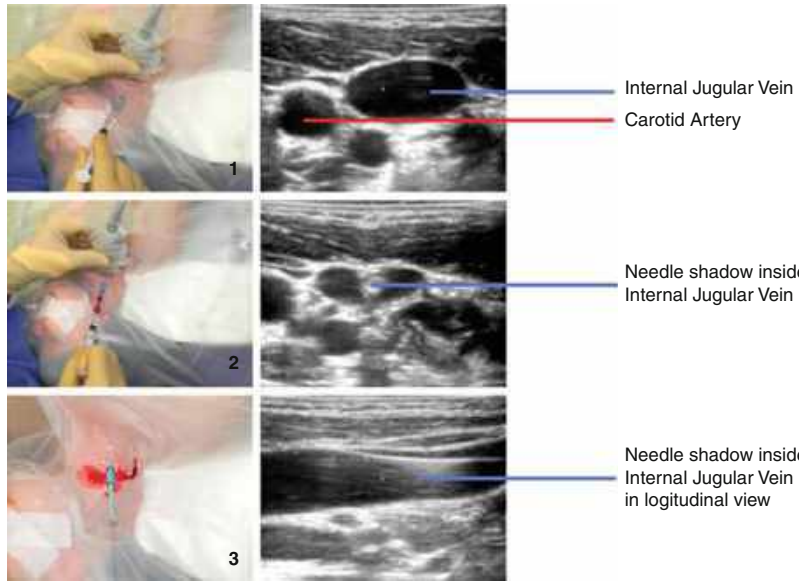

Fig. 34.11 CentralVenous. Ultrasound-guided central venous access – internal jugular vein – middle approach (**1**) The probe of the ultrasound is placed in a transverse position on the patient's neck, caudal to the needle insertion site. Track the internal jugular vein from the angle of the mandible down into the supraclavicular fossa using the US probe in the transverse orientation. This should ensure patency, overlap with carotid artery and depth from skin, and identify any vascular anomaly or clot. The internal jugular vein should be positioned in the middle of the screen. The needle should be angled 30–40° from the skin and a distance back from the ultrasound that correlated to the depth of the vessel from the skin. (**2**) Advance the needle slowly in 0.5 cm increments while identifying central compression of the vessel. Once the needle enters the vessel, a bright image will be identified. At this point flashback of blood is obtained in the syringe. If not, withdraw the needle while aspirating looking for free flow. While using the catheter-in-needle technique, thread the catheter into the vein and aspirate blood. (**3**) Thread the wire and obtain longitudinal view of the vessel by rotating the probe 90°. The wire is easily identified in the intraluminal space. Dilate the skin and follow the technique described above for catheter placement

almost posterior to the artery, thus arterial puncture is most likely distal to the inguinal ligament [101].

Technique

Identify the puncture site at 1–2 cm inferior to the inguinal ligament and 0.5 cm medial to the femoral artery, with the needle directed toward the natural course of the vein, the umbilicus. Seldinger technique or catheter-over-needle techniques are accepted methods. However, catheter-over-needle technique with a small 24-g angiocath provides more stability in small neonates and infants. Once the vein is cannulated, thread the catheter over the needle into an intraluminal position, and the needle is withdrawn, leaving the catheter in place. As with the Seldinger technique, thread the flexible J-tip guidewire through the lumen of the needle or catheter to lie inside the vein. Use a vessel dilator and then finally place the permanent catheter all the way to the hub while retrieving the wire. Assure patency of all ports of the catheter and secure in place with sterile dressing.

Arterial puncture is the most common complication of the femoral access site. If arterial puncture occurs, retrieve puncture device and apply pressure to the arterial site to avoid hematoma, which could potentially compress the vein and make venous cannulation difficult, if not impossible on that side. Infection and thrombosis of the femoral or iliac veins are also known complications from prolonged intravenous access.

Table 34.6 Umbilical venous catheter selection

Umbilical venous catheter size selection based on weight	
Infant weight (kg)	Catheter size (French)
1–3.5	5
>3.5	8

Umbilical Vein (UVC)

The umbilical vein is an easy and reliable source of central venous access in the neonatal period. With the advent of fetal diagnosis, prenatal care and delivery of children with congenital heart disease is managed under controlled circumstances. The neonatologist routinely accesses the umbilical vein during this period to ensure reliable delivery of prostaglandins. Umbilical vein catheters (UVC) can be placed in most neonates up to age 1 week and in some newborns up to several weeks of age. The appropriate size catheter is determined by the weight of the infant (Table 34.6).

Technique

Use aseptic solution to clean the umbilical area. Complete sterile technique is warranted to access of the umbilical site. The umbilical vein is large and does not require dilation prior to its cannulation. Gently pull the cord toward the infant's feet and attempt to probe the umbilical vein with the catheter, advance slowly. Might encounter slight resistance at 4–5 cm, if so, this usually indicates that the catheter has entered the portal vein. Do not advance any further at this point. Pull back 1 cm and advance the catheter while being flushed; this should guide the catheter toward the inferior vena cava.

Passage to the IVC depends on the patency of the ductus venosus, which is usually present for the first few days of life. Several formulas have been developed to predict the length of insertion. The measurement of the sternal notch to the umbilicus × 0.6 should correlate with the catheter tip being at the junction of the inferior vena cava and the right atrium [102]. Correct position is confirmed radiographically as soon as possible to determine it is through the ductus venosus into the IVC.

In general, UVC access should be discontinued within 10 days after placement to decrease the risk of complications. If used for induction of anesthesia, reliable access should be secured to ensure that UVC could be removed postoperatively allowing for continued IV therapy by means of other access site.

The most common complication from UVC is infection [103]. Others include thrombosis, portal hypertension, liver necrosis, necrotizing enterocolitis, and air embolism [104, 105].

Surgical Central Venous Access

Percutaneous-Inserted Central Venous Catheters (PICC)

Percutaneously inserted central catheters are largely employed in patients expected to require long-term intravenous access. Site of placement, personnel responsible, and technique are largely an institutional preference. In the pediatric cardiac population, the interventional radiologist with ultrasound and fluoroscopic guidance generally performs it. Despite the apparent ease of placement, a recent study reported initial correct catheter tip location in only 14.2 % of cases without fluoroscopic guidance and required catheter manipulation in 85.5 % of the cases [106]. In many instances PICC placement is performed on patients with no or minimal respiratory support and usually requires a careful sedation strategy, performed by an experienced cardiac anesthesiologist to avoid acute changes in Qp:Qs.

Common sites of cannulation into the central circulation are via antecubital vessels (cephalic and basilic vein), axillary, saphenous, and scalp veins.

The technique follows that of any central line placement, aseptic technique, prepped and draped. The vein is entered using an angio-catheter under ultrasound guidance, needle is withdrawn, and a 2 Fr non-styleted silicone catheter is passed with a forceps to a distance expected to be at the SVC-RA junction. When fluoroscopy is used, a guidewire is initially passed and identified to confirm central positioning of the catheter and length. Then PICC

catheter is threaded over the wire and flushed with heparin solution. To secure in place, a 3-point suture technique is used.

Tunneled Catheters

Surgical placement of tunneled central catheters is generally reserved for patients needing long-term intravenous access and history of difficult IV access. In the pediatric population with congenital heart disease, those patients listed for heart transplantation requiring intravenous inotropic support may benefit the most from tunneled intravenous access. This is also true for patients with complicated post heart transplant course needing constant blood draws. Benefits of surgical placement of tunneled central venous catheter must be weighed against the risk of general anesthesia to tolerate the line placement. It is advisable to review a recent chest radiograph and echocardiogram prior to anesthesia induction in children who recently underwent placement of a surgical tunneled catheter. Potential pneumothorax and pericardial effusion could go clinically unnoticed due to the severity of illness associated in patients with CHD.

Cutdown Central Access

Venous cutdown is rarely indicated in the perioperative period. With the widespread use of real-time ultrasound for difficult peripheral and central venous access, the cutdown technique is less commonly performed. It requires surgical skills, is time consuming, and inappropriate for emergency situation other than for ECMO cannulation. The technique follows that of any surgical procedure; full barrier precautions, a surgical cutdown tray, prepped and draped.

Technique

A small transverse (with respect to the vessel) incision is performed on the surface of the skin at the elected site of cannulation. A small segment of the vein is dissected from the surrounding fat and subcutaneous tissue. Ligatures or nylon is passed around the distal and proximal end of the vein, to control inflow and outflow of blood. Catheterization of the vein is performed under direct visualization. Distal ligature can be tightened to control the bleeding and the proximal ligature used to help secure the catheter in place.

Intracardiac-Transthoracic Vascular Access

Postoperative management of complex congenital heart disease requires intracardiac monitoring. The hemodynamic data derived from intracardiac lines can assist in the evaluation of contractility, preload, afterload, and rhythm disturbances. An intracardiac line also provides direct access to the central circulation for the infusion of medications to support adequate hemodynamics during this vulnerable period. These lines can be positioned in the right atrium (RA) for pharmacotherapy or monitoring RA pressure, which is indicative of right ventricular function, right ventricle preload, and afterload. Lines can also be positioned in the left atrium (LA), and these measure LA pressure and is indicative of left ventricle function, preload, and afterload. Finally, lines can also be positioned in the pulmonary artery (PA) and transduced continuously.

The surgeon places the intracardiac lines during the final stages of the operation, and a sterile connection to the RA catheter is passed to the anesthesiologist to initiate inotropic and/or vasopressor support when central venous cannulation was waived at the start of the surgical procedure. The decision to waive percutaneous central access will depend on institutional preference, preoperative hemodynamic stability, patient size, weight, and surgical repair to be performed. If the patient's hemodynamic condition allows, IJ, subclavian, and femoral venous sites are spared from cannulation to decrease the risk of future thrombosis. This is especially important in single-ventricle patients. Tightening of all connection and meticulous attention to air entry into any intracardiac line is warranted due to the risk of serious air embolism, likely catastrophic in single-ventricle patients. Intracardiac lines should be removed once information from their monitoring is not longer essential for the management of the patient. Adequate coagulation profile and alternative IV access should be present at the time of removal. Checking hematocrit 1-h post line removal and monitoring for signs of

tamponade, and transthoracic echocardiography might be indicated after line removal to assess pericardial fluid collection.

Arterial Access

Indications for arterial catheterization and monitoring include the need for continuous monitoring of systemic arterial blood pressure, frequent blood sampling, monitoring adequacy of oxygenation and ventilation in patients with critical respiratory disease, and monitoring of cardiac output and oxygen delivery in patients with cardiac or systemic disease. Arterial catheterization provides a visible real-time and beat-to-beat waveform that translates into a biphasic pressure tracing, with certain characteristics that contribute to additional diagnostic information (see arterial waveform in the Monitoring section).

Site selection of arterial monitoring in the patient with CHD mandates complete understanding of the cardiac anatomy and surgical repair planned. In patients with patent ductus arteriosus (PDA), preductal placement in the right radial artery is preferred. Other considerations are patients with Blalock-Taussig shunts (BT shunts) from the innominate artery, in which a false decrease in arterial blood pressure on the radial site distal to the brachiocephalic artery is often seen. A right radial catheter is also preferred for coarctation repairs. For major aortic arch reconstruction, a femoral arterial catheter may also be placed in addition to the right radial for assessing residual arch obstruction.

Arterial catheters can be placed in the radial, ulnar, posterior tibial, and dorsalis pedis vessels, provided that collateral flow is sufficient. Femoral arterial catheters are easier to place in the pediatric population, and rates of local infection and positive catheter tip cultures are similar when compared to the radial site [107]. However, femoral arterial catheterization in neonates has been associated with transient limb ischemia (17 %) in patients ranging from 23 to 40 weeks gestational age [108]. In an emergency situation, the femoral site might represent the most easy cannulation site, despite the inherent risk. Sixteen to nineteen percent of children with Down's syndrome have abnormal radial vessels, which make cannulation difficult.

Catheter size depends on the patient size and cannulation site. Small-size (24 gauge) catheters are used to cannulate distal arterial sites (radial, posterior tibial, and dorsalis pedis) in neonates and infants, and 22-gauge catheters are more appropriate for toddlers and older patients. A 2.5-Fr 5-cm single lumen catheter is used for proximal femoral arterial access in small neonates and infants. A 3-Fr 5–8-cm single lumen catheter is adequate for most toddlers and preschool children. With the introduction of real-time US for cannulation of central venous access and peripheral IV access, the attention has turned to utilizing this technique for distal arterial access in neonates and infants. Furthermore, femoral arterial access is now performed routinely with US-guided technique, limiting the puncture attempts and possible damage to the artery.

Complications from arterial cannulation include thrombus formation, emboli, distal ischemia, and infection. Modified Allen test to confirm adequacy of ulnar collateral arterial flow is indicated when cannulating the radial artery (adequate perfusion of the hand while the radial artery is occluded). Mottling of the skin distal to the catheter is indicative of poor perfusion and likely related to thrombus formation or arterial occlusion. A pale, cool extremity following arterial catheter placement is a clear indication of arterial blood flow occlusion and like to result in distal ischemia if catheter not immediately removed. The risk of infection related to arterial catheterization is extremely low in the pediatric population (6.2 % after 48 h), and it seems to be independent of the duration of catheter placement.

Ultrasound-Guided Arterial Access

Distal arterial cannulation in neonates and small infants can be technically challenging. Failed attempts at threading an angio-catheter once the needle is perceived intra-arterially by or through a guidewire result in arterial intimal damage

and difficulty for future attempts. The use of ultrasound-guided arterial catheterization requires short time for arterial line placement, fewer attempts, and fewer sites for successful attempt, when compared with the blind technique [109, 110]. In the same study, dorsiflexion of the wrist significantly reduced the mean cross-sectional area of the artery by 19 % in 30 small children, age 40 +/− 33 months, which is important when considering the positioning of the patient and the overall technique [109].

The percutaneous technique of cannulation of a peripheral artery is similar for almost all arteries and no different than the ultrasound-guided technique. CDC recommendation includes a minimum of a cap, mask, sterile gloves, and small sterile fenestrated drape during peripheral catheter insertion. Maximal sterile barrier precautions should be used for the femoral site. Also, consider full barrier precautions when placing peripheral arterial line catheters using a guidewire technique (Seldinger technique).

Technique

Apply sterile gel to the transducer, cover with sterile sleeve, and add some gel at skin to improve image quality. While holding the probe with the nondominant hand and the needle with the dominant hand, align the center of the probe with the center of the vessel in a transverse approach or short axis technique. The longitudinal approach is difficult in small infants due to the short straight length of the radial artery at the wrist. Insert a 24-g angio-catheter (neonates and small infants) or a 22-g angio-catheter (larger infants and toddlers) at a 45° angle aligned with the center of the transducer. The distance from the insertion site to the transducer should mirror the distance of the transducer to the depth of the artery. After initial puncture, move the probe proximal and distal from the insertion site to identify the tip of the needle. Once identified, focus on the ultrasound screen and advance the needle aiming to keep the tip present in the screen as it approaches the lumen of the artery. Confirm the needle in the vessel at the screen first and then proceed to drop the probe and utilize your nondominant hand to assist with the thread of the catheter. The thru-thru technique focuses on going past the anterior and posterior wall of the artery with the catheter, the needle is withdrawn and the angio-catheter pulled back gently until pulsatile flow confirms intravascular placement. At this point, a 0.015 or 0.018 wire is threaded intraluminal and the catheter advanced. Attempts to advance the guidewire or catheter against any resistance should be avoided as this will damage the arterial wall and make subsequent cannulations on that site difficult (Fig. 34.12).

Other Common Sites of Cannulation

Umbilical Artery

The umbilical artery is used in critically ill newborns, in whom peripheral arterial access is difficult and the femoral artery represents a high risk of limb ischemia. Once the vessel is identified, a 3.5-Fr or 5-Fr catheters is gently advanced. Optimal locations for the catheter tip are just above the aortic bifurcation, below the inferior mesenteric artery or middorsal aorta above the diaphragm [111]. Undesirable positions are the near the renal arteries, celiac plexus, or superior mesenteric artery [112].

Posterior Tibial (PT)/Dorsalis Pedis (DP)

Cannulation of the PT or DP is indicated when cannulation of the radial arterial site becomes impossible from multiple failed attempts, small arterial size for cannulation, and previous cannulation via cutdown technique. Due to its distal location, however, systolic and diastolic pressure readings are subject to dramatic temperature and perfusion changes typical of cardiopulmonary bypass. Flattening or damped arterial waveforms are not uncommon while attempting to wean from cardiopulmonary bypass. In this situation a transient aortic root pressure can be transduced while peripheral arterial circulation improves. Because it is a small vessel, there is a high incidence of both unsuccessful cannulation and post cannulation arterial occlusion.

Fig. 34.12 –ArterialAcesss. Ultrasound-guided arterial access. (**1**) Sterile technique. (**2–3**) Initial scan of the radial artery on a transverse approach or short axis technique with ultrasound probe. While holding the probe with the nondominant hand and the needle with the dominant hand, align the center of the probe with the center of the vessel. (**4–5**) Insertion of 22 g angio-catheter at a 45° angle aligned with the center of the transducer. The distance from the insertion site to the transducer should mirror the distance of the transducer to the depth of the artery. Initial filling with blood of the back chamber should prompt a (**6**) thru-thru technique, which focuses on going past the anterior and posterior wall of the artery with the catheter; the needle is withdrawn and the angio-catheter pulled back gently until (**7**) pulsatile flow confirms intravascular placement. (**8**) At this point, a 0.015 or 0.018 wire is threaded intraluminal and the catheter advanced. (**9**) Catheter secured in place and all air cleared from the line

Monitoring

In pediatric cardiac anesthesia, adequate and reliable monitoring is essential. The components of the "standard for basic monitoring" of the American Society of Anesthesiologist were recently revised in July 2011. This document states that during all anesthetics, the patient's oxygenation, ventilation, circulation, and temperature shall be continually evaluated (http://www.asahq.org/For-Members/Standards-Guidelines-and-Statements.aspx – Basic Anesthetic Monitoring). In addition to these standard components, inva sive pressure monitoring, mixed venous oxygenation, and specialized neuromonitoring a re standard for patients undergoing cardiac surgery. Coagulation and transesophageal echocard iography will be cover in separate chapters.

Basic Electrocardiogram

Electrocardiogram (ECG) monitoring is routine for all children undergoing general anesthesia and especially useful during surgical repair

of congenital heart defects. It allows for the prompt detection of arrhythmias, ischemia, conduction defects, and several electrolyte disturbances [113].

ECG measures the potential difference between two electrodes. The 5-electrode system is the favored method and routine for the intraoperative and postoperative management of patients with CHD. This system utilizes leads in all 4 extremities and one precordial lead, usually placed in the V_5 position. The utility of monitoring the precordial lead simultaneously is the improved capability of detecting ST segment trends, hence ischemia.

In pediatric patients, the ST segment is usually isoelectric. However, mild elevation or depression of the ST segments >1 mm in limb leads and up to 2 mm in precordial leads may be normal [114]. Most modern ECG monitors in the operating room environment provide automated analysis of the ST segment.

The incidence of arrhythmias is low in infants younger than 2 years of age without congenital heart disease. Still, up to 2 % of normal children have premature ventricular contractions on routine ECG, without clinical or structural evidence of heart disease [115]. On the contrary, arrhythmias are frequent in patients with palliated CHD. Therefore, it is critical to monitor ECG in this patient population.

Intraoperative variables influence the manifestation or worsening of rhythm disturbances in patients with CHD. Common causes of ECG changes are listed in Table 34.7 [116]. The presence of hypercarbia in patients managed by mask and light anesthesia has been associated with arrhythmias in pediatric patients [117]. Furthermore, known triggers that provoke PVCs (hypoxia, hypercarbia, drugs, toxins, and myocardial abnormalities) may potentially cause sustained ventricular arrhythmias in these patients, and thus, continuous monitoring is warranted.

Most common sources of error during the use of ECG are improper lead placement and artifacts. Artifacts can occur due to equipment malfunction, poorly grounded equipment, and electrocautery used for surgery.

Table 34.7 Common causes of ECG changes

T waves	Peaked	Hyperkalemia
	Flattened	Normal newborns, hypokalemia, digitalis use, hypothyroidism, pericarditis, myocarditis, ischemia
ST segment	Prolonged	Hypocalcemia
	Shortened	Hypercalcemia
QTc interval	Prolonged	Hypocalcemia
	Shortened	Hypercalcemia

Noninvasive Blood Pressure Monitoring (NIBP)

During surgery for CHD, NIBP monitoring is the main source of blood pressure measurement during induction of anesthesia, intubation, and intravascular access. Once the invasive arterial access has been secured, noninvasive measurements are obtained from a different limb as a backup and confirmatory source to the invasive arterial monitoring tracing. The site chosen for BP measurement may be influenced by the patient's cardiac diagnosis or previous surgery. Patients with aortic arch obstruction, such as coarctation, should have the BP measured in the right arm. In patients with a previous Blalock-Taussig shunt, the contralateral side or the leg should be the preferred site for BP monitoring due to potential underreading from vessel distortion. Furthermore, the presence of an aberrant right subclavian artery associated with other common congenital heart diagnosis requiring surgery should warrant caution when using transesophageal echocardiography (TEE) during the surgical procedure. The TEE probe may produce a marked decrease or dampening in invasive and noninvasive blood pressure in the right arm due to mechanical compression of the aberrant vessel. This will also affect the pulse oximetry waveform.

Intraoperative measurement of NIBP is achieved by automated sphygmomanometers using the oscillometric method to detect variations in the pressure within a blood pressure cuff during deflation. The systolic and mean arterial pressures are identified during deflation, and the diastolic pressure is then calculated from these two measurements. The American Heart

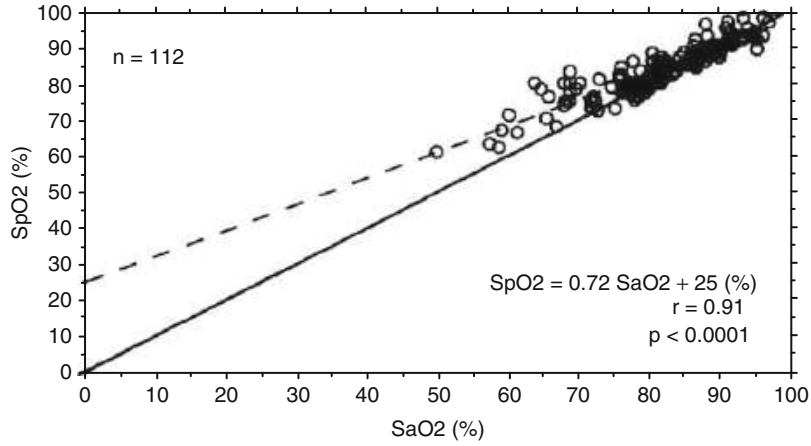

Fig. 34.13 Pulse oximetry Accuracy. Comparison of arterial oxygen saturation measured with the pulse oximeter (SpO2) and CO-oximeter (SaO2). The solid line is shown for reference. Linear regression of the 112 simultaneous measurements yields the dashed line (Reproduced with permission reference [121])

Association recommends a cuff for which inflatable bladder is 40 % the circumference of the midpoint of the limb or 20 % greater than the diameter of the extremity [118]. In general, a cuff too large underestimates the blood pressure and a cuff too small overestimates it.

The measurement of NIBP is limited in obese patients and should warrant caution in patients requiring frequent or prolonged monitoring due to the risk of skin avulsion, venostasis, and nerve damage [119, 120].

Pulse Oximetry

Pulse oximetry is standard of care and mandatory for the administration of all general anesthetics and sedation procedures. It is the primary monitoring device to detect reductions in oxygenation related to respiratory compromise, cardiac compromise, or inadequate perfusion in patients with congenital heart disease. Most commercially available devices comprise of a probe placed on a thin part of the patient's body and a display showing a pulsatile waveform and a numerical percentage of oxygen saturation.

This monitoring technique works on the principle of infrared absorbance of biologic tissues. Light of two different wavelengths is passed through the patient (fingertip, earlobe, cheek, or tongue) to a photodetector. Only oxyhemoglobin and reduced hemoglobin are measured at these wavelengths. Changing absorbance of each wavelength is measured, and saturation is calculated as (oxyhemoglobin)/ (reduced + oxyhemoglobin).

Pulse oximetry is limited at saturations below 80 % and tends to overestimate the true value of arterial saturation [121] (Fig. 34.13). Anesthesia and critical care physicians should keep this in mind when managing patients with cyanotic heart disease. In addition, pulse oximetry becomes nonfunctional during periods of non-pulsatile flow (extracorporeal circulation without ejection or severe vasodilatory shock). Other means of adequacy of peripheral tissue oxygenation should be considered during non-pulsatile flow (NIRS, lactate, and mixed venous oxygenation).

Capnography

Monitoring capnography ($ETco_2$) and respiratory gases is standard in all intubated patients requiring general anesthesia. In addition to $ETco_2$, inhaled and exhaled anesthetic agents and oxygen are routine throughout the administration of anesthesia. Today, the capability of measurement of expiratory CO_2 during procedural sedation in non-intubated patients through CO_2-enabled nasal cannulas has proved invaluable in combination with pulse oximetry for safe and successful sedation. Normal capnograph depicts breathing pattern displayed in the form of real-time end-tidal CO_2 ($ETco_2$) against time.

Table 34.8 Clinical conditions associated with abnormalities in $ETco_2$

Increases in $ETco_2$
1. Sudden
Sudden increase in cardiac output
Release of tourniquet
Injection of sodium bicarbonate
2. Gradual
Hypoventilation
Increased metabolism (carbon dioxide production)
Decreases in $ETco_2$
1. Sudden
Sudden hyperventilation
Sudden decrease in cardiac output
Massive pulmonary embolism
Air embolism
Ventilator disconnection
Ventilator circuit leakage
Obstruction of the endotracheal tube
2. Gradual
Hyperventilation
Decrease in metabolism
Decrease in pulmonary perfusion
Absent $ETco_2$
Esophageal intubation
Accidental extubation

Reproduced with permission reference [122]

Changes in $ETco_2$ have important implications; decreases are associated with low cardiac output, circuit malfunction, hyperventilation, shunt, or pulmonary embolism. In addition, acute decreases during the intraoperative period may alert the anesthesiologist of mechanical obstruction of pulmonary blood flow during heart dissection in the surgical field. On the other hand, increases in $ETco_2$ may warn of malignant hyperthermia, hypoventilation, endobronchial intubation, or marked increase in cardiac output [122] (Table 34.8).

Temperature

The measurement of body temperature is standard during all anesthetics procedures and plays a very important role in the management of pediatric patients undergoing hypothermic cardiopulmonary bypass. While temperature in the hypothalamus is believed to be the most accurate measurement of core temperature, the use of bladder temperature and nasopharyngeal temperature catheters has shown to be the good estimates of pulmonary artery temperature, generally referred as the "gold standard." Other investigators have shown that nasopharyngeal, not tympanic, temperature best reflects brain temperature [123]. Furthermore, current practice supports multisite temperature measurement to ensure adequate cooling and warming monitoring during CPB.

In patients undergoing cardiac surgery, hypothermia provides both myocardial and neurological protection. Induced hypothermia is the main protective strategy for brain protection during cardiopulmonary bypass or total circulatory arrest. It reduces the metabolic rate of the brain tissue and preserves high-energy phosphates [124]. Brain temperature is not measured but indirectly assumed from other core temperature sites, typically from the nasopharynx, rectum, bladder, and esophagus. The brain temperature is 0.5–1 °C more than the core temperature, and, within the brain, the temperature varies from 0.5°C to 1 °C from deep to superficial structures [125].

During surgery, the use of an external heat exchanger to control blood temperature results in large temperature gradients between blood and body tissues. This is important because during the rewarming phase of CPB, peripheral temperature measurements underestimate brain temperature, which could inadvertently result in cerebral hyperthermia associated with poor neurologic outcome. Furthermore, neuronal metabolic oxygen consumption in neurons is increased during this time when O_2 delivery could be compromised from alterations in cardiac output immediately following CPB.

Management of Cardiopulmonary Bypass: In patients undergoing CPB, pH, *temperature*, cerebral perfusion pressure, and hematocrit have important effects on cerebral perfusion. Carbon dioxide is the leading variable responsible for cerebral vascular reactivity. Therefore, hypercapnia leads to vasodilation, and hypocapnia leads to

vasoconstriction. The solubility of CO_2 increases in blood with reductions in temperature, affecting intracellular acid–base status. Thus, despite a total normal concentration of CO_2 in blood, the measured arterial $PaCO_2$ is reduced. There are two strategies during CPB to manage acid–base status, alpha-stat and pH-stat. During alpha-stat, non-temperature correction of blood gases is employed; this allows for autoregulation to be maintained. In pH-stat strategy, CO_2 is added to the sweep gas to maintain $PaCO_2$ at 40 mmHg as body temperature is reduced. With the latter strategy, autoregulation is lost, and cerebral perfusion pressure is directly related to changes in cerebral blood flow, allowing for greater oxygen delivery and more even distribution of blood flow.

Urinary Output

Urinary output by means of invasive catheterization is routinely monitored during cardiac surgery. Acceptable output is considered 0.5–1 ml/kg/h and a signal of adequate renal perfusion (cardiac output). Alternatively, decreased urine output strongly suggests acute kidney injury (AKI), a common complication observed among children exposed to cardiopulmonary bypass (CPB) for cardiac surgery and is associated with significant mortality and morbidity [126]. Mechanical causes of urinary catheter obstruction or dislodgement should be ruled out to avoid unnecessary changes in perfusion strategy or medical management. Excessive urine output can been seen during CPB, generally associated with hyperglycemia, hypervolemia, osmotic agents commonly used on in the pump prime, and mannitol and diuretics such as furosemide.

CPB-associated AKI is multifactorial in etiology, and proposed mechanisms include inflammation, ischemia-reperfusion injury, loss of pulsatile blood flow, microemboli, and diminished renal blood flow during periods of severe hypotension, prolonged aorta cross-clamp time, and low-flow bypass times [126, 127]. Oliguria may be present during the first 24–48 h after cardiac surgery in the presence of normal cardiac output and normalizes once the transient inflammatory injury to the kidney has subsided.

Hematuria may indicate hemolysis, which is common during prolonged CPB due to hemolysis. However, this should raise suspicion of a transfusion reaction if it develops subsequent to blood product exposure.

Invasive Cardiovascular Monitoring

Arterial Waveform

The arterial waveform results from distension of the proximal aorta during the stroke volume in ventricular systole. The rapid upstroke can be seen as the inotropic component of the arterial waveform, and therefore, the steeper the incline, the better the contractile function of the myocardium. A slow incline may suggest poor contractility but is also associated with aortic stenosis and high systemic vascular resistance. The rounded portion of the waveform reflects length of ventricular volume ejection, aortic distention (capacitance), and runoff from distal branches. The descending limb of the waveform is comprised of an initial fall and second peak (dicrotic notch) that descends to a nadir defined as the diastolic blood pressure (Fig. 34.14).

In children, there is augmentation of the dicrotic notch; this is secondary to greater vessel compliance and greater amplification due to slower wave transmission time. *As the dicrotic notch moves closer to the diastolic nadir in the descending limb of the waveform, this indicates low peripheral resistance*.

As the pressure waveform moves away from the proximal aorta, the initial upstroke becomes steeper, and systolic maximum becomes progressively more peaked. In general, the further away from the aorta, the higher the systolic blood pressure and the lower the diastolic blood pressure and mean values.

Other important information derived from the arterial waveform is respiratory variations seen in the presence of hypovolemia. This is characterized by decreases in arterial blood pressure

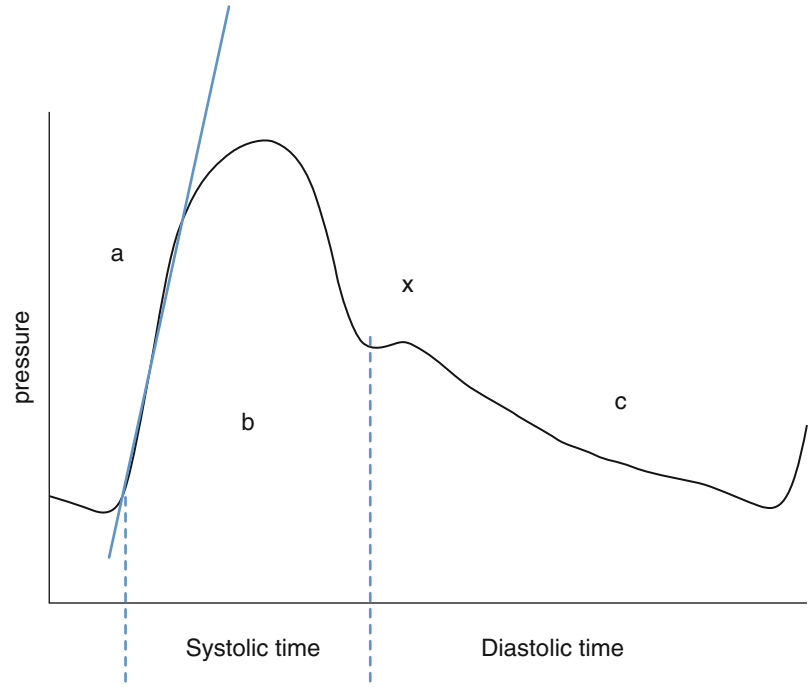

Fig. 34.14 Interpretation of the arterial line tracing. (**a**) Rapid upstroke and downslope correlates with systolic function; the steepness of the rise relates to myocardial contractility. Delayed upstroke correlates with poor myocardial contractility or high systemic peripheral vascular resistance. (**b**) Area under the curve representative of total stroke volume. (**x**) Dicrotic notch that correlates with closure of the aortic valve. (**c**) Runoff that correlates with diastole. Short systolic time can be seen during hypovolemia or high systemic peripheral resistance, also affecting area under the curve (stroke volume)

during positive pressure ventilation. This drop in blood pressure occurs because positive pressure ventilation decreases venous return, which is very pronounced in hypovolemic patients.

In the post-bypass period, arterial tracing of most distal sites (dorsalis pedis/posterior tibial) is frequently dampened. This is in part due to changes in temperature and peripheral vascular resistance during long and extreme operations (deep circulatory arrest and selective cerebral perfusion). Direct aortic root pressure is a more accurate source of arterial blood pressure while waiting for resolution of the damped waveform. Other mechanical problems may result in complete loss of the arterial tracing (spasm, kinking, or clotting). An appropriately sized noninvasive blood pressure cuff should always be present.

Cardiac Output Monitoring

Cardiac output (CO) is rarely measured in the pediatric population during the intraoperative period. CO can be calculated using the Fick method, in which cardiac output is equal to the oxygen consumption divided by the arteriovenous oxygen content difference. Other techniques include dye dilution (indocyanine green), thermodilution (thermistor in a pulmonary artery catheter), and Doppler and magnetic resonance imaging. In general, thermodilution is the most commonly used technique in the critical care setting. The Fick method is considered the preferred and most reliable technique in conditions of low cardiac output and less accurate in conditions of high cardiac output. Advantages and limitations of the various methods in patients with congenital heart disease are listed in [128] (Table 34.9).

More commonly, surrogate markers of adequate peripheral perfusion and tissue oxygenation (pulse oximetry, NIRS, mixed venous oxygenation, urine output, and lactate) are used during the perioperative period to infer adequacy of cardiac output due to the risks and limitation of pulmonary artery catheterization. Placement of these catheters is technically challenging in pediatric patients, based on both size and variable anatomy and doubts regarding the accuracy of

Table 34.9 Cardiac output methods

Method	Advantage	Disadvantage
Fick principle	Shunt detection, small blood sample	Oxygen consumption measurement cumbersome
Dye dilution	Shunt detection	Calibration, large blood sample
Thermodilution	No blood samples, frequent repetition possible	Inaccurate with right-to-left shunts
Doppler	Semi-invasive	Accurate with careful attention to performance details

the data obtained. The surgeon can place a pulmonary catheter intraoperatively if there is a need to monitor pulmonary artery pressures in the postoperative period.

Several noninvasive cardiac output monitors are currently being used in clinical practice. Available technologies are founded on Doppler ultrasound, pulse contour analysis, bioimpedance-bioreactance, partial CO_2 rebreathing, and pleth variability index. To date, there is limited evidence for accuracy in the pediatric population and no evidence to suggest their routine use in clinical anesthesia practice. Their application is limited in univentricular circulations and intracardiac shunts.

Mixed Venous Saturation, Central Venous Saturation, and Lactate Levels

Mixed venous oxygenation (SvO_2) is used as indicator of cardiac output. Based on the Fick principle, if arterial saturation, hemoglobin, and oxygen consumption are stable, a fall in SvO_2 indicates decreased cardiac output. SvO_2 can be measured by drawing a blood sample from the distal port of a pulmonary artery catheter in good position (balloon deflated and not wedged). Under normal circumstances, SvO_2 is 75 % with an arterial saturation of 95–100 %, and it quantitates the extent to which the organism is relying on compensatory mechanisms to match oxygen consumption with demand. In general, SvO_2 and lactate are concordant variables and representative of oxygen consumption (SvO_2 decrease) and anaerobic threshold (lactate production).

Continuous central venous saturation monitoring ($ScvO_2$) can be performed by using specific detectors placed in the venous line of the circuit or by using central venous catheters (CVCs) that incorporate fiber-optic oxygen saturation sensors. During pediatric cardiac surgery, goal-directed therapy with continuous $ScvO_2$ monitoring is associated with excellent early 1st stage palliation for hypoplastic left heart syndrome [129]. In the same population, high levels of lactate have been associated with bad outcomes if detected during cardiopulmonary bypass [130]. In addition, a recent study from Ranucci M. et al. suggests that patients who experience a $ScvO_2$ nadir value <68 % during CPB developed hyperlactatemia (>3 mmol/L) during CPB, and this was associated with increase in the postoperative major morbidity and mortality rate in the pediatric cardiac population (Fig. 34.15) [131]. When combined, low $ScvO_2$ and hyperlactatemia should prompt optimization of pump flow, vasodilators, and hemoglobin as strategies to increase oxygen delivery.

Right Atrial Pressure (RA) and Left Atrial Pressure (LA)

Infants and children undergoing open-heart surgery may require intracardiac monitoring. When intracardiac monitoring is indicated, pressure data and waveform tracing assist in the assessment of contractility, preload, afterload, rhythm disturbances, and valve function. In patients with difficult peripheral intravenous access and those in whom central venous access is intentionally omitted due to size limitation or single-ventricle physiology, a right atrial catheter can be placed for the primary purpose of delivering pharmacotherapy.

Right atrial pressure monitoring is indicative of RV function, RV preload, or right ventricular end-diastolic pressure (RVEDP) and afterload. Normal RA values are between 1 and 7 mmHg.

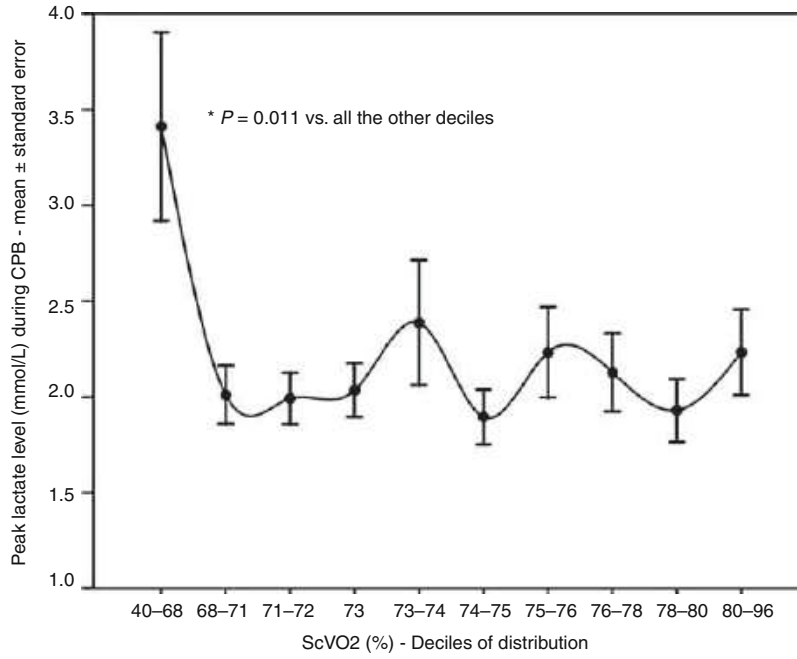

Fig. 34.15 Peak whole blood lactate/ ScVO2. Peak whole blood lactate according to the nadir ScVO2 value. Patient population divided into deciles of distribution and, for each decile, the mean value of peak lactates (+/− standard error of the mean) was calculated. Significance assessed with the Kruskal-Wallis test. The value of peak lactate did not significantly change for values of nadir ScVO2 above 68 %. Significantly higher lactate is present in the first decile of distribution (nadir ScVO2 40–68 %). Reproduced with permission from reference [131]

Many patients with congenital heart disease require higher filling pressures (>5–10 mmHg) due to diastolic dysfunction, right ventricular hypertrophy, or post-cardiopulmonary bypass stunning. Low RA pressures may be indicative of dampened waveform, hypovolemia, or vasodilatation. On the contrary, high RA pressures may be associated with hypervolemia, pericardial effusion, tamponade, RV dysfunction, tricuspid valve regurgitation or stenosis, and pulmonary hypertension.

Because of the difficulties and risk associated with placement of pulmonary artery catheters in the pediatric population, direct measurement of left atrial pressure (LAP) is often performed. LAP reflects preload or left ventricular end-diastolic pressure (LVEDP) and indicates left ventricular function. Normal range for LAP is 5–10 (equal to diastolic pulmonary artery pressure). The surgeon places the LAP catheter via the right superior pulmonary vein or left atrial appendage, during the surgical procedure. Because of access to the systemic circulation and risk of embolization of air, clots, and foreign material, caution is warranted when manipulating a LAP catheter. For this reason, LAP catheter should never be used for bolus or infusion of medications because of the possibility of embolic events.

The use of intracardiac lines in patients with single-ventricle physiology or common atrial line aids in assessment of ventricular function, volume status, and atrioventricular valve integrity following the Norwood procedure. In the case of the second-stage palliation or cavopulmonary shunt, intracardiac monitoring allows for measurement of transpulmonary gradient when a central venous catheter is placed in the IJ and no obstruction is present between SVC and PA (pulmonary artery – common atrial pressure).

RA and LA catheters are considered safe, and the benefits of hemodynamic monitoring in this patient population far outweigh the associated risks. In a study of 351 PICU patients recovering from congenital heart defect surgery with intracardiac lines, the rate of occurrence of bleeding with catheter removal was 36.7 % as measured by doubling mediastinal output in the following hour. However, only 8.3 % required intervention, fluid resuscitation, pleural drainage, catheter wiring for retention, chest tube suctioning, and one surgical removal [132]. Removal of intracardiac catheters can be complicated by hemorrhage and tamponade.

General rules for safely removing intracardiac lines include:

- *CV surgeon should be available at the time of removal.*
- *Check most recent coagulation profile.*
- *INR < 1.5 and platelets > 70.*
- *Ensure adequate IV access prior to removal.*
- *Chest tube patency.*
- *Have blood immediately available.*
- *Ensure adequate monitoring (heart rate, blood pressure, and work of breathing).*
- *Check HCT one-hour post line removal or sooner if bleeding is suspected.*

Neurological Monitoring

Today, neurologic injuries are considered an uncommon but unfortunate source of complication during congenital heart surgery. The incidence of acute neurologic complications after open-heart surgery in children has been reported close to 3 % [133]. While proficient intraoperative neuromonitoring may minimize neurologic injury, it is important to recognize that central nervous malformations preceding surgery are common in patients with congenital heart disease [134], specifically those with hypoplastic left heart syndrome [135], making this population at risk for worse neurologic outcome. The high incidence of white matter injury prior to surgical intervention may be related to abnormal in utero brain development as suggested by other authors [136]. With the associated extreme physiologic variables typical of surgical repair of congenital heart surgery, measures to reduce neurologic injury and preserve function are warranted.

Near-Infrared Spectroscopy (NIRS)

Brain hypoxia is widely thought as the primary mechanism of neurologic injury in the pediatric cardiac patient. Timely recognition of alterations of cerebral oxygen balance currently provides the best opportunity for improving oxygen delivery strategies prior to irreversible brain injury.

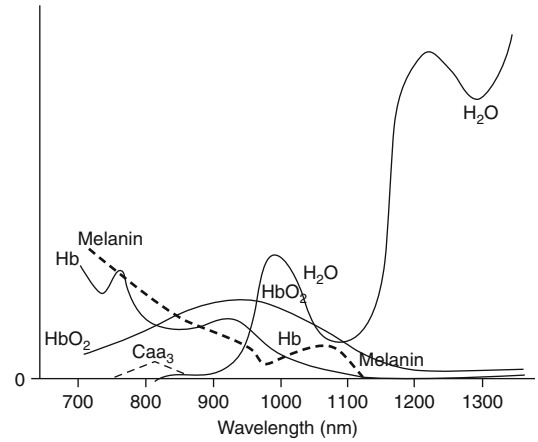

Fig. 34.16 NIRS Spectra. Absorption spectra for oxygenated hemoglobin (HbO_2), deoxygenated hemoglobin (Hb), Caa3, melanin, and water (H_2O) over wavelengths in NIR range. The presence of melanin as found in human hair can significantly attenuate Hb, HbO_2, and Caa3 signals. Used with permission from reference [137]

Near-infrared spectroscopy (NIRS) is a noninvasive optical technique used to monitor brain tissue oxygenation. This technique uses the principles of optical spectrophotometry that make use of the fact that biological material, including skull, is relatively transparent in the near-infrared range. Most commercially available devices utilize 2–4 wavelengths of infrared lights at 700–1,000 nm, where oxygenated and deoxygenated hemoglobin have distinct absorption spectra [137, 138]. Within the NIR range, the primary light-absorbing molecules in tissue are metal complex chromophores: hemoglobin, bilirubin, and cytochrome (Fig. 34.16).

It is estimated that around 85 % of cerebral regional oxygen saturation (rSO2) is derived from cortical tissue with the remaining 15 % derived from overlying extracerebral tissue. NIRS measures "mean" tissue oxygen saturation, which accounts for hemoglobin saturation in venous, capillary, and arterial blood within the sample. Therefore, when sampling cerebral cortex, the average tissue hemoglobin distribution is 70 % venous and 30 % arterial [139]. Consequently, baseline cerebral rSO2 may vary between individuals, in part, as a consequence of interindividual variations in cerebral A/V ratio.

Since the approval of the first commercial cerebral oximetry device in 1993 by the Food and Drug Administration (FDA) and INVOS 3,100 (Somanetics Corporation, Troy, MI, USA), other devices have also emerged on the market, NIRO 500 (Hamamatsu Photonics, Hamamatsu, Japan) and the Foresight (Casmed, Branford, CT). With distinct variations, all monitors work by sensor electrodes placed on the forehead (and somatic sites), with a light-emitting diode and optodes for sensing. An external unit then processes the information from the sensors and displays a numerical value between 15 % and 95 %, presented as a trend against time.

In the pediatric patient with CHD, mixed venous saturation (SvO_2) is used to monitor and determine adequacy of cardiac output and generally used as a surrogate for cerebral oxygenation during pediatric cardiovascular surgery [140]. Tortoriello and colleagues demonstrated a positive correlation between rSO_2 and SvO_2 in pediatric patients undergoing cardiac surgery [140]. Furthermore, one study suggests that rSO_2 is more sensitive for cerebral desaturation and thus an early and sensitive monitor of adequacy of brain perfusion because SvO_2 primarily represents lower torso oxygenation status [141]. Also, significant correlation has been reported between cerebral rSO_2 and superior vena cava ($ScvO_2$) while breathing room air or oxygen 100 % [142].

The Somanetics INVOS system is the most widely used cerebral oximeter (rSO_2) in the pediatric population. A baseline cerebral oximetry (rSO_2) value is recorded prior to intubation while breathing room air. Cerebral hypoperfusion or hypoxia may be suspected when the rSO_2 decreases more than 20 % below baseline [143]. NIRS data is collected continuously during the operation, and therapy is aimed at restoring baseline or above baseline rSO_2. Thus, each patient's baseline rSO_2 serves as his own goal for adequacy of therapy. During a down trend, the surgeons, perfusionist, and anesthesiologist may decide to increase the pump flow rate, evaluate cannula positioning, increase hematocrit, increase inspired oxygen, increase pCO_2, or modify anesthetic level. In general, strategies to increase rSO_2 are aimed at increasing oxygen delivery and decreasing cerebral metabolic rate of oxygen. Therefore, increasing FiO_2, slightly increasing $PaCO_2$, and optimizing total cardiac output, hemoglobin, and anesthesia depth will promote cerebral vasodilation and improved regional oxygen delivery.

The INVOS system has multisite NIRS monitoring capabilities. There is increasing evidence suggesting that placing sensors in somatic tissue allows monitoring of specific tissues perfusion. The relationship between cerebral and somatic rSO_2 measured in cerebral, renal, muscle, and splanchnic sites has been compared with blood lactate levels, and all show inverse correlation, strongest being for cerebral rSO_2, followed by splanchnic, renal, and muscle. The authors suggest that cerebral and renal $rSO_2 < 65$ % as measured by NIRS predicts increased lactates in acyanotic patients after cardiac surgery and helps identify patients at risk for global hypoperfusion caused by low cardiac output syndrome [144]. A more recent study, designed to evaluate four regional oxygen saturation (cerebral, renal, hepatic, and muscular) in children <5 years of age during cardiac procedures, found that the period before CPB (after sternotomy) as a vulnerable phase with potential risk for ischemic insult. The authors suggest that this phase is usually related to handling and dissection of the heart, pericardial suspension, vena cava cannulation, and aortic cannulation and that aggressive monitoring is warranted during this phase [145].

Multiple clinical studies suggest that low cerebral saturations with NIRS correlate with adverse neurological outcome [146]. In addition, NIRS may identify catastrophic cerebral arterial or venous obstruction from cannula malposition during cardiopulmonary bypass [147, 148].

Transcranial Doppler Ultrasound

Transcranial Doppler ultrasound (TCD) monitoring provides real-time surveillance of cerebral blood flow and embolic events during congenital heart surgery. Available devices employ a 2-MHz pulse-wave transducer positioned and

secured on the temple of the patient (temporal window). This position allows for insonation of the middle cerebral artery (MCA). Baseline values are obtained of peak systolic velocity, end-diastolic velocity, mean flow velocity, and pulsatility index. These values are then recorded continuously, and concerning changes are addressed by optimizing pump flow rate and/or cannula positioning.

Important clinical studies have highlighted the utility of this technology in determining the threshold of detectable cerebral perfusion during low-flow CPB in neonates and the level of bypass flow necessary during regional low-flow perfusion for neonatal arch reconstruction [149, 150].

In regard to emboli detection, carotid artery emboli during congenital heart surgery are common events, specially prevalent following removal of the aortic cross-clamp, and their presence did not correlate with postoperative neurologic deficits [151]. Nevertheless, interventions in response to embolic signals associated with decrease in cerebral blood flow should include adjusting vacuum-assisted venous drainage, de-airing maneuvers during cross-clamp removal, and repositioning of the venous cannula.

Electroencephalography and Bispectral Index (BIS)

Multichannel electroencephalography (EEG) has been used in infants undergoing CPB as a rough guide to anesthetic depth and to determine electrocerebral silence before deep hypothermic circulatory arrest (DHCA) [152]. However, difficulties with electrode placement, wave interpretation, and signal interference have made this technology cumbersome and complex. Alternatively, some centers use raw and processed EEG, monitored continuously with a real-time neurologist oversight [153]. Baseline EEG data is recorded following induction of anesthesia, and it is continuously evaluated for signs of slowing relative to baseline. EEG slowing without change in anesthesia depth may signify derangements between metabolic need and cortical perfusion. However, authors have reported that postoperative slowing of the EEG is common following pediatric heart surgery and not associated with adverse neurologic outcome [154]. Therefore, due to technical limitations, conflicting evidence for its use, and manpower, its use has fallen out of favor and replaced by newer technology capable of displaying processed EEG.

The bispectral index (BIS) monitor (Aspect Medical Systems, Newton, MA) is one device currently approved by the FDA to assess the depth of anesthesia. The device uses a sensor placed to the forehead and temple. Through Fourier transformation and bispectral analysis of one-channel processed EEG, the device displays a single number between 0 (isoelectric EEG) and 100 (awake) on a screen. The device also features unprocessed EEG waveform that could be used to identify or recognize EEG burst suppression or electrical silence, which may guide the need for further cooling prior to DHCA.

Other Monitors

Transesophageal Echocardiography (TEE)

Ungerleider et al. first described the use of intraoperative epicardial echocardiography to document the success of repair of congenital heart disease [155]. This experience confirmed the need for pre- and post-bypass examinations and the utility of echocardiography in intraoperative decision-making. With the development of pediatric transesophageal probes, the use of this technology has become part of the routine monitoring armamentarium for all pediatric open-heart surgery procedures. TEE has become an important diagnostic tool to evaluate ventricular function, as well as a mechanism for assessing atrioventricular and semilunar valve competence, outflow obstruction, and intracardiac shunts. In addition, it serves as an important tool to evaluate cardiac function and volume status during complex surgical procedures outside the cardiac operating room.

Table 34.10 Syndromes with cardiac disease and associated difficult airways

Syndrome	Cardiac disease	Airway abnormality	Anesthetic considerations
Apert syndrome	+/− CHD: PS, overriding aorta, VSD	Maxillary hypoplasia, narrow palate +/− cleft palate, tracheal stenosis	Possible difficult intubation
Arthrogryposis multiplex congenita	+/− VSD	Associated hypoplastic mandible, cleft palate, Klippel-Feil syndrome, torticollis	Difficult intubation, associated cardiac disease, minimal muscle relaxant required, +/− malignant hyperthermia
Beckwith-Wiedemann syndrome	Cardiomegaly	Macroglossia: regresses with age	Difficult intubation Hypoglycemia
			Neonatal polycythemia
CHARGE association	+/− CHD: TOF (most commonly)	Micrognathia, short neck, cleft lip/palate, choanal atresia, subglottic stenosis, tracheoesophageal fistula	Difficult intubation
Cornelia de Lange syndrome	+/− CHD: VSD	High arch palate, micrognathia, spurs at anterior angle of mandible, large tongue, +/− cleft palate, short neck	Difficult intubation Associated cardiac disease
Marfan syndrome	Dissecting aortic aneurysm, aortic insufficiency	Narrow face, narrow palate	Difficult intubation
Mucopolysacharidoses			
Type IH (Hurler)	Severe coronary artery and valvular heart disease, cardiomyopathy	Coarse facial features, short neck, tonsillar hypertrophy, narrowed laryngeal inlet and tracheobronchial tree	Difficult intubation
			Postobstructive pulmonary edema
Type 1 H/S (Hurler-Scheie)	+/− Valvular heart disease, most commonly mitral	Macrocephaly, micrognathia	+/− Difficult intubation
Type 1S (Scheie) or Type V	Aortic insufficiency	Mandibular prognathism	+/− Difficult intubation
Type II (Hunter)	Valvular heart disease, coronary artery disease, cardiomyopathy	Coarse facial features, tracheomalacia, macroglossia, macrocephaly, macroglossia	Difficult intubation
Type IV (Morquio)	Late onset aortic insufficiency, PHTN	Mildly coarse facial features, prominent mandible, short neck	Difficult intubation
			Restrictive pulmonary disease
Pompe disease	Cardiomegaly, ventricular septal hypertrophy, cardiomyopathy	Large tongue	Difficult intubation
			Muscle weakness sensitive to muscle relaxants
			Congestive heart failure, sensitive to myocardial depressants
Rubinstein-Taybi syndrome	+/− CHD	Maxillary hypoplasia, narrow palate, micrognathia, microstomia	Difficult intubation
			Cervical spine instability
			Associated cardiac disease
Smith-Lemli-Opitz syndrome	+/− CHD: TOF, VSD	Micrognathia +/− cleft palate, recurrent pneumonia	Difficult intubation
			Associated cardiac disease
Treacher-Collins syndrome	+/− CHD	Malar, mandibular hypoplasia, +/− cleft lip, +/− choanal atresia, +/− macro- or microstomia	Difficult intubation
			Associated cardiac disease

(*continued*)

Table 34.10 (continued)

Syndrome	Cardiac disease	Airway abnormality	Anesthetic considerations
Trisomy 21 (Down syndrome)	AV canal, VSD, ASD	Small mouth, hypoplastic mandible, protruding tongue, unstable cervical spine	+/− Difficult intubation
			Associated cardiac disease
			Less muscle relaxant required
			Increased risk of post-intubation stridor
Turner syndrome (Noonan syndrome)	Coarctation of aorta in females Pulmonary artery coarctation in males	Narrow maxilla, small mandible, short neck	Difficult intubation
			Associated cardiac disease
			Hypertension

ASD atrial septal defect, *AV* atrioventricular, *CHD* congenital heart disease, *PS* pulmonary stenosis, *TOF* tetralogy of Fallot, *VSD* ventricular septal defect
Modified with permission from Wheeler M. et al. The pediatric airway. In Cote CJ et al. (ed) A practice of anesthesia for infants and children. 4th ed

Most centers rely on a group of experienced cardiologist to perform the intraoperative echocardiographic assessment. However, several large studies have reported outcomes from anesthesiologist performing TEE examination to guide volume replacement, need for inotropes, and need for surgical revision and return to bypass in the pediatric population [156, 157].

Appendix

See Table 34.10.

Anesthetic Techniques for Specific Cardiac Pathology

35

Richard J. Ing, Steven P. Goldberg, and Mark D. Twite

Abstract

The current surgical goals for the repair of congenital heart defects in children are the anatomical separation of the pulmonary and systemic circulations without regurgitation or stenosis of any functional heart valves and the preservation of myocardial function. Advances in perioperative care have resulted in low morbidity and mortality in children undergoing heart surgery, and even for the most severe diagnosis of hypoplastic left heart syndrome, 70 % of patients are currently expected to survive to adulthood [1]. This chapter will focus on the anesthetic considerations for specific cardiac lesions and their surgical repair.

Keywords

Anesthetic techniques • Anomalous left coronary artery arising from the pulmonary artery • Cardiomyopathies • Congenital heart disease • Heart transplantation • Left-to-right shunt lesions • Obstructive left-sided heart lesions • Pericardial effusion and tamponade • Right-sided heart lesions • Single ventricle anatomy • Transposition of the great arteries • Vascular rings and slings • Ventricular assist

Introduction

The current surgical goals for the repair of congenital heart defects in children are the anatomical separation of the pulmonary and systemic circulations without regurgitation or stenosis of any functional heart valves and the preservation of myocardial function. Advances in perioperative care have resulted in low morbidity and mortality in children undergoing heart surgery, and even for the most severe diagnosis of hypoplastic left heart syndrome, 70 % of patients are currently expected to survive to adulthood [1]. This chapter will focus on the anesthetic considerations for specific cardiac lesions and their surgical repair.

Cardiac surgical outcomes continue to improve even in very low birth weight infants weighing less than 2.5 kg [2, 3]. The current trend is to operate on the heart early and surgery should not be delayed for the sole purpose of allowing the infant to gain weight [3]. It has been shown that children with congenital heart disease (CHD) delivered before the gestational age of 38 weeks have worse neurodevelopment scores than children delivered after 38 weeks [4]. Older age at surgery together with postoperative low cardiac output (CO) syndrome (LCOS) has been found to be associated with worse health-related quality of life scores at 4 years of age [5].

The anesthetic approach for each child undergoing surgery depends on the specific cardiac anatomy, the patient's multisystem organ reserve, and any associated pathophysiology. It is essential that for every patient, there is a thorough review of available data, including EKG, echocardiogram, and cardiac catheterization laboratory data, in addition to a physical exam where particular attention should be paid to airway assessment and the cardiac exam. Many centers now review pertinent data in joint conferences with cardiologists, cardiac surgeons, and anesthesiologists to arrive at a consensus management plan.

Left-to-Right Shunt Lesions

A left-to-right shunt exists when there is a communication between the systemic and pulmonary circulations that allows the mixing of better oxygen-saturated blood with less oxygen-saturated blood independent of where the anatomical lesions occur. The degree of shunting will depend on the size of the defect and the resistance to blood flow. Common left-to-right shunt lesions include atrial septal defect (ASD), ventricular septal defect (VSD), atrioventricular septal defects (AVSD), patent ductus arteriosus (PDA), and partial anomalous pulmonary venous return (PAPVR). Anesthetic precautions common to all of these lesions include the avoidance of air emboli and the awareness of anesthetic drug effects on both pulmonary vascular resistance (PVR) and systemic vascular resistance (SVR). All anesthetic agents depress myocardial function in a dose-dependent manner, with infants less than 6 months of age being most susceptible [6, 7]. Therefore, a balanced anesthetic technique, using several different anesthetic drugs in lower doses than if a single agent was being used, will help maintain hemodynamic stability and CO [8]. In addition, careful attention must be made to the inspired oxygen concentration and ventilation parameters such that adequate oxygenation is maintained but the degree of left-to-right shunting of blood is not made worse by inadvertently lowering the PVR. Close attention to airway management is particularly important before the anesthesiologist's attention is directed toward other procedures associated with preparing the patient for surgery, such as arterial and central venous line placement.

(a) Atrial Septal Defects

There are four types of ASD: secundum, primum, sinus venosus, and coronary sinus. The most common is the secundum ASD. An ASD may be an isolated congenital heart defect or it may be associated with other congenital heart defects where it may provide a lifesaving communication between the pulmonary and systemic circulations, for example, in transposition of the great arteries (TGA) and hypoplastic left heart syndrome (HLHS). Physiologically there is

a left-to-right shunting at the atrial level, which is dependent on the size of the defect and the compliance of the right and left ventricles. This shunt causes volume overload of the right heart, which is well tolerated in childhood but may lead to congestive heart failure and eventually pulmonary arterial hypertension by the second decade of life. The risk of atrial arrhythmias increases as volume overload increases and there is progressive dilation of the atria. An ASD may be discovered during a stroke work-up for paradoxical emboli. An ASD with a documented pulmonary-to-systemic blood flow ratio (Qp:Qs) of $\geq$1.5:1 indicates the need for surgical or percutaneous closure [9]. Anesthetic considerations during surgical closure on cardiopulmonary bypass (CPB) include adopting an anesthetic technique that allows early extubation of the patient either in the operating room or soon afterward in the intensive care unit. Many surgeons will repair an ASD through a mini-sternotomy for cosmetic reasons and try to perform the repair without using any blood products. Anesthetic considerations during percutaneous device closures in the cardiac catheterization laboratory include the need for transesophageal echocardiogram assistance to help determine if there is an adequate rim of septal tissue to hold the device and administering antibiotics prior to device placement. After the device is deployed, possible complications include damage to heart valves, device embolization, and arrhythmias.

(b) Ventricular Septal Defects

There are multiple types of VSDs, named for their location in the interventricular septum, with the perimembranous VSD being the most common. Indications for surgical repair include failure to thrive, congestive heart failure, or a large shunt with or without pulmonary arterial hypertension. In patients with pulmonary hypertension secondary to an unrestrictive ventricular septal defect (VSD), cardiac surgery will be required within the first 2 years of life and ideally throughout the first year, if irreversible pulmonary vascular disease is to be prevented [10]. Surgery in this situation is seldom delayed and is usually completed during infancy if congestive heart failure not responsive to medical therapy and failure to thrive are present [10]. With a moderate VSD, LV hypertrophy may be seen on EKG and on chest X-ray various degrees of cardiomegaly may be documented [8]. Surgical repair of a VSD is usually by patch, or sometimes by primary closure, on cardiopulmonary bypass. Some VSDs in older children may be amenable to transcatheter closure techniques in the cardiac catheterization laboratory. Transcatheter techniques may also be used as an adjunct for difficult to close muscular VSDs, including some of the so-called "Swiss cheese" VSDs, during surgical closure on CPB.

Anesthetic considerations include postoperative conduction disturbances, which may be transient or permanent. Heart block and junctional ectopic tachycardia are seen most frequently. Children undergoing straightforward VSD repair should be good candidates for fast track techniques.

(c) Patent Ductus Arteriosus

The younger and more premature the infant, the more likely a patent ductus arteriosus (PDA) will be present. Because many of these patients are surgically repaired at the NICU bedside, the anesthetic management of this lesion in the premature infant will be discussed in more detail. The ductus may be patent in as many as 70–80 % of premature infants weighing less than 1,000 g [11, 12].

Failure of spontaneous ductal closure is associated with excessive intravenous fluid administration, the presence of left-to-right shunt with persistent pulmonary hypertension of the newborn (PPHN), hypercarbia, sepsis and hypoxia, or ventilator dependency [13]. A persistent right-to-left shunt through the PDA results in low oxygen saturations. However, these children do not usually have their PDA ligated until the pulmonary vascular resistance (PVR) falls, as the PDA is acting as a "pop-off" for CO. On the other hand when the PVR is lower, a persistent left-to-right shunt through the PDA may result in low diastolic blood pressure, making it difficult to wean the premature infant from inotropic drug and ventilator support [12] and conceivably increasing the risks for necrotizing enterocolitis. Following a failed medical trial of PDA closure with

nonsteroidal drugs such as indomethacin, it often becomes necessary for the premature infant to undergo bedside surgical PDA ligation. More recently, the development of small intravascular occluder devices allows cardiologists to close PDAs percutaneously at the neonatal intensive care unit (NICU) bedside under ultrasound guidance [14–16]. Bedside surgery in the NICU avoids transportation of critically ill very low birth weight infants to the operating room with the attendant risks of extubation, hemodynamic instability, central access line disruption, and hypothermia. Prior to patient positioning, the child should have endotracheal tube (ETT) intubation performed if they are not already intubated. A chest X-ray confirms the position of the ETT and sidedness of the aorta. The aorta is commonly left sided and usually patients are positioned for a left thoracotomy. Once the infant is placed in the lateral decubitus position, special attention is given to securing the ETT to prevent kinking, inadvertent extubation, and endobronchial intubation. There should also be adequate soft padding of bony limb prominences to avoid pressure trauma. An appropriately small surgical diathermy pad is usually placed across the buttocks. A blood pressure cuff placed on a lower limb allows the surgeon to ensure the PDA is ligated and not the descending aorta. Similarly, two pulse oximeter probes placed on the upper and lower limbs are useful. Anesthesia intravenous access, which is separate from inotropes and other medications, is needed for the rapid administration of blood in a surgical emergency, should there be a friable PDA hemorrhage during surgical ligation. A unit of leukoreduced gamma-irradiated red blood cells should be at the bedside and checked before surgery begins. All intravenous infusions are continued, and inotropic support such as dopamine in the range of 5–20 mcg/kg/min should be available in-line to be administered during intraoperative moments of hemodynamic instability. The current trend is to avoid the administration of midazolam because of the concerns for accelerated neuroapoptosis and possible deleterious side effects in premature infants brains [17]. Fentanyl in the dose range of 10–20 mcg/kg together with muscle relaxation allows surgical quiescence and the inhibition of the metabolic endocrine stress response [18, 19]. Care should be exercised to ensure no air bubbles are present in the intravenous lines during anesthesia medication infusion. Prior to the initiation of surgery, antibiotic prophylaxis in the form of a first-generation cephalosporin in the dose range of 25–40mcg/kg is usually administered.

Increasing the inspired oxygen concentration by 10–15 % usually maintains oxygen saturations in the range of 88–92 % together with a 2–3 mmHg increase in the inspired ventilator pressure that prevents lung atelectasis during thoracotomy. Caregivers ought to remember to decrease these adjusted ventilator parameters back to baseline following completion of surgery during chest closure. A manual ventilation circuit should be close at hand to institute hand ventilation if needed. It should not be left with oxygen flowing under the surgical drapes, as a high oxygen concentration in the surgical field can ignite fires with diathermy use, especially if alcohol-based skin preparation fluids are used [20]. One important complication following PDA ligation is left vocal cord palsy (LVCP), which may occur in 40–60 % of patients and is due to the course of the recurrent laryngeal nerve around the PDA. These infants are significantly more likely to develop bronchopulmonary dysplasia, reactive airway disease, and the need for gastrostomy tube placement compared to infants who underwent PDA ligation without developing LVCP [21]. Surgery itself may be a risk factor for neurodevelopmental morbidity and retinopathy of prematurity [22, 23], with some of these changes persisting into adulthood [24].

(d) Atrioventricular Septal Defects

These defects have multiple synonyms describing various components of the endocardial cushion defect. The complete form of AVSD is characterized by (1) a large primum ASD above the valve, (2) a large inlet VSD below the valve, and (3) a multileaflet common atrioventricular valve rather than separate tricuspid and mitral valves. A classification scheme developed in 1966 by Kirklin and Rastelli has three types of defect, A, B, and C, based on how

much of the superior bridging leaflet crosses the crest of the VSD. As many as 30 % of patients with AVSD defects will have trisomy 21 and these patients require special considerations for their anesthesia [25]. The surgical repair is usually undertaken between 3 and 6 months of life. The "midpoint" of the common valve is found by saline insufflation and brought together with a stitch. The cleft in the left-sided valve is then closed to create a competent valve. The VSD is usually patched with synthetic material, with the top of the patch being anchored to the valve leaflets. The ASD is patched, usually with autologous pericardium, as regurgitant blood from the left AV valve striking a synthetic patch may result in severe hemolysis. Specific anesthetic considerations include postoperative heart block and elevated pulmonary artery pressures or pulmonary hypertensive crisis. Surgical placements of left atrial and pulmonary pressure lines may be helpful in guiding the management of postoperative inotropes and pulmonary vasodilator therapies such as inhaled nitric oxide.

(e) Aortopulmonary Window

Aortopulmonary window (APW) is a relatively uncommon congenital cardiac malformation characterized by a communication between the ascending aorta and the pulmonary trunk. It is classified as proximal (I), distal (II), total (III), or intermediate (IV) [26]. The pressure gradient between the aorta and pulmonary artery produces a significant shunt depending on the size of the defect and the relative resistances of the pulmonary and vascular beds. Pulmonary hypertension can develop quickly and uncorrected APW has a high mortality in the first year of life. Surgical correction is contraindicated in patients with a PVR $>$ 10 Wood units m^2 and when the Qp:Qs is less than 1.5 [27, 28]. Surgical repair of APW is usually achieved on CPB via median sternotomy. There are anecdotal case reports of transcatheter closures. The anesthetic management of APW is very similar to that of truncus arteriosus. Due to the large left-to-right shunt, efforts should be focused on maintaining PVR to decrease diastolic runoff with resulting poor coronary perfusion. Pre-bypass, arterial saturations should be maintained around 80 %, and in order to achieve this, the lowest possible FiO_2 should be used and a ventilator strategy be adopted that maintains a slightly elevated $PaCO_2$. If this strategy is not working, then asking the surgeon to snare the pulmonary artery may be helpful. All patients with APW are at risk of pulmonary hypertension in the post-op period and typical strategies such as inhaled nitric oxide, paralysis, and deep sedation should be used.

(f) Truncus Arteriosus

The aorta and pulmonary artery begin their development as a single artery, the common truncus arteriosus, arising as a single great vessel from the top of the primitive heart. Cells at the upper rim of the truncus should descend in a spiral pattern to divide the truncus into the two great arteries, with the aorta to the left and pulmonary artery to the right. If this division never happens, the result is a common arterial trunk (CAT). There are three major anatomical patterns. This defect is highly associated with DiGeorge syndrome. Surgical repair is done on cardiopulmonary bypass and involves dividing the aorta and re-anastomosing it to the truncal valve, which can have a variable number of cusps. A valved conduit is usually used to attach the right ventricle to the pulmonary artery. Surgical outcomes of common arterial trunk (CAT) and truncal valve surgery (TVS) repair from 2000 to 2009 in The Society of Thoracic Surgeons' Congenital Heart Surgery Database have recently been analyzed. It was found that mortality for CAT repair with TVS in comparison to isolated CAT repair was 30 % and 10 % ($p = 0.0002$), respectively [29]. Fetal diagnosis does translate into earlier surgical repair in at least one study; however, this did not result in improved mortality. The postoperative mortality for this lesion is reported to be as high as 10 % [30]. Long-term problems are competency of the truncal valve and the need to replace the RV-to-PA conduit. Anesthetic considerations are very similar to APW. The main issues are related to the large left-to-right shunt and subsequent congestive heart failure and pulmonary hypertension. Induction of anesthesia in children with severe CHF should be done carefully. Typically a combination of

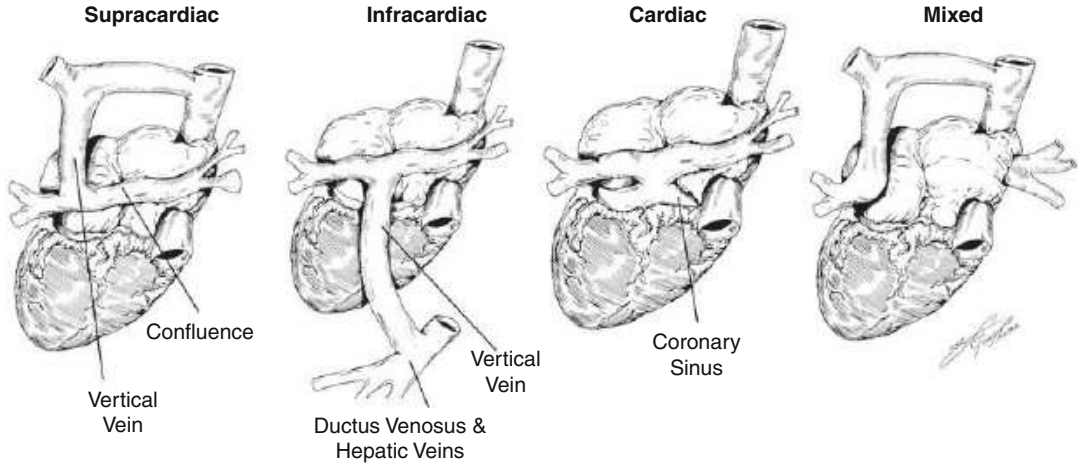

Fig. 35.1 Types of anomalous pulmonary venous return

fentanyl, ketamine, or etomidate and a neuromuscular blocker is used. An inhalational induction with sevoflurane should be done cautiously with careful titration. Patients presenting late in infancy may have significant pulmonary hypertension and this should be managed with inhaled nitric oxide, paralysis, deep sedation, and alkalization if necessary. All patients with truncus arteriosus should be assumed to have DiGeorge syndrome and receive irradiated blood products in order to prevent graft-versus-host disease, and close attention should be paid to correcting plasma calcium levels.

(g) Total and Partial Anomalous Pulmonary Venous Return

Embryologically, the primitive pulmonary veins grow forward from the lung beds to join the left atrium on the posterior aspect of the heart. If that fusion fails, the pulmonary veins must find some alternative way to drain into the heart. In total anomalous pulmonary venous return (TAPVR), the veins come together in a confluence that drains to the heart, usually by way of a vertical vein. This oxygenated blood passes into the left heart by way of an ASD, which must be present and not restrictive for initial survival. There are four anatomical subtypes: supracardiac, cardiac, infracardiac, and mixed (Fig. 35.1). Obstructed TAPVR is a surgical emergency. Infracardiac TAPVR is the most common variant to present with obstruction due to its long course through the liver. Supracardiac TAPVR can present with obstruction of the vertical vein between the pulmonary artery and left bronchus. Children commonly present soon after birth with signs of tachypnea, dyspnea, cyanosis, hypoxemia, and severe metabolic acidosis. A chest X-ray shows congested lung fields and a small heart. A recent single institution study of 207 TAPVR patients over a 10-year follow-up period revealed a survival rate of 51 % in patients with TAPVR and a univentricular heart compared to 85 % in TAPVR with biventricular hearts [31]. Surgical repair of the various forms of TAPVR has a common theme of creating an anastomosis between the venous confluence and left atrium, with patch closure of the ASD. The most common long-term complication of repair is pulmonary vein stenosis, which can be very difficult to treat. Infants with obstructed TAPVR may present urgently for surgical repair and be critically ill. Anesthetic management should focus on gaining arterial and central venous access quickly while treating ongoing metabolic acidosis and hemodynamic instability. TEE is usually contraindicated due to risk of further compression and obstruction of the pulmonary veins. Post-bypass pulmonary hypertension can be a significant problem and should be managed in the standard fashion with inhaled nitric oxide, paralysis, and deep sedation. Pulmonary injury

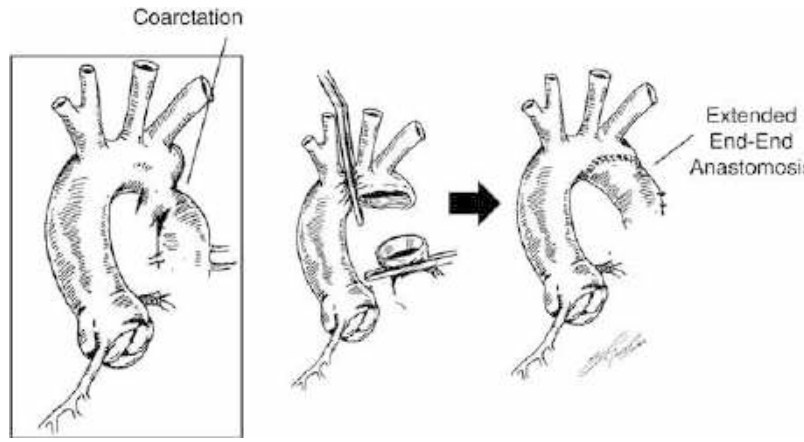

Fig. 35.2 Coarctation of the aorta showing position of aortic clamps and extended end-to-end repair

may be the result of both the pulmonary edema from the venous obstruction pre-bypass and the systemic inflammatory response to cardiopulmonary bypass.

Obstructive Left-Sided Heart Lesions

The anesthetic principles of these challenging lesions depend on the degree of left-sided heart obstruction and the age of presentation. Some patients are diagnosed during fetal life, and management can vary from planned cesarean neonatal delivery via an exit procedure in hypoplastic left heart syndrome with intact atrial septum to urgent cardiac catheterization laboratory surgical hybrid intervention with carotid artery cutdown in the neck for controlled access in critical neonatal aortic stenosis [32, 33]. Many of these described infants die soon after birth, unless they are transferred to centers that can recognize and treat low CO in neonates with the expertise to manage the metabolic derangements, organ dysfunction, and cardiac interventions needed to repair these challenging cardiac malformations. The anesthesiologist needs to gather information about the diagnosis, organ reserve, metabolic derangements, and planned course of surgical intervention in order to decide which vasopressors and anesthetic medications will be most appropriate for this pathophysiology. The principal pathophysiology for all left-sided obstructive lesions is that a diminutive left-sided heart structure results in a pressure-overloaded ventricle and/or atrium, the consequences of which determine myocardial subendocardium viability. The worst outcomes are seen in patients with aortic atresia and mitral stenosis where ventricular coronary fistulae may be present [34]. The degree of myocardial dysfunction determines the feasibility of surgical correction, or whether the child should be listed for heart transplantation. It is important to maintain an adequate CO and diastolic blood pressure in order to maintain coronary perfusion pressure. In addition, any patient with a high LVEDP will tolerate excessive intravenous fluid administration and a high SVR very poorly.

(a) Coarctation of the Aorta

Repair of coarctation of the aorta can occur at any age (Fig. 35.2). The age of presentation, degree of aortic obstruction, and resultant left ventricular function determine the severity of illness at presentation and the complexity of the surgery and anesthesia. Preparation is usually for a left lateral thoracotomy; however, patients with aortic arch hypoplasia may require surgical repair on CBP. Central access and arterial line monitoring in the right radial artery is preferred. Regional techniques, such as a thoracic epidural or paravertebral nerve blocks, may be useful adjuncts for early extubation in children undergoing a thoracotomy. One-lung ventilation should be considered and sodium nitroprusside

and esmolol have been found to be a good combination of medications to administer for control of blood pressure postoperatively [35].

(b) Aortic Stenosis

When administering anesthesia to a patient with aortic stenosis of any form, the goal is to maintain coronary artery perfusion at all times. Inadvertent coronary hypoperfusion can cause myocardial ischemia, arrhythmias, and low CO. This cascade of events can quickly lead to hypotension and the risk of cardiac arrest.

1. Supravalvar Aortic Stenosis

This lesion may occur in isolation, but the diagnosis of supravalvar aortic stenosis (SVAS) is often associated with William's syndrome. This syndrome presents the anesthesiologist with particular challenges [36]. William's syndrome has an incidence of 1:20,000 live births and is characterized by multiorgan involvement including facial malformations, cardiac lesions (SVAS, peripheral pulmonary stenosis, ventricular hypertrophy, coronary ostial stenosis, mitral valve prolapse, coronary artery lesions, coarctation of the aorta, PDA, VSD , tetralogy of Fallot), developmental delay, distinctive personality and behavioral traits, and neonatal hypocalcemia [36–40]. The disease is an elastin arteriopathy as a result of chromosome deletions on 7q11.23 [39, 41]. Should cardiac arrest occur under anesthesia, these children are very resistant to resuscitative efforts [39, 40, 42]. Very often the peripheral pulmonary stenosis can lead to a pressure-overloaded RV, which tolerates an increased afterload poorly and may subsequently develop myocardial dysfunction. The combination of significant LV and RV dysfunction in these children is challenging. Avoid tachycardia, maintain sinus rhythm, maintain preload, use propofol with extreme caution, avoid increases in PVR, and maintain relatively high SVR (i.e., use of ketamine infusion) [6, 39]. Elective surgical procedures should be completed in centers capable of providing ECMO expeditiously [43].

2. Valvar Aortic Stenosis

Valvar aortic stenosis (AS) presents in 3–6 % of children who have congenital heart disease, with a 4:1 male to female ratio. Twenty percent may have associated cardiac anomalies [44]. During early infancy, 10–15 % of patients with severe aortic valve obstruction present with congestive cardiac failure [45]. Neonates presenting in cardiogenic shock with critical aortic stenosis are a critical care emergency and should be started on prostaglandin (PGE_1) to try to restore ductus arteriosus patency. Endotracheal intubation is achieved if needed, metabolic acidosis corrected and inotrope administration instituted [46]. Once hemodynamic stability has been achieved and the metabolic derangements corrected, these patients often go to the cardiac catheterization laboratory to attempt percutaneous balloon valvuloplasty. This is usually via carotid artery cutdown and a catheter-directed intervention.

3. Subaortic Stenosis

Fixed subaortic stenosis is caused by a thin fibrous membrane (80 %) or thick fibromuscular band [46, 47]. This lesion is usually progressive in nature and is associated with aortic regurgitation, VSD, coarctation of the aorta, and a predisposition to infective endocarditis [46]. Repair will require CPB and the anesthetic principles are similar as for the pathophysiology described above. Maintain CO, coronary perfusion, and a normal to raised SVR to achieve this. Avoid tachycardia.

(c) Shone's Complex

Shone's anomaly, first described in eight cases in 1963, outlines a syndrome of multilevel obstructive cardiac lesions on the left side of the heart [48]. The original description included a parachute mitral valve where the chordae converge to insert into one papillary muscle together with an associated supra-annular mitral ring together with subaortic stenosis and coarctation of the aorta. These lesions coexist as a developmental complex with varying dominance of any one of the particular lesions in the eight different cases originally described. The striking features common to all are a supravalvar mitral ring and subaortic stenosis [48]. Operative mortality is adversely affected by the severity of mitral valve disease, the degree of left ventricular hypoplasia, and the need for multiple operative procedures [49, 50]. In one study 15-year survival was found to be 89 % [50].

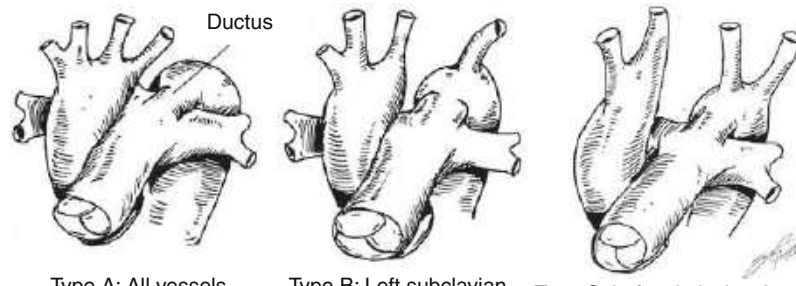

Fig. 35.3 Classification of interrupted aortic arch

The most important anesthetic consideration is to determine the most dominant left-sided lesion, since this will guide anesthetic management. Essential anesthetic principles are to maintain CO, sinus rhythm, coronary perfusion, and SVR and to avoid tachycardia. At all times caregivers should pay strict attention to the ST segment on ECG and monitor for myocardial ischemia and arrhythmias.

(d) Interrupted Aortic Arch

Interrupted aortic arch (IAA) occurs in 1 % of patients with cardiac malformations. There are three types: type A, discontinuity distal to the left subclavian artery (43 %); type B, discontinuity between the left carotid and left subclavian arteries (53 %); and type C, discontinuity between the innominate and left carotid arteries (4 %) (Fig. 35.3). If left untreated, 75 % of these patients die within the first month of life and 90 % within 1 year [51, 52]. There is evidence that primary surgical repair, rather than a staged operation, may have a more favorable long-term result. In order to minimize the risk for developing cardiomyopathy and potential need for heart transplantation later in life, any aortic arch obstruction must be surgically completely repaired [53]. As many as 68 % of patients with IAA may have a DiGeorge phenotype including absent thymus, hypocalcemia, and face and palate anomalies [54]. Repair will require CPB and often deep hypothermic circulatory arrest (DHCA). Ideally, a femoral or umbilical arterial catheter should be placed, as the aortic arch repair may involve the subclavian arteries and render invasive arterial monitoring in the arms inaccurate. Central access for inotropes and peripheral venous access for transfusion are recommended. All red blood cells should be irradiated and leukoreduced to prevent graft-versus-host disease. Surgical repair may injure the recurrent laryngeal nerve and cause vocal cord paralysis, which only has about a 35 % recovery rate [55]. Vocal cord paralysis should be considered if there is post-extubation stridor or cricopharyngeal incoordination.

Right-Sided Heart Lesions

Patients with right-sided obstructive lesions may have obstruction at the level of the tricuspid valve, the right ventricular outflow tract, the pulmonary valve, or the pulmonary arteries. Many lesions, such as tetralogy of Fallot, have multilevel obstruction and other associated cardiac pathology. The lesions covered in this section include Ebstein malformation of the tricuspid valve, tetralogy of Fallot, and pulmonary atresia with and without a VSD.

(a) Tetralogy of Fallot

Stenson first described this anatomical lesion in 1671. In 1888, Fallot reported five patients with "*la maladie bleu*" whose hearts had an obstructed RV outflow together with a large VSD, overriding aorta, and RV hypertrophy (Fig. 35.4). Finally it was Abbott in 1924 who described the heart malformation as "tetralogy of Fallot" (TOF) [56]. If diagnosed in utero or soon after birth, the current surgical management is to undergo full anatomical repair close to 3 months

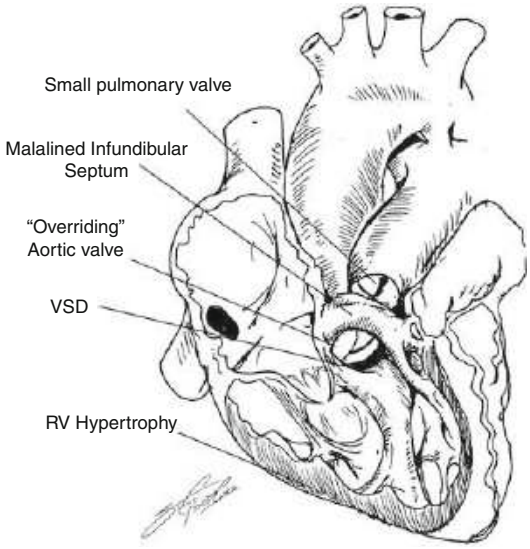

Fig. 35.4 Tetralogy of Fallot

of age utilizing CPB. Syndromes associated with TOF include DiGeorge, VACTERL, and CHARGE syndromes, and these are present in 20 % of patients with TOF [57]. Patients with TOF are well known for their "tet spells." With a nonrestrictive VSD, the major determinant of right-to-left shunting and hence cyanosis is the degree of RVOT obstruction. A decrease in SVR and/or an increase in RVOT obstruction will increase right-to-left shunting and worsen cyanosis. The majority of "tet spells" are the result of pulmonary infundibular spasm due to endogenous sympathetic catecholaminergic stimulation, which causes an acute increase in right-to-left shunting of blood [58] with almost abolition of pulmonary blood flow. Older children with unrepaired TOF will often squat during a "tet spell." Squatting increases intra-abdominal pressure, thereby increasing RV preload and SVR, which reduces the degree of the right-to-left shunt. Propranolol may be used preoperatively in children with TOF to lessen the severity of "tet spells" through relaxation of the RVOT infundibular muscle. Children on propranolol therapy should continue the medication until the day of surgery. Early concerns were raised that the use of beta-adrenergic blocking drugs may lead to hemodynamic instability in the early postoperative period, thereby increasing the overall risk of primary corrective surgery [59]. However, a study by Graham et al. suggests that any blunting of inotropic or chronotropic activity in propranolol-treated patients can be overcome with increased inotropic medications or temporary pacing, without increased morbidity or mortality [60]. Factors that increase the risk of a "tet spell" at the time of surgery include significant polycythemia in chronically cyanosed patients, prolonged preoperative fasting of the child resulting in dehydration causing a decrease in RV preload, a surge in endogenous catecholamines in an uncooperative child during mask induction of anesthesia causing RVOT spasm, and inhalational sevoflurane induction causing a decrease in SVR. In addition, sevoflurane at high levels causes direct myocardial depression. Inadequate ventilation may also cause hypoxia and hypercarbia and a subsequent increase in PVR. Treatment of a "tet spell" in the operating room involves increasing inspired oxygen content to 100 % to help maximize systemic oxygenation, administering phenylephrine 5–10 mcg/kg IV to increase systemic blood pressure which leads to improved pulmonary blood flow [61], and giving an IV fluid bolus 20 ml/kg to support the blood pressure and increase RV preload. Administering abdominal compression by placing the child in a knee-chest position or manually compressing the abdominal aorta will help to increase SVR [62]. Increasing the depth of anesthesia, by increasing the inhalational agent, in order to relax the infundibular spasm may also be helpful. However, anesthesiologists must remember that high levels of inhaled agent will decrease SVR and directly depress myocardial function, and they must consider administering IV fentanyl 5–10 mcg/kg to help balance the anesthetic technique and limit the amount of inhaled agent used. The acute use of β-blockers, such as IV esmolol 50 mcg/kg [63, 64] and IV propranolol 0.1 mg/kg, may be helpful to relieve infundibular spasm [65].

For patients undergoing complete repair of TOF, the anesthetic technique should follow a standard technique undertaken for any pediatric CPB surgery. Due to the high incidence of

DiGeorge syndrome in patients with TOF, irradiated blood products should be used and close attention should also be paid to calcium levels. Post-CPB, most patients will require vasopressor support with low-dose dopamine and milrinone to help with RV dysfunction. The use of milrinone, with a loading dose of 50–75 mcg/kg over 30 min followed by an infusion of 0.75 mcg/kg/min, has been shown to reduce the risk of low cardiac output syndrome in children after congenital heart surgery [66]. Arrhythmias and heart block are common after VSD repairs because of the close proximity of the conduction system to the VSD patch. Epicardial pacing may be required postoperatively, but it is usually temporary until edema around the VSD patch repair resolves. Epicardial pacing required for longer than 10 days is usually an indication that a permanent pacemaker will be required. Junctional ectopic tachycardia (JET) may occur after repair of TOF. The use of milrinone and dopamine may be risk factors for its occurrence [67, 68]. The diagnosis of JET is made by a rapid heart rate, typically 180–260 beats per minute; a narrow QRS complex on ECG; and atrioventricular conduction dissociation. Postoperatively a rapid heart rate will be poorly tolerated when the systolic and diastolic function of the heart is impaired. Treatment strategies include magnesium infusion, active surface cooling of the patient, amiodarone therapy, and pacemaker strategies [69]. Prophylactic amiodarone started at the time of rewarming during CPB has also been shown to decrease the incidence of JET after TOF repair [70].

The older repaired TOF patient often returns for repeat surgery involving placement of a valved pulmonary artery conduit to address the free pulmonary insufficiency created during the first surgical repair during infancy. Anesthetic planning should include a full assessment by a cardiologist and an intraoperative preparation for redo sternotomy with the possibility of extensive bleeding during heart dissection prior to the initiation of CPB. Intravascular monitoring and access therefore should be appropriate with at least two good wide-bore intravenous cannulae for volume resuscitation.

(b) Pulmonary Atresia with Ventricular Septal Defect

In this variation of pulmonary atresia, there is a variable degree of hypoplasia of the pulmonary arteries. This can range from relatively normal-sized vessels to very small or even absent vessels. In the latter case, blood flow to the lungs is maintained by an equally variable number and size of collateral vessels called multiple aortopulmonary collateral arteries (MAPCAs). For the time that the pulmonary vascular bed is exposed to high-pressure flow directly from the aorta via MAPCAs, the risk of developing pulmonary hypertension is increased. Surgical repair is complex and often staged. If the pulmonary arteries are very small, then a shunt, usually a modified BT shunt, is used to increase pulmonary blood flow and encourage vessel growth. The definitive repair involves first identifying the MAPCAs on cardiac catheterization which supply blood to their respective lung segments. These must be preserved and are detached from the thoracic aorta and reimplanted on the native pulmonary arteries. This process of recruiting all of the extraneous sources of blood flow and incorporating them into a single main source of pulmonary blood flow is known as "unifocalization." Continuity between the main PA and RV is restored with a valved conduit (Fig. 35.5). A decision is made, based on pulmonary artery anatomy and pressures, whether or not the VSD can be safely closed. Several problems can be anticipated in post-CPB. There may be RV dysfunction secondary to increased PVR. Therapeutic strategies include inotropic support and manipulating ventilation parameters to lower PVR. This problem may be further exacerbated by lung reperfusion injury due to previously poorly perfused areas of the lung now receiving increased blood flow. Lung protective strategies should be adopted including optimizing PEEP and limiting free radical injury from high inspired oxygen concentrations. There may be significant bleeding due to multiple suture lines and aggressive blood component replacement is usually required.

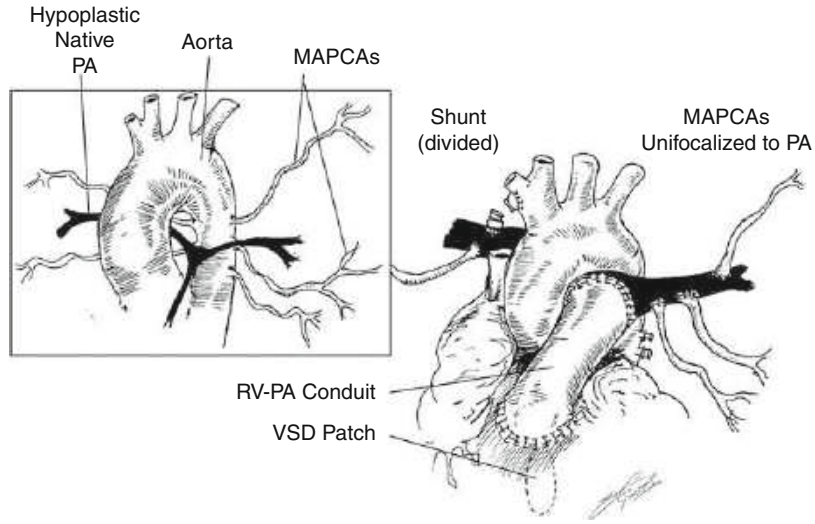

Fig. 35.5 Pulmonary Atresia with MAPCAs showing repair with unifocalization and placement of an RV-PA conduit

(c) Pulmonary Atresia with Intact Ventricular Septum

Unlike pulmonary atresia with a VSD, pulmonary atresia with an intact ventricular septum usually has normal-sized pulmonary arteries but there is membranous atresia of the pulmonary valve. The surgical goal for this lesion is to restore pulmonary blood flow. Initially PGE_1 should be initiated to maintain a patent ductus arteriosus and allow blood to flow to the lungs. For these infants the catheterization laboratory is often the first step, where percutaneous radiofrequency or laser-assisted perforation of the atretic pulmonary valve and subsequent balloon dilation may be attempted. The intervention procedure is technically challenging and the anesthesiologist should always be prepared for cardiac tamponade should the very thin right-sided vessels or ventricle in neonates undergo perforation and bleeding within the pericardial cavity or chest. One study reported a 25 % incidence of cardiac perforation, postoperative femoral vessel occlusion, and intraoperative arrhythmias [71]. The serious problem with PA–IVS is often with the coronary artery supply to the myocardium. Sometimes, the coronary blood supply to the right ventricle is via fistulas from the coronary artery into the ventricular cavity itself which makes the RV the source of coronary blood flow, so-called RV-dependent coronaries (Figs. 35.6 and 35.7). The surgical

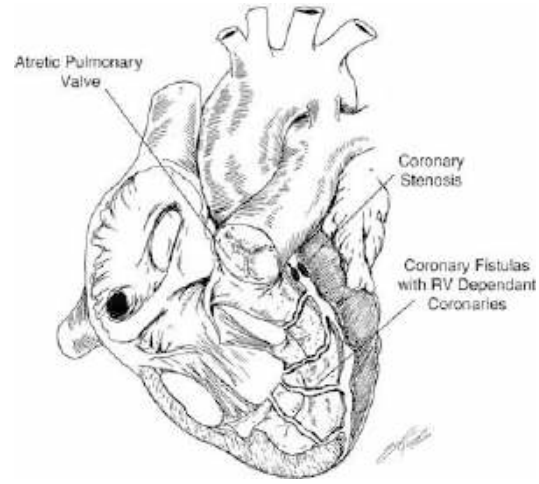

Fig. 35.6 Pulmonary Atresia with intact ventricular septum showing right ventricular dependent coronary system

repair options are based on whether or not the coronaries are RV dependent. In the case of normal coronary circulation, surgical correction consists of opening up the RV outflow tract. This may involve a transannular incision and patch, much like a TOF repair, restoring a two-ventricle system, associated with a modified BT shunt as required. However, if the RV perfuses the coronaries in a retrograde manner, the obstructed RV cannot be decompressed by opening the RVOT, because the fall in right ventricular end diastolic pressure will "steal" blood from the coronary

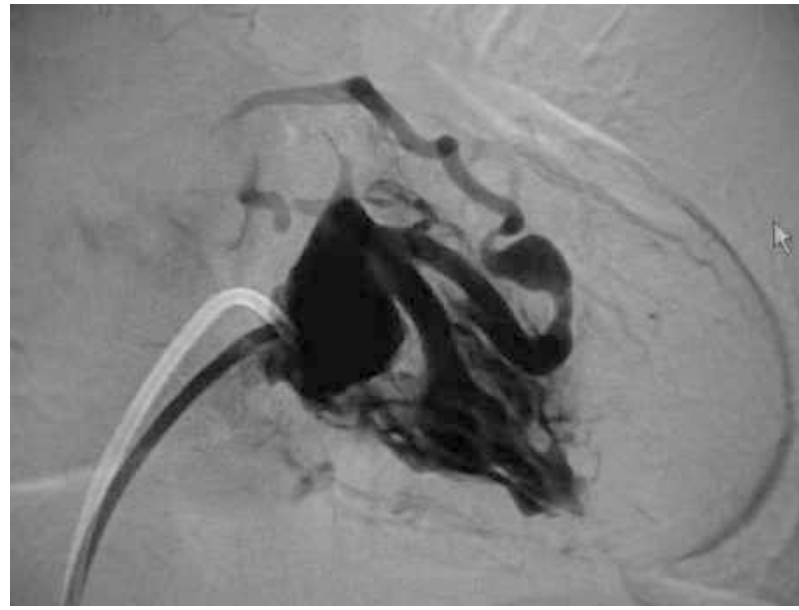

Fig. 35.7 Angiogram in the cardiac catheterization laboratory with injection of contrast into the right ventricle demonstrating right ventricular dependent coronary sinusoids

arteries. In this scenario, patients are usually converted to a Glenn and then Fontan in order to preserve the right ventricle solely as a high-pressure retrograde pump to provide coronary blood flow.

(d) Ebstein Malformation of the Tricuspid Valve

Ebstein malformation of the tricuspid valve or Ebstein's anomaly is a congenital heart lesion with an incidence of 1:20,000 live births, first described in a 19-year-old man in 1866 by William Ebstein. It is characterized by an inferior displacement of an abnormal tricuspid valve with abnormalities of the distal attachment. This results in a large atrialized portion of the RV and thus a smaller RV (Fig. 35.8). The RV often has impaired function and due to the large RA, there may be impaired filling of the left ventricle [72, 73]. Associated left-sided heart lesions include prolapse of the mitral valve and left ventricular non-compaction [74]. Surgical approaches to the symptomatic infant with Ebstein's anomaly are multiple. The size of the trabeculated portion of the RV together with its inlet and outlet portions determines if the patient is a candidate for a single-, one-and-a-half-, or two-ventricle cardiac repair [75–79]. Patients may present at birth with RV inflow or outflow obstruction requiring prostaglandins to maintain a PDA, atrial septectomy, or urgent cardiac surgery. In infancy, the presence of a small dysfunctional RV with severe tricuspid regurgitation, multiorgan dysfunction from RV failure, and little chance of a successful two-ventricular repair may require a single-ventricle palliation with a right ventricular exclusion procedure (RVEP) [76, 78]. Still, other patients may only present in adulthood. Electrophysiologic abnormalities, including Wolff–Parkinson–White syndrome, bundle branch block, and arrhythmias, may be present [80]. Pooling of blood in a large RA may slow intravenous induction of anesthesia and response to inotropes [81]. Slow circulation times are important, particularly if the child with Ebstein's anomaly needs to be placed in the prone position for surgery and requires intravenous epinephrine resuscitation for low CO [82]. Care should be exercised with central line insertion, paying strict attention to the ECG to avoid arrhythmias.

Single Ventricle Anatomy

This comprises a heterogeneous group of children with CHD where the severity of the heart lesion and the diminutive size of one ventricle prohibit the safe complete anatomical

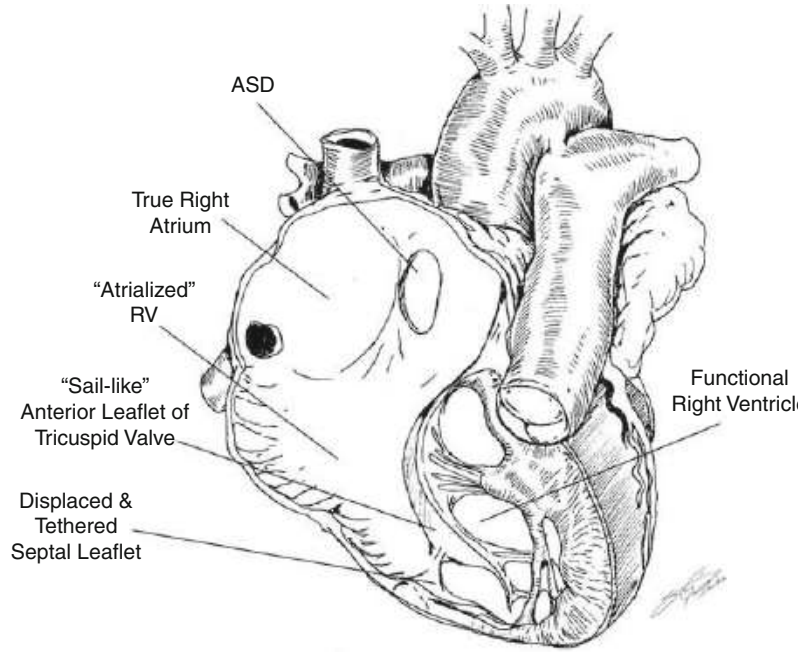

Fig. 35.8 Ebstein's anomaly

biventricular surgical repair of the heart. These patients therefore have to undergo staged surgical palliations, ultimately leading to the Fontan operation or total cavopulmonary anastomosis. Outcomes have steadily improved and in the modern era 70 % of surgically palliated children, even with the severe form of hypoplastic left heart syndrome, are now expected to survive to adulthood [1]. Palliative surgeries are usually performed in three stages, depending on the congenital anatomical heart lesion.

(a) Tricuspid Atresia

Ticuspid atresia (TA), first described by Kreysig in 1817, has an incidence of about 1 in 10,000 live births [83]. The muscular type (89 %) and membranous type (7 %) are the most common variants [83]. In the "Ebsteinoid" type (1 %), tricuspid valve leaflet fusion occurs. In all forms of TA, the RA is hypertrophied and a stretched patent foramen ovale or an ASD is necessary for survival. Classification of TA depends on the tricuspid valve morphology and the associated cardiac and vascular defects [84]. Infants may present with cyanosis soon after birth if TA is associated with decreased pulmonary blood flow, or if pulmonary blood flow is initially adequate, they usually present later in infancy with heart failure. The LV receives and ejects the entire CO, and if TA is left unrepaired, the LV becomes progressively volume overloaded and myocardial dysfunction soon develops. If an inadequate ASD is present, these infants will undergo an urgent atrial balloon septostomy in the cardiac catheterization laboratory. The latter scenario is exceptional though. Following confirmation of the diagnosis and depending on the morphology of the heart, the great vessel position, the size of the ventricles, and the degree of pulmonary blood flow, a management plan is decided upon. Either the infant may undergo total palliation in one operation (exceptionally), or three-staged surgeries are embarked upon as for all single-ventricle palliations described in more detail below.

(b) Stage 1 Palliation

The Approach to Stage 1 Pallination is determined by the degree of pulmonary and systemic blood flow.

1. Inadequate Pulmonary Blood Flow

In this situation a modified Blalock–Taussig shunt (MBTS) is created, usually via a median sternotomy, and CPB is avoided. In patients with inadequate Qp, propofol is not recommended for the induction of anesthesia [6, 85]. The SVR is

lowered by a factor of 30 % with propofol [6]. An arterial line and central venous access is required. It is imperative to ensure inotropes are available in-line centrally before surgery begins. Typically, dopamine 3–5 mcg/kg/min and/or epinephrine 0.05–0.075 mcg/kg/min may be required. In order to improve oxygen delivery and decrease a right-to-left shunt as previously reported, the hematocrit should be around 40 % [86]. If the hematocrit is low, a preemptive blood transfusion may be required. Many times this simple therapeutic intervention will obviate the need to initiate CPB for surgical completion of the shunt. In these children, when Qp < 1, there is little to be lost by administering as high an inspired oxygen concentration as necessary to ensure an oxygen saturation close to 80 %. For these patients, an alternative technique involves stenting the PDA in the cardiac catheterization laboratory. The short-term results are good for selective cases and this may be a suitable alternative to cardiac surgery. This newer catheterization intervention will need more outcome studies in order to determine if there is any benefit to be gained compared to the stable pulmonary blood flow achieved with the surgically placed MBTS [87].

2. Excessive Pulmonary Blood Flow

In this situation a pulmonary artery (PA) band is surgically placed via a median sternotomy or by thoracotomy at the surgeon's discretion, without the need for CPB. An invasive arterial line and central venous access is recommended. Furthermore, an additional invasive pressure transducer is required as the surgeon uses a sterile needle to transduce the pulmonary artery pressure distal to the band in order to gauge when the band is tight enough. Usually a pulmonary artery pressure reduced to 1/3–1/2 of the systemic arterial pressure is adequate to protect the lung from developing pulmonary hypertension.

The afterload applied by the PA band to the pulmonary ventricle acutely may induce myocardial dysfunction until pressure load-initiated myocardial remodeling has occurred [88]. Myocardial dysfunction at this point in the operation is expected and often prompts the initiation of an infusion of either dopamine 3–5 mcg/kg/min or epinephrine 0.03–0.05 mcg/kg/min. Extubation in the operating room is not recommended.

3. Inadequate Systemic Blood Flow

Anesthetic considerations for this form of pathophysiology are directed toward hypoplastic left heart syndrome (HLHS) and its variants [89, 90]. This diagnosis is seen in 1.2–1.5 % of all congenital heart defects [91]. Until recently HLHS accounted for 25 % of cardiac deaths in the first week of life and 15 % during the first month of life [89]. This group of patients requires surgery soon after birth, including an atrial septectomy to improve mixing of oxygenated blood, an aortic arch reconstruction together with a pulmonary shunt. These collective procedures are referred to as a stage 1 Norwood procedure [92]. An alternative palliative approach utilizes a cardiac catheterization hybrid procedure involving stenting of the PDA and PA branch banding, which can be done without CPB. Patient selection for hybrid procedures may include small or premature infants to avoid CPB, Jehova's witnesses, comorbidity precluding CPB, and institutional preference [93, 94]. Currently the literature does not indicate better outcomes with this hybrid approach beyond the second-stage palliated surgery for HLHS [95].

The anesthetic approach to the Norwood procedure includes intra-arterial pressure monitoring which should preferably be achieved in the right radial artery to enable cerebral perfusion pressures to be measured during selective anterograde cerebral perfusion for aortic arch reconstruction. Central venous access is required and usually femoral vessels are used in order to avoid neck vessels. Alternatively, some surgeons insert transthoracic lines. This minimizes venous complications and preserves the internal jugular vein and SVC for the next surgical stage, the modified Glenn procedure or cavopulmonary anastomosis [96].

In single-ventricle patients, the most important anesthetic principle is to maintain the balance of pulmonary/systemic blood flow as close to 1:1 as possible. To achieve this, maintaining a good CO is essential. This is augmented by inotropic support as necessary, aiming for the peripheral oxygen saturation to be as close to 80 % with as low an inspired oxygen concentration as feasible. It is essential to avoid

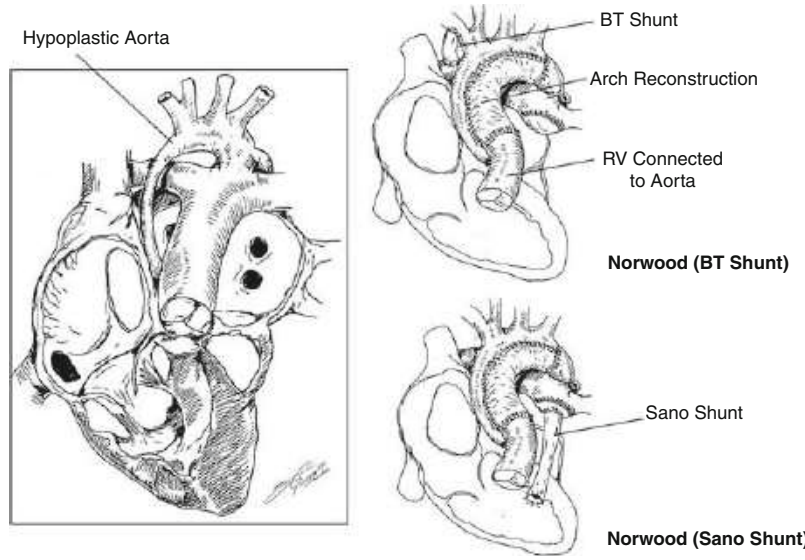

Fig. 35.9 Hypoplastic left heart syndrome demonstrating repair with a Stage 1 Norwood surgery using either a BT shunt or a Sano shunt

hyperventilation with a high inspired oxygen concentration as this causes hypocarbia with subsequent alkalosis and hyperoxia, thereby lowering the PVR and increasing the Qp:Qs ratio >1. The consequence of a high pulmonary blood flow may be a low systemic blood flow, resulting in decreased oxygen delivery to vital organs with subsequently impaired tissue perfusion and a metabolic (lactic) acidosis that quickly ensues. Early studies found preoperative metabolic acidosis to be a risk factor for greater mortality following surgical repair [45]. This unique pathophysiological state of increased pulmonary blood flow at the expense of systemic blood flow unwittingly places the infant at risk of sudden cardiac arrest in the perioperative period despite excellent oxygen saturations [45].

Stage 1 surgery requires periods of low flow or CPB-initiated deep hypothermic cardiac arrest (DHCA) at 18–20 °C. The child's head should be cooled slowly and consistently utilizing a pH-stat-regulated CPB technique to prevent cerebral vasoconstriction and ensure equal cooling and hypothermic protection of all cerebral structures [97]. This operation creates systemic blood flow without ventricular outflow obstruction and prevents pressure loading of the single ventricle. Surgery is completed with an MBT shunt or right ventricular to pulmonary artery (RVPA) shunt (Sano variation) [98]. Either shunt ensures stable pulmonary blood flow while the infant grows (Fig. 35.9). The RVPA shunt, commonly called a Sano shunt, confers greater perioperative hemodynamic stability, a higher diastolic blood pressure in the immediate postoperative period, and greater heart transplantation-free survival at 12 months of age as compared to the MBT shunt [99]. Recently it has been found that SVA preterm infants with a patent aortic valve benefit more from an MBT shunt compared to an RVPA shunt. Importantly in this group of patients, the RV function and anatomy, but not shunt type, determine the need for subsequent heart transplantation [100].

Ideally if surgical anatomical repair has been achieved and myocardial function has been preserved, the postoperative recovered, extubated, HLHS patient should achieve a Qp:Qs ratio of close to 1:1 in room air. Intensive early postoperative monitoring of high-risk patients has been shown to achieve good outcomes [101, 102]. Many of these patients have pulmonary venous abnormalities or associated parenchymal lung disease and a period of increased inspired oxygen, and meticulous monitoring of postoperative oxygen saturations and weight gain has become essential to good clinical interstage surgical outcomes [103, 104].

(c) Stage 2 Palliation: Bidirectional Superior Cavopulmonary Anastomosis

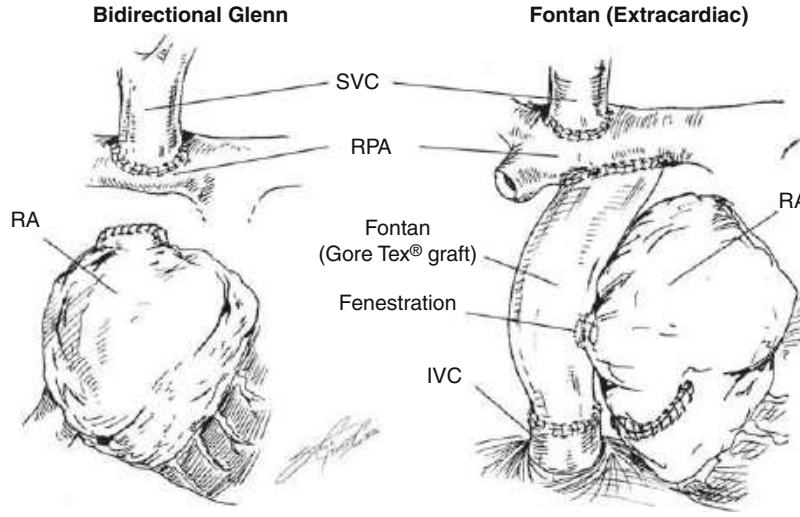

Fig. 35.10 Hypoplastic left heart syndrome and a Stage 2 Bidirectional Glenn palliation followed by a Stage 3 Fontan palliation

The second stage, a bidirectional superior cavopulmonary anastomosis or modified Glenn procedure, is usually completed at 3–6 months of life when the MBT shunt can no longer provide adequate pulsatile flow and the PVR is low enough for passive, increased pulmonary blood flow. Currently good outcomes even for children living at high altitude are expected with this stage II repair which involves takedown of the MBTS or RVPA shunt and separation of the SVC from the right atrium and anastomosis to the PA [105, 106] (Fig. 35.10). This procedure is usually performed on CPB. The main anesthetic goals are to avoid the neck vessels for venous access and, post-CPB, pay strict attention to the acid base status of the patient while striving for early postoperative extubation when CPB time is less than 150 min [96, 107]. Near-infrared spectroscopy (NIRS) monitoring of cerebral oxygenation is a useful adjunct to detect possible intraoperative CPB cannula-induced venous obstruction if intravenous pressure monitoring is not placed in the neck [108, 109]. If NIRS is not available, another option might be to utilize the external jugular vein for pressure monitoring. It has been validated in at least one study to be as good as the internal jugular vein to measure central venous pressure in this group of patients undergoing a bidirectional superior cavopulmonary anastomosis [110]. Anesthetic techniques should be aimed at early postoperative extubation and spontaneous ventilation, both of which will improve pulmonary blood flow. Patients should also have the head of the bed elevated to 45° to facilitate passive return of blood from the head to the lungs. Following early extubation, it has been reported that a mild respiratory acidosis is well tolerated and may cause cerebral vessel vasodilation and augment blood return to the lungs, improve arterial oxygenation, reduce oxygen consumption, and lower arterial lactate levels in children with a bidirectional superior cavopulmonary anastomosis [111].

(d) Stage 3 Palliation: Total Cavopulmonary Anastomosis

Currently, the total cavopulmonary anastomosis, also known as the modified extracardiac Fontan procedure with or without fenestration, is most commonly performed with a polytetrafluoroethylene (PTFE) conduit (Fig. 35.10). Compared to intracardiac baffles, this extracardiac procedure is technically easier to perform, avoids long atrial suture lines that are prone to arrhythmia development, and minimizes intracardiac prosthetic material [112, 113]. The pathophysiological principle of this final stage III surgery for SVA palliation is the creation of venous return within the Fontan circulation devoid of a ventricular pump. In Fontan

physiology, blood flow to the lungs is non-pulsatile and is influenced by three main mechanisms: the PVR and CO, breathing, and exercise. If the PVR is low, the first mechanism, CO increases venous return to the lungs as systemic CO increases. The second mechanism, breathing, depends on the negative intrathoracic pressure generated during the inspiratory phase of spontaneous breathing, increasing venous return to the lungs, which is also referred to as the "respiratory pump" [114–116]. The third mechanism, exercise, utilizes the fact that peripheral vasculature skeletal muscle surrounding venous capacitance vessels augments venous return to the heart during exercise. Patients for a Fontan procedure often require a premedication prior to surgery in part due to their age, around 2–3 years, and in part because they have already undergone numerous procedures and often are fearful of health-care providers. An inhalational induction of anesthesia with sevoflurane is well tolerated. Invasive vascular lines are placed under anesthesia. The current trend is to avoid the jugular venous system. In high-risk patients an intracardiac line may be placed surgically at the time of chest closure; however, the femoral vessels offer a very good correlation of intrathoracic filling pressures and, in this scenario, pulmonary artery pressure [117]. The anesthetic aim should be to strive for early spontaneous ventilation utilizing the respiratory pump [114–116]. The hemodynamic benefits of early endotracheal extubation have been shown, and depending on the safest place to extubate, this should ideally occur either within the operating room or very soon after return to the cardiac intensive care unit [118, 119].

Long-term complications of the Fontan circulation include congestive hepatopathy, the development of pulmonary venous and arterial collaterals, protein losing enteropathy, plastic bronchitis, and coagulation changes including thromboembolic disease [120]. These complications occur in 11 % of children and they generally present 8 years after Fontan completion [121]. Treatment strategies for plastic bronchitis include inhaled and oral corticosteroids, bronchodilators, mucolytics, antibiotics, inhaled tissue plasminogen activator and heparin, bronchoscopic cast extraction, thoracic duct ligation or embolization, and orthotopic heart transplantation [122–127].

Transposition of the Great Arteries

Prior to Jatene's first successful anatomical correction of transposition of the great arteries (TGA) in 1975, numerous surgical hurdles had been documented, most notably technical difficulty of coronary artery transfer [128, 129] (Fig. 35.11). Types of TGA include TGA with intact ventricular septum (85 %), TGA with VSD (10–25 %), and TGA with VSD and LVOTO (30 %) [130]. Other associated anomalies may be pulmonary or subpulmonary stenosis and coarctation of the aorta. TGA with intact ventricular septum is usually repaired during the first 2 weeks of life to prevent deconditioning of the systemic ventricle, which has been working as a low-pressure RV with the pulmonary circuit. Older patients or failed repairs may be operated on successfully via staged reconditioning and banding of the systemic ventricle outflow tract prior to anatomical surgical correction [131]. Anesthetic preparation for a patient undergoing CPB surgical repair includes invasive monitoring lines. A surgically placed left atrial line will be helpful on weaning from CPB and in the postoperative period, as the aim is to maintain a good CO with a low left atrial pressure. Inotropes will be required and milrinone and epinephrine are a good combination. Nitroglycerine 1–2 mcg/kg/min is commonly administered to prevent surgical inflammation-mediated coronary artery spasm and help control preload [132].

Vascular Rings and Slings

Intrathoracic vascular anomalies as a result of abnormal signaling during embryological development may result in obstruction or compression of the esophagus, trachea, or bronchi [133] (Fig. 35.12). Anesthetic management includes the preparation for a difficult airway with the ability to complete a fiber-optic intubation or bronchoscopy if necessary. For simple resections of a double aortic arch, surgical repair is

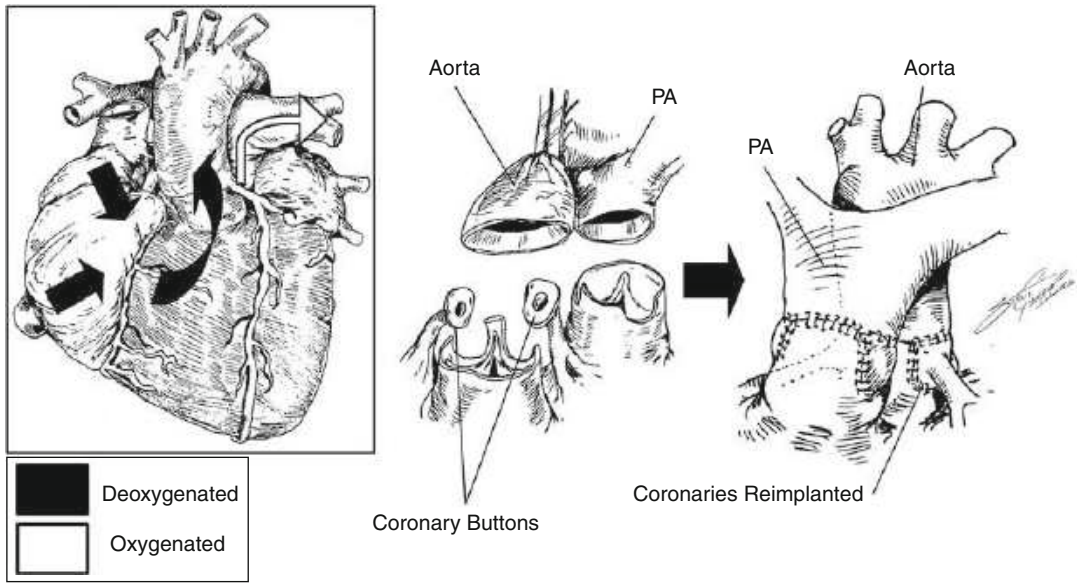

Fig. 35.11 Transposition of the Great arteries repaired with an arterial switch procedure

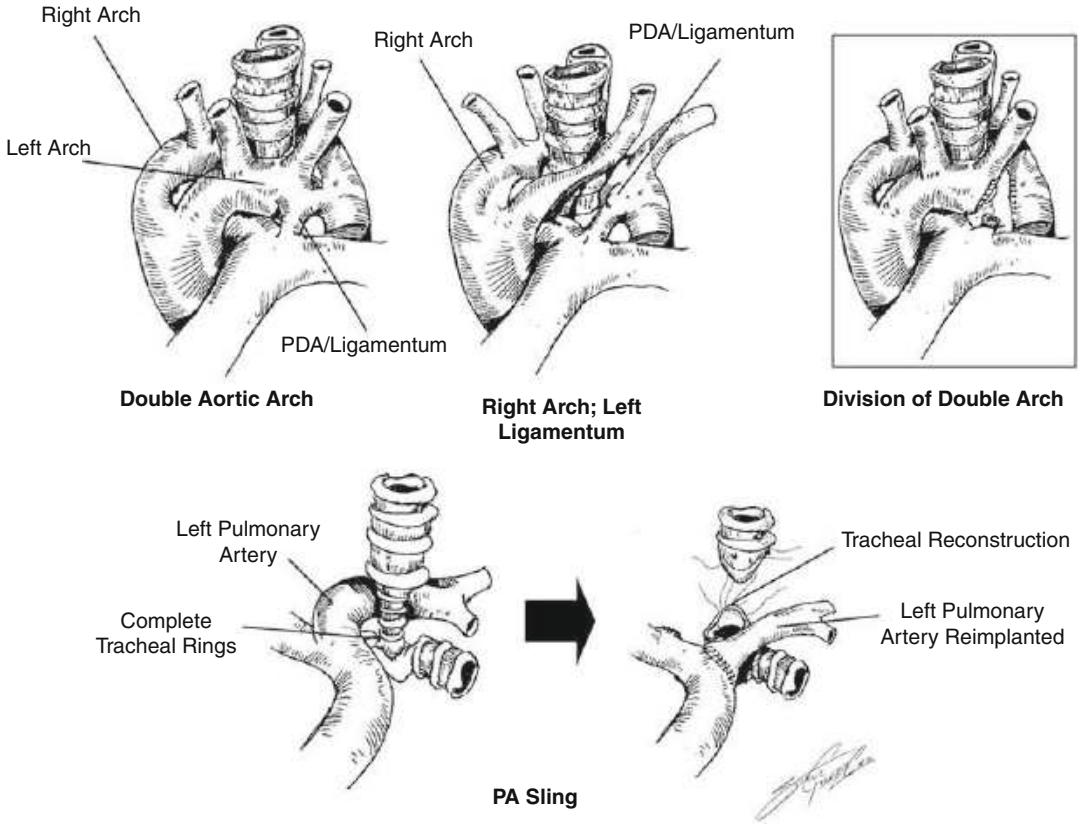

Fig. 35.12 Vascular rings and slings

usually completed via a lateral thoracotomy and prepared for in the same way as PDA ligation. However, if there are complete tracheal rings or long segment tracheal stenosis that may sometimes accompany intrathoracic vascular anomalies, vascular repair and a tracheal slide operation may sometimes be undertaken on CPB. Caudal opiates may be helpful for postoperative analgesia [134, 135].

Anomalous Left Coronary Artery Arising from the Pulmonary Artery

First described in 1911 by Abrikossoff, anomalous left coronary artery arising from pulmonary artery (ALCAPA) is also known as Bland–White–Garland syndrome [136, 137]. Anomalous left coronary artery arising from the pulmonary artery without associated severe cardiac disease occurs in 0.25–0.5 % of live births [138, 139]. Infants commonly present with tachypnea, tachycardia, and diaphoresis with feeds. There may also be cardiomegaly on chest X-ray, and usually on presentation, there is severe myocardial dysfunction commonly with an ejection fraction less than 20 % [140]. ALCAPA may also present in older children and adults with arrhythmias and sudden cardiac arrest on exertion [141]. In this lesion, as PVR falls soon after birth, there is a steal of coronary artery blood flow away from the myocardium. This results in myocardial ischemia, and if there is infarction of supporting papillary muscles, there may also be mitral valve regurgitation. These pathophysiological features increase the risk of further myocardial ischemia, arrhythmias, and cardiac arrest during anesthesia for corrective cardiac surgery [142]. An intravenous hemodynamically stable anesthetic induction agent such as etomidate as compared to an inhalation anesthetic technique is recommended in these patients [142]. Following termination from CPB, it is not uncommon for these infants to require a period of left ventricular support during myocardial recovery [142].

Cardiomyopathies

Cardiomyopathy (CM) is defined as a disease of the myocardium with cardiac dysfunction. The classification and therapeutic options continue to evolve as discoveries are made about the genetics, heart structural changes, cellular events, and multiorgan involvement [143–148]. The anesthesiologist may consider the classification of CM as either dilated, hypertrophic, restrictive, arrhythmogenic, left ventricular non-compaction, or unclassified [143, 149, 150]. The diagnosis of CM adds significant clinical risk to children undergoing anesthesia [151, 152]. This is particularly true for children with any form of CM associated with poor myocardial function and evidence of cardiac failure [149–155]. Importantly the need for inotropic support during general anesthesia in children with cardiomyopathy-related heart failure is as high as 60–96 % [152, 154]. Another study showed that cardiac arrest under general anesthesia in patients with CM for noncardiac surgery is associated with a mortality rate of 50 % [151]. Children with severe heart failure undergoing general anesthesia are at significant risk for cardiovascular complications. Anesthesia should only be administered by anesthetists familiar with managing all aspects of circulatory support at centers with extensive experience in heart failure [151, 152, 154].

(a) Dilated Cardiomyopathy

Dilated cardiomyopathy (DCM), the commonest form of CM (60 %), usually presents with few symptoms or signs in children until myocardial dysfunction is severe [156]. On preoperative history and examination, cough, decreased exercise tolerance, failure to thrive, syncopal episodes, or chest pain should prompt a thorough examination, looking for evidence of cardiac failure. An echocardiogram is essential to determine cardiac function. An electrocardiogram (ECG) can be helpful to discern arrhythmias, bundle branch block, or prolonged QTc interval. When echocardiography and ECG are used together, they have been shown to be useful as a screening tool for sudden cardiac death in children [157]. A lateral chest X-ray is useful in

certain cases of cardiomegaly where left atrial enlargement may cause narrowing and obstruct the tracheal or left main bronchus. If detected preoperatively it might be useful to add PEEP during positive pressure ventilation under anesthesia to maintain a patent airway [133]. The hemodynamic goal in patients with DCM is to maintain blood pressure and CO while considering the dose-dependent myocardial depressant and vasodilator properties of the anesthetic agents being administered [6]. Avoiding bradycardia and hypotension is a key element to maintaining coronary perfusion, cardiac contractility, adequate CO, and thus safe anesthetic outcomes in these patients [152, 154, 158].

(b) Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy (HCM) is the second most common variant (20 %) of cardiomyopathies. It may be asymptomatic or present with syncopal episodes, chest pain, decreased effort tolerance, or sudden cardiac death [156, 159]. The youngest children at presentation have been found to have the worst survival [160]. This is influenced by the risk of an arrhythmogenic myocardial substrate in patients with HCM [161]. The major anesthetic implications are that a small left ventricular cavity size predisposes to decreased diastolic relaxation and a high LVEDP often results [162]. Patients are prone to worsening dynamic left ventricular outflow tract (LVOT) obstruction if hypovolemic or, on the other hand, pulmonary edema with overzealous intraoperative intravenous fluid administration [153]. Dynamic LVOT obstruction (peak gradient greater than 30 mmHg) has been found to be present in 50 % of children in one series of HCM [163]. Medical therapy for HCM includes β-blockers, which have been shown to decrease the incidence of sudden cardiac death in patients with HCM [164]. Preoperatively it is useful to gather echocardiography data including a two-dimensional left ventricular mass (2DLVmass) index. If the 2DLVmass is greater than 150 g-2 ($N = 60$g-2), the risk of anesthesia-associated cardiac arrhythmias may be greater in a severe form of infantile HCM [153, 165]. Furthermore, intraoperative tachycardia associated with a low diastolic blood pressure was poorly tolerated in the same series of patients by intraoperative documentation of myocardial ischemia on ECG ST segment waveform analysis [153]. In patients with severe HCM under anesthesia, myocardial ischemia predisposes them to the risk of arrhythmias and cardiac arrest [153, 165]. Regional anesthetic techniques, together with the maintenance of assisted or spontaneous ventilation, may be an advantage in these patients. The deleterious hemodynamic side effects of vasodilation and a decrease in diastolic blood pressure are avoided [153, 166]. Propofol should be avoided due to its vasodilation properties and the risk of hypotension, low diastolic blood pressure, and decreased coronary perfusion pressure [6, 153].

(c) Restrictive Cardiomyopathy

Restrictive cardiomyopathy (RCM) has an incidence of 2–5 % in children. It is characterized by impaired ventricular filling and normal or decreased diastolic volume of either the LV, RV, or both [148]. At the time of presentation, the atria are often severely dilated and the PVR is usually very high from restricted forward blood flow through the noncompliant left ventricle [167]. Unfortunately, unless pulmonary vascular reactivity is documented at cardiac catheterization, these children may not be candidates for an orthotopic cardiac transplant [167, 168]. Due to the high LVEDP, the main anesthetic goal is to maintain a normal CO and coronary perfusion pressure. Overhydration with intravascular fluids is poorly tolerated in the presence of a high LVEDP. Since the PVR in these patients may or may not be reactive, maintain as low PVR as possible by avoiding hypoxic pulmonary vasoconstriction due to hypoventilation or a high PVR from overventilation with too large a delivered tidal volume. Further anesthetic attention should be directed at avoiding a respiratory or metabolic acidosis which can cause an increase in PVR [169].

(d) Arrhythmogenic Right Ventricular Dysplasia Cardiomyopathy (ARVDC)

In arrhythmogenic right ventricular dysplasia cardiomyopathy (ARVDC), myocytes of the RV free wall are replaced by adipose and fibrous

tissue. These areas act as loci for arrhythmia generation and the LV may also be involved [170]. Patients usually present at 10–50 years of age [171, 172]. In approximately 50 % of patients, inheritance is autosomal dominant with variable penetrance. Symptoms include syncope, atypical chest pain, dyspnea, or palpitations [173]. Sudden cardiac death may be the only heralding sign. Ultrafast magnetic resonance imaging with ECG gating is useful in confirming fibro-fatty myocardial infiltration [174]. Patients may present for placement of an internal cardiac defibrillator (ICD), or radiofrequency catheter arrhythmia ablation. These patients may be predisposed to torsade de pointes as they may be on antiarrhythmic agents including sotalol and amiodarone [175]. Anesthesiologists should avoid catecholamine-induced arrhythmias and prepare for external cardioversion/defibrillation in the operating room [150]. Propofol has been documented to be safe as an induction and maintenance anesthetic agent in ARVDC [176]. Pancuronium and epinephrine are best avoided. Antiarrhythmic medication should be continued for all surgical procedures except for during radiofrequency catheter arrhythmia ablations.

(e) Non-compaction Cardiomyopathy

In this condition, certain parts of the myocardium show deep trabeculations with various degrees of dysfunction. Neonates with non-compaction cardiomyopathy and severe myocardial dysfunction often require heart transplantation [177]. Electrocardiogram changes include tall QRS complexes (43 %), ST–T wave abnormalities (37 %), and left bundle branch block (20 %) [178]. Diagnosis may be confirmed by cardiac MRI [179]. Patients with non-compaction cardiomyopathy have an associated neuromuscular disorder in 80 % of cases [178]. These include Duchenne and Becker muscular dystrophy, myotonic dystrophy, myoadenylate deaminase deficiency, mitochondriopathy, Friedreich ataxia, Charcot–Marie–Tooth disease, and Barth syndrome [178, 180]. The potential for hyperpyrexia, hyperkalemia, and rhabdomyolysis with anesthesia should be considered. Muscle relaxants should be cautiously used, and caregivers must ensure full muscle strength has returned prior to extubation of the trachea.

Pericardial Effusion and Tamponade

Acute or subacute accumulation of fluid or gas in the pericardial space causes cardiac compression, impaired diastolic ventricular filling, a smaller stroke volume, lower CO, and systemic arterial hypotension. When the intrapericardial pressure reaches a critical level, there is increased sympathetic system tone, resulting in increased catecholamine release, tachycardia, and a high SVR. Eventually compensatory mechanisms fail and circulatory collapse occurs [181]. Causes of pericardial effusion and tamponade in children are numerous including postoperative, post-pericardiotomy syndrome, infectious disease, malignancy, chemotherapy, penetrating trauma, and iatrogenic causes [182, 183]. A common and potentially very serious iatrogenic cause is inadvertent vascular injury during the insertion of central venous lines, particularly in neonates [184]. To prevent pericardial effusion from occurring due to catheter migration, some authors recommend that the tip of a catheter inserted centrally via the neck or upper body should be at the level of the SVC–RA junction, which is outside the pericardial sac [185, 186]. Alternatively, it may be safer if the tip is inserted just within the RA, similar to a clapper in a bell, as the pericardial reflection may be 1–2 cm above the SVC–RA junction [187]. Another common iatrogenic cause of pericardial effusion in congenital heart disease is bleeding post cardiac surgery. Postoperative pericardial effusion and impending cardiac tamponade should be suspected and ruled out with echocardiography urgently in the presence of clinical signs of low CO, low cerebral oxygen saturation, tachycardia, poor peripheral perfusion, increased central venous pressure, poor pulmonary compliance, oxygen desaturation, and decreased urine output. A pericardial effusion is usually drained with a subxiphoid needle approach with ultrasound or fluoroscopic guidance. The anesthetic

principle is to maintain spontaneous ventilation for as long as possible and an adequate preload and high SVR. The patient will often be tachycardic due to elevated catecholamines and a small fixed stroke volume from the external fluid compression. This tachycardia should be maintained. Once the fluid has been drained from the pericardial space, hemodynamic stability usually returns promptly. Typical anesthetic combinations used include ketamine, fentanyl, and midazolam augmented with low-dose inhalational agents. A well-designed radionucleotide regional blood flow study during cardiac tamponade in dogs found no difference when ketamine was compared to fentanyl and midazolam or isoflurane [181]. The one interesting finding of this study in dogs was that the subcortical regions of the brain had better regional blood flow preservation with isoflurane [181].

Heart Transplantation and Ventricular Assist Devices

In children the common indications for heart transplantation include end-stage CHD, cardiomyopathy, and re-transplantation [188]. The important anesthetic considerations are that many of these patients are critically ill with evidence of multiorgan dysfunction, from myocardial dysfunction, while waiting for a heart donor. Specifically hepatic, renal, central nervous system, and coagulation dysfunction must be looked for. Not uncommonly these patients will be on ECMO or a mechanical ventricular assist device (VAD) may have already been implanted as a bridge to transplantation [189]. If they have undergone multiple procedures in the past, vascular access may be difficult and surgical access into the chest after multiple sternotomies can be particularly challenging. An adequate supply of blood products in the operating room for the initiation of surgery and weaning from CPB is essential [190]. Nitric oxide is often needed for weaning and separation from CPB and has been found to be a useful adjunct and lifesaving in some children requiring heart transplantation even if the PVR is greater than six Woods units [191]. A meticulous aseptic technique in immunosuppressed children is essential. Each institution has an immunosuppression regimen that will necessitate intraoperative medication administration. Attention directed at preload, contractility, heart rhythm, and afterload will assist in achieving hemodynamic stability during surgery. Intravenous dopamine, milrinone, epinephrine, and isoproterenol are commonly used, affording adequate chronotropy, inotropy, and control of SVR during heart transplantation surgery [192, 193]. Inhaled nitric oxide and nitroglycerine are useful adjuncts to lower the PVR during weaning from CPB [192, 194]. Nitric oxide should be continued in the perioperative period to prevent a rebound increase in PVR and deleterious change in respiratory compliance [195]. The main anesthetic goal in patients with a VAD is to maintain CO. Ketamine is well tolerated as an anesthetic induction agent, and although hypotension occurs frequently in these patients under anesthesia, it usually responds to alpha receptor agonist administration such as phenylephrine or vasopressin together with intravenous fluid administration [196]. External cardiac compressions should not be initiated during an arrhythmia or low CO state when the VAD is in situ since cannula disruption and myocardial trauma may occur [197]. Treating low CO in a patient with a VAD includes consideration of medications administered, excluding pericardial tamponade, VAD cannula kinking at the bedside, and thrombosis [198].

Lung Transplantation

A 16-year-old boy with pulmonary fibrosis received the first successful pediatric lung transplantation in 1987 at the University of Toronto [199]. Since that time lung transplantation has become a therapeutic option for many children with end-stage pulmonary disease, and to date, over 1,500 lung transplantations have been successfully completed [200, 201]. In 2009 there were 127 pediatric lung transplantations worldwide [200]. The successful transplantation of

ABO-incompatible lungs in an infant has also recently been reported [202]. In a recent series the median survival rate for lung transplantation in pediatric patients with idiopathic pulmonary hypertension compared to all indications is 5.8 years vs. 4.5 years, respectively [200, 203]. However, in children the long-term complications still include allograft rejection and immunosuppression-related morbidity [204]. Many children for lung transplantation have cystic fibrosis and may be colonized with Burkholderia cepacia complex (BCC). Many pediatric lung transplantation centers regard BCC colonization to be an absolute contraindication to lung transplantation [201]. Because of their smaller size compared to adults, children often require CPB for successful lung transplantation. This is thought by some to be a contributing factor to primary graft dysfunction [205]. However, a large single center study did not find this association in children [206]. Strict aseptic technique is required for all procedures. The nasal route for endotracheal intubation is not recommended for fear of lung contamination with bacterial organisms. Lines should be placed in preparation for CPB. The femoral artery is preferred for arterial cannulation since the arms may be elevated for a clamshell thoracic incision and a poor blood pressure will be recorded. In small children the use of a double-lumen endotracheal tube will not be feasible. A pulmonary artery catheter is helpful to monitor pulmonary arterial pressures, particularly in those patients with pulmonary hypertension [207]. Lung transplant patients are prone to hypotension soon after induction, from vasodilation, worsening pulmonary hypertension, and RV dysfunction [208]. Thiopental is not recommended as an induction agent; it has been associated with bronchospasm and pulmonary hypertension [208, 209]. Inotropes and vasopressors should be available. Bleeding can be extensive postweaning from CPB; therefore, preparation needs to be made to transfuse blood products expeditiously. Usually a bronchoscopy will be required just prior to weaning from CPB to check the bronchial suture lines for airway anastomosis and lumen patency and there should be no air leaks. Additionally, suctioning the airway of blood and secretions will facilitate ventilation on weaning from CPB [208]. The transplanted lungs should be ventilated gently with a low inspired oxygen concentration upon weaning from CPB to prevent oxidative injury, and small tidal volumes should be used with the addition of inhaled nitric oxide for control of PVR if necessary. Intravascular fluids are restricted to the bare minimum, and recently it has been found that the administration of intravenous colloid is associated with lower postoperative PaO_2 values and a reduced rate of ICU discharge in lung transplant patients [210]. Postoperative analgesia and respiratory mechanics are effectively managed with a thoracic epidural. It is prudent to first ascertain a set of normal coagulation parameters and ensure a post-CPB platelet count and function is adequate prior to carefully placing a thoracic epidural catheter in a sterile manner. This facilitates early extubation following surgery [211]. Propofol, sevoflurane, and remifentanil are commonly administered anesthetic medications titrated to effect while preserving CO [208, 211]. Dexmedetomidine has been documented as a useful adjunct for postoperative sedation in children undergoing lung transplantation [211]. Despite the success of pediatric lung transplantation, complications post lung transplantation still remain to be challenging. Systemic arterial hypertension necessitating medical therapy has been found in children following lung transplantation [212]. Other long-term complications include renal dysfunction (17 % by 7 years), malignancies (23 % by 9 years), diabetes mellitus (34 % within 5 years), and bronchial obliteration syndrome (56 % within 5 years) [200, 213].

Pulmonary Hypertension

Pulmonary hypertension is defined as the presence of a mean pulmonary artery pressure greater than 25 mmHg at rest, with a capillary wedge pressure $\leq$15 mmHg and pulmonary vascular resistance index (PVRI) $\geq$3 Wood units m^2 [214, 215]. Recently, a pediatric pulmonary hypertension classification system has been proposed which recognizes the important roles of

abnormal childhood lung development, chromosomal abnormalities, genetic syndromes, and pathological insults [216]. The anesthesiologist needs to be aware that anesthesia for children with pulmonary hypertension has been shown to confer greater risk for cardiac arrest with an incidence of 117 per 10,000 anesthetics and a mortality rate of 0.78 % [217]. This is in sharp contrast to the incidence of cardiac arrest of 1.4 per 10,000 anesthetics in the general pediatric population [218]. In the cardiac catheterization laboratory, the incidence of cardiac arrest is even greater at 210 per 10,000 anesthetics with a mortality rate of 1.4 % [219]. In the 2010 perioperative cardiac arrest registry, more cardiac arrests in patients with congenital heart disease have been reported during noncardiac surgery in the general operating room (54 %) than during cardiac surgery (26 %) and cardiac catheterization (17 %) combined [151]. From these statistics it can be seen that anesthetizing the child with pulmonary hypertension should ideally only be done in centers with the medical expertise and experience to manage severe pulmonary arterial hypertension. The main anesthetic principle is to ensure adequate coronary perfusion to the right ventricle, remembering that the RVEDP may be higher than normal and consequently a higher diastolic blood pressure may be required to prevent the RV from failing. Anesthesia should not inadvertently worsen pulmonary hypertension by increasing any reactive PVR or decreasing SVR [6]. Hypoxia, hypercarbia, pain, metabolic, or respiratory acidosis should all be avoided. Inhaled nitric oxide should be available, as well as invasive monitoring and inotropes to augment a failing RV. The ideal anesthetic agent for patients with pulmonary hypertension probably does not exist because all anesthetic agents depress the myocardium and lower the SVR in a dose-dependent manner. The current trend is to use a combination of anesthetic agents in a carefully titrated manner to avoid hypotension and myocardial depression. Examples include dexmedetomidine and remifentanil, or propofol and ketamine, all at lower doses than one would use if a single agent were being administered. Ketamine as the main or primary anesthetic agent has been used successfully and is proposed by some authors to be an excellent anesthetic agent in the presence of pulmonary hypertension and concurrent active pulmonary vasodilator therapy [220, 221]. However, ketamine's widespread adoption for clinical use in all patients with pulmonary hypertension, particularly those patients not on active pulmonary vasodilator therapy, remains to be tested prospectively.

Eisenmenger Syndrome

The Eisenmenger complex was first described in 1897 in a patient with a VSD, cyanosis, and pulmonary vascular disease (Eisenmenger 1897). This was later expanded in 1958 to the physiological concept of Eisenmenger syndrome, defined as the presence of pulmonary hypertension due to a high PVR with reversed or bidirectional shunt at aortopulmonary, ventricular, or atrial level [222, 223]. In these patients, pulmonary hypertension precludes corrective surgery because the PVR persists or worsens after corrective closure of the communicating defect [224]. In order to develop Eisenmenger syndrome, a large communication must be present. It should be greater than 0.7 cm in diameter when aortopulmonary, 1.5 cm when interventricular, or 3 cm when inter-atrial [222]. Hemoptysis is a very worrying prognostic sign as it was the cause of death in 29 % of Wood's initial series [222]. Many of these patients may live beyond 30 years of age and present for incidental surgery [223]. In these patients the PVR and SVR are approximately equal and the shunt is balanced. Increased cyanosis is easily induced by increasing the right-to-left shunt by either raising the PVR or lowering the SVR [224, 225]. The main anesthetic principle is to be aware that there is both a fixed PVR component and an associated smaller reactive PVR component. Anesthesia should not inadvertently worsen pulmonary hypertension by increasing any reactive PVR [6]. Hypoxia, hypercarbia, pain, and acidosis should all be avoided [224]. Phenylephrine should be available to increase diastolic blood pressure and improve coronary perfusion pressure should hypotension

develop intraoperatively. By maintaining a high SVR and excellent coronary perfusion pressure, pneumoperitoneum may be well tolerated in patients with Eisenmenger syndrome undergoing laparoscopic cholecystectomy. Anesthetists need to pay strict attention to the $PaCO_2$ to avoid increases in PVR. An arterial line is helpful to measuring beat-to-beat blood pressure and for checking regular arterial blood gases [226, 227]. Laparoscopic surgery may be preferable to open abdominal surgery due to smaller incisions; less analgesia requirements postsurgery and less respiratory depression from diaphragmatic splinting; and a potentially reduced functional residual capacity. This will prevent hypoxia and hypercarbia and therefore help ensure a lower PVR postoperatively. These patients should be recovered in an ICU following all major surgery.

Conclusion

The delivery of a safe anesthetic in children with congenital heart disease depends on understanding the underlying cardiac pathology. A tailored anesthetic technique will result in hemodynamic stability and fewer complications.

Intra-operative Anticoagulation, Hemostasis and Blood Conservation

36

Philip Arnold and Prem Venugopal

Abstract

The manipulation of blood and coagulation and the transfusion of human blood products are of critical importance to the management of the pediatric cardiac surgical patient. The objective of this chapter is to discuss three different, but closely related, subjects: anticoagulation during cardiac bypass, blood conservation, and the management of bleeding. As background the physiology of clot formation and the risks and benefits of transfusion of human blood products are reviewed.

The larger part of the chapter is a discussion of surgical site bleeding in the period immediately following cardiac bypass. It is argued that management should be focused on the control on bleeding (rather than correction of specific coagulation defects) and the effectiveness of treatments should be assessed within this context. During severe bleeding, the distinction between "surgical" and "medical" bleeding is often artificial, and optimal management relies on a combination of surgical measures and use of procoagulants. The roles of specific approaches to reduce bleeding, including the use of blood products, of drugs, and of specific surgical measures, are reviewed. Newer approaches, including the use of factor concentrates and the off-label use of medications, are also discussed. A practical approach to the bleeding patient, including the patient with life-threatening blood loss, is provided. The role of coagulation tests and their integration into clinical management is examined.

Surgery utilizing cardiac bypass is not possible without profound systemic anticoagulation of the patient. Anticoagulation with heparin and reversal with protamine is discussed. The importance of heparin-induced thrombocytopenia in pediatric practice is unclear as is the role of thrombin inhibitors as alternative anticoagulants. The final section deals with methods to reduce the use of blood products: principally allogeneic red blood cells. A context for making best use of blood products in both high- and low-income countries is provided.

Introduction

The objective of this chapter is to discuss three different, but closely related, subjects. Surgery utilizing cardiac bypass is not possible without profound systemic anticoagulation of the patient. Bleeding remains a significant clinical problem during surgery. Blood conservation refers to a series of methods aimed at reducing the need for blood products (principally allogeneic red cells) during surgery.

Since the inception of cardiac surgery, problems associated with bleeding and anticoagulation have been recognized. During the first successful use of cardiopulmonary bypass in a human being, it was necessary to hasten the end of surgery due to clots forming in the oxygenator. Postoperative bleeding has been reported as a common problem during early heart surgery [1], and coagulopathy as a cause of excess bleeding was recognized. The link between blood transfusion and heart surgery is also close. Early bypass circuits could require up to 14 units of fresh blood. The advantage of reducing use of allogeneic blood was apparent even in the early days of heart surgery.

Bleeding

Bleeding of some degree is an inevitable consequence of surgery or trauma. The impact this has on the patient will depend on the severity of bleeding. Minor or trivial bleeding will be of little consequence and is likely to be self-limiting or respond to simple surgical measures. The severest bleeding is an immediate threat to the life of the patient through exsanguination, and to avoid this will necessitate aggressive transfusion and surgical measures. The expectation is that such bleeding will worsen due to deterioration in the coagulation system, and preventing this will require intensive therapy. Between these extremes is a wide range of severity. Significant bleeding of a lesser degree has the potential to delay surgical closure, to cause cardiovascular instability, to increase the requirement for transfusion, to cause life-threatening complications such as tamponade of the heart, or to deteriorate into more immediately life-threatening bleeding [2]. The impact on patient's outcome of such bleeding cannot be separated from the impact of therapy (medical or surgical) it necessitates [3]. Clinicians do,

however, make choices in the treatment of such patients, and the choice of one therapeutic option over another will impact on patient outcome.

Negative Effects of Transfusion

To the public, the most feared complication of blood transfusion is the transmission of blood-borne viruses. The risk is extremely low within first world countries. In the UK no child has contracted any viral infection from transfusion in the last 4 years [4]. It should be recognized that this risk relates to a country with relatively low endemic incidence of blood-borne viruses, routine selection of donors, screening of donated blood, and a highly organized central system of blood banking relying on volunteer donors. In other locations the risk may be higher. Bacterial, parasitic, and prion infections may also be transmitted by blood transfusion. The risk will vary depending on location and should be extremely low in countries where these infections are not endemic. A particular concern in the UK has been risk of transmission of prion infection resulting in fatal neurodegenerative disease. Five cases of probable transmission of prion infection (three resulting in clinical disease) via blood transfusion have now been described, all within the UK. The risk to any individual is extremely low (www.cjd.ed.ac.uk).

Other adverse effects directly attributable to blood transfusion are also rare. It is often the impression of clinicians caring for these patients that patients who are transfused more have more complications, have longer intensive care and hospital stays, and are more likely to suffer lasting injury. This appears to be confirmed by observational studies in adult cardiac surgical [5] and critically ill patients [6]. Similar findings have been seen in some groups of critically ill children [7], and transfusion is a risk factor for infection in pediatric cardiac surgical patients [8, 9]. Causation is hard to determine as risk factors for bleeding are risk factors for other adverse outcomes [3, 10, 11]. Therapies, other than transfusion, used in the treatment of bleeding have also been associated with adverse effects: noticeably antifibrinolytic treatment [12] and recombinant VIIa [13].

Physiology of Clot Formation

The normal coagulation process leads to the formation of plugs of platelets and fibrin over holes in blood vessels. In recent years the understanding of the process by which this happens, as well as the processes that prevent this happening inappropriately, has changed considerably [14]; see Fig. 36.1. While older models have presented coagulation as a liner process involving circulating plasma proteins, modern models are considerably more complex. Cellular elements are central to control and initiation of the process, and the importance of activated platelets is emphasized:

- Thrombin formation is vital for the formation of clots. The process leading to this relies on a balance of procoagulants and inhibitors. Disturbance of this balance rather than deficiency of any single element will lead to bleeding:
  - Low levels of factor concentration to some extent can be balanced by low levels of inhibitors.
  - Increasing factor concentration (with agents such as FFP) will not necessarily improve clot formation.
  - The effect of inhibitors is underestimated by in vitro coagulation tests.
- Cellular elements are vital to normal clotting. Whole blood tests such as thromboelastography may be better indicators of coagulopathy during bleeding than tests on plasma samples (such as prothrombin time (PT)).
- While all aspects of coagulation may be impaired, the clinical implications of these different impairments may not be equal.
- Clot formation cannot occur without adequate fibrinogen and platelets. No treatment aimed at other parts of the coagulation process can make

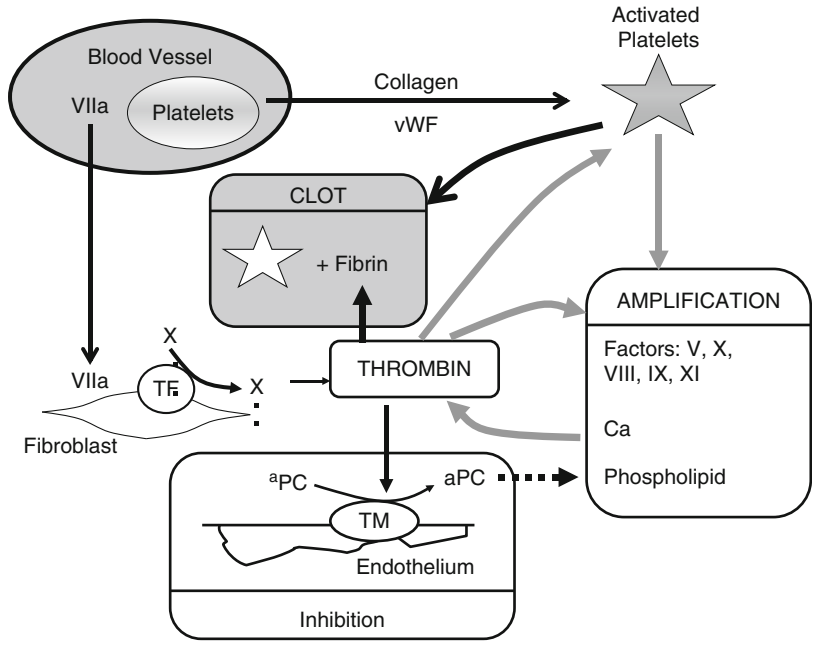

Fig. 36.1 This figure demonstrates the major pathways involved in normal coagulation. Coagulation is initiated by leakage of factor VIIa and platelets from traumatized blood vessels. When platelets come into contact with von Willebrand factor (VWF) and collagen, they undergo a process of activation, which includes the release of procoagulants, a dramatic increase on surface area, and expression of adhesion molecules (for other platelets and fibrin). Factor VIIa, usually present in low concentrations within blood vessels, makes contact with tissue factor (TF) bound to cells (principally fibroblasts but subsequently white cells). This leads to the production of a small quantity of thrombin which initiates a positive feedback loop (involving a number of factors, further conversion of factor VII to VIIa, and activation of platelets), producing large quantities of thrombin. This leads to production of fibrin (from fibrinogen), which, together with activated platelets, forms clot. The major inhibitor is the protein C (PC) system which inactivates factors VIII and V. In the absence of endothelium bound thrombomodulin (TM) (e.g., in in vitro blood tests), little active protein C is produced. Subsequent stabilization of the clot by factor XIII, inhibitors other than protein C, and the fibrinolytic system is not shown for simplicity (Reproduced from Arnold [15])

up for deficiencies of these elements. It is also likely that deficiency of these elements is central to acquired coagulopathy during surgery.

Causes of Excessive Bleeding During Pediatric Heart Surgery

Children undergoing cardiac surgery are at high risk of bleeding. A number of factors contribute to this increased risk:

- Congenital heart disease, particularly cyanotic disease, and critical illness can be associated with abnormal coagulation [16]. The coagulation system of term neonates is balanced and fully functional; however, levels of many clotting proteins and inhibitors are low [17]. This may be reflected in increased vulnerability to derangement.
- Cardiac surgery inevitably involves the opening and closing of major vascular structures. Aspects of surgical technique will lead to greater or lower risk of bleeding.
- Cardiac bypass can result in coagulopathies. These will tend to be of greater severity in smaller children due to greater hemodilution [18], relatively larger artificial surface, use of deep hypothermia [19], and greater return via pump suckers.
- Bleeding can cause coagulopathy mainly due to loss, dilution, and consumption of clotting proteins and platelets [14]. Concentrations of

different components of the coagulation system will fall at different rates. In a previously intact coagulation system, platelets reach critical levels after loss of around 2 blood volumes, while fibrinogen will fall to critical levels after loss of 1.5 blood volumes [14]. These effects are variable between individuals, and the implications will be more severe when the coagulation system is already deranged.

Assessment and Treatment of the Bleeding Patient

Bleeding has detrimental effects for the patient. Current methods of reducing bleeding can minimize such adverse effects but can also have negative effects. A decision to use a particular approach or agent will depend on the balance of benefits to risk of adverse effects. When more than one therapeutic option exists, the risk benefit of different therapies, rather than the efficacy of a single option against placebo, is important.

In an individual patient, therapy is guided by clinical assessment of the surgical site, from risk factors for bleeding in similar populations and from use of coagulation tests. Therapies can be directed to the treatment of established bleeding or to the prevention of bleeding. Even in high-risk populations, therapies given prior to evidence of bleeding are likely to involve "treatment" of patients who would not otherwise have developed bleeding. A decision to initiate such therapy depends on the risk of bleeding as well as the efficacy and risks of treatment. It is only appropriate to treatments with established safety.

Significant bleeding is more likely to occur in smaller patients, following deep hypothermia and following longer bypass [10, 19, 20]. While multiple abnormalities in coagulation will occur, thrombocytopenia, platelet dysfunction, and low fibrinogen levels are of greater relative importance, and therapies aimed to relieve these are likely to be more effective.

Clinical observation of the patient will give an indication of the severity of bleeding and should be the primary indication for treatment. Diffuse bleeding, an absence of an obvious bleeding point, an absence of clots within the surgical field, and a failure to resolve with simple surgical techniques imply bleeding secondary to coagulopathy. Bleeding which can be localized to a small number or single point is likely to respond to routine surgical techniques. Often this distinction is less clear. Derangement of coagulation occurs to some degree in all children after cardiac bypass. In the presence of mild or moderate coagulopathy, hemostasis can often be achieved by surgical techniques alone, though surgical methods to control bleeding may also have negative consequences and greatly prolonged surgical time is inherently undesirable. Further bleeding will potentially worsen coagulopathy, and diffuse "coagulopathic" bleeding will make it harder to identify specific bleeding points. In more severe bleeding, surgical and medical management should be concurrent in an attempt to achieve hemostasis.

Coagulation Tests

The role of coagulation tests has been recently reviewed by the author [15]. The objective is to identify specific defects in the coagulation system and direct therapy toward this defect. There are limitations to this approach and to the tests being used. Testing requires the mixing of the blood or plasma with activator in vitro and observing the formation of clot. Global tests may not adequately reflect the local conditions at sites of bleeding, and in vitro tests will (to a lesser or greater extent) exclude analysis of cellular elements normally involved in clot formation. When tests indicate multiple abnormalities, they do not indicate which abnormalities are of greater importance and are priorities in treatment. The time required to get results from coagulation tests can delay treatment. Clinical judgment is required as to whether the additional data from tests will add to management. Often it is better to initiate therapy before results are known or to delay performing tests until after initial therapy (based on clinical observation and known risk factors).

Coagulation monitoring, combined with rigid treatment protocols, has been used in adult heart surgery to limit use of blood products.

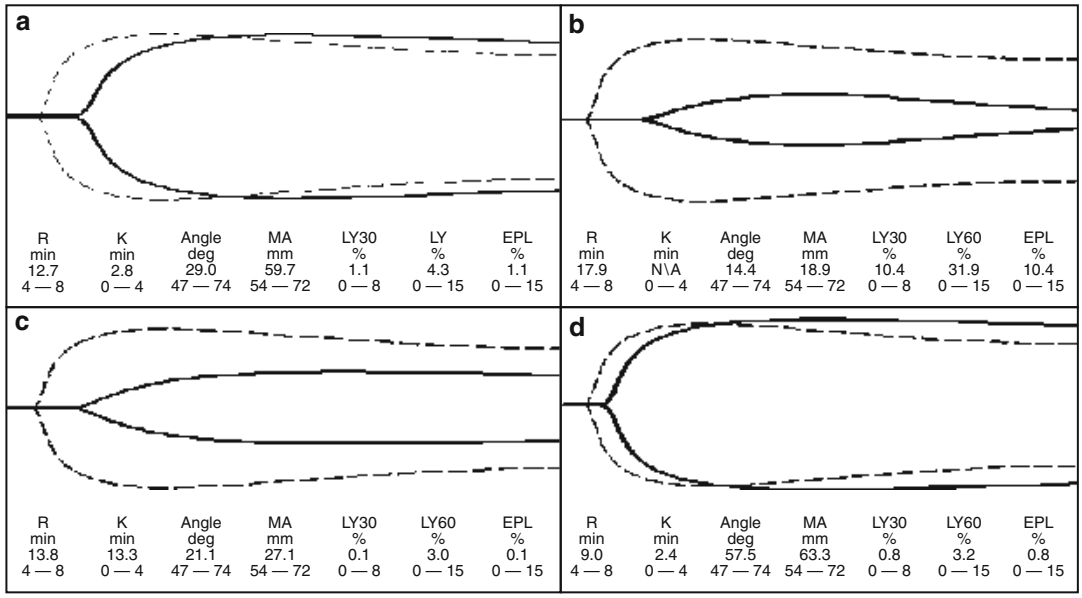

Fig. 36.2 The ability of thromboelastogram to follow changes in coagulation through a case is demonstrated. *Dotted lines* show a "normal" trace. The patient was a newborn who had undergone an aortic arch repair. The baseline trace (**a**) demonstrates a mildly elongated R time but is otherwise normal. After bypass, platelets were administered empirically due to excessive bleeding. Bleeding continued and a TEG was performed to identify the cause of bleeding. This demonstrated a low amplitude and excess fibrinolysis (**b**). Tranexamic acid was given with some effect (**c**) followed by infusion of cryoprecipitate (**d**). Following this, bleeding reduced dramatically and the TEG returned to the baseline (Reproduced from Arnold [15])

This approach is likely to be most successful in populations in which empirical treatment with blood products is common and abnormal coagulation tests are less common. The experience of using thromboelastogram during heart surgery in infants has been that abnormalities of coagulation tests are very common even in patients without significant bleeding. Without considerable adaptation, such protocols would be unlikely to reduce product use. A description of use of thromboelastography (TEG) in this way in children [21] demonstrated a reduction overall in blood product use, though use of platelets increased.

Point of care tests offer practical advantages, (results are available to clinicians sooner), as well as more theoretical advantages. As tests of whole blood, they are subject to the function of cellular and particular components. Thromboelastography in particular offers additional information unavailable from other tests, including evidence of fibrinolysis and indicators of poor platelet function (Fig. 36.2). The most commonly used point of care test is the activated clotting time, which is a crude test of coagulation and will be prolonged in any cause of abnormal clotting.

Some form of monitoring of coagulation is to be recommended during ongoing bleeding, especially when repeated doses of agents are given. In this context, the role of tests is to confirm the adequacy of replacement and exclude excessive replacement, rather than specific values acting as triggers for treatments. Optimal values, minimal effective values, and "toxic" values are poorly defined for either laboratory or point of care tests. Coagulation is likely to deteriorate as bleeding continues, and tests should be interpreted in this context. Practice in the authors' institution is summarized in Fig. 36.3. Initial administration of platelets and fibrinogen (cryoprecipitate) is based on clinical observation of the extent of bleeding combined with awareness of risk factors, rather than coagulation tests.

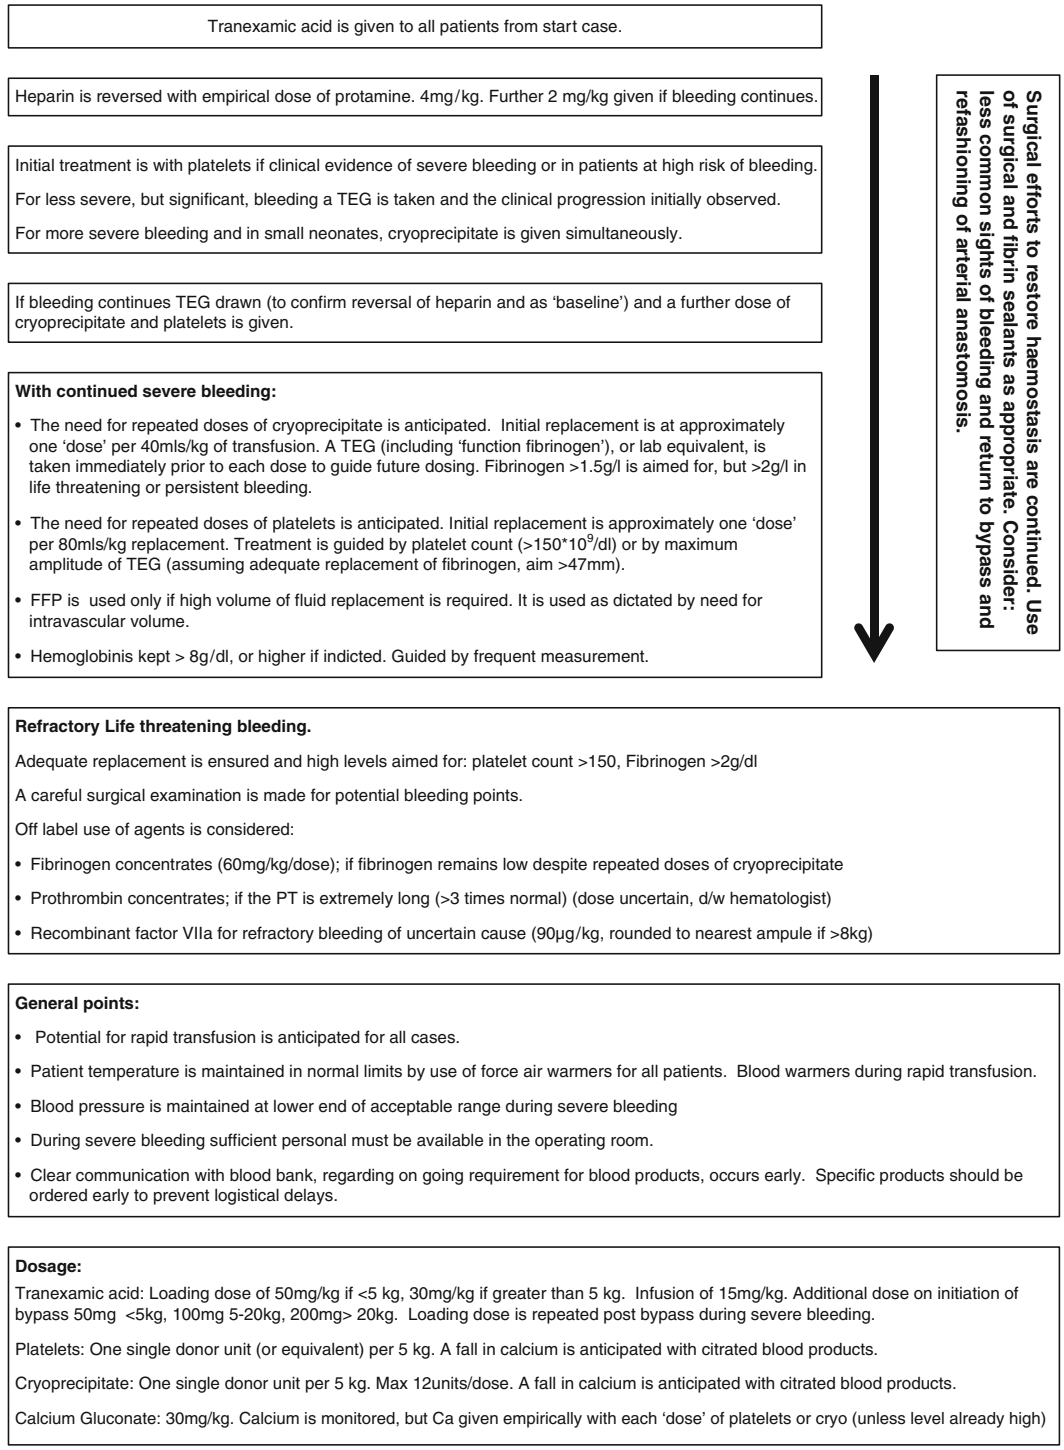

Fig. 36.3 The authors' approach to management of bleeding after cardiac bypass. Progression from each step is taken on the basis of a clinical assessment of bleeding. Severe bleeding is treated actively with rapid progression through the steps described. In less severe bleeding, avoidable use of treatments (in particular allogeneic blood products) is reduced by a more considered approach

With ongoing severe bleeding, the need for repeated doses of products (in particular fibrinogen) is anticipated. A fibrinogen concentration of 1.5 g/l is aimed for and confirmed by laboratory or TEG assays. A failure to respond clinically or continued poor clot strength on TEG is an indication for further platelet transfusion, and higher fibrinogen concentrations (2 g/l) are then aimed for.

Life-Threatening Refractory Bleeding

Rarely severe bleeding will continue despite what appears to be optimal management. This situation is grave and likely to be associated with a high mortality.

In such cases it is necessary to confirm that management has been optimal to this point. A high index of suspicion of residual "surgical" bleeding is required, and all potential bleeding points should be carefully examined. If bleeding persists, it may be necessary to reinstitute cardiopulmonary bypass and have a relook at all the potential surgical bleeding sites. This also gives an opportunity to correct the metabolic derangement, optimize the temperature and buys time to rethink the strategy for further management. Adequate treatment of coagulopathy should also be confirmed, especially replacement of platelets and fibrinogen. It is likely that multiple doses of clotting factors have been given and replacement may still be inadequate. Clotting tests should be performed to confirm this and further products/drugs given. The mechanism of such continued severe bleeding is not clear. It is likely that buildup of inhibitors, platelet dysfunction, and deficiencies of other parts of the coagulation system are each responsible in part. The use of high-risk or unproven therapies (surgical or medical) can be justified on "compassionate" grounds. This includes "off-label" use of fibrinogen concentrates, prothrombin concentrates, and recombinant VIIa. These are discussed further below. The option of packing the wound and waiting while continuing with "medical" management should be considered. The patient should not be transferred out of the operating room until bleeding is no longer an immediate threat to life.

Blood Products for Treatment of Bleeding

Platelets

Platelets are central to the formation of clot. Dysfunction of platelets and thrombocytopenia are common after cardiac bypass and during severe surgical bleeding [14, 22]. Low platelet numbers, and coagulation variables associated with poor platelet function/numbers (such as TEG-MA), have been associated with increased bleeding [20, 22]. Administration of platelets is effective in reducing bleeding. It is reasonable that platelets should be administered for bleeding which persists after reversal of heparin and initial attempts to achieve hemostasis surgically. During significant bleeding or in high-risk patients, it is unlikely that waiting for the results of coagulation tests will help in the decision to administer platelets. During severe bleeding, platelet count will continue to fall and the need to give further platelets should be anticipated. Monitoring of coagulation tests is helpful to confirm adequate replacement. Platelet counts greater than 100–120,000/μL are normally optimal, though higher levels should be aimed for during more severe bleeding to anticipate further falls. It is the authors' opinion that in the absence of bleeding, there is no indication for platelet transfusion regardless of the results of clotting studies.

Fresh Frozen Plasma

It is believed that FFP (and similar blood products) will lead to improvement in bleeding, by restoring the concentration of coagulation proteins and fibrinogen. However, there is relatively little data to support the role of FFP in reducing bleeding. In a small observational study of children undergoing heart surgery, a number of patients had continuing bleeding after transfusion of platelets; if these patients were then given FFP, bleeding increased, while if cryoprecipitate was given, bleeding decreased [20]. A systemic review of the use of FFP to treat or prevent bleeding due to acquired coagulopathy failed to demonstrate benefit [23]. The evidence is, however, poor and it would be premature to abandon the use of FFP. Nevertheless, it is appropriate to question the optimal use of this agent.

Prothrombin time (PT) reflects the concentration of important clotting proteins. When FFP is administered to non-bleeding patients with only marginally raised PT (<1.7), it has little effect on coagulation tests [24]. When administered to patients with higher PT, it is more effective at improving coagulation tests but only in large volumes [24]. In the presence of bleeding, the situation is more complex due to loss of factors in spilt blood. It is unlikely that in the absence of an improvement in coagulation tests, bleeding will be improved.

There may be several reasons for a lack of efficacy of FFP in treatment of bleeding. FFP is a complex mixture of proteins, including inflammatory proteins and inhibitors of coagulation. Most importantly it lacks potency. Cryoprecipitate has 4–8 times the concentration of fibrinogen. Administration of larger volumes (40 ml/kg) will not be possible except during very severe bleeding and may be counterproductive due to dilution of red cells and platelets. During very severe bleeding, it is common to administer large volumes of fluids other than blood products, and replacement of this fluid with FFP will allow administration of useful volumes. Such an approach is unlikely to correct established coagulopathy but may help to limit the development of further coagulopathy secondary to bleeding [25]. Other, more effective, blood products should take precedence, and it should not generally be administered in excess of the need to maintain intravascular volume.

Larger volumes can also be given by addition to the bypass prime or by administration during ultrafiltration (on or off bypass). In this approach FFP is given prior to clinical evidence of bleeding, and while it appears effective at reducing bleeding in small infants [26, 27], it is a potentially unnecessary administration of a blood product. This may be a useful approach for high-risk patients.

Cryoprecipitate

Cryoprecipitate is a source of fibrinogen, von Willebrand factor, and factors VIII and XIII. During bleeding it is primarily used to increase fibrinogen, and the clinical significance of the other factors is unclear. One unit for every 5 kg is expected to raise fibrinogen by 1–2 g/l. A unit is the volume of cryoprecipitate derived from a single blood donation. The volume and constituents will vary considerably between different blood banks and individual donations. US standards state that an individual unit should contain *on average* at least 150 mg fibrinogen and 80 units of factor VIII. The product may be presented as individual units or as a pool of 4–5 units from separate blood donations.

As described above, fibrinogen differs from other coagulation proteins in being a substrate for clot formation rather than a control protein. Its role in coagulation is central and deficiency is common, both following cardiac bypass and during bleeding [22, 28, 29]. During severe bleeding, fibrinogen concentration can fall rapidly. Empirical use of one unit per 5 kg is appropriate for patients who continue to bleed after platelet use [20]; large numbers of units are required for larger patients. During severe bleeding, repeated transfusions should be given though the interval of doses is uncertain and should be guided by clinical response and coagulation tests. A fall in ionized calcium should be expected during transfusion.

Factor Concentrates

Human factor concentrates differ from other blood products in their manufacture. They are highly purified and contain standardized concentration of a single factor or a small number of clotting proteins. Other proteins are removed, and they are pasteurized to reduce risk of transmission of infection. The final product is presented as a powder and does not require cross matching. Recombinant factor concentrates are widely used for treatment of hemophilia, and development of others, appropriate to acquired bleeding, is underway (http://www.profibrix.com/fibrocaps/overview.html).

Human fibrinogen concentrates are licensed in the UK and USA for treatment of congenital fibrinogen deficiency. They are currently used for treatment of acquired bleeding in a number of European countries as the main source of fibrinogen supplement [30, 31]. Potential

advantages over cryoprecipitate include ease of storage and administration, low volume of administration, lower risk of viral transmission, and low immunogenicity. The advantage of easier administration and better availability is not trivial and should allow higher fibrinogen concentrations to be obtained rapidly.

A recent review described 14 case reports and trials of administration of fibrinogen concentrates for acquired bleeding with apparently beneficial effects [30]. Two reports have made direct head-to-head comparisons to cryoprecipitate, including a small randomized study in pediatric cardiac patients. This described superior reduction in bleeding with concentrates (60 mg/kg) and a reduced need for surgical re-exploration (though a surprisingly high rate of re-exploration is reported in the cryoprecipitate group) [32]. Several commentators have argued for a change to use of fibrinogen concentrates in place of cryoprecipitate for supplementation of fibrinogen [31]. More evidence is required to demonstrate equivalence to cryoprecipitate. Current evidence of efficacy, the lower theoretical risk of infection, and the logistics of administration have already led to a change in practice in some countries. These should not prevent proper trials being conducted.

The ease and apparent safety of administration of relatively large doses of fibrinogen makes other indications possible: the prophylactic administration in high-risk groups, the targeting of higher fibrinogen concentrations during active bleeding, and the use in thrombocytopenia. Preventative use during adult surgery reduced postoperative bleeding and transfusion [33, 34]. Modest reduction in blood loss may not be adequate justification for use of this product, and large trials will be required to demonstrate genuine benefit.

There is uncertainty as to the optimal "target" level for fibrinogen replacement. Traditional algorithms have targeted relatively low fibrinogen concentrations (1 g/l). During active bleeding it is likely that higher concentrations will be more effective [29]. In vitro work suggests concentrations of 2 g/l will ensure clot strength, though some improvement has been noted up to 3 g/l [35]. The desirable level may be individual to each patient and clinical assessment of response is important.

A further possible indication is as an alternative to platelet therapy in moderate to severe thrombocytopenia or platelet dysfunction. In animal models, elevating fibrinogen concentration improved bleeding and clotting tests in the presence of thrombocytopenia. In humans (including children undergoing heart surgery), clot strength measured on thromboelastogram is dependent on both platelet count and fibrinogen concentration [28]. Bleeding after bypass is commonly associated with moderate to severe thrombocytopenia, and common practice is to elevate platelet count to at least $100*10^9$/dl. It is possible that lower platelet counts will be tolerated with higher fibrinogen concentrations. This will require testing in controlled trials, both to ensure efficacy of this approach and to establish any definite advantage in this change of emphasis.

Prothrombin complex concentrates (PCCs) vary in content but are generally mixtures of factors II (prothrombin), VII, IX, and X plus the coagulation inhibitors proteins S and C. PCCs are considered more effective and safer for urgent reversal of warfarin than FFP [36]. Content is not standardized between manufacturers, and some brands previously used had low efficacy, due to low levels of factor VII, or high risk of thrombosis due to absence of inhibitors. PCCs have also been used in other causes of acquired coagulopathy and bleeding [37, 38]. Generally they have been reserved for severe bleeding, and the risk/benefit, including risk of thrombosis, is uncertain. Optimal dosing in this situation is unclear. Tissue factor-activated ROTEM and PT may be helpful in guiding therapy [39]. Widespread use of these agents cannot currently be recommended; however, off-label use in refractory life-threatening bleeding may be indicated.

Deficiency of factor XIII during surgery in children has been described. Factor XIII has a unique role in coagulation, catalyzing the formation of cross bridges between fibrin molecules. Administration of factor XIII can reduce bleeding after adult heart surgery, though this effect is not consistent. In vitro factor XIII fails to improve

coagulation in the absence of fibrinogen supplementation. The role of either recombinant or human factor XIII in bleeding is therefore uncertain. Factor XIII has also been reported to reduce myocardial edema [40] and duration of pleural effusions in children following heart surgery [41]. The significance of these findings is also uncertain.

Pharmaceutical Agents in Treatment of Bleeding

Antifibrinolytics

The most commonly used drugs to modify bleeding are synthetic antifibrinolytic drugs (tranexamic acid and epsilon-aminocaproic acid) and the biological protease inhibitor aprotinin.

Considerable data exists to support the efficacy of both these groups of drugs in reducing blood loss [42] including children undergoing cardiac or orthopedic surgery [43, 44]. Moderate reductions in blood loss or transfusion are not sufficient justification for use of these drugs, and evidence of reductions in serious complications of bleeding is lacking in children. If these drugs are generally useful in preventing life-threatening consequences of either bleeding or transfusion, then it is expected that mortality or long-term morbidity would be reduced with treatment. Such large prospective and retrospective studies have not been performed in pediatric cardiac patients, while in adult cardiac surgical patients, such an advantage has not been demonstrated [12]. In adult trauma patients, the large CRASH II study demonstrated a reduction in mortality with tranexamic acid [45].

Studies in pediatric cardiac surgical patients have mainly concentrated on postoperative chest drainage as a marker of efficacy. Mean reduction in drainage in trials of synthetic antifibrinolytics ranges from 4 to 19ml/kg over 24 h [44, 46, 47]. No study has reported an increase in bleeding, and tranexamic acid also produced a modest reduction in red cell transfusion. The largest reduction in blood loss was in studies examining children undergoing late correction of cyanotic heart disease. Only 163 (of 1,061) patients did not have cyanotic disease and 6-hour blood loss in this group was not reduced. Evidence is lacking of effect on life-threatening blood loss or mortality [44], as is evidence on adverse effects. Observational data is often conflicting, and adverse effects potentially attributable to antifibrinolytics are not uncommon in pediatric cardiac patients irrespective of treatment. In an adult study, prolonged infusion of tranexamic acid was associated with renal dysfunction [48]. Observational studies (one in children) have reported an association between tranexamic acid and seizures [49]. The incidence of seizures in these studies was surprisingly high and the significance of this association is unclear.

Aprotinin has recently been reintroduced (for use during adult heart surgery) in a number of jurisdictions. Safety concerns in adult patients have never been substantiated in children. Unfortunately, the evidence for effectiveness of aprotinin in children is extremely poor due mainly to the small size of studies. Of 18 studies, some had as few as 10 patients and only one more than 100. Meta-analysis appears to show benefit in terms of reduced transfusion [47] and avoidance of transfusion [43]. Given efficacy in reducing blood loss in other patient populations, it is likely that aprotinin will reduce bleeding in pediatric heart patients, but no advantage, in terms of reducing blood loss or transfusion, has been shown for aprotinin over synthetic antifibrinolytics in children [47]. The higher cost of aprotinin, combined with a higher risk of anaphylaxis on repeat exposure, appears sufficient justification to not routinely use aprotinin, in preference to tranexamic acid, given the absence of evidence of greater efficacy.

Dosing regimes in studies and clinical practice have varied greatly. A study addressing the pharmacokinetics (PK) of aprotinin indicated that dosing regimes used, in small infants, are inadequate to maintain target plasma concentrations [50]. Improved dosing regimes based on such data may maintain target plasma concentration, though the optimal target concentration is still uncertain. Only one small study has addressed

the pharmacokinetics of epsilon-aminocaproic acid [51], and no study has been published describing the PK of tranexamic acid in children undergoing heart surgery (though studies are currently underway). The relationship between plasma concentration and effect has not been described for tranexamic acid in children or adults. Firm dosing recommendations cannot be made at this point in time.

Recombinant Factor VIIa

Recombinant factor VIIa (rVIIa) has an established role in the treatment of hemophilia with inhibitory antibodies to factor VIII as well as a number of rare bleeding disorders. There has been considerable "off-label" use outside of these indications principally in the treatment of bleeding following trauma or surgery. In 39 US hospitals, 3,655 administrations to children were recorded, 20 % in cardiology and cardiac surgery [52]. Administration was more common in younger children.

rVIIa administered in common doses will lead to plasma levels many times the normal activity of the endogenous factor. This exerts a beneficial effect on bleeding by producing a surge in production of thrombin. This process will be inhibited by hypothermia or acidosis, and thrombin cannot lead to clot formation in the absence of adequate fibrinogen and platelets. These factors must be corrected prior to administration of rVIIa.

Evidence of efficacy of rVIIa comes mainly from case reports and case series. Often these describe an apparently dramatic effect in the face of catastrophic bleeding. There have also been 26 controlled trials of off-label use, of which 5 focused on surgical use. None of these trials have demonstrated reduced mortality, though several have shown reduced transfusion or bleeding. A single randomized trial in pediatric cardiac surgical patients demonstrated neither efficacy nor toxicity [53]. A review of rVIIa in pediatric cardiac patients identified reports of use in 169 patients. The conclusion was that while improvement could be demonstrated in bleeding, randomized controlled trials are required to establish benefit and risks. 20 % of patients on ECMO who received rVIIa suffered significant thromboembolic events [54].

Two systemic reviews of toxicity have been conducted and appear to show increased risk of thrombosis in some groups: including the elderly and adult cardiac surgical patients [13, 55]. Neonates treated with either FFP or rVIIa had a similar incidence of thrombosis (7 %) [56]. Thrombotic complications occurred in 10.8 % of children who received off-label rVIIa, and the overall mortality in those receiving rVIIa was 34 % [52]. Thrombosis is common in patients recovering from severe bleeding episodes. Use of rVIIa is likely to increase the risk of thrombosis, although the impact of this (and the benefit of the drug) will vary in different clinical situations.

The optimal dose of rVIIa is not known. A dose of 90 μg/kg is recommended for treatment of hemophilia, while the doses used for acquired bleeding have varied greatly. In children with hemophilia, the half-life of the drug is shorter than in adults, and this has been used to justify larger doses or more frequent repetition of the dose. In case series, 20 children bleeding after heart surgery received a mean dose of 83 μg/kg repeated two hourly without apparent complications and with reduction in bleeding [57]. A review of use of rVIIa in pediatric heart surgery recommended a dose of 40–60 μg/kg and repeated within 2 h, if bleeding continues [53].

The authors currently use rVIIa only when faced with severe refractory bleeding, with a high risk of patient death from exsanguination. The adequacy of conventional therapy is first confirmed. A dose of 90 μg/kg is given and repeated at 2 h, depending on response.

Specific Surgical Techniques for Treatment of Bleeding

Surgical hemostasis in pediatric population, especially in the neonatal and infant group, provides a different set of challenge compared to the adult population. The tissues are generally less friable and there are no degenerative changes in the vessel wall; however, there are extensive suture lines in high-pressure vessels, and small

volume losses can have a significant impact on the hemodynamic status of the patient. Bleeding can be classified into bleeding due to vessel injury or openings/holes in the cardiac structures, suture line bleeding, diffuse nonsurgical ooze, or a combination of the above.

Surgical treatment of bleeding works in continuum with medical management of bleeding, and various surgical techniques can be utilized to reduce surgical bleeding:

- If the cause of the bleed is a vessel branch, they can be controlled using electrocautery or ligaclips or by over sewing with surgical sutures.
- Suture line bleeding can be controlled by reinforcing the suture line with finer surgical sutures.
- Various topical hemostatic agents are used to achieve hemostasis along suture lines and ooze through the raw surface.

Topical hemostatics can be divided into various categories [58]:

- Sealants: fibrin sealants, autologous topical fibrin spray, thrombin sealants, and gelatin sponge-based sealants
- Adhesives: cyanoacrylate adhesives, serum albumin-glutaraldehyde (BSAG) glue, and gelatin-based adhesives
- Hydrogels: polyethylene glycol (PEG) polymer
- Regenerated cellulose
- Microfibrillar collagen

These agents tend to work through a combination of pathways, which produce a local area of stasis long enough for the clots to form. This could be in the form of local pressure effect, local high concentration of fibrin (providing a lattice for clots to initiate), or formation of a physical seal (cyanoacrylate). They assist rather than replace the normal clotting process. All the materials are biodegradable after a period of time.

Fibrin sealants, one of the earliest groups of agents used for topical hemostasis, are generally combinations of thrombin, calcium, aprotinin, fibrinogen, and factor 13 [59, 60]. They represent the end of coagulation cascade and form a stable fibrin plug. The present group of fibrin sealants is derived from pooled human plasma, which carries a risk, albeit low, of viral infection; recombinant fibrinogen is currently undergoing trials. In contrast thrombin sealants contain only thrombin (of human, bovine, or recombinant origin) and require fibrinogen from the patient's circulation to form clots.

Polyethylene glycol (PEG) is a synthetic water-soluble bioabsorbable hydrogel which brings about hemostasis predominantly by local stasis [61]. Gelatin-based adhesives are made by a combination of human thrombin and bovine gelatin [62]. They form a matrix for clot formation. Oxidized regenerated cellulose is a topical hemostatic agent more commonly used for controlling diffuse bleeding from raw surface areas. It is unique in that it is plant derived. Cyanoacrylate adhesives are synthetic glue based on *N*-butyl-2-cyanoacrylate that rapidly polymerize on contact with water or blood. They are used when major suture line bleed is anticipated. Newer methods of achieving hemostasis have been utilized predominantly in noncardiac settings. Plasma jet, which consists of high energy flow of ionized gas, seals small blood vessels and is useful for large raw surface (such as during liver resection) [63]. Argon beam laser has been used for similar purposes.

Such topical hemostatic is not a replacement for good surgical technique or for optimal medical management of the patient [64]. Regardless of the surgical techniques employed, the patient's own hemostatic mechanisms must be functional. There has to be a constant dialogue between the surgeon and the anesthetist to produce a favorable outcome.

Anticoagulation

The normal process of clotting exists to produce thrombus when blood contacts extravascular tissue. Blood will also form clots when in contact with foreign material, including the tubing and components of an extracorporeal circuit. To prevent this, it is necessary to treat the patient with potent anticoagulants. Heparin has proved extremely successful in its primary role of preventing macroscopic clots forming. The availability of an effective antagonist

allows profound anticoagulation to be maintained throughout bypass, which can be rapidly reversed (limiting postoperative bleeding) after separation from bypass. Heparin is not, however, a perfect anticoagulant: it does not prevent the activation of platelets and is a poor inhibitor of fibrin bound thrombin. This leads to biochemical evidence of thrombin formation and is likely to be a factor in coagulopathy, inflammation, and fibrinolysis following bypass. A further concern is heparin's ability to initiate immune responses, including heparin-induced thrombocytopenia (HIT). The true incidence of this syndrome in children is unclear [65, 66].

Optimization of Heparin Therapy

Both excessive and inadequate heparin can lead to adverse effects, including increased bleeding. Inadequate heparin can lead to rapid clotting of the bypass circuit and will endanger the patient's life. Heparin is usually administered in two parts: a dose is given to the patient prior to initiation of bypass and a further dose is added to the pump prime. The activated clotting time (ACT) is most commonly employed to detect inadequate dosing and guide administration of further heparin during bypass. While the initial heparin dose is fairly standardized (3–4 mg/kg), the heparin dose added to the prime and the frequency of further dosing during bypass is likely to be highly variable between institutions. A failure to give further doses during prolonged bypass will lead to low levels at the end of bypass, and this correlates to signs of increased thrombin formation [67]. Unmodified ACT is a poor monitor of heparin concentration during bypass [68–70]. In principle an improved understanding of the pharmacokinetics of heparin during bypass could lead to improved dosing regimen [16, 67]. Currently, knowledge to support such an approach is limited and variability in pharmacokinetics could prevent such rational dosing. The available data does support the use of a larger initial dose of heparin [71] and earlier re-dosing regardless of the ACT [16].

The "gold standard" for measuring heparin concentration is antifactor Xa assay. This test is impractical for bedside use. An estimate of heparin concentration can be made by protamine titration (Medtronic Hepcon Plus, Medtronic, Minneapolis, USA). Reduced thrombin generation has been demonstrated with use of this method [70]. In infants the device tends to underestimate the heparin concentration [70], and in one study this led to inadequate dosing with protamine, increased bleeding, and prolonged PICU stay. The same group repeated the trial with a modified protocol (allowing for this underestimation) and demonstrated shorter PICU stay and reduced bleeding [72]. Whether similar effects could be achieved with more frequent re-dosing of heparin without monitoring is uncertain.

Antithrombin (ATIII)

Heparin has no direct anticoagulant action but functions by increasing the potency of antithrombin. In infants ATIII levels are low and other heparin cofactors (such as α2-macroglobulin) may be of greater importance. Even lower levels are found in infants and children with congenital heart disease and are likely to fall further on initiation of bypass [73], unless a source of ATIII is added to the prime [74]. Low levels of ATIII can be associated with a lack of response to heparin, though the significance of low levels found in congenital heart patients is unclear. Sources of ATIII include human and recombinant concentrates and FFP. Several case series have described use of ATIII supplements during ECMO in children [75, 76]. The clinical benefit of such an approach is unclear. A randomized trial of use of ATIII during bypass in neonates is currently underway (clinicaltrials.gov NCT01158729).

Reversal of Heparin

The major advantage of heparin over other anticoagulants is the availability of an antagonist able to rapidly reverse anticoagulation. Excessive bleeding will result from inadequate dosing of protamine due to free heparin, while unbound

protamine can itself disturb coagulation. Ideally the dose of protamine administered should be in proportion to the heparin concentration at that time. Often this is estimated from the initial heparin dose, though this is unlikely to adequately account for prolonged bypass and other intraoperative factors [16]. Protamine titration (described above) can be used to estimate protamine dose and diagnose inadequate reversal. Protamine dosage derived from this test should be increased by 50 % to allow for a tendency to underestimate heparin concentration in small infants [71, 72]. Modification of thromboelastogram (TEG) with heparinase is believed to be a sensitive test of residual heparinization. The authors practice is to administer protamine 4 mg/kg to all patients. In the presence of bleeding, a further 2 mg/kg is given, and evidence of residual heparinization is sought using heparinase-modified TEG. Even if initial reversal of heparin is adequate, redistribution of heparin from tissues to the circulation can cause re-heparinization. The significance of this to pediatric practice is uncertain, but it should be excluded as a cause of bleeding.

Heparin-Induced Thrombocytopenia (HIT)

Heparin-induced thrombocytopenia is a syndrome related to the use of heparin, characterized by a fall in platelet count and thrombotic complications. It is mediated by antibodies to a complex formed by heparin with platelet factor 4 (PF4). The resulting heparin-PF4-IgG complex is responsible for activation of platelets and the resulting thrombotic complications.

The frequency of HIT will vary with exposure to different types of heparin, degree of exposure, and the context of the exposure to heparin. Relatively high rates have been described in adult heart surgery [77]. The true rate of HIT in adult and children remains controversial, and incidences of 0 % to 2.3 % have been described in children. The incidence in children undergoing heart surgery has been described as 0.5 %, 1.2 %, and 2.3 % in different case series [66]. Difficulty in diagnosis of this syndrome arises, as the clinical features (thrombosis and thrombocytopenia) occur in this population in the absence of HIT, while the most commonly used diagnostic tests (detection of HIT antibodies) have a very low specificity [77]. Clinically the diagnosis is more likely when thrombocytopenia is delayed (typically 5–10 days), thrombosis is present, and there is no other likely cause for thrombocytopenia. Functional testing using washed platelets appears to be a more specific for HIT [65]. HIT is a very rare diagnosis in the author's institution: whether this reflects under diagnosis in a clinical setting or overestimates of frequency in studies is uncertain.

When a diagnosis of HIT is made, heparin should be discontinued immediately. This may not be sufficient to prevent thrombotic complications in children or adults, and use of an alternative anticoagulant should be considered even in the absence of overt thrombosis [65, 66]. As warfarin should also be avoided during the acute phase, choice of anticoagulant is limited to agents, such as direct thrombin inhibitors, which most clinicians will be unfamiliar with. Platelet transfusion should also be avoided, and specific imaging to exclude occult thrombosis should be undertaken.

A particularly difficult problem is the need for repeat cardiac surgery in children with previous HIT. The difficulties of managing bypass without the use of heparin in children are substantial. It is considered safe to reexpose patients to heparin after a relatively short period (100 days) if HIT antibody titers have fallen to low or undetectable levels [77]. This is not possible in patients in whom surgery cannot be delayed and antibody titers remain high. In such patients, HIT can be avoided by use of potent platelet inhibitors (such as epoprostenol or tirofiban) prior to administration of heparin [77], or heparin can be entirely replaced with other anticoagulants. Alternative anticoagulants described in this situation include the direct thrombin inhibitors (bivalirudin, argatroban, and lepirudin) and the Xa antagonist danaproid. Use of these agents has generally been associated with increased blood loss presumably due to long duration of action and a lack of

effective antagonists. Bivalirudin is perhaps the most promising of these agents having a reliably short half-life. Dosing and monitoring remains uncertain and some adaption of bypass techniques is required [78]. In a single trial, bivalirudin compared favorably to heparin as routine anticoagulant in adult patients without evidence of HIT [79]. Considerable work is required before such an approach could be recommended for routine treatment of children.

Blood Conservation

Blood conservation covers a ranged of measures aimed at reducing the use of allogeneic blood. For the purpose of this discussion, this will be largely confined to use of allogeneic red cells. The techniques described can be used in isolation but in clinical practice are more likely to be used in combination.

Drivers for Blood Conservation

There are several reasons to wish to reduce the use of red cells, and different techniques may be more effective with regard to specific drivers. For example, some techniques may reduce transfusion of the individual patient but will not reduce costs. Drivers for reduced use of blood products include:

- Perceived patient benefit of reduced transfusion
- Cost reduction
- Reduced availability of safe blood products
- Patient's cultural or religious objections to transfusion
- Specific medical reasons to avoid transfusion

The potential negative impacts of blood transfusion have been discussed at the beginning of this chapter. Blood transfusion is a relatively costly intervention, though realistic estimates of the true costs are difficult. Within the UK, a unit of red cells currently costs a hospital £120–£140 ($190–$220); however, the actual cost of administering blood to a patient may be three times such acquisition costs. Cost savings may be a considerable driver to blood conservation and justify the use of relatively expensive techniques to reduce blood usage; however, due to the smaller volume of transfusion, cost will be relatively less in children.

Doctors working in higher income countries have become accustomed to the ready availability of safe blood products. Implications for cardiac surgery in lower income countries and countries with high endemic rates of blood-borne infection are discussed below. The potential for unforeseen circumstances to affect the safety or availability of blood products is a concern, in particular the potential impact of emerging infections.

There may be specific reasons to avoid blood transfusion in a specific patient. Medical reasons to avoid transfusion are very rare, though patient antibodies may make transfusion difficult. When patients or families have very strongly held religious objection to blood transfusion, this raises particular ethical difficulties. In the UK, blood products would not be withheld from a child due to parental objections, if denial of transfusion would endanger the child [80]. Different ethical positions may be taken in different countries. Cases where older adolescents themselves object to transfusion on ethical or religious grounds are rare and should be looked at on a case-by-case basis.

Specific Measures to Reduce the Use of Allogeneic Red Cells

Table 36.1 summarizes the blood conservation measures available in pediatric heart surgery.

Increasing the patient's hemoglobin concentration in the preoperative period has the potential to reduce subsequent transfusion. Due to lower absolute blood volumes of pediatric patients, such strategies used alone will be of only limited benefit; for example, increasing the hemoglobin concentration of a 5-kg child by 2 g/dl will increase the total hemoglobin by only 80 g or one eighth of a unit of blood. Used in combination with other methods effectiveness is

Table 36.1 Available methods to reduce red cell transfusion during pediatric heart surgery

Technique	Notes
Maximization of preoperative red cell concentration	Only limited benefit in small patients if used alone
Treatment of iron deficiency	There may be additional benefits to treatment with iron supplements
Erythropoietin	
Autologous pre-donation	Generally limited to older and larger patients. Logistically difficult
Intentional hemodilution	Very limited role if any
Normovolemic	
Hypervolemic	
Minimization of hemodilution during bypass	These measures would be parts of continuous improvement in most units
Reduction in pump prime	More dramatic reduction in dilution may allow asanguineous primes in small infants [86]
Microplegia	
Retrograde priming	Suitable for large/stable patients only
Conventional ultrafiltration	
Increasing hematocrit at end of bypass	
Re-transfusion	Simple and inexpensive. Pros and cons relative to use of cell savers uncertain
Washing prime with cell savers	More concentrated red cells and contaminates removed
Modified ultrafiltration	Multiple additional benefits including reduced body water. Greatest benefit likely in small patients
Modification of surgical technique	
Use of cell salvage	In small infants may not salvage sufficient blood to process even in severe bleeding
Use of lower-volume blood packs	In small infants provides several discrete transfusions from single donor
Defining transfusion threshold	Optimal thresholds remain unclear but some evidence that lower hemoglobin levels can be tolerated in stable patients
On bypass	
Post bypass	

increased. Asanguineous bypass primes, discussed below, are not possible in the presence of anemia. Iron deficiency is likely to be the most common reason for an abnormally low hemoglobin concentration and is more common in children with heart disease. Iron deficiency may have detrimental effects other than a reduction in red cell mass and should be treated with oral iron supplements. Administration of erythropoietin as a sole intervention has had mixed results. Multiple doses in patients over 3 years of age may be effective [81].

Autologous pre-donation has been successfully used in children [82–84]. It will require several donations preceding surgery, is relatively expensive, and requires well-organized systems to be effective. One study described giving general anesthesia to facilitate donation via the femoral vein; this allowed use in children as young as 6 months [83]. It is unsuitable for small infants, for ill children, or for urgent surgery. To the author's knowledge, it is not available in any hospital in the UK.

Much use of red cells comes from the need to minimize the reduction in hemoglobin concentration due to hemodilution during bypass. This can be minimized by reducing the volume of the bypass circuit [85, 86]. Techniques to facilitate this included use of smaller components (particularly oxygenators); use of narrower or shorter tubing, and remote pump heads; omission of components such as arterial line filters or hemofilters; "microplegia"; and vacuum-assisted venous drainage [86]. Most of these measures will involve compromises in the normal conduct of bypass (such as reducing access of the perfusionist to the pump) or omission of devices believed to improve patient safety such as arterial filters. Impressively small circuits allowing asanguineous primes in small infants have been described and appear to convey very real benefits [85]. Whether these translate fully to routine practice remains to be seen.

Assuming some degree of hemodilution can be tolerated on bypass, it is desirable to increase the hemoglobin concentration at the end of bypass [86]. Residual prime can be transfused via the arterial cannula or placed in a bag and transfused at a more appropriate point. It is likely that such blood will contain free hemoglobin, activated platelets, inflammatory cytokines, and heparin and be of relatively low hematocrit.

Return via a cell saver will allow concentration of the blood and removal of undesirable contaminates; however, any functioning clotting proteins, albumin, or platelets will also be removed [86]. Opinion as to the optimal technique is divided. A further advantage to use of cell savers is that it allows the return of blood spilt due to bleeding following bypass, though processing of small volumes may be impractical.

Ultrafiltration can be performed on bypass or immediately following bypass (modified ultrafiltration) [87]. By removing excess water (and electrolytes), red cells are concentrated. On bypass this is limited by the need to maintain adequate volume in the pump. Modified ultrafiltration (MUF) performed after bypass allows this volume to be reduced further, allowing removal of significant volumes of excess water [87]. Multiple benefits to MUF have been proposed in addition to increased red cell concentration. Benefits are likely to be greatest in the smallest patients.

If lower hemoglobin concentrations are targeted, less allogeneic blood will be transfused [88]. However at some point, low hemoglobin concentrations will be associated with patient harm. During hypothermic low-flow bypass in infants, it has been shown that hematocrits of 24 % or higher are associated with better psychomotor scores at 1 year [89]. The application of this finding to other patient groups is uncertain. Optimal postoperative hematocrits are also poorly defined. A study could detect no evidence of benefit targeting higher hematocrits (mean Hb 13 vs. 11 g/dl) after cavopulmonary connection [90]. A randomized control trial of 637 stable pediatric intensive care patients demonstrated no benefit of permissive versus restrictive transfusion strategies (mean Hb 10.8 vs. 8.7 g/dl) [88]. A subgroup analysis in non-cyanotic children after heart surgery ($n = 125$) appeared to show no detrimental effect for similar restrictive strategies [91]. There is some evidence that more restrictive red cell transfusion is appropriate for stable patients after heart surgery. Higher levels are probably desirable in cyanotic children, though precise targets are uncertain.

International Perspective

Cardiac surgery cannot be performed without access to blood transfusion. In the sections above, the risks and benefits of different techniques, including transfusion of allogeneic blood products and measures to reduce transfusion, have been discussed. Methods of preparation, storage, and administration of blood products will vary in different countries and will change in any one country over time. Time from donation to administration, use of additive solutions, screening and payment of donors, population prevalence of blood-borne infections and routine use of viral inactivation, radiation, and leukodepletion will all differ between locations, and this potentially impacts both on safety and efficacy of the products. Some products discussed may not be available in all locations.

One welcome trend is to the wider availability of congenital heart surgery in newly developed and developing nations. Many of these countries will have poorer infrastructure for providing health care including blood transfusion [92]. In a survey conducted by the WHO in 2006, almost half of countries, which responded, collected insufficient blood to meet the needs of their population. Routine screening for HIV, syphilis, or hepatitis was not performed in 41 of 148 countries. Robust local arrangements for blood transfusion should be in place wherever pediatric heart surgery is practice. Clinicians should be aware of any limitations in the local supply of blood products.

Chapter Conclusion

The manipulation of blood and coagulation and the transfusion of human blood products are of critical importance to the management of the pediatric cardiac surgical patient. Heparin-protamine remains the agent of choice for anticoagulation during cardiac bypass. Newer agents will require considerable evaluation and are likely to continue to be used only in rare cases when heparin or protamine is contraindicated.

Optimization of the administration of heparin and protamine is a more promising approach to improved anticoagulation in the short to medium term.

A number of specific actions can be taken to reduce the requirement for blood transfusion. While using less blood is desirable, it is not an end in itself and the effect of specific interventions on outcome needs to be considered. Particularly impressive results have been obtained by minimization of the size of the bypass circuit, and this may bring considerable benefits beyond the reduced use of allogeneic blood. This technique represents a significant change to perfusion practice, and the true benefits, and risk, will only be appreciated with wider application beyond "enthusiasts."

Bleeding in the period following bypass is a considerable problem. By focusing attention on patients with significant bleeding, unnecessary transfusion can be avoided, while patients most likely to suffer harm receive prompt and appropriate treatment. Optimal management requires communication between members of the operating room team as well as the transfusion laboratory. Communication between the surgeon and anesthesiologist is particularly critical, and "surgical" and "medical" therapy should be considered complementary. There remains much uncertainty concerning optimal strategies for bleeding. It is the authors' contention that high-quality clinical research, stressing the risks and benefits of treatments, can be conducted into bleeding in this context.

Transport and Transfer of Care of Critically-Ill Children

37

Mark D. Twite and Richard J. Ing

Abstract

Healthcare systems are complex and require a large number of healthcare providers to deliver safe, effective care to patients. Many errors in the delivery of healthcare are due to failures of organizational structure such as communication, leadership, and teamwork. Many strategies have been developed to address these failures and have resulted in safer patient care.

Keywords

Checklists • Handover • Safety • Transport

Introduction

Caring for children with complex congenital heart disease requires a "medical village." The healthcare providers that work in this medical village have varying levels of education and occupational training. It is essential that healthcare providers communicate effectively and work well together as a team. Communication is the most important aspect of human interaction. It is often assumed that healthcare providers are able to communicate effectively although many may not have received formal education in this area [1]. Communication should always occur in a respectful manner between healthcare colleagues regardless of the provider's role and level of training [2]. Communication between healthcare providers should always respect patient confidentiality and be open, honest, and repeatable [3].

When children are critically ill in the hospital setting, their care demands round-the-clock staffing which results in the frequent handover of care between teams working shifts. In addition, a critically ill child may require frequent trips within the hospital to the operating room and other locations such as radiology. Many children newly diagnosed with congenital heart disease, who may be critically ill, are transferred from outside facilities to tertiary care centers. These intra- and interhospitals transfers of patient care require frequent handovers among multiple healthcare providers. Patient handovers may be defined as "the transfer of information and professional responsibility and accountability between individuals and teams" [4]. Handovers should be an interactive process of passing patient-specific information from one healthcare team to another,

with the purpose of maintaining the continuity of safe patient care [5]. For patients, handovers are high risk and prone to errors and can lead to diagnostic and therapeutic delays and precipitate adverse events [6]. The Joint Commission reports that "communication failures" among healthcare providers are the root cause in the majority of sentinel events, of which at least half are because of communication breakdowns during handovers [7]. Other studies have concluded, from the root cause analysis of patient deaths, that poor teamwork, ineffective communication, and a lack of leadership are key contributing factors [8, 9].

This chapter will discuss handover communication and the anesthesiologist's role in safely transporting critically ill children to different locations in the hospital for diagnostic or therapeutic procedures.

Patient Handovers

Patient handovers may occur several times a day for the same patient and involve multiple healthcare providers. There are patient handovers when providers change shifts, when a patient arrives from the operating room, and before and after a patient is transported within the hospital for a procedure. There will also be handovers when patients are transferred between different hospitals. The quality of information exchanged during the handover process is common to all of these different scenarios. When information is lost or miscommunicated, errors are likely to occur. Handover failures have been identified as a significant source of medical failures and account for 20 % of malpractice claims in the United States [10]. Standardization of information transfer helps ensure that information is transferred efficiently and consistently and reduces variability [11]. A number of standardized protocols have been developed to promote information transfer, for example, the SBAR protocol (Situation, Background, Assessment, and Recommendation) [12] and the Australian ISOBAR protocol (Identify, Situation, Observation, Background, Agreed plan, and Read back) [13, 14]. However, standardization can have its limitations. A rigid protocol may remove the potential for conversations which are essential to effective information transfer, as two-way interactions though conversation can offer "rescue and recovery" opportunities during the handover process [15]. The success of any handover protocol will depend on its ease of use and how relevant it is to a particular situation. In his book, the *Checklist Manifesto*, surgeon-author Dr. Atul Gawande's simple premise is that performing simple tasks well and consistently in the form of a checklist is often superior to other costly, complex improvement strategies [16].

There have been many studies on patient handovers related to pediatric cardiac surgical patients due to the complex nature of their care and the low threshold for errors [17–20]. Some of these studies have examined surrogate platforms of quality management to improve the handover process such as the formula 1 (F1) racing and aviation industries. The problem with using such surrogate industries is that while there are a few similar elements, there are more differences. For example, in the F1 industry, there are similarities in terms of effective communication and team expediency [21, 22]. However, the average F1 pit stop is only 7 s compared to the handover of a complex child with congenital heart disease, which presents a far more substantive communication challenge. Furthermore, F1 racing cars are predictable machines unlike the complex nature of biological systems. In the aviation industry, the concept of the "sterile cockpit" is used to minimize interruptions and distractions. The Federal Aviation Administration enacted regulations to prohibit crew members from performing nonessential duties, including conversation, while the aircraft is involved with the phases of flight most commonly associated with error: taxi, takeoff, and landing [23]. In a similar manner, it is essential that during patient handovers, all nonessential conversations be stopped. Many high reliability industries such as F1 racing, aviation, and nuclear power industries use failure modes and effect analysis to identify potential failures on the basis of past experiences with similar products or processes. In the healthcare industry, root cause analysis is being used more frequently to quickly identify the source of a problem so that safeguards

may be implemented to prevent further patient harm [24]. A four-step quality improvement process designed by Dr. W. Edwards Deming, one of the early developers of quality improvement, the "Plan-Do-Study-Act" cycle, can then be used to refine processes development [25]. In many industries, this process has now evolved further into popular strategies such as Six Sigma, Total Quality Management, and the Japanese continuous improvement *kaizen* philosophy made famous by Toyota [26].

Sustained success in the "medical village" of pediatric congenital cardiac patient care requires not only pursuit of quality and safety with a continual systematic improvement process but healthy team dynamics [27]. Healthcare providers have diverse backgrounds including different cultures and levels of occupational training. It is essential that the handover process occurs in a positive, respectful, and supportive environment to facilitate the transfer of all relevant information for all care providers.

The Institute of Medicine report in 2000 suggested that most human errors in healthcare are not the result of poor knowledge or ability, but because of other aspects of performance such as communication, teamwork, and leadership [28]. Medical errors probably rank in the top five leading causes of death, but underreporting makes this a difficult number to ascertain. Most often, it is not a single error that leads to an adverse event. Rather, it is a succession of events that, while minor in isolation, lead to an adverse event if they occur together, the so-called "Swiss cheese" model [29]. An effective handover process can mitigate the Swiss cheese model by ensuring all information is effectively communicated [30]. Several recommendations for the handover process are supported in the literature, including:

1. Standardize processes (e.g., through the use of checklists and protocols).
2. Complete urgent clinical tasks before the information transfer.
3. Allow only patient-specific discussions during verbal handovers.
4. Require that all relevant team members be present.
5. Provide training in team skills and communication [31].

There is very good evidence that safety checklists do improve patient outcomes. A checklist developed at Johns Hopkins University School of Medicine reduces bloodstream infections related to the insertion of central lines [32]. The checklist focuses on five evidence-based interventions during catheter placement recommended by the Center for Disease Control: hand washing, cleaning the skin with chlorhexidine, avoiding the femoral site if possible, using full barrier precautions (gown, mask, hat, and gloves), and removing catheters when no longer needed. When this checklist was initially introduced at Johns Hopkins intensive care units, there was institutional backing for staff education, routine surveillance, reporting and investigation of infections, and a focus on teamwork, with empowerment of all team members to speak up if the checklist was not followed. This checklist was so successful it has now been widely adopted by many healthcare institutions [33]. In 2006 the World Health Organization (WHO) launched the "Safe Surgery Save Lives" campaign in response to the global need to improve outcomes in surgery. This resulted in an evidence-based Surgical Safety Checklist (Fig. 37.1) [34]. This checklist has successfully reduced death rates and inpatient complications in many hospitals worldwide [35]. The mechanisms by which such checklists have had such a huge impact are more than just the evidence-based content of the list. Improvements may also be due to changes in team dynamics and a change in the culture of safety at institutions [36].

Many healthcare teams now develop their own checklists to facilitate patient handover. An example of a postoperative cardiac surgical patient handover protocol is shown in Fig. 37.2. Any such checklist should be refined with "Plan-Do-Study-Act" cycles. The handover process should be divided into three steps: preparation for handover, the handover itself, and then time for questions. In preparation for patient handover, relevant information should be collected and documented and adequate warning given to the receiving team so that all providers may be present. The content of the handover will be specific

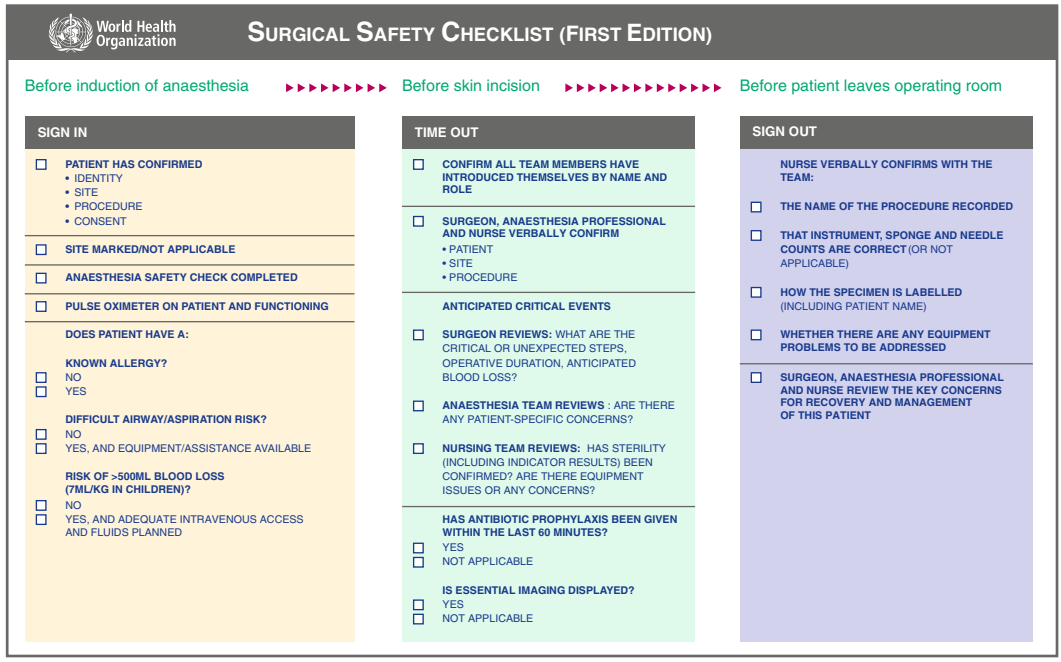

Fig. 37.1 *World Health Organization Surgical Safety Checklist*. This checklist is freely available to healthcare providers around the world and may be modified for local use (http://www.who.int/patientsafety/safesurgery)

for the healthcare teams caring for the patient. It is essential that if a "sterile cockpit" rule is followed during the handover, there is adequate time at the end of the handover for open dialogue so that information can be clarified and a continuity of care plan formulated.

Transporting Critically Ill Children

Each hospital should have a plan for intra- and interhospital transports that addresses five key areas:

1. Pretransport coordination and communication
2. Transport personnel
3. Transport equipment
4. Monitoring during transport
5. Documentation

The transport plan should be developed by a multidisciplinary team and should be evaluated and refined regularly using a quality improvement process. There are well-established guidelines to help promote safe patient transport [37]. The anesthesiologist fulfills a critical role in the "medical village," receiving a handoff from the critical care team prior to the patient being transported from the intensive care unit, and then delivering a handoff communication back to the intensive care team following completion of the diagnostic or therapeutic procedure. Preparation is essential for the anesthesiologists to fulfill their role within the healthcare delivery team. The anesthesiologist's care of a patient is challenging because of the short amount of time spent with the patient while undergoing procedures that may contribute to considerable hemodynamic instability. Preparation should follow a five-point plan:

1. *Examine the Patient's Medical Record*

   It is important to start with the basic information: name of the patient and other patient identifiers to confirm identity (time-out), weight, allergies, and fasting status. Current medical history should be reviewed so that there is a clear understanding of the child's pathology and resultant physiology and why they require transportation for a specific procedure. Next, review the pertinent past medical

Children's Hospital Colorado: CVOR to CICU Handover

The transfer of critically ill patients from the CVOR to the CICU should follow a systematic approach. The ANESTHESIOLOGIST is responsible for the care of the patient until the report process below is complete. The CICU nurses assessment of the patient must occur AFTER the report process is complete so that there are no distractions during the process below.

Staff to be present for the handover: INTENSIVIST, SURGEON, ANESTHESIOLOGIST, NURSE, RT

BEFORE LEAVING CVOR

- **PUMP Check**
  - **With CICU nurse**
  - **Check programming**
  - **Correct labels**
- **PACEMAKER**
  - **Check thresholds**
- **ORGANIZE**
  - **Arterial, central and peripheral lines color labels etc**
- **PREPARE for transport:**
  - **Airway equipment**
  - **Pacemaker and cables**
  - **Drugs**
  - **Correct bed**
  - **Transport monitor working and cables organized**
  - **Oxygen or Blender**

TRANSFER OF CARE IN THE CICU

- **PARK & BRAKE the patient's bed on arrival in the CICU**
- **VENTILATOR**
  - **Check initial ventilator settings**

history including birth history and other noncardiac medical problems. Pay particular attention to previous anesthetic records and any problems with airway management or vascular access. Review current laboratory data and any available information obtained by diagnostic imaging including radiology, echocardiography, and cardiac catheterization. Finally, review the current hemodynamic and respiratory status.

2. *Interview the Patient's Family and Healthcare Providers*

   It is essential to speak with the healthcare providers currently looking after a patient. Bedside nursing staff may contribute essential information that may not be apparent from the medical information. For example, ask about current vascular access, what drugs are running where, and any future drugs that may be needed while the child is undergoing a procedure. Respiratory therapists are also essential in providing information about current ventilator settings and the use of inhaled nitric oxide. A child's family can provide useful insight into previous anesthetics and how the child has done. It is also essential that the anesthesiologist communicates their concerns to the healthcare team and family about how the proposed transport and anesthetic may impact the patient's current medical status.

3. *Examine the Patient*

   It is important to have a thorough understanding of a patient's current baseline status so that any changes that occur during the transport or procedure may be acted upon quickly. Specifically, baseline blood pressure, oxygen saturations, heart rate, respiratory rate, breath sounds, and peripheral pulses are important to assess.

4. *Preparation*

   When transporting a critically ill child, it is important to be prepared for both the transport and at the destination location. The receiving team should be fully briefed about the patient prior to their arrival. The destination location should be fully set up for the delivery of a safe anesthetic, including warming the room temperature as appropriate. Monitors and equipment must be checked and all drugs required should be drawn up and readily available. The crib or bed on which the patient is being transported should have a fully charged transport monitor and a full oxygen tank or full air/oxygen blender. The anesthesiologist must be equipped to handle any untoward event such as an accidental extubation, emergent intubation, or hemodynamic collapse. Although not present on all monitors, end-tidal capnography is recommended during patient transport as it has been shown to rapidly detect inadvertent endotracheal extubation [38]. Proper preparation is essential and time-consuming.

   The safest route to transport the patient to the new location should be considered well in advance of leaving the intensive care unit. This is very important for patients on extracorporeal membrane oxygenation (ECMO) support as the equipment takes up a lot of space. For example, there may only be one elevator that is of adequate size to accommodate all of the equipment (ECMO pump, ventilator, nitric oxide), the patient's bed, and a large team of healthcare providers. Although transporting patients on ECMO support is logistically difficult, it can be safely done. The ECMO team must be present at the time of transport, as 80 % of patients transported on ECMO support require a significant change in management [39].

5. *Plan the Anesthetic*

   At least one study has shown that in 72 % of intrahospital transports of critically ill children, a significant change in at least one physiological variable occurred [40]. The patient's physiological status will determine the degree of invasive anesthetic monitoring required for transport as well as the appropriate sedative technique. Consideration should be given to whether the patient can be placed on an anesthesia machine ventilator or the intensive care unit ventilator. This will determine if an anesthetic based on an inhalational agent or total intravenous anesthetic technique is more appropriate [41]. If inhaled nitric oxide is required, it is essential to communicate with the respiratory therapy team so that it is available and set up correctly.

   Proper preparation is essential for the anesthesiologist caring for the complex critically ill patient. Remaining "vigilant" during transport and procedures will significantly contribute to patient safety and improved outcomes.

Conclusion

The delivery of high-quality, safe healthcare is essential for every patient. Children with complex congenital heart disease require a "medical village" of healthcare providers to care for them. Effective handovers are an essential component to the safe continuity of care for patients. It is important to get the basics right, first time, every time, for every patient. There are evidence-based checklists that are helpful to reduce medical errors and facilitate the handover process. Anesthesiologists are healthcare providers familiar with transporting critically ill children and frequent handovers of care.

Fast-Tracking and Regional Anesthesia in Pediatric Patients Undergoing Congenital Heart Surgery

38

Alexander Mittnacht and Cesar Rodriguez-Diaz

Abstract

Early extubation and adequate postoperative pain control are central components of fast-tracking pediatric patients undergoing congenital heart surgery (CHS). The term fast-tracking is typically associated with the multidisciplinary approach to decreasing morbidity and costs associated with prolonged hospital length of stay. Planning an anesthetic for fast-tracking CHS patients typically includes the use of short-acting anesthetic drugs and, frequently, the use of regional and in particular neuraxial anesthesia techniques. This chapter will focus on the anesthesiologist's role in fast-tracking pediatric patients undergoing CHS, including anesthetic management, patient selection, and risks and benefits of such an approach.

Introduction

Fast-tracking in cardiac surgery refers to perioperative patient management including day of surgery admission, anesthetic management allowing for early extubation, adequate postoperative pain control, rapid mobilization, and hospital discharge in an attempt to decrease morbidity and reduce costs. From an anesthesiologist's perspective, fast-tracking is often seen synonymous with early extubation; however, it must be recognized that safely fast-tracking a patient requires a multidisciplinary approach including surgeons, anesthesiologists, intensivists, nurses, and social workers [1]. Early extubation as one of the components of fast-tracking is poorly defined, and the term is frequently used when the endotracheal tube is removed within 6–8 h after surgery [2]. This chapter will focus on the anesthesiologist's role in fast-tracking pediatric patients undergoing congenital heart surgery (CHS): the anesthetic management allowing for rapid emergence and removal of the endotracheal tube and adequate intra- and postoperative pain control.

Background and History

Fast-tracking was introduced to patient management when costs started to play a more significant role in patient care back in the late 1970s and early 1980s. Diagnosis Related Groups (DRG) had been introduced around the same time in an effort to reduce Medicare reimbursements to hospitals. With this reimbursement model, less resource use mostly driven by shorter length of intensive care unit (ICU) and hospital stay was suddenly linked to financial benefits for the hospitals. Early extubation during that time was almost a necessity since reliable mechanical ventilators and sedatives with minimal side effects for small patients were not available and, thus, prompted physicians to minimize time of the patients spent on mechanical ventilation. Barash and colleagues published their experience on early extubation in pediatric cardiac patients in 1980 [3]. They reported that early extubation in the OR could be safely accomplished in small children including neonates using an already then popular inhalational-based anesthetic technique. Further reports about early extubation in the pediatric cardiac patient population followed [4, 5], and the increasing experience with this approach led to recognizing and reporting of possible benefits of early extubation and fast-tracking in the pediatric cardiac population [6]. However, a decade later, following rapid developments in the field of CHS allowing palliation and repair of congenital heart disease (CHD) in even younger and previously inoperable children, an opioid-based anesthetic technique became popular due to the hemodynamic stability it rendered. High-dose opioid-based anesthesia was reported in the early 1990s to reduce stress response, morbidity, and mortality [7, 8]. With the advent of an opioid-based technique, prolonged postoperative ventilation became necessary.

Fast-tracking, albeit without calling it "fast-tracking," was already being performed in adult cardiac surgery in the mid 1980s due to the increasing number of coronary revascularization cases performed, crowding the intensive care units [9]. In 1994 the term "fast-track" in cardiac anesthesia was introduced by Engelman and colleagues in their manuscript titled "Fast-Track recovery of the coronary bypass patient," which also included a complete care plan, all of which was associated with reduced length of hospital stay [10]. Subsequently, the benefit and need of high-dose narcotic-based anesthesia were challenged, and fast-tracking in cardiac surgery became popular and eventually routine practice in adults undergoing cardiac surgery in the late 1990s [11, 12]. While fast-tracking pediatric patients is more controversial, there has been a growing trend to adopt this approach in children and even infants undergoing CHS.

Anesthesia Technique

The anesthetic goal in fast-tracking pediatric patients undergoing CHS is to safely facilitate earlier mentioned goals including early extubation and adequate intra- as well as postoperative analgesia without significant respiratory depression. Similar to early reports back in the 1980s, an inhalational-based anesthetic, supplemented by a limited amount of intravenous opioids, with or without a neuraxial technique is commonly used, and details will be discussed.

Most patients who qualify for fast-tracking are admitted on the day of surgery, and frequently intravenous access had not yet been established. Therefore, an inhalational induction technique with sevoflurane is typically chosen for induction and well tolerated even in patients with right-to-left shunting associated with decreased systemic vascular resistance (SVR) (e.g., tetralogy of Fallot). If true contraindications to an inhalational induction technique apply, intravenous access should be established and ketamine or etomidate can be used as induction agents.

With a true inhalational-based fast-tracking technique, the inhalational agent has to be administered throughout the case, including on cardiopulmonary bypass (CPB). The CPB machine must therefore be equipped with a vaporizer. Alternatively, a continuous infusion of intravenous agents with hypnotic properties such as

propofol or ketamine can be used during CPB [13]. Propofol when administered as a continuous infusion causes less severe and sudden decrease in SVR compared to bolus administration and is well tolerated by most patients with congenital cardiac disease [14]. As a short-acting hypnotic with favorable pharmacokinetic and pharmacodynamic properties, it is frequently used during CPB for patients who are fast-tracked. If however, a decrease in SVR must be avoided or significant desaturation with right-to-left shunting occurs, a high opioid technique or the use of ketamine should be considered. Ketamine administered as a continuous infusion maintains stable hemodynamics in most CHS patients.

In a fast-tracking anesthetic, intravenous opioid use is typically restricted, and shorter-acting opioids are preferred. Fentanyl is frequently used and often limited to a cumulative dose of 5–6 mcg/kg [15, 16], significantly less compared to the doses used in a high-dose opioid technique, with doses typically ranging from 50 to 100 mcg/kg. Remifentanil is an ultrashort-acting opioid that is metabolized by nonspecific esterases in plasma and tissues. Its context-sensitive half-time is 9 min and is not affected by cardiopulmonary bypass [17]. Due to its rapid elimination, it is an ideal agent to conduct a high-dose opioid anesthetic with fast recovery, even facilitating early extubation [18–20]. Due to its rapid elimination, however, adequate analgesia must be provided after an infusion of remifentanil is discontinued.

One of the goals and challenges in fast-tracking patients undergoing CHD surgery is to provide adequate pain control without significant respiratory depression immediately or soon after surgery. While opioids such as fentanyl or morphine can be titrated to effect and are still most frequently used even in patients who are fast-tracked, significant postoperative respiratory depression may be seen possibly precluding early removal of the endotracheal tube. Neuraxial techniques as well as non-opioid-based drugs such as intravenous administered acetaminophen, as well as opioid-sparing drugs such as dexmedetomidine, can be used to supplement or decrease the amount of opioid required for adequate pain control in this setting.

Dexmedetomidine is a sedative agent that confers sedation by selectively binding to central α_2 adrenoceptors. Respiratory indices and upper airway patency are maintained during dexmedetomidine sedation in children [21–24]. It has been reported to reduce stress response in patients undergoing cardiac surgery [25]. In typical doses used in CHS (up to 0.8 mcg/kg/h), dexmedetomidine is very well tolerated. Hemodynamic effects such as bradycardia, hypo- and hypertension, decrease in cardiac output, no effect on the pulmonary vascular bed, as well as an increase in pulmonary vascular resistance all have been described; however, these side effects are highly dose dependent and rarely of clinical relevance [26, 27]. Many practitioners start a dexmedetomidine infusion early, timing it such that adequate plasma levels are achieved before the endotracheal tube is removed and avoiding bolus administration which has been linked to more serious side effects [28, 29]. Additional favorable properties supporting dexmedetomidine's role in the fast-tracking setting are the reduced incidence of emergence delirium after inhalational anesthesia in children [30–32] and its possible role in the treatment of postoperative arrhythmias such as junctional ectopic tachycardia and reentry supraventricular tachycardia [33]. Although at this point it is only approved by the FDA for use in adults for up to 24 h, it has been widely used in children even for prolonged periods of time [34].

Acetaminophen is a non-opioid, centrally acting analgesic. Its intravenous formula has recently been introduced in the USA and had been available in Europe for many years. It is currently FDA approved for use in children older than 2 years of age [35]. Acetaminophen has been used in adult and pediatric cardiac patients as part of a comprehensive analgesic regimen [36]. It seems attractive for fast-tracking since it does not cause respiratory depression, hemodynamic instability, platelet dysfunction, or potential kidney injury; however, there is limited experience with its use in the pediatric cardiac surgery setting in the USA at this point.

Hepatic injury is a known serious side effect, and pediatric dosing and contraindications should be carefully considered. Other intravenous NSAIDs, such as ketorolac or indomethacin, have been linked to side effects such as gastrointestinal bleeding, bronchospasm, and kidney injury, which is why they are not commonly used in the cardiac surgery setting. In a small study in children undergoing CHS, however, the use of ketorolac was not associated with adverse events [37].

Surgical techniques related to a fast-tracking approach to CHS may also impact anesthetic management. Minimal invasive surgical techniques are often used [38], some of which (e.g., an axillary incision or thoracotomy) may require lung isolation [39]. Cardiopulmonary bypass techniques frequently used in eligible patients who are planned for fast-tracking include no cross-clamp techniques, less cooling including normothermic CPB, and selective perfusion strategies, all of which require advanced neuromonitoring to detect and avoid air embolization, hypo-, and hyperperfusion [40]. Modified ultrafiltration (MUF) is often part of a fast-tracking protocol, and effects on hematocrit and coagulation should be anticipated [41].

Regional and Neuraxial Anesthesia

The use of regional anesthesia and in particular neuraxial blockade is a controversial topic in patients undergoing surgery with CPB requiring full heparinization [42, 43]. While safety issues will be discussed below, there is increasing evidence that a neuraxial technique can be used safely and may offer benefits in the cardiac surgery setting. Epidural (including caudal) as well as intrathecal, single-shot, and continuous catheter techniques are frequently used. Regional blocks such as paravertebral blockade as well as intercostal and local infiltration techniques complement the armamentarium. While a thorough review of the individual techniques would go beyond the scope of this text, each individual technique will be discussed regarding benefits, concerns, and evidence regarding safety and outcome in the pediatric cardiac surgery setting. It must also be recognized that drugs mentioned below must be used in their specific formula for neuraxial use as specified by the manufacturer, since additives such as certain preservatives have been found to be neurotoxic when injected via the neuraxial route [44]. Additionally, regional and in particular neuraxial techniques in the setting of subsequent heparinization and/or the presence of anticoagulants must be performed according to the guidelines published and regularly updated by the American Society of Regional Anesthesia (ASRA) [45].

Neuraxial Catheter Techniques

The use of thoracic epidural catheters for pain management in CHS has been reported. When compared to single-shot techniques or intravenous analgesia, thoracic epidural catheter provided superior analgesia in a small series of children undergoing CHS [46]. Similar results were reported by Petersen and colleagues who compared caudal epidural, lumbar epidural, thoracic epidural, and intrathecal blocks using a combination of morphine or hydromorphone and local anesthetic [47]. The majority of patients were extubated in the OR, and the use of a thoracic epidural catheter technique provided superior pain control with overall fewer adverse events compared to other neuraxial techniques. It seems obvious that local anesthetic delivered at the corresponding thoracic level will provide superior pain control. The administration of local anesthetics at the thoracic level is easily titratable and provides the additional advantage of sympathetic blockade and superior blunting of stress response otherwise not achieved by lower epidural blockade and single-shot opioid-only-based techniques. Regardless of overall positive experience reported from many institutions, there probably remains the strongest bias against such a technique in the pediatric cardiac surgery setting. This may be partially due to the fear of catastrophic consequences of an epidural hematoma at the thoracic level and level of difficulty of such a technique in infants and small children

particularly when performed by inexperienced trainees.

The insertion of an epidural catheter at the lumbar or caudal level and advancement of the catheter cranially in order to achieve adequate blockade at the thoracic level is another neuraxial technique described in children undergoing cardiac surgery [48–53]. While this technique seems to offer the advantage of not manipulating a needle in the thoracic epidural space, the epidural canal is heavily vascularized, and the risk of advancing a catheter over a longer distance may actually carry a higher risk of injuring an epidural vein compared to the thoracic approach. Correct positioning of the catheter tip at the thoracic level is not always achieved, and the latter points may explain why catheters placed in the thoracic region seem to provide superior pain control with fewer side effects [47].

The use of a spinal catheter in children undergoing CHS has been described. Humphreys and colleagues randomized 60 children younger than 24 months to a group of patients receiving intravenous opioids versus high-dose spinal infusion of bupivacaine and morphine [54]. The spinal catheter group had lower inflammatory markers and lactate levels compared to the intravenous opioid group. Even though this technique is feasible, spinal catheters have fallen out of favor due to reports of cauda equina syndrome [55], and at this point this is not a frequently performed technique in children undergoing CHS.

Single-Shot Neuraxial Technique

Given the resistance of many practitioners of placing neuraxial catheter in children undergoing CHS with full heparinization, single-shot neuraxial techniques offer the benefits of simplicity of such a technique and avoidance of manipulating a catheter in the epidural space. Single-shot epidural techniques are typically administered in younger children at the caudal epidural space. Since administering a local anesthetic at the caudal or even lumbar epidural level will not reach adequate thoracic levels, single-shot caudal techniques are mostly limited to the use of hydrophilic opioids and in particular preservative-free morphine. Morphine, easily administered via the caudal space in younger children (typically but not limited to children <5 years of age), will provide a long-lasting analgesic effect. Its peak analgesic effect is 4–7 h [56], and its duration of action has been reported up to 24 h [57]. The analgesic effect obtained from the administration of morphine into the caudal epidural space varies, however, and is somewhat less predictable compared to a single-shot intrathecal technique, probably due to septations in the caudal epidural space [58]. Even though neuraxial opioids do not offer the potential advantages of a sympathetic thoracic epidural block achieved with local anesthetic agents, epidurally and intrathecally administered opioids have been shown to provide excellent analgesia [59, 60], blunt the stress response to surgery and cardiopulmonary bypass [61–63], improve pulmonary function [64], and reduce time on mechanical ventilation [65, 66].

Alternatively, single-shot intrathecal techniques are frequently used in older children (typically >4–5 years of age). Intrathecally administered preservative-free morphine provides adequate and predictable pain relief in children undergoing cardiac surgery [67]. The use of intrathecal local anesthetics in children undergoing cardiac surgery including high spinal anesthesia has been described and typically is well tolerated. Hypotension is less frequently observed compared to adult spinal anesthesia [59, 68]. Even though single-shot techniques may provide somewhat inferior pain control when compared to a thoracic epidural catheter technique, they are quite popular among many practitioners since single-shot techniques require less time, and potential risks associated with an indwelling catheter are avoided [69].

In addition to the already discussed use of local anesthetics and opioids, alternative drugs such as the alpha2 receptor agonist clonidine [70–72], ketamine [73, 74], and magnesium [75–78] have been added mostly for epidural anesthetics trying to minimize side effects from neuraxially administered opioids such as respiratory depression and to prolong analgesic effects.

At this point the experience in the USA with these additives is still limited and not yet routinely practiced [79].

Other Regional Blocks

Regional techniques circumvent many of the serious side effects feared when performing neuraxial techniques in patients with subsequent full heparinization. Various techniques including paravertebral blocks [80, 81], interpleural infusion of local anesthetics [82, 83], and subcutaneous wound infiltration techniques [84] all have been described in CHS. Intercostal blocks can be easily performed by the surgeon in the field and parasternal intercostal blocks performed prior to skin closure. Chaudhary and colleagues conducted a double-blind randomized trial in 30 children undergoing CHS comparing 0.08 mL/kg/space of 0.5 % ropivacaine to 0.9 % saline injected in 5 parasternal spaces on each side before skin closure [85]. They reported no complications, improved pain scores, less postoperative opioid requirement, and shorter time to endotracheal extubation. Additionally, infusion of local anesthetics via paravertebral catheters has emerged as an alternative to the epidural catheter route for management of post-thoracotomy pain. When performed unilaterally, they have been found to provide comparable pain control with fewer side effects such as nausea, vomiting, and hypotension, when compared to an epidural catheter technique [86]. Although the risk of spinal/epidural hematoma in anticoagulated patients after a paravertebral block has not been clearly defined, it has been recommended to follow the same guidelines used for neuraxial blockade [87].

Side Effects and Complications

Typical side effects from neuraxially administered opioids should be anticipated for effective treatment and/or prevention. Nausea and vomiting is frequently seen, and prevention with commonly used drugs such as serotonin 5-HT3 receptor antagonists or a combination of drugs should be considered if very early extubation is planned [88]. Pruritus occurs in a very high percentage of cases especially following intrathecal opioid administration, and even though diphenhydramine is a popular choice for treatment, small amounts of naloxone or even mild sedation with dexmedetomidine are more effective choices [89, 90]. Respiratory depression is common, and especially following early extubation, mild hypercarbia and respiratory acidosis are frequently seen. This is usually very well tolerated even in children with mild pulmonary hypertension and, with experience in fast-tracking, rarely requires reintubation. Close observation in a monitored unit is recommended for 24 h after neuraxial morphine administration, which rarely is a problem in children undergoing CHS. Continuous positive airway pressure can be applied nasally or via a face mask in children with increased respiratory effort. Urinary retention is usually not a problem in this patient population since most cardiac patients including children have a urethral catheter inserted. Hemodynamic side effects typically seen with neuraxially administered local anesthetics in adults such as hypotension and bradycardia are less pronounced in children [91].

The most feared complication of a neuraxial regional anesthetic technique, however, is an epidural hematoma, due to the temporal proximity of the neuraxial block with the administration of heparin for CPB. Unlike in adults, the preoperative insertion of an epidural catheter in an awake child is rarely possible. Typically, neuraxial techniques are performed in the anesthetized child, and time from neuraxial manipulation to heparin administration varies greatly [92]. At this point, there is a steadily growing number of reports on the use of thoracic epidural anesthesia in adult and pediatric cardiac surgery, including conscious patients undergoing off-pump or minimal invasive coronary bypass grafting, mostly from Canada, Europe, and Asia [93–96]. Many of these adult patients were fast-tracked, often even without intensive care unit (ICU) stay, with selected patients even discharged from the hospital the day of surgery. The fact that very few cases of

epidural hematomas associated with neuraxial anesthesia are reported in the literature may not accurately reflect the actual risk of such a technique in the cardiac surgery setting. Given the seemingly very low incidence of this serious complication, it will require many more patients to be enrolled in well-designed prospective studies for an accurate risk calculation. In the meantime, the most recent and widely quoted estimation of the risk of epidural hematoma with thoracic epidural anesthesia in patients undergoing cardiac surgery is 1 in 12,000, with 95 % confidence intervals of 1:2,100–1: 68,000, and 1 in 1000 with 99 % confidence [97]. Intrathecal risks from a different older source of risk assessment are quoted as 1 in 3,610 and 1 in 2,400, respectively [98]. Even when underreporting of such complications is assumed [99], there is increasing evidence that neuraxial anesthesia can be performed safely even in patients undergoing cardiac surgery with full heparinization. Chakravarthy et al. [100] presented an audit of 2,113 cardiac surgery thoracic epidural anesthesia cases over a 13-year period with no permanent neurologic deficits, a 0.9 % dural puncture rate, and 0.2 % transient neurologic deficits. Jack et al. published their experience of thoracic epidural catheter placement in 2,837 patients undergoing cardiac surgery [101]. No epidural hematoma was seen in this series. Similar results were reported by Royse et al. [102], who reviewed 874 cardiac surgery cases involving epidural anesthesia over a 7-year period with no complications attributable to epidural catheter use. Pastor et al. [103] reported 714 uneventful cases over a 7-year period, emphasizing their use of safety guidelines in which antiplatelet drugs were discontinued 7 days before surgery and routine coagulation tests and neurologic examinations were performed. No neurologic complications were reported in a series of 4,298 patients undergoing epidural catheter placement while under general anesthesia [104]. As pointed out earlier, careful attention to the most recent guidelines on neuraxial anesthesia in the setting of anticoagulant and antiplatelet agents is of paramount importance [105]. To date, there has only been one case of epidural hematoma reported in pediatric patients undergoing CHS. Rosen and colleagues reported a case of an adolescent who developed an epidural hematoma 2 days after surgery and epidural catheter placement. With the catheter still in situ, intravenous heparin was started for prosthetic valve thromboprophylaxis, and additionally alteplase was administered for management of a thrombosed central venous line [99]. Summarizing the safety concerns of neuraxial anesthetic techniques in patients undergoing CHS, these techniques can be performed with minimal risk as long as current guidelines are followed.

Fast-Tracking Patient Selection

Commonly applied criteria for selecting patients who are good candidates for fast-tracking are often based on anesthesiologist's or surgeon's preferences and institutional standards. It should also be noted that early extubation, which is the component of fast-tracking most readily effecting anesthetic management, is applied to patients who are extubated in the OR as well as several hours after the procedure in the ICU. While it could be argued that every patient could be woken up at the end of the procedure, there are obviously objective extubation criteria that must be fulfilled in order to be eligible for extubation regardless if this is in the OR or ICU. In selecting patients for fast-tracking, some of the information such as age, comorbidities, and planned procedure are known preoperatively, and the anesthetic regimen can be planned accordingly. The intraoperative course and patient's response to CPB are often unpredictable, and the ultimate decision if patients can and should be fast-tracked including the assessment of extubation criteria can only be performed immediately prior to extubation and must be made on an individual basis. The practice in CHS has commonly been, however, to exclude certain patients from fast-tracking altogether. Young age, for example, is frequently mentioned as a reason for not including patients in a fast-tracking protocol. This is despite the fact that there are multiple studies even in neonates and infants [106], showing that

early extubation as part of fast-tracking can be accomplished safely even in this young age group. Patients with preexisting pulmonary hypertension (PHT) are also frequently not considered for fast-tracking. Similar to other factors discussed in patient selection, it should be noted that PHT per se may not be a strict contraindication for early extubation and fast-tracking. In a recent study, children with PHT undergoing CHS were successfully extubated early [107]. In a retrospective analysis on factors associated with early extubation, PHT was not found to be an independent predictor of OR extubation [15], and preoperative PHT did not predict patients who were not extubated in the OR in a similar prospective study [108]. In the latter study, however, PHT following CPB was the most commonly noted factor listed by the attending anesthesiologist when extubation was deferred. The ultimate decision to safely extubating patients with PHT will not only depend on right-sided pressures, which at this point defines PHT, but rather on a combination of right ventricular function and pulmonary vascular resistance [109]. Even in the setting of PHT, patients can often be extubated as long as right ventricular function is adequate and no inhalational pulmonary vasodilators are required. Additional factors frequently mentioned as contraindications for early extubation are long CBP and aortic cross-clamp time [110–112]. It must be recognized that inflammatory response to CPB varies significantly, and with modern perfusion techniques aiming to minimize hemodilution and inflammatory response, even longer CPB times are not necessarily a contraindication for early extubation and fast-tracking. Obviously, patients should be hemodynamically stable, with adequate oxygenation, and any coagulopathy be corrected. In a prospective study on early extubation in children undergoing CHS, it was a simple preoperative surgical risk classification (Risk Adjustment for Congenital Heart Surgery (RACHS) score) and the presence of Down's syndrome, aside from certain age groups, that were identified as the strongest predictors of the anesthesiologist's decision to defer planned extubation at the end of the procedure to a later time point [108]. Since this decision was made based upon the anesthesiologist's assessment of extubation criteria at the end of the procedure, the authors concluded that preoperatively known factors such as surgical complexity of the planned procedure already capture important components of commonly used selection criteria such as long CPB time. To summarize selection criteria for patients who may be good candidates for fast-tracking, it can be concluded that many of the traditionally applied exclusion criteria have been challenged; often, a fast-tracking strategy can be applied and modified or changed to a high opioid technique should obvious contraindications present. Using such as strategy will allow early extubation and fast-tracking in many children undergoing CHS.

Benefits and Concerns of Fast-Tracking in CHS

While fast-tracking can certainly be accomplished in children undergoing CHS, the debate continues if such an approach is safe and if there are any benefits over a traditional approach [113, 114]. At this point, there is good evidence from multiple retrospective [15, 115–117], as well as prospective observational studies [108], that fast-tracking can be accomplished safely. Preisman and colleagues randomly allocated 100 consecutive children (age 1 month to 15 years) presenting for CHS to anesthetic management aiming for fast-tracking and OR extubation versus a traditional approach with elective postoperative prolonged mechanical ventilation [118]. There was no significant difference in mortality, reintubation rate, reoperation for bleeding, abnormal radiograms, infection, and other miscellaneous complications. Hospital and ICU stay was significantly shorter in the fast-tracked group. The authors do acknowledge though that the study was not adequately powered to conclude on the safety of fast-tracking, something that could only be accomplished with a large multicenter study.

Typical benefits associated with fast-tracking and early extubation include less sedation which

often leads to lower inotropic (hemodynamic) support, fewer mechanical ventilation-associated complications, more rapid patient mobilization, increased patient comfort and satisfaction, reduced parental stress, decreased length of ICU and hospital stay, and possibly decreased costs [118]. Additionally, certain types of CHS patients may benefit more than others from fast-tracking and in particular from early extubation and spontaneous ventilation. In patients with single ventricle physiology undergoing bidirectional Glenn or Fontan procedure, early extubation and spontaneous ventilation have been associated with improved hemodynamics including lower caval pressures and increased cardiac output and systemic blood pressure [119, 120]. Mild hypercarbia and mild respiratory acidosis are usually well tolerated and may actually improve oxygenation and pulmonary blood flow in these patients. It must be mentioned though that patient selection is crucial in fast-tracking, and potential benefits must be weight against risks on an individual basis. Prolonged periods of CPB are frequently associated with various degrees of inflammatory response leading to changes in respiratory mechanics, oxygenation, upper airway edema, among other factors that may preclude patients from fast-tracking. Obvious contraindications to fast-tracking and in particular early extubation must be recognized and standard extubation criteria fulfilled. Hemodynamically unstable patients and ongoing coagulopathy are both not uncommon in CHS and typically necessitate stabilization which is better accomplished in a well-sedated mechanically ventilated patient.

While patient's safety obviously comes first, in current times with expanding healthcare costs, cost containment has become an important issue. A meta-analysis of available studies on early extubation concluded that early extubation is associated with lower ICU and hospital length of stay without increased morbidity or mortality [121]. While numerous studies have shown a decrease in LOS, cost savings associated with fast-tracking patients in CHS has been reported, but not been conclusively proven [106, 107, 120]. Most studies reporting on cost savings acknowledge difficulties in comparing historical control groups to contemporary patient care, and prospective studies are mostly nonrandomized and inadequately powered. Nevertheless, results from randomized studies in adult cardiac surgery did show cost benefits from fast-tracking patients [122], and it is unlikely that these findings cannot be extended to CHS. Summarizing the risk-benefit assessment of fast-tracking CHS patients, it needs to be acknowledged that as so often in medicine robust data from well-controlled, possibly even multicenter studies is not available; however, the same argument would also apply to not fast-tracking CHS patients.

Conclusions

Fast-tracking patients undergoing CHS has become a viable alternative to a more traditional approach in CHS. Safely accomplishing this requires a multidisciplinary approach, careful patient selection, and recognizing contraindications. In eligible patients, fast-tracking can be beneficial and offer benefits.

Post-Operative Sedation and Analgesia

39

Ellen Rawlinson and Richard F. Howard

Abstract

A key aspect of care for the cardiac child in the postoperative period is the provision of appropriate analgesia and sedation, yet relatively little attention has focused on this often-challenging area of care. Appropriate analgesia is important for controlling the stress response to surgery as well as for humanitarian reasons. Analgesic strategies should encompass both the provision of baseline analgesia and the management of breakthrough and procedural pain. Sedation aims to reduce anxiety and distress and facilitates compliance with treatment. There are no ideal analgesic or sedative medications, so the choice of agent represents an inevitable compromise and should be informed by the needs of the specific situation. In the critically ill cardiac child, there is no clear correlation between drug dose and clinical response, so objective assessment of pain and sedation is imperative. The COMFORT scale represents the most suitable clinical assessment tool currently available; there is insufficient evidence as to support the routine use of neurophysiological techniques at present. Tolerance to analgesic and sedative medication and the subsequent appearance of withdrawal symptoms are common, particularly following prolonged or high-dose therapy. Strategies to avoid withdrawal include drug rotation, daily interruption of infusions, and the use of long-acting agents, but no approach appears capable of reliably preventing its occurrence. Future developments include the use of volatile agents such as desflurane and xenon, although there are significant economical and practical limitations to their use.

Introduction

The management of postoperative sedation and analgesia may have significant effects on both quality of care and outcomes. As the specialty of pediatric cardiac surgery has developed, the emphasis has understandably been on improving treatments for the primary disease, with little attention paid to supportive care. However, recent successes with fast-track programs for children undergoing cardiac surgery have highlighted the value and importance of appropriate anesthetic and analgesic techniques in the perioperative period. Similar attention to detail with respect to postoperative approaches to sedation and analgesia offers the opportunity to extend those benefits to all children [1].

General Principles

Providing appropriate analgesia and sedation in children is often challenging, and the postoperative cardiac child poses additional specific problems. Following cardiac surgery, children may have multiple noxious stimuli including chest drains, sternotomy wounds, presence of endotracheal tubes, and need for mechanical ventilation. Cardiac bypass is often followed by a period of unpredictable and labile physiology further complicating management. Clinical requirements vary considerably from those of the well child undergoing fast-track surgery to the neonate with complex congenital heart disease and a low cardiac output state.

The ideal analgesic or sedative drug has yet to be developed, so the choice of pharmacological agent represents an inevitable compromise. Most drugs have significant effects beyond their primary sedative or analgesic role, and while these can often be beneficially exploited in specific situations, side effects can be troublesome. It is therefore imperative that strategies are tailored to the need of the individual, as inappropriate use of medication may have profound adverse consequences. Deleterious effects are seen with both under- and oversedation. Inadequate sedation in the non-paralyzed child may lead to ineffective ventilation, accidental extubation, and the loss of essential monitoring lines, while the paralyzed child may be aware and yet unable to communicate distress. Oversedation can delay weaning from ventilation, increasing the risk of associated complications, and prolong intensive care stay. The hemodynamic effects of excessive sedative agents may promote otherwise unnecessary use of inotropes and intravenous fluids, and higher doses of drugs promote the development of tolerance and subsequent withdrawal phenomena. Inadequate analgesia may have important short- or long-term effects. Pain and consequent suffering can have an immediate detrimental effect on cardiorespiratory physiology and other body systems. Tissue injured in infancy and untreated pain are known to produce centrally mediated alterations in nociceptive pathways and changes in response to mechanical and thermal stimuli that may alter the child's response to subsequent pain and surgery [2, 3]. In spite of widespread recognition of the importance of managing pain, 44 % of children who remembered their PICU admission reported memories of painful experiences [4].

The pharmacokinetics and pharmacodynamics of many drugs are affected by a variety of factors in the perioperative period. Fluid shifts and hemodynamic changes both during and following bypass are associated with significant alterations in renal, hepatic, and skeletal muscle blood flow, with the use of vasoconstrictors and vasodilators imposing further changes. Acid–base disturbance will affect the balance of ionized and unionized drug and protein binding, and hypothermia reduces the activity of metabolic enzymes [5]. In general, neonates have immature metabolic systems and are relatively sensitive to the effects of medication, whereas older children often display drug clearances that exceed that of adults, leading to relative insensitivity to various agents. Studies with morphine have demonstrated an increase in volume of distribution and a reduction in drug clearance following cardiac bypass that is more marked in those who require inotropic support [6]. The rational choice of agent requires an understanding of the pharmacology and how this may be affected by surgical intervention.

Analgesia

Analgesia refers to the process of preventing or alleviating both the sensory component of pain and the associated emotional distress that it causes. There is a moral obligation to relieve treatable pain that is never more obvious than when caring for those who are unable to articulate their needs. Pain is associated with adverse physiological responses collectively referred to as the "stress response" that is characterized by circulatory changes (tachycardia and vasoconstriction), immunosuppression, hypercoagulability, and a persistent catabolic state. The stress response may be greater in neonates than other age groups and is associated with increased morbidity and mortality in those undergoing cardiac surgery [7]. Successful analgesic strategies will encompass the provision of baseline analgesia to address ongoing noxious stimuli, including additional analgesia for breakthrough pain, as well as appropriate management strategies for painful procedures.

Maintenance Analgesia

Opioids form the mainstay of analgesia following cardiac surgery due to their high efficacy, but the overall approach should be *multimodal* using both pharmacological and non-pharmacological means to reduce pain and pain responses [8]. Acetaminophen and nonsteroidal anti-inflammatory drugs (NSAIDs) reduce opioid requirements in postsurgical pain [9]. Infiltration of local anesthetic into the surgical wound and around chest drain sites may have similar effects; a continuous infusion of bupivacaine into the sternotomy wound via a dedicated tunneled catheter has been shown to reduce postoperative morphine requirements by 75 % in the first 24 h following cardiac surgery [10]. More complex regional anesthetic techniques may also be helpful when used as part of an analgesia strategy; they are discussed in more detail elsewhere.

Morphine and fentanyl are the most commonly used opioids for both maintenance and breakthrough analgesia (Table 39.1). Their analgesic effects are mediated mainly through μ and κ receptors located both peripherally and centrally while interaction at other receptors may contribute to adverse effects such as respiratory depression and nausea and vomiting. Potent lipid-soluble synthetic opioids such as fentanyl, remifentanil, and sufentanil have additional benefits in that they modify the stress response to surgery. When given intraoperatively in doses exceeding that required for simple analgesia, they reduce ventricular arrhythmias, postoperative complications, nitrogen loss, and mortality [11, 12].

Morphine has low lipid solubility with a consequently slow onset time and long duration of action. It undergoes hepatic metabolism to produce the active metabolite morphine-6-glucuronide (M6G) and the inactive morphine-3-glucuronide (M3G) that are both renally excreted. Accumulation of M6G in renal failure can lead to excessive sedation and delay extubation. Neonates are particularly sensitive to morphine and have clearance rates that are around 25 % of normal adult values. Cardiac surgery appears to delay the normal maturation process, which occurs by 1–3 months in infants undergoing noncardiac surgery but not until 6–12 in infants undergoing cardiac surgery [13]. Opioid receptors are more widely distributed at birth and so morphine has more widespread sensory effects in early life and may therefore be sufficient for both analgesia and sedation in neonates, whereas older infants and young children will require additional sedative agents [14]. Morphine may stimulate significant histamine release and inhibit compensatory sympathetic responses such that vasodilatation causes hypotension following bolus administration.

Fentanyl, a synthetic opioid, has an analgesic potency around 100 times that of morphine. It causes less histamine release than morphine, but can still reduce cardiac output via its negative chronotropic effect on heart rate. It is highly lipid soluble with a rapid onset of action and when given as a bolus has duration of 30–60 min. The initial rapid offset is due to redistribution to peripheral compartments. During long-term infusions (days), accumulation

Table 39.1 Opioid and non-opioid analgesic agents

Drug	Attributes	Dose	Comments
Opioids			
Morphine	Analgesia with sedation	IV loading dose:	Delayed recovery in neonates
		0.1–0.2 mg/kg	Caution in asthmatics (histamine release)
		IV infusion:	Hepatic metabolism with renal excretion of active metabolites – reduce dose in hepatic and renal impairment
		5–60 μg/kg/h	
		Neonates:	
		5–20 μg/kg/h	
Fentanyl	Procedural analgesia/ pulmonary hypertension	IV bolus:	Accumulation after continuous infusions
		5–50 μg/kg	Respiratory depression
			Hypotension with large boluses
	Analgesia/anesthesia	IV infusion:	
		1–20 μg/kg/h	
Remifentanil	Very rapid onset and offset	IV infusion:	Metabolized by tissue and plasma cholinesterases – offset is independent of infusion duration
	Profound analgesia	Analgesia	
		0.1–0.3 μg/kg/min	Profound respiratory depression
		Anesthesia	Hyperalgesia – alternative analgesia must be in place before infusion ceases
		0.5–1.5 μg/kg/min	
Alfentanil	Analgesia – 1/4 potency of fentanyl	IV bolus:	High protein binding with small volume of distribution
		50–100 μg/kg	Respiratory depression
	Rapid onset and offset	IV infusion:	Duration prolonged by cytochrome P450 3A4 enzyme inhibition
		0.5–2 μg/kg/min	
Codeine phosphate	Oral analgesia (qds)	PO child:	Converted to morphine by cytochrome P450 2D6 leading to wide variation in bioavailability
		0.5–1 mg/kg	
		PO >12 years:	Causes constipation
		30–60 mg (max 240 mg)	
Tramadol	Oral analgesia (tds-qds)	PO and IV child:	Blocks serotonin and noradrenaline in addition to opioid receptors
		1–2 mg/kg/dose	Uncertain efficacy in children as sole agent
		PO and IV >12 years:	
		50–100 mg (max 400 mg)	
Non-opioid			
Paracetamol	Opioid-sparing analgesia	PO: 15–20 mg/kg qds	Low analgesic potency as single agent
	Hyperthermia	Neonate max 60 mg/kg/day	Potentially hepatotoxic – reduce doses in critically ill and fluid restricted children
		IV: 10–15 mg/kg qds	
		<10 kg max 40 mg/kg/day	
Diclofenac	Opioid-sparing analgesia	PO and PR: 1 mg/kg tds	Not used in children under 6 months
			Potentially nephrotoxic
Ibuprofen	Opioid-sparing analgesia	PO: 5–10 mg/kg tds	As above

occurs in these compartments that can lead to prolonged sedation. Metabolism is exclusively hepatic with no active metabolites and little drug excreted unchanged through the kidneys, so clearance can be significantly affected by reductions in hepatic blood flow. Low-dose infusions provide good analgesia, whereas high-dose infusions reduce metabolic demands and hemodynamic responses to stimuli, which can be useful in managing critically balanced systemic and pulmonary circulations, pulmonary hypertension, and low cardiac output states [1].

The aim immediately following bypass should be to ensure adequate drug loading while keeping continuous infusions to the lowest level required. Demand-led systems such as patient-controlled analgesia (PCA) with a modest background continuous infusion is an effective way to meet these requirements and can be used in children as young as 5 years. Nurse-controlled analgesia (NCA) is an option for the younger child or for those physically unable to operate the handset [15]. Whenever possible enteral administration avoids the need to maintain intravenous access and allows tapering of medication to continue beyond discharge from PICU. Long-acting opioids such as modified release morphine preparations or methadone can be effectively administered this way.

Procedural Analgesia

Children undergoing cardiac surgery are exposed to repeated procedural pain during their intensive care stay, including that associated with tracheal suctioning, blood sampling and placement of vascular cannulae, chest drain insertion and removal, and wound manipulation and dressing. Such invasive procedures are often performed without supplemental analgesia, particularly in neonates and young infants. Simply increasing background infusions will promote drug accumulation and tolerance, but may not provide the short-lived but intense analgesia required during such brief, highly noxious, and damaging nociceptive inputs.

The use of topical anesthetic agents is well established in pediatric practice. Proprietary creams such as Ametop (4 % w/w amethocaine base preparation) or EMLA (eutectic mixture of local anesthetic agents lidocaine and prilocaine) provide good analgesia for procedures such as venous cannulation with a low incidence of side effects, although the 30–60 min required for effect may limit their use in time critical scenarios. LAT gel (lidocaine–adrenaline–tetracaine gel) is a newer agent with an onset of around 10 min that may address this. In the emergency department, it has been shown sufficient to permit wound suturing and has consequently reduced the number of children referred for general anesthesia [16]. Subcutaneous infiltration of local anesthetic (LA) prior to procedures such as chest drain and arterial or central line insertion can eliminate afferent pain conduction and should not be omitted, even in well-sedated patients. Buffering LA solutions, for example, lidocaine + bicarbonate (10:1), and using fine 30G needles reduce the pain associated with infiltration [17].

Non-pharmacological approaches such as nonnutritive sucking, tactile stimulation, swaddling, and heel massage should be used in addition to pharmacological techniques whenever possible [18]. In older children, psychological preparation by nursing staff, play therapists, and families is important. In all circumstances, clinicians should ensure that the procedure is necessary and consider whether an alternative would be less painful, for example, venepuncture is less painful than heel lances. Personnel with the necessary skills and experience should perform procedures in an optimal environment and after sufficient time has elapsed for analgesic measures to be effective. There should be a clear plan of action should the analgesic strategy prove insufficient or the procedure fails [19].

In neonates, the administration of oral sucrose solution has been shown to reduce pain scores following a variety of noxious events such as venepuncture, heel lance, and nasogastric tube insertion. It is safe and easy to use and should be employed along with other non-pharmacological techniques, although the optimal dose remains unclear and its

effectiveness in unstable or ventilated neonates may require further investigation [20]. In children over 6 years, nitrous oxide (50–70 % mix with oxygen) may be used to provide analgesia and sedation. The technique may be used as part of a strategy for procedures including chest drain removal, dressing changes, and venepuncture, although it requires cooperation on the part of the child and its use is contraindicated in the presence of a pneumothorax [21].

Intranasal administration of highly potent opioids such as remifentanil can be given easily and quickly, following which it provides profound analgesia for around 15 min. Administration in this manner avoids the bradycardia and hypotension that may be associated with intravenous therapy. Intravenous remifentanil has an evanescent action and has been used successfully for painful procedures in ventilated neonates in intensive care units [22]. Despite its potential to cause hypotension, remifentanil may have a place for ventilated patients requiring endotracheal tube changes or other brief painful procedures, without requiring any modification to preexisting sedation strategies.

Ketamine produces dissociative anesthesia with analgesia with a rapid onset and short duration of action. It may be used for a variety of procedures such as chest re-exploration or closure. Ketamine is a direct myocardial depressant; hemodynamic stability is usually maintained due to its sympathomimetic actions but caution should be taken in children with limited myocardial reserve. It causes dose-related respiratory depression, although spontaneous ventilation is normally maintained, and cerebral vasodilatation so should be avoided in patients with raised intracranial pressure. There are minimal effects on pulmonary vascular resistance so it can be used safely in patients with pulmonary hypertension, as long as airway obstruction and hypoventilation are avoided.

Sedation

The term sedation means the act of calming. Once adequate analgesia is established, some critically ill children will require additional therapy to achieve this. The aims of a sedative regime are to reduce anxiety and distress in the child and facilitate their compliance with treatment. Depending on the needs of the clinical situation, sedation leads to a reduction in conscious level that can range from alert, but settled, to virtual anesthesia. Potential additional benefits include a reduced recall of unpleasant events, enhanced analgesia, a reduction in metabolic rate and oxygen demand, and a better-preserved sleep pattern. Details of commonly used sedative agents are given in Table 39.2. Despite the widespread use of sedatives to facilitate mechanical ventilation, high-quality evidence to guide clinical practice is still limited [23]. Sedation protocols have been shown to reduce the duration of mechanical ventilation, intensive care and hospital stay, the use of neuromuscular blockade, and drug costs in critically ill adults. The majority of PICUs use a written guideline, although there is considerable variation in practice; a recent systematic review included 39 studies describing 39 different sedation regimes with 21 different scoring systems [24]. Daily interruption of sedative infusions reduces the duration of mechanical ventilation and intensive care stay in critically ill adults, and this has recently been confirmed for children [25]. Concerns that this practice could lead to an increase in adverse events such as unplanned self-extubation or cardiovascular instability have not been shown.

Midazolam is the most commonly used agent for sedation in general PICUs, a choice that is supported by UK Consensus Guidelines [23]. It provides clinically effective sedation in the majority of cases, and its antegrade amnesic effects may contribute to the low levels of negative recall in PICU survivors treated with this agent [4]. Although its use following pediatric cardiac surgery has been described, it has negative effects on cardiac index and reduces the catecholamine response to hypotension [26]. This effect is particularly marked in the presence of hypovolemia, so it should be used with great caution following cardiac surgery where hypovolemia is common. Midazolam is a tautomer (structural isomer) that converts to an unionized form at plasma pH allowing rapid

Table 39.2 Sedative agents

Drug	Attributes	Dose	Comments
Benzodiazepines			
Midazolam	Sedation with anterograde amnesia	Bolus:	Delayed recovery and withdrawal following prolonged infusion
		0.1–0.2 mg/kg	
		IV infusion:	Hypotension in presence of hypovolemia
		2–10 μg/kg/min	
Lorazepam	Long acting – used for midazolam withdrawal	PO: 0.02–0.1 mg/kg tds	May itself cause withdrawal
			Respiratory depression
α-2 Adrenoceptor agonists			
Clonidine	Sedation with analgesia and anxiolysis	PO: 1–5 μg/kg tds	Rebound hypertension can occur following cessation of therapy
		IV infusion:	
		0.5–3.0 μg/kg/h	
Dexmedetomidine	Sedation with analgesia and anxiolysis	IV infusion:	Hypotension and bradycardia
		0.01–0.1 μg/kg/h	
Propofol	Rapid onset and recovery	IV infusion:	Contraindicated by manufacturer
	Amnesia	max 4 mg/kg/h (limit length of infusion)	Risk of propofol infusion syndrome (monitor for rising lactate and acidosis)
	Reduction in PONV		May cause hypotension
Chloral hydrate	Well tolerated	PO: 30–50 mg/kg qds (max 200 mg/kg/day)	Paradoxical excitement may occur
			Avoid in renal and hepatic impairment
Alimemazine	Phenothiazine with anti-emetic properties	PO: 2–4 mg/kg qds (max 90 mg/dose)	Avoid in renal and hepatic impairment
Promethazine	Phenothiazine with anti-emetic properties	PO: 1–2 mg/kg qds (max 50 mg/dose)	Risk of extrapyramidal side effects
Haloperidol	Butyrophenone-producing dissociated sedation	PO: 0.05–0.1 mg/kg/day	Risk of extrapyramidal side effects, notably dystonia
		IV Bolus:	Lowering of seizure threshold
		0.01–0.1 mg/kg qds	
		IV Infusion:	
		25–85 μg/kg over 24 h	

passage across the blood–brain barrier. After a bolus dose, peak sedation occurs at 5–10 min with duration of 30–120 min. Administration by continuous infusion prolongs the duration of action considerably, and sedative effects may persist for up to 48 h following discontinuation. Midazolam is hydroxylated in the liver by cytochrome P450 isoenzyme 3A4 and then undergoes glucuronidation. The elimination half-life in a PICU population has been shown to be 5.5 (± 3.5) h, considerably longer than the 1.2 (± 0.3) h observed in healthy children [27]. Prolonged sedation may be due to the accumulation of the active metabolite α-hydroxymidazolam in patients with renal impairment, failure of metabolism in those with generalized hepatic impairment, or substrate competition for isoenzyme 3A4 with agents such as erythromycin.

The α_2-adrenoceptor agonists clonidine and dexmedetomidine are being used with increasing frequency for sedation in PICU. Dexmedetomidine is a newer agent with 8 times the affinity of clonidine for the α_2-receptor (α_2: α_1 of 2000:1). It was approved for use in the USA in 1999 but did not receive a product license in the European Union until 2011. These drugs produce stable sedation without respiratory depression and decrease the need for other sedatives and analgesics. In addition, they have analgesic properties and produce anxiolysis that is comparable to benzodiazepines. α_2-Adrenoceptors are widely

distributed throughout the peripheral and central nervous systems and in a variety of organs. Analgesic effects are probably mediated via presynaptic receptors that inhibit the release of substance P and norepinephrine. Postsynaptic activation in the central nervous system inhibits sympathetic activity and mediates the dose-related reductions in heart rate and blood pressure seen with both agents [28]. Dexmedetomidine has been specifically investigated in children following cardiac surgery. It appears generally well tolerated in all age groups (including neonates) and across a broad spectrum of cardiac pathology including children with uni-ventricular circulations [29]. Hypotension and bradycardia are seen more commonly than with conventional sedation regimes [30]. In children undergoing electrophysiological studies, dexmedetomidine significantly depressed sinus node and atrioventricular node function, so caution should be exercised in children at risk of bradyarrhythmias [31].

Propofol, a phenol derivative, has never been licensed for the provision of sedation in critically ill children and is contraindicated by regulatory authorities in both the UK and the USA. Its longer-term use has been associated with the rare but frequently fatal propofol infusion syndrome characterized by acidosis, rhabdomyolysis, and bradyarrhythmias and mediated by impairment of fatty acid oxidation and mitochondrial activity at the subcellular level [32]. However, sedation with propofol has attractive clinical qualities and offers a rapid onset and offset with a "clear-headed" recovery, and its use continues for short-term sedation in selected cases, notably those where early wake-up and extubation are anticipated [33]. It may also be used intermittently to provide sedation for brief procedures, although bolus administration may be associated with hypotension particularly in those with impaired ventricular function.

As with opioids the enteral route should be used where possible. Chloral hydrate and promethazine, given together, have been shown to be more effective than midazolam in providing adequate sedation [34]. The overall requirement for sedative drugs can be reduced by attention to environmental factors. The benefits of music therapy and massage have been demonstrated in adults, while watching videos reduces sedation requirements for echocardiography in children [35]. The importance of normalizing sleep patterns is increasingly recognized as even short periods of sleep deprivation have adverse effects on pulmonary function, healing, and the immune system [36]. Controlling the level of noise is critical as it is a major contributor to sleep disruption and is commonly complained about by survivors [23].

Neuromuscular Blockade

Neuromuscular blockade (NMB) may be used to promote ventilator synchrony, particularly when employing less physiological techniques such as inverse ratio, deliberate hypo- or hyperventilation, or high-frequency oscillatory ventilation. It facilitates deliberate hypothermia as part of the management of low cardiac output states or following cardiac arrest. NMB is indicated in the management of conditions such as pulmonary hypertension or raised intracranial pressure and may occasionally be used to protect surgical repairs, for example, tracheal reconstruction or vascular anastomoses [37]. The use of NMB is reported in 14–16 % of ventilator support days in PICU, and these children have a higher than average overall mortality rate [38]. The use of sustained neuromuscular block has been shown to reduce energy expenditure and oxygen consumption in critically ill children, although the effects were only modest in those who were already sedated [39]. There is wide variation in practice but vecuronium is used most commonly due to its relative lack of adverse side effects [40]. Other agents may have significant hemodynamic effects either through a direct action, such as the vagolysis seen with pancuronium, or via histamine release.

The assessment of neurological state and level of sedation is hampered by NMB, and prolonged immobility may lead to muscle atrophy, contractures, and pressure sores. Critical illness polyneuropathy and myopathy in children appear

to have similar features to that seen in adults, and NMB may represent a risk factor for its development [41]. Objective monitoring of NMB is possible by transcutaneous electrical stimulation of peripheral nerves (most commonly the ulnar). In adults, monitoring NMB with train-of-four (TOF) pattern stimulation has been shown to reduce total drug dose requirements and promote faster recovery of spontaneous ventilation. In PICU, results may be affected by peripheral edema and hemodynamic status and in small children are easily confounded by direct stimulation of muscle groups.

Assessment of Pain and Sedation

Objective assessment of pain and sedation is important, as the response to drugs in the critically ill child is not predictable from dose alone. The levels of analgesia and sedation achieved depend on many factors including the pharmacokinetics and pharmacodynamics of each drug, the underlying disease process, the duration of administration, and the tolerance and interaction with other drugs. The overall aim should be to give the minimum dose necessary to avoid the problems of oversedation and reduce the development of tolerance. Increased sedative use in the first 24 h of weaning from mechanical ventilation is associated with failure of extubation in infants and children [42].

In an intensive care environment, distinguishing whether distress is due to inadequate analgesia or inadequate sedation can be difficult as there is significant overlap in symptomatology [19]. Self-reporting is the preferred method for pain assessment, although this is often not possible due to age, intubation, sedation, or cognitive impairment. A multitude of structured assessment tools are available although these are generally underutilized, despite the observation that improving documentation can improve the management of pain [19]. There is currently no gold standard for evaluating the level of sedation in the critically ill child, although the majority of PICUs routinely use one of the available scoring systems to assess agitation and pain in children [33].

Clinical Assessment Scales

Behavioral observational scales based on facial expressions, vocal and motor responses, posture, and physiologic signs are the primary tools available, although such indicators are neither sensitive nor specific to pain [23]. However, the COMFORT scale was specifically designed to measure the levels of pain and distress in critically ill children requiring mechanical ventilation [43]. It has been validated for children of all ages and all levels of neurological development and is the most commonly used and most suitable tool currently available for this purpose [33]. In its original form, it comprises 8 variables, each rated 1–5: alertness, ventilator response, blood pressure (MAP), muscle tone, calmness/agitation, physical movement, heart rate, and facial expression. The scale ranges from 8 to 40 with a target range of 17–26. However, evaluation of some parameters is subjective, it cannot be used in paralyzed patients, only provides intermittent data and in practice can be cumbersome to use. In addition, it includes hemodynamic variables that can be affected by factors other than sedation (notably pacing in cardiac patients), although a simplified scale has been described that does not include physiological variables but which has equal validity to the original scale in some circumstances, in critically ill infants after cardiac surgery the full version of COMFORT was superior [44].

The FLACC (Face, Legs, Activity, Cry, Consolability) scale is a behavioral tool, designed for use with young children after surgery and in widespread use. It scores five criteria to give a total between 0 and 10 [45]. In keeping with many other pain assessment techniques, it was initially developed to assess postoperative pain in developmentally normal children, but has subsequently been validated for use in children with cognitive impairment as well as critically ill adults and children [46]. When self-reporting is clinically possible, there are variety of suitable scales appropriate for use in children from around 4 years of age. Younger children may use a version of the Faces Pain Scale, and older children may use one-dimensional tools such as the visual analogue scale (VAS) or numeric rating scale (NRS) [47].

Neurophysiological Scales

The interest in neurophysiological techniques as a potential objective measurement of sedation is driven by the drawbacks of clinical assessments. The underlying principle is that there is a relationship between the electroencephalogram (EEG) and the level of sedation. Light anesthesia produces mainly α-waves and a reduction in β-waves, whereas δ- and θ-waves appear with deeper anesthesia, and when sedation is excessive δ-waves become continuous. The bispectral index monitor (BIS) was developed to assess intraoperative depth of anesthesia and prevent awareness in adults. It utilizes a mathematical analysis of the EEG to generate a single dimensionless number that ranges from 0 (equivalent to EEG silence) to 100 (equivalent to awake and alert). Adults under general anesthesia have scores between 40 and 60, but there are no well-defined "ideal values" for critically ill children receiving sedation [48]. BIS has the advantage that it is noninvasive, safe to use, and provides continuous monitoring of conscious level. It offers reasonable discrimination between adequate and inadequate sedation but appears less sensitive to the distinction between adequate and excessive sedation [49]. Correlation with COMFORT scores is highly variable, but this is not surprising as BIS is measuring hypnosis, whereas COMFORT is designed to measure pain and distress of which sedation is only a component [50].

BIS values can be affected by a number of factors common in PICU including polypharmacy, temperature changes, hypotension, hypoglycemia, and cerebral ischemia. Pacemakers and electrical interference from equipment are additional confounders. Contraction of frontalis muscle increases BIS values due to interference from the electromyogram (problematic at lighter levels of sedation). However, BIS values decrease with NMB in both awake volunteers and those receiving moderate sedation, suggesting that BIS may not adequately distinguish those receiving NMB but who are inadequately sedated. The only other neurophysiological monitor to be assessed in children is middle latency auditory evoked potentials, which records the EEG changes in response to a repetitive click. This technique has similar limitations to the BIS monitor and an additional drawback of producing constant stimulation with repeated sounds [48]. There is currently insufficient evidence to justify routine use of any neurophysiological monitor in PICU.

Long-Term Sedation and Withdrawal

In a subgroup of children following cardiac surgery, sedation and ventilation will be required beyond the immediate postoperative period. This group includes children with ongoing medical problems such as cardiac failure, systemic sepsis, or pulmonary hypertension, as well as those with residual cardiac lesions not amenable to immediate intervention. The formation of a tracheostomy to reduce sedative requirements is rarely appropriate, in part because of the technical issues associated with tracheostomies in children but also because sedation is often required as part of the medical management strategy. These children are at particular risk of developing physiologic tolerance to their sedative and analgesic medications, followed by symptoms of withdrawal once they are stopped.

Tolerance refers to adaptations at a cellular level that occur in response to the presence of the drug in question. When drugs are withdrawn, these adaptive mechanisms, now devoid of substrate, take time to respond and may produce symptoms clinically recognizable as withdrawal [51]. The cellular mechanisms responsible for tolerance remain poorly characterized. For opioids a number of responses have been observed including a decrease in receptor numbers (downregulation), internalization of receptors (desensitization), and alterations in the response of intracellular signaling pathways [52]. In comparison, tolerance to neuromuscular blocking agents is mediated by an increase in receptors located outside the neuromuscular junction. Acute tolerance (tachyphylaxis) to opioids is well described and may occur rapidly, even within the time frame of pediatric surgery.

The classical signs of opioid withdrawal include neurological excitability, gastrointestinal dysfunction, autonomic instability, and poor organization of sleep states. Benzodiazepine withdrawal symptoms are similar, but also include agitation, visual hallucinations, facial grimacing, small-amplitude choreic or choreoathetoid movements, and seizures [53]. The incidence of withdrawal from midazolam has been reported as high as 30 % and withdrawal from fentanyl at over 50 % [54, 55]. However, a more recent UK survey of children sedated mainly with morphine and midazolam reported an incidence in intubated children of 13 % and in a subgroup of cardiac children of only 5 % [51]. Children experiencing withdrawal receive higher daily and total doses of sedative medications. They also have more frequent use of physical restraints, are more likely to be receiving NMB on day 3, and have a longer PICU admission. Features of withdrawal develop early after cessation of drug therapy, occurring within 6 h in one-third of children and in 98 % within 24 h [51].

Assessment of withdrawal can be difficult as many symptoms have alternative etiologies, and until recently research in critically ill children has been hampered by the lack of an acceptable assessment tool. Many studies and institutions use modified scoring systems based on the Neonatal Abstinence Score (NAS), which was originally devised for neonates exposed to opioids through maternal addiction. The NAS is not validated for use in children in PICU and makes no allowance for the benzodiazepines that most children receive in addition to opioid therapy. Furthermore, it includes reflexes such as the Moro which cannot be assessed in children older than 3 months. The Withdrawal Assessment Tool-1 (WAT-1) is recently described by 11-point scale with a maximum score of 12, designed to assess withdrawal from both benzodiazepines and opioids in children. A WAT-1 score of 3 or higher correlated highly with nurses' assessment of withdrawal and demonstrated sensitivity at of 87 % and specificity of 88 %. In a subsequent study to test the psychometric properties and generalizability of the scale, 17 % had episodes of clinically significant withdrawal requiring treatment with either benzodiazepine or opioid [56]. Although it has been criticized for not including more symptoms specific to benzodiazepine withdrawal, it appears easy to use in practice and should support further research in this area [57].

Strategies to avoid the development of tolerance begin with steps aimed at reducing the total dose of sedative agents administered. The assiduous use of pain and sedation scoring systems, daily interruption of sedative infusions, and the non-pharmacological methods already described have important roles to play here. There is little evidence to support any particular approach to weaning sedative medications and where protocols have been described adherence is problematic. The practical lesson appears to be that any weaning protocol should be flexible enough to accommodate a range of clinical scenarios that account for length of exposure and symptoms [58]. It is common practice in many units to taper doses by 5–10 % of the original dose per day, but this does not appear to reliably prevent withdrawal [51]. Other approaches include routine cycling between pharmacological drug groups, changing to long-acting enteral agents such as methadone and diazepam, and the use of alternative means of drug delivery such as transdermal fentanyl.

Future Developments

Volatile anesthetic agents are used extensively in operating rooms worldwide. They provide reliable anesthesia and amnesia with limited and generally well-tolerated effects on end-organ systems. They potentially have much to offer as sedatives for PICU but the practical obstacles to their routine use are significant and good evidence for long-term safety is lacking.

Isoflurane is the most extensively investigated agent and is an effective sedative in adults and children, both as a single agent and in combination with opioids [59]. It is a potent bronchodilator, acting via mechanisms that differ from conventional agents, and has been successfully used in status asthmaticus refractory to traditional

management. It also produces a dose-dependent decrease in EEG activity and is effective at treating status epilepticus of varying etiologies refractory to conventional therapy. Isoflurane is a vasodilator and adverse events include hypotension requiring treatment with either fluids or vasopressors. Withdrawal phenomena have been described in as many as 50 % of patients following inhalation for several days and are characterized by agitation, tremors, and non-purposeful movements [60]. Desflurane has the fastest onset and offset of action of all clinically available volatile agents. When compared to propofol in adults following major surgery, it produced deeper, more hemodynamically stable sedation but with a faster, more reliable wake-up and quicker mental recovery. Data in children and for time periods exceeding 24 h are lacking but desflurane sedation appears to have many qualities desirable following cardiac surgery.

The major limitation to greater use of volatile agents lies in practical problems associated with their administration. The majority of PICU ventilators do not have the facility to simply add a vaporizer, and those that do (such as the Servo 900 series) have mostly been superseded. Anesthetic machines used in the OR are an alternative but are often equipped with ventilators without the capabilities or multiple ventilatory modes commonly provided by modern PICU machines. Scavenging of waste gases for the protection of staff also presents difficulties as most PICUs will not have access to central waste gas services. Redesign and construction are costly but a number of ad hoc solutions have been successful. Ventilator exhaust ports can be connected to a T-piece attached to a 3-l self-inflating bag and wall suction applied to the distal end of the T-piece to provide adequate scavenging with no discernable environmental pollution, although care must be taken to avoid obstruction and resultant barotraumas. A novel potential solution to some of these problems is found in the Anesthetic Conserving Device (AnaConDa®; Sedana Medical AB, Sundyberg, Sweden). AnaConDa® is a modified heat and moisture exchanger that is inserted between the Y-piece of the breathing circuit and the endotracheal tube connector. Isoflurane is administered via a standard syringe driver to a vaporizer rod where it evaporates and enters the inspiratory gas mixture. It contains a carbon particle filter to which 90 % of exhaled isoflurane adheres and is then returned to the patient in the next breath, although the remaining 10 % returns in the exhaled gases and requires scavenging. It has been successfully used in children, although the additional 100-ml dead space appeared excessive for children <30 kg. In these cases the device can be placed in the inspiratory limb, although with this setup the advantage of agent recycling is lost [61].

Xenon is a noble gas with anesthetic and analgesic properties that produces pleasant, well-tolerated sedation in volunteers. It has a low potency and a minimum alveolar concentration for anesthesia of 70 % of 1 atm. The mechanism of action is believed to be via potent noncompetitive inhibition of the N-methyl-D-aspartate (NMDA) subtype of the glutamate receptor and also via activation of neuronal potassium channels that modulate neuronal excitability [62]. Chemically it is virtually inert and is of particular interest in cardiac critical care because of its cardiostable and neuroprotective properties particularly in neonatal models of hypoxic brain injury [63]. In post-cardiac surgical adults sedated with xenon, there were no changes in heart rate or mean arterial pressure, and filling pressures and systemic vascular resistance were higher than in patients sedated with propofol [64]. Coadministration of isoflurane reduces the required xenon concentration even further, and neuroprotective effects are seen even when it is given after the test insult. Xenon is produced by fractional distillation of air which is costly, although recent work suggests that sedation may be economically viable in the setting of critical care, as the majority of costs are associated with initial priming of the circuit and so reduce with increasing lengths of sedation. Clinical use would require closed circuit delivery but viable mechanisms to provide this have been described.

Anesthesia in the Cardiac Catheterization Laboratory and MRI

40

Warwick Ames, Kevin Hill, and Edmund H. Jooste

Abstract

Modern pediatric cardiac catheterization laboratories (CCL) have become highly specialized units with an increasing focus on interventional procedures. Furthermore, the cardiac MRI examination is being increasingly used in the management of congenital heart disease patients. The following section will discuss the delivery of anesthesia in these two unique and challenging environments. Patients range from tiny infants to elderly adults, and the sedation needs from monitored anesthesia care to a general anesthetic. Familiarity to the CCL, safety awareness in the MRI suite, and a sound knowledge of the disease processes and procedure-specific requirements are critical to procedural success and safe outcomes. The anesthetic concerns and potential complications will be discussed for the most common procedures encountered in the CCL, for example, electrophysiological studies, valvuloplasties, defect occlusions, transcatheter valve insertion, angioplasty, and stent placement.

Introduction

Modern pediatric cardiac catheterization laboratories (CCL) have become highly specialized units with an increasing focus on interventional procedures [1]. Familiarity to the CCL, sound knowledge of the disease processes, and procedure-specific requirements are critical to procedural success and safe outcomes.

Design of a Cardiac Catheterization Suite/Environment

A typical cardiac catheterization suite encompasses both procedure room and control room adjacent to one another. The American College of Cardiology has guidelines in terms of room size and layout. But there are several issues related specifically to anesthesia that should be considered when designing a cardiac catheterization suite [1]. Designs should promote efficiency and safety while allowing for maximal viewing options [2, 3].

Biplane imaging is typically required for pediatric laboratories to assist in accurate positioning of electrophysiological catheters and interventional devices. These x-ray gantries always present a problem for the anesthesia provider. Firstly, the close proximity of the biplane C-arms immediately creates competition for space. When in use, the x-ray devices can make it difficult to access the patient, particularly in an emergency and the gantries often obscure the monitors from anesthesia view [2]. Tables may be floor or ceiling mounted (Fig. 40.1). Of note, many newly designed suites are integrating the need for concomitant surgical procedures, the so-called hybrid laboratory. Typically, hybrid rooms are larger than a standard O.R. to accommodate not only for increased equipment needs but also staff calculations have shown that in hybrid procedures, 8–20 people are typically needed per case [4] (Fig. 40.2).

Fig. 40.1 Typical cardiac catheterization laboratory (CCL) demonstrating limited space at the head of the table

Fig. 40.2 Hybrid cardiac catheterization laboratory demonstrating the larger square footage of the room required to accommodate the increased personnel and equipment needs

Preparation/Sedation/General Anesthesia

The anesthesia team should have a good knowledge of the layout of the CCL and where the anesthesia supplies are situated. In addition to a standard general anesthetic setup, make sure there are appropriate emergence and procedure-specific medications available, for example, epinephrine, isoproterenol, and adenosine. The room is often cooled to prevent overheating of the CCL machines, and this combined with the exposed patient and cold flush fluids invariably leads to hypothermia so have a warming blanket for all but the shortest procedures. For interventional cases, confirm that blood has been ordered and have blood in the room prior to any intervention. For the complicated ICU patients, it is a good idea to simplify lines and medications before transporting the patient to the CCL, but be attentive to not discontinue critical infusions and medications like prostaglandin, nitric oxide, and glucose maintenance infusions. Place defibrillator pads if appropriate, and if transthoracic pacing wires are present, make sure you have access to them and have a pacing box available. Catheter-induced bradycardias and junctional rhythms are frequent and may require pacing. It is advised that the IV access the anesthesia team uses should be in the upper arms to prevent the dilemma of trying to resuscitate through a vessel that might either be obstructed by the interventionists' catheters or distal to the vessel injury and thus not helpful in resuscitation. Blood pressure cuffs should not be placed in the same leg that is used for cannulation. It should also be remembered that blood pressure measurements from a cuff on an arm that is elevated above the head will represent a lower than actual blood pressure. End-tidal CO_2 monitoring is crucial in the CCL and is a useful surrogate for pulmonary artery blood flow and cardiac output. The end-tidal CO_2 monitor is often the first monitor to provide

Table 40.1 Normal hemodynamics values in children

Right atrial pressure	3–5 mmHg (mean)
Right ventricle pressure	20–30 mmHg (systolic) and 3–5 mmHg (end diastolic)
Pulmonary artery pressure	12–15 mmHg (mean)
Pulmonary capillary wedge press	5–8 mmHg (mean)
Left atrial pressure	5–8 mmHg (mean)
Left ventricle pressure	65–110 mmHg (systolic) and 3–8 mmHg (end diastolic)
Pulmonary vascular resistance	<2 Wood units $\times$ m^2
Systemic vascular resistance	15–20 Wood units $\times$ m^2

information of a pending catastrophe. Arterial lines are most often placed by the cardiologist in the femoral artery, but because these tracings might be dampened or interrupted frequently during the case with certain of their catheters, it is advisable to place a separate arterial line in unstable patients.

For the majority of the pediatric cases, a general anesthetic is required. Unique procedure-specific situations will be discussed under the various headings below. Sedation is reserved for the motivated older child and adult patients. In general, children less than ten will require deep sedation for even the simplest procedure. But for the sedation cases, intermittent boluses of a benzodiazepine like midazolam and opioids like fentanyl or morphine are normally sufficient. Ketamine can be added to further deepen the sedation in the hemodynamically unstable patient with minimal respiratory depression. For those patients that are more cardiovascularly stable, a propofol infusion at 25–150 mcg/kg/min will provide excellent sedation but at the expense of potential respiratory depression. Different combinations of dexmedetomidine, ketamine, and/or propofol have been used, and it would be advisable to use medications that the providers are most comfortable with [5–9]. It is not what you use but how you use it.

A general anesthetic plus endotracheal tube is recommended for procedures that are expected to be long, where trans-esophageal echocardiography will be used, for patients with poor function or supra-systemic right-sided pressures and for patients with a history of previous pulmonary edema or hemoptysis. General anesthesia can be achieved via volatile anesthetics or intravenous anesthesia, but the goal is clear: the provision of a stable anesthetic with a well ventilating patient to mimic "normal" hemodynamics for the diagnostic catheterization (Table 40.1).

For induction of anesthesia in the sickest of patients, ketamine or etomidate should be used. For the patients that will remain intubated post procedure, a more opioid-based anesthetic can be used. Sevoflurane or isoflurane is most often used as a maintenance agent and titrated to effect. Any changes in the depth of anesthetic or oxygen concentration should be communicated with the CCL team. The major advantages to a general anesthesia with endotracheal tube are that of a secure airway, the ability to control ventilation and therefore influence the PaO_2 and $PaCO_2$, the ability to provide peep and suction the airway if necessary, and the ability to administer a neuromuscular blocker so to prevent patient movement. The counter viewpoint is that positive pressure ventilation may create wide swings in the hemodynamic parameters, and the various anesthetics may have negative inotropic effects and decrease systemic vascular resistance. For purely diagnostic or truly minimally invasive procedures in the sickest of patients, a very light sedation, with liberal use of local anesthetic, and reassurance may be in the best interest of the patient. The anesthesia team needs to anticipate the painful parts of the procedure and provide timely extra pain relief/sedation. These critical moments include IV access, placement and exchange of sheaths, and during interventions such as balloon dilation, device deployment, etc.

In sedation cases, the local anesthetic to the groin site might need to be readministered especially prior to pulling the sheaths at the end of the procedure. A smooth extubation and emergence are critical to successful anesthetic as an agitated, coughing, or bucking patient may lead to hypertension and excessive leg movement that may cause the access sites to rebleed. It is advisable to have someone hold pressure on the access site during the emergence/extubation period to further decrease this risk. Regional techniques have been used in adult cardiac catheterization labs in patients with severe chronic obstructive pulmonary disease or reactive airway disease [10], but there is no data in the literature of its use in the pediatric population. Conceptually, a caudal regional anesthetic could reduce the need for deeper sedation or anesthesia. In addition, this might decrease postoperative pain and patient movement and thus the risk of groin hematoma. While caudal anesthesia is relatively safe, central neuraxial blockade may not be recommended for the fact that many patients require heparinization in the CCL.

Post-catheterization Care

The Standard American Society of Anesthesiologist guidelines should be followed. In addition to monitoring the standard vital signs, some centers perform a chest x-ray on patients who required neck access and an echocardiography examination on the patients who have undergone an endomyocardial biopsy. These patients need to have the puncture sites regularly inspected for bleeding, and the patients are not allowed to flex their hips for at least 4–6 h, to allow for the clot at the puncture site, to become more stable. It is advisable to have the access site visible, that is, not hidden under blankets, for transport and in the postoperative care unit as significant bleeding can occur in short period of time. In addition, the presence of an arterial pulse on the ipsilateral leg to the femoral artery puncture site should be documented. A diminished or absent pulse could mean arterial spasm or thrombosis and should be communicated to the cardiologist. If not resolved in 2 h, the patient will require admission and a heparin infusion. For the sicker patients, an ICU admission will be required until they stabilize.

Hemodynamic Assessments

Accurate hemodynamic assessment is a critical part of the cardiac catheterization, and the data will influence decisions to intervene surgically or in the catheterization laboratory. To ensure the most accurate data, hemodynamic evaluation should be performed under stable conditions, and changes in oxygenation, ventilation, sedation, and volume status should be minimized. Whenever possible, data should be obtained with the patient breathing 21 % FIO_2. If supplemental oxygen is necessary, then PaO_2 levels should be measured in addition to saturations as these will affect oxygen content calculations. From the cardiologists perspective, hemodynamic data can be broadly subdivided into saturations, pressures, and calculations [11]. Saturation data is used to determine shunting and to calculate flows. Four primary saturation data points are necessary for calculations – mixed venous (MV), pulmonary venous (PV), pulmonary arterial (PA), and systemic arterial (SA) saturations. Because there is potential sampling error, several different sources of saturations (i.e., right and left pulmonary arteries) are used for each data point. Saturations can estimate left to right shunts which manifest as a step up in saturations from the mixed venous to the pulmonary arterial bed and right to left shunts which cause a drop in saturations from the pulmonary veins to the systemic circulation. The pulmonary to systemic flow ratio (Qp:Qs) is helpful for many congenital defects and can be quickly calculated during the case using the following formula: Qp:Qs = [(systemic arterial saturation – mixed venous saturation)/(pulmonary vein saturation – pulmonary arterial saturation)].

Pressure measurements are obtained in all chambers of the right and/or left heart, in the

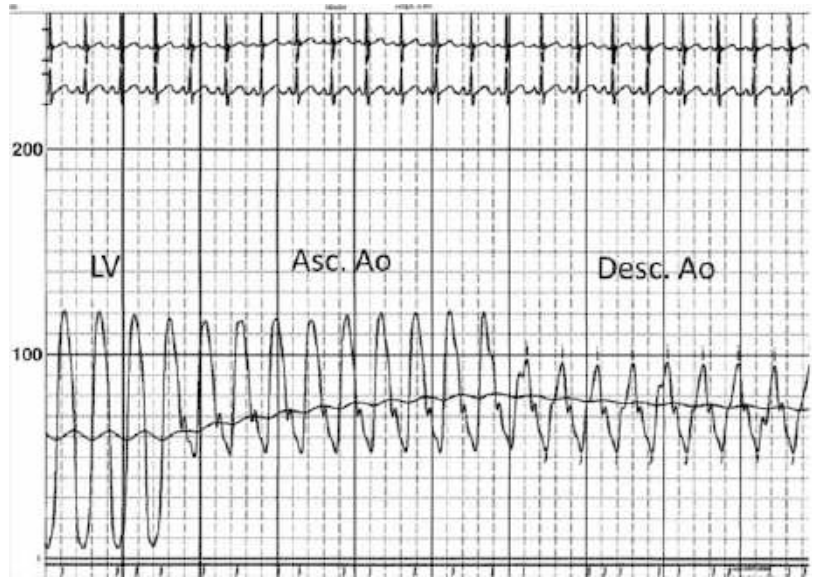

Fig. 40.3 A pressure tracing is obtained as a catheter is withdrawn from the left ventricle to the descending aorta in a child with coarctation of the aorta. The initial tracing is a ventricular waveform with a peak pressure of 120 mmHg. As the catheter crosses the aortic valve, the waveform changes to a more typical aortic trace with a higher diastolic pressure. As the catheter is withdrawn to the descending aorta, there is a 20–25 mmHg drop in pressure identifying a discrete coarctation of the aorta

branch pulmonary arteries, and when necessary, across the aorta. Pulmonary capillary wedge pressures are used to estimate left atrial pressures when there is no intra-atrial communication. Pressure data provides a wealth of information that can be used to determine severity of stenosis, filling pressures, and pulmonary arterial pressures. Pressure data should always be interpreted in the context of the patient's overall condition. For example, with decreased cardiac output, an aortic stenosis or coarctation gradient may be significantly less than when myocardial function is unaffected and cardiac output is normal (Fig. 40.3).

Calculations are used to estimate flows and resistance. Flow calculations rely on a simple principle: if the concentration of a substance is known before and after a vascular bed and the rate of addition or subtraction of that substance is known, then flow can be calculated. The two most common methods are (1) the Fick principle which uses oxygen content as the concentrate and oxygen delivery (VO_2) as the estimate of oxygen addition/extraction [12] and (2) thermodilution which measures the change in temperature associated with injection of cold saline. Resistances (pulmonary vascular resistance and systemic vascular resistance) can be calculated using a derivation of Ohms law: resistance = change in pressure/flow [11].

Fick calculation for determination of flows and resistance

Cardiac output (Qs) (L/min/m^2)	$\frac{VO_2}{(Hb)(Ao\text{-}MV\ sat)(13.6)}$
Pulmonary blood flow (Qp) (L/min/m^2)	$\frac{VO_2}{(Hb)(PV\text{-}PA\ sat)(13.6)}$
Qp:Qs	$\frac{(Ao\ sat - MV\ sat)}{(PV\ sat - PA\ sat)}$
Pulmonary vascular resistance (WU × m^2)	$\frac{Mean\ PA\ pressure - mean\ PCWP}{Qp}$
Systemic vascular resistance (WU × m^2)	$\frac{Mean\ Ao\ pressure - mean\ RA\ pressure}{Qs}$

[a]Calculations assume a fractional inspired O_2 content of $\leq$0.21. If breathing a higher inspired O_2 content, then this should be accounted for in the denominator for flow concentrations by adding 0.0032 × P_{O2}; VO_2 = oxygen consumption (ml/min/m^2), Hb (mg/dL); saturations measured as fractional saturation (i.e., 0.96 for a saturation of 96 %); 13.6 is a constant derived from the O_2 content/g Hb (1.36 mL O_2/g of Hb) and multiplied by 10 to convert Hb from g/dL to g/L. WU (Wood units).

Interventions

Percutaneous intervention has now surpassed diagnostic catheterization as the more common reason for referral for catheterization. Each intervention has the potential to alter hemodynamics and carries unique risks. The purpose of the following section is to provide a broad overview of

the most commonly performed percutaneous pediatric interventions and associated hemodynamic and safety considerations.

Valvuloplasty

Transcatheter valvuloplasty is most commonly performed for aortic or pulmonic stenosis and more rarely for mitral or tricuspid stenosis [13–16]. Decisions to proceed for catheterization are typically based on echocardiographic Doppler gradients and clinical criteria such as symptoms, ventricular hypertrophy, or myocardial dysfunction [17]. Class I indications for intervention, according to American Heart Association guidelines, include a peak systolic catheterization gradient $\geq$40 mmHg for valvar pulmonary stenosis and $\geq$50 mmHg for valvar aortic stenosis. However, lower gradients are used when there are associated morbidities including exertional symptoms, ventricular hypertrophy, or ventricular dysfunction [17]. The most severe scenario is critical aortic or pulmonic stenosis in the newborn where systemic or pulmonary blood flow is dependent on a patent ductus arteriosus. Valvuloplasty involves rapid inflation of a low-pressure balloon ($<$1 atm). Balloon inflation is not intended to dilate the valve annulus but rather to tear the valve leaflets, which are often partially fused. The tear ideally occurs along the fused commissure but is largely uncontrolled, and an excessive or poorly positioned tear will cause valve incompetence. Because excess motion of the balloon across the valve can cause shear-related valve injury, proceduralists often use rapid ventricular pacing or adenosine [18, 19]. These maneuvers are used to stabilize the balloon during inflation by transiently lowering cardiac output. Balloon inflation obstructs all antegrade blood flow, and the anesthesia providers should anticipate a drop in cardiac output and blood pressure. These effects may be less significant if some cardiac output or pulmonary blood flow is maintained via a ductus arteriosus, or in the case of pulmonary valvuloplasty, via an atrial septal defect. While balloon valvuloplasty typically improves obstruction, there is the noted risk of creating valvar insufficiency. Severe aortic insufficiency can cause acute hemodynamic instability. Insufficiency may be better tolerated in patients with more significant or long-standing stenosis because the hypertrophied ventricle is less compliant. Therefore, patients with more moderate stenosis may actually be at higher risk with acute aortic insufficiency. Pulmonic insufficiency is better tolerated acutely than aortic insufficiency. However, for pulmonary valvuloplasty, there is risk of the "suicide right ventricle" where relief of valvar obstruction unmasks dynamic subvalvar obstruction. This can be prevented or treated with volume infusion and/or beta blockade.

Defect Occlusion

Devices and sometimes coils are now routinely used to close atrial septal defects (ASDs), persistent ductus arteriosus (PDAs) (Fig. 40.4), collateral vessels, and some ventricular septal defects (VSDs) [20–24]. Indications for closure are determined by the degree of shunt – generally estimated based on the degree of right (ASD) or left (PDA, VSD) heart dilation by echocardiogram [17]. For the PDA, most cardiologists also recommend closure if the ductus is audible as there is believed to be a risk of endocarditis [17]. Devices for these defects have evolved with some of the more currently used devices demonstrated in Fig. 40.5. Most devices are delivered with a release mechanism, so positioning can be adjusted before final release. These devices often require larger and longer delivery sheaths, which must be exchanged during the case. This can be painful and should be anticipated with increased analgesia and anesthetic depth. The sheath may need to be placed in the left heart which risks air introduction and embolism, a particular concern during spontaneous respiration which can create negative intra-atrial pressures and "suck" air into the larger delivery sheath. Wire- or device-related cardiac or vessel trauma or perforation can also complicate delivery, particularly when vigorous manipulation is necessary to ensure positioning. Finally, after

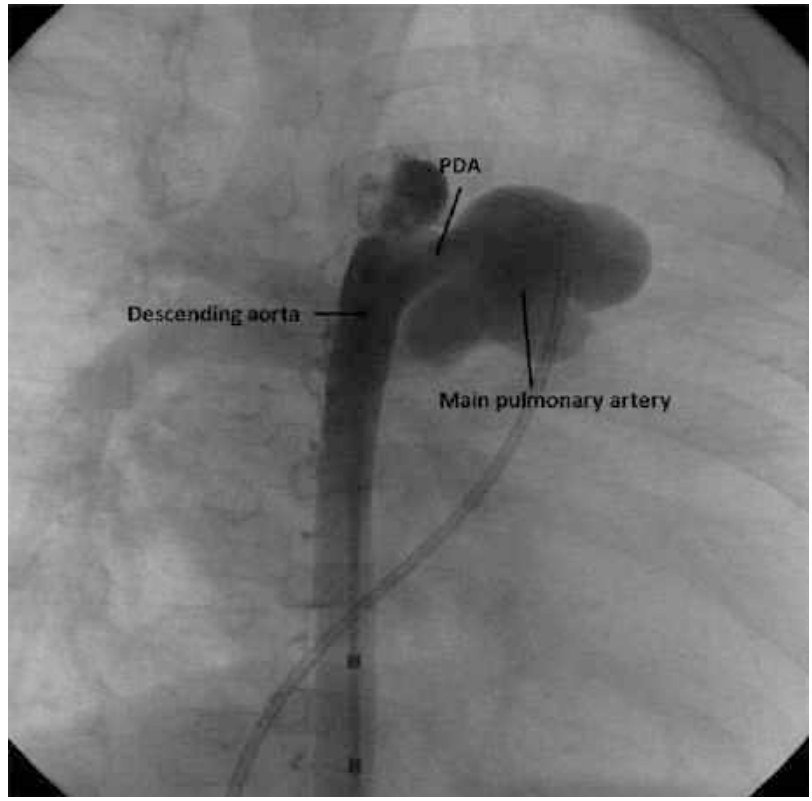

Fig. 40.4 An AP angiogram in the descending aorta demonstrates a large, tubular patent ductus arteriosus with left to right shunt and fill of the pulmonary arteries

device release, there is always a risk that the device is unstable and becomes dislodged. In this scenario, percutaneous device retrieval may be necessary although there are times when surgical retrieval is the only feasible solution.

Angioplasty and Stent Placement

Angioplasty and stent placement are most commonly used in the pulmonary arteries but are also options for systemic venous, pulmonary venous, or systemic arterial (i.e., coarctation) stenosis [25–33]. Angioplasty is most effective when an intimal tear is created, which can sometimes require high pressure (up to 20 atm). Cutting balloons are specially designed angioplasty balloons with tiny blades embedded in the balloon [34]. These balloons actually score the intima to create a more controlled tear. Because of the intimal tear, angioplasty can be painful. It is helpful to anticipate this stimulus and ensure adequate sedation and analgesia. The most significant risk with angioplasty is for vascular dissection, perforation, or aneurysm. These complications can result in acute decompensation and might require emergent chest tube placement and percutaneous intervention (i.e., covered stent or coil embolization) to control the bleed. Stents are used when angioplasty is ineffective. Stents usually require larger and longer delivery sheaths as well as precise positioning. The painful stimulation and precision required for placement might necessitate deepening of sedation or redosing of a muscle relaxant as it is imperative that the patient does not move. Stent placement risks vessel rupture or stent malposition in which case the stent may need to be deployed in an alternate location since the partially deployed stent can no longer be retrieved into a sheath. A vessel tear may lead to life-threatening hemoptysis or hemothorax and difficulty in securing the airway in a sedation case. Following the angioplasty or stent placement, the anesthesia

team should in addition monitor for a worsening respiratory function caused by a lung reperfusion syndrome as a result of the high flow and high pressure now seen by the pulmonary vascular bed. Diuretics and possible continued post-procedure ventilation may be required.

Transcatheter Valve Implantation

Recently, valves have been mounted within a stent framework and can be delivered via a percutaneous approach [35]. In the USA, the Melody® valve (Medtronic Inc., Minneapolis, MN) is approved under a humanitarian device exemption to treat stenosis or insufficiency of a right ventricular outflow tract conduit [36] (Fig. 40.6). These valves require large delivery sheaths (22 French), and procedures can be long and complicated, particularly when other pulmonary arterial interventions are necessary. The wires used for valve delivery are stiff, and there is some risk of distal pulmonary arterial perforation. The conduit is often thickly calcified and must be dilated to an adequate size before valve placement. This may cause conduit dissection although this is often a contained dissection. Finally, coronary anatomy should be assessed before valve implantation as the conduit may sit in close proximity to the coronaries, and compression is well described during stent placement in the right ventricular outflow tract. Because of the large size of the delivery sheath and the complexity of the procedure, it is prudent to admit these patients to a high care setting for overnight observation.

Post Heart Transplant Surveillance and Endomyocardial Biopsies

Endomyocardial biopsies (EMB) are still the standard of care in the management of post

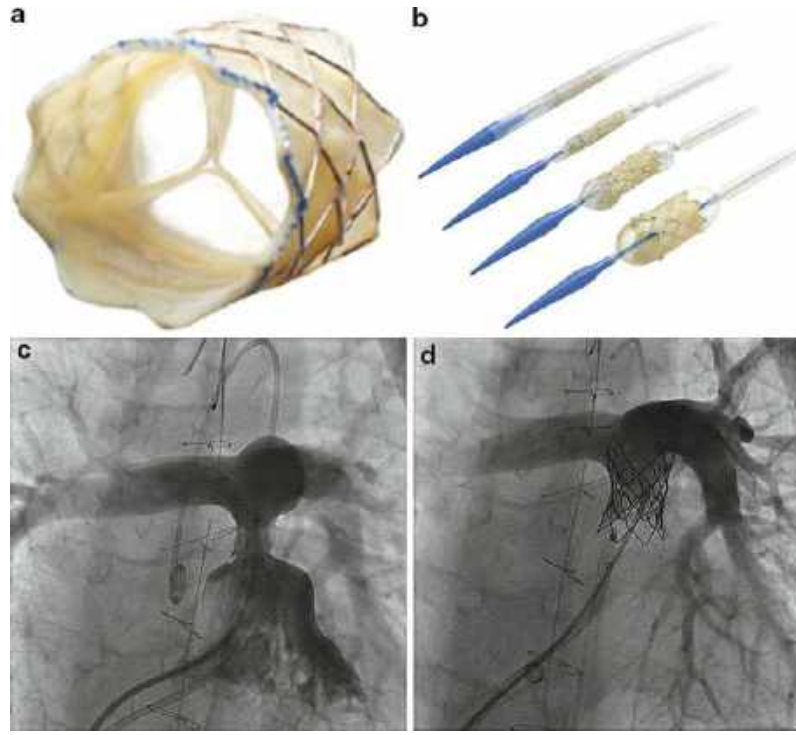

Fig. 40.6 (**a**) The Melody® valve (printed with permission Medtronic, Minneapolis, MN) is approved under a humanitarian device exemption for treatment of insufficiency or stenosis of a right ventricular outflow tract conduit. (**b**) The valve is seen crimped on a balloon and then in various states of expansion. (**c**) An AP angiogram in the main pulmonary artery demonstrates reflux of contrast back to the right ventricle consistent with severe pulmonary insufficiency. (**d**) After Melody® valve implantation, there is no longer any pulmonic insufficiency

heart transplant patients, and some institutions use EMB in the evaluation of myocarditis and cardiomyopathy. On average, although this is program-dependent, a patient may have 6 EMBs in the first 6 months following a transplant and then 3 times in the next 6 months and then for the following year, roughly every 2–3 months. The frequency decreases overtime but is often required at least once a year from then on. Patients either come for right-sided hemodynamics and biopsies or a full surveillance catheterization with right and left heart hemodynamics, EMB, and coronary artery angiograms. The prior is a relatively quick procedure that might only last for 30 min and can easily be done with sedation in the older child or a general anesthetic with a laryngeal mask (LMA). This procedure is often performed through the right internal jugular vein, and the patient is able to sit up soon after the procedure. The second, encompassing right and left heart catheterization and coronary angiography, will take longer. In most of these extended catheterizations, it is common practice to place an ET tube and provide general anesthetic in all but the most motivated teenagers. Sterility and standard clean practices should be enforced in these immune compromised patients. Furthermore due to the denervated heart, direct-acting agents like epinephrine should be used to treat bradycardias and hypotension and indirect agents like atropine and ephedrine should be avoided.

In addition to the standard precautions, the anesthesia team should anticipate the three major potential complications from these procedures: pericardial tamponade, tricuspid valve damage, and coronary artery spasm or damage.

Pericardiocentesis

Pericardiocentesis may be performed as a diagnostic or therapeutic procedure. It is often performed with the patient in the semi sitting position with a needle through a subxyphoid approach using local anesthetic. The anesthesia team should manage this patient in the standard fashion of volume loading, keeping the patients breathing spontaneously with incremental doses

of midazolam and ketamine [37]. It is important to avoid neuromuscular blockade and positive pressure ventilation as this may lead to cardiovascular collapse.

Electrophysiological Studies/ Transcatheter Ablation

Transcatheter radiofrequency ablation (RFA) is an evolving technique that is used to treat aberrant conduction pathways. The technique is used for a variety of children: from the newborn infant with congenital persistent reentrant tachycardia to surgically corrected or palliated adolescents with persistent volume and pressure overload in the right atrium or extensive suture lines, causing supraventricular tachycardias (SVT).

SVT has an incidence of 1 in 250–1,000 children. Presentation later in life is associated with increased recurrence [38]. Left-sided pathways have better cure rates than right-sided pathways [39]. Defined aberrant pathways such as AV reentrant tachycardia or AV nodal reentrant tachycardia or atrial ectopic tachycardia should be relatively quick procedures, requiring a single ablation. However, many pathways are left sided which further complicates matters by necessitating transseptal puncture for mapping and ablation purposes. Mapping of scar-based lesions require three-dimensional mapping and often require multiple ablation burns to destroy the aberrant pathway.

Placement of electrical monitors, a defibrillator, and surface electrodes are required. Typically, four electrode catheters are placed transcutaneously in the femoral and internal jugular vessels. Catheters inferior to the heart are positioned in the right atrial appendage, His-bundle area, and right ventricular apex, and the superior catheter is placed in the coronary sinus to record electrical activity from the left AV groove.

The pattern of EKG recordings during normal sinus rhythm, tachycardia, and during arrhythmia (if inducible) is used to definitively diagnose the aberrant mechanism. A separate ablation catheter is then manipulated into position to deliver radiofrequency energy (300–750 kHz) to the cardiac tissue causing a localized burn. If the position of the catheter is correct, the burn should obliterate the pathway in a few seconds. Radiofrequency ablation remains the first-line therapy for AV node reentry tachycardia but amongst potential complications, discussed below, is damage to the AV node. This risk is greater in smaller children because the distance between the AV node and the reentry pathway is smaller. To this end, cryotherapy is preferred by some. The "burn" is created more slowly, permitting the procedure to be stopped if there are signs of AV node damage, so-called cryomapping in which the cardiologists looks for transient AV block or lengthening of the PR interval by >50 % [40]. Also the catheter, when freezing, actually sticks to the atrial wall and so cannot migrate or drift causing unwanted damage. The disadvantage of cryoablation is that the catheters tend to be much large (because the catheter must carry coolant, normally nitrous oxide, within the catheter) and less malleable making positioning difficult especially in small children. It is also reported to have a lower efficiency and higher recurrence rate when compared to RFA [40, 41].

Over-pacing or isoproterenol infusions are typically used to induce a tachycardia and so expose the aberrant pathway. However, hypotension will be associated with this, and although typically short lived, the insertion of an arterial line or another method to assess perfusion should be considered. Potential complications include complete heart block (transient or permanent), femoral artery spasm, brachial plexus injuries, retroperitoneal hematoma, cardiac perforation and tamponade, systemic emboli, and rarely AV valve damage that may require urgent surgical repair. Ablations in the anterior and mid-septum regions appear to have a higher incidence of AV block, when compared to non-septal pathways. There is greater risk for children under the age of 4 years, weighing less than 15 kg, and if the electrophysiologist is relatively inexperienced [42, 43].

The demands then of the procedure are that of time and immobility. The patient is required to lie still for many hours, and the close proximity of

the AV node for some reentrant pathways requires precise catheter positioning. Movement, be it patient initiated or that of breathing, is best avoided. Although it is possible in older children (>10 years old) to perform the procedure either with no or light sedation [44, 45], general anesthesia with neuromuscular blockade is typically preferred. The downside is that the aberrant pathway is often most active when the patient is awake. These tachycardias are catecholamine sensitive and so are often diminished after induction of anesthesia. Bispectral index (BIS) monitoring can be used, not to prevent awareness, but uniquely to maintain a lighter level of anesthesia. The use of BIS as an awareness monitor has been extensively studied yet remains controversial [46–48]. It should be remembered that BIS can be erroneously altered by drugs routinely used during an EPS/RFA. Isoproterenol causes an elevated BIS, as do ketamine, ephedrine, and physostigmine [49].

Anesthesia: Generally, when presented with a patient with a potential arrhythmogenic lesion, such as Wolff-Parkinson-White syndrome, the anesthetic goal is to prevent the occurrence of a supraventricular tachycardia. In the EP laboratory, however, the specific goal is not to alter the normal and aberrant electrophysiological conduction, either attenuating or damping the lesion in question. It is imperative that the cardiologist is able to easily elicit the tachydysrhythmia, and therefore the anesthetic should be carefully considered.

Standard anesthetic preoperative assessment should be performed including discontinuing antiarrhythmic drugs at least five half lives before the procedure [40]. Patients should be counseled to the fact that, while under anesthesia, it may be necessary to "awaken" them to a lighter level of anesthesia and that awareness may result. Many congenital heart defects are associated with the potential for dysrhythmias particularly in volume and pressure overload conditions. It maybe that the anesthetic must be tailored to that specific lesion, but the effect of the anesthetic on the conduction pathway must also be considered. Early reports suggested that volatile anesthetic agents like enflurane affected the AV node and conduction pathways (either aberrant or normal) in varying degrees [50]. More recent data suggest that more modern inhalationals such as isoflurane and sevoflurane have no significant effects on cardiac conduction in children with SVT and so are useful in EPS protocols [51, 52]. A recent study on the efficacy of desflurane found no data suggesting the drug obscured conduction or altered interpretation by the cardiologist of the underlying tachydysrhythmia [53]. However, there may be an increased frequency of postoperative nausea and vomiting in patients receiving inhalational anesthesia particularly in association with nitrous oxide [54]. Apart from the distress PONV brings to the recovering patient, coughing or straining is best avoided for fear of bleeding from the femoral access sites. To this end, intravenous anesthesia with propofol has become the mainstay of anesthesia for EPS and RFA at many institutions and has demonstrated a reduced incidence of PONV over isoflurane and nitrous anesthesia [52]. Animal and human data have shown that propofol will neither facilitate nor prevent atrial reentrant tachycardias [55, 56], although there are some reports of propofol associated bradycardia and suppression of atrial dysrhythmias [57, 58]. Human data on other available intravenous anesthetics are surprisingly scant. Animal data would suggest that ketamine would promote a dysrhythmic state and therefore is ideal in an EP study. Conversely, thiopental may prevent the initiation of atrial reentrant tachycardias. Finally, dexmedetomidine, an alpha adrenergic agonist that has an increased utilization in all anesthesia and sedation specialties, would not be an ideal adjunct to anesthesia for RFA. Sinus node function has been found to be significantly affected as evidenced by an increase in sinus cycle length and sinus node recovery time [59]. The use of dexmedetomidine is best reserved for the end of the study when the ideal recovery scenario is that of a sedated and quiescent patient, immobile and lying still to avoid recurrent bleeding from access sites. Opioids are used sparingly because the procedure is not particularly stimulating or painful. In addition, the enhanced vagal tone associated with the use of opioids, such as fentanyl, can hinder the

identification of the aberrant pathway by delaying the recovery time of the sinus node [60]. For similar reasons, remifentanil, an ultrashort-acting opioid often used in total intravenous anesthesia, is also not ideal for RFA or electrophysiological studies. Animal data demonstrate depression of the SA and AV nodes, increasing the likelihood of bradycardia [55, 61].

In summary, the ideal anesthetic in an otherwise normal heart would be that of total intravenous anesthesia with propofol, with or without ketamine, minimal opioid usage, and dexmedetomidine in the post-procedural period.

Hybrid Stage I Palliation

The hybrid stage one procedure was introduced initially as a strategy for neonates with hypoplastic left heart variants in an attempt to avoid cardiopulmonary bypass and delay the Norwood procedure until these fragile neonates are older in the hope that avoiding this major surgery in the neonatal period would lead to improved neurologic and cardiac function [62, 63]. Initially performed on the highest risk children or used as a bridge to transplant, it has more recently become the procedure of choice at some centers. In essence, the intervention creates what is achieved during a Norwood procedure: an unobstructed systemic cardiac output using a stent in the ductus arteriosus and a controlled pulmonary blood flow using bilateral pulmonary artery banding. If there is a restricted atrial septum, a transcatheter septostomy (or potentially stent) is performed. The aortic arch reconstruction and bidirectional cavopulmonary connection are then performed around 4–5 months of age [62]. The procedure requires a large room to accommodate the surgical and catheterization staff with the appropriate operating room infection control standards and fluoroscopy equipment. In general, the surgeon will do a sternotomy and band the pulmonary arteries prior to the cardiologist placing the ductus arteriosus stent through a sheath often inserted directly into the pulmonary artery. The atrial septostomy/stent is performed last if at all through the right atrial wall. In centers that perform these procedures frequently, the patients may even extubate at the end of the intervention [62].

Complications

In a recent multicenter registry assessment, Martin et al. [64] documented major adverse events (need for surgery, arrhythmia requiring pacing, cardiac arrest or 30-day mortality) in 3 % of all pediatric catheterization procedures including 25 % of all procedures involving neonates (<1mo) and 7 % of all procedures in infants (<1 year) [64]. It is clear from Bergersen et al. [65–67] that the younger (<1 y/o), sicker, cyanotic patients with low cardiac output states and interventional procedures are at the greatest risk. Therefore, it is paramount that the anesthesiologist be ready to deal with complications during the procedure. Intervention-specific complications were discussed earlier. This section will focus more broadly on some of the complications associated with cardiac catheterization, and it should be stressed that the providers should focus on anticipating the complication rather than reacting to a sudden crisis [68].

Arrhythmia

Rhythm abnormalities of all sorts can be seen in the cardiac catheterization laboratory. Risk should be anticipated based on prior history. Supraventricular tachycardias can be induced by wire or catheter manipulation. Sometimes, the tachycardia can be easily aborted with a catheter-stimulated PAC. Otherwise, adenosine or cardioversion may be needed. First-, second-, and even third-degree heart block are sometimes seen, particularly when a stiff wire or long sheath is being manipulated across the right ventricular outflow tract. If the heart block is quickly recognized, the wire or sheath positioning can be adjusted and the block usually resolves. If heart block persists, then temporary pacing can be delivered via a transvenous pacing catheter.

Ventricular arrhythmias are the most feared rhythm derangement and may be more common in certain patient populations. For example, in a patient with repaired tetralogy of Fallot and pulmonary insufficiency or stenosis, there may be a history of QRS prolongation or ventricular tachycardia. These higher risk patients might benefit from pre-procedural placement of defibrillator pads. Catheter-induced mild bradycardias may initially be treated with atropine, but if not self-resolving or if clinically significant, epinephrine and cardiopulmonary resuscitation may be required.

Embolism

Systemic or pulmonary thromboembolism can be a devastating complication of cardiac catheterization. Particular caution is necessary when there is a left to right communication or when left heart catheterization is being performed. Most interventionalists anticoagulate with heparin whenever left heart catheterization is being performed and for most interventions, with the activated clotting times maintained above 200 for the duration of the procedure. Air is another source of embolism and is a greater risk with larger sheaths or with spontaneous respiration when negative intra-atrial pressure can create a vacuum effect. If a significant air embolism is suspected or is seen on fluoroscopy, the anesthesia providers should administer 100 % oxygen and provide other supportive care like epinephrine if needed. If the air has collected in nondependent areas of the heart, the cardiologist can attempt to aspirate the air with catheters.

Vascular Complications

Vascular injury can occur at any time or in any vessel or structure of the heart and can range from superficial vessel injury (i.e., intimal staining with power injections) to vessel dissection or perforation. Vascular trauma can also occur at the access site resulting in post-procedural diminished pulses (arterial spasm or occlusion) or swelling (venous occlusion). A heparin infusion is often initiated if there is concern for vessel occlusion that is refractory to simple maneuvers such as loosening of the pressure dressing. An arteriovenous fistula can also complicate vascular access and is usually detected post procedure as a thrill overlying the region of access. Subcutaneous hematoma is sometimes seen in the recovery period and usually manifests as pain and discoloration that develops hours to days after the procedure is completed. To minimize risk of rebleeding and other vascular complications, it is critical for the anesthesia team to have a smooth extubation and a calm sedated child in the postoperative period.

Blood Loss

In addition to the obvious bleeding that occurs with major vessel injuries, there is also an often underestimated blood loss that occurs from frequent blood sampling and leakage from around the sheaths, catheters, and access ports. This blood loss can be masked by the dark environment, drapes, and various shields used to protect against the radiation. Blood loss can also occur in body compartments such as the pericardial sack or even into the retroperitoneal space [69]. As previously mentioned, it is advisable that the IV access the anesthesia team uses should be in the upper arms to facilitate resuscitation.

Cardiac Perforation

Cardiac perforation can be caused by almost any procedure done in the CCL: wire manipulation, atrial septostomies, EMBs, valvuloplasties, and electrophysiological studies especially with left-sided pathways that require transseptal puncture [66, 68]. While not all perforations lead to clinically significant tamponade, a high index of suspicion should be maintained if the patient becomes unexpectedly hypotensive. If a tamponade is suspected, contrast may be seen in the pericardial sack on fluoroscopy, or there may be acute change in the cardiac silhouette.

An echocardiography exam should be done, and if a tamponade is confirmed, then pericardiocentesis should be performed and a pigtail catheter left in place. Notify the cardiac surgeon in the event a surgical repair is needed, and consider ordering additional blood products, including clotting factors if there is massive bleeding. In certain circumstance, when the ongoing bleeding is significant, the aspirated blood may be given back to the patient as an autologous transfusion. It has been suggested that the blood first be washed with a cell salvage system to decrease the risk of embolism and decrease the concentration of inflammatory mediators [70]. While the majority of the cardiac tamponades are self-limiting, some will require surgical closure [71].

Pulmonary Edema

Pulmonary edema can occur from excessive fluid administration, in balloon dilations of the atrial septum when all flow from the left atrium is obstructed, dilation of pulmonary veins, and also post-balloon or post-stent placements in the pulmonary arteries. In the latter, the sudden increase in blood flow and pressure may lead to fluid extravasation. These patients may require an ICU admission and post intervention mechanical ventilation with peep and diuretics prior to being able to be extubated [72, 73].

Contrast Effects

Adverse reactions to contrast agents may be anaphylactoid and related to the total dose administered. This reaction may be life threatening and has a higher incidence in atopic patients and patients with allergies to other medications. It appears from recent literature that patients with iodine and shellfish allergies are not at more risk of an allergic reaction to contrast than any other patient with a history of medication allergies [74]. Contrast-induced nephropathy remains a concern in patients with preexisting renal dysfunction, dehydration, and a high dose of contrast [75]. While there is no clear data in children to support specific preventative measure, the general practice is to keep the total dose of contrast to below 6–10 ml/kg. In adult studies, they have found that sodium bicarbonate-containing solutions and N-acetylcysteine are protective [76–78].

Peripheral Nerve Injury

In an attempt to improve the image and decrease the amount of radiation, you are required to get the arms out of the fluoroscopy field. A brachial plexus injury may occur from prolonged overextension and or abduction of the arms above the head, with an even greater risk in low cardiac output states. The arms should be rotated as little as possible outward and as minimally extended at the shoulder as possible. Minimize the time that the arms need to be placed in extreme positions to facilitate unique camera angles and document your positioning and requests from the cardiologist on the anesthesia record.

Radiation Safety

Radiation exposure is increasingly recognized as an important concern for children undergoing cardiac catheterization [79]. Radiation can result in localized injury to tissues such as skin, hair, eyes, and bone. These effects are deterministic meaning that a large number of cells must be affected and injury is not seen until a certain threshold dose is crossed. Radiation can also result in systemic effects such as cancer induction. These effects are stochastic, meaning that only a single cell need be affected to induce the cancer and there is no threshold safety level. For both deterministic and stochastic effects, limiting radiation dose will decrease risk [80]. While newer technology has allowed adequate imaging quality at lower frame rates, children remain at increased risk. They have a longer lifespan to experience the potential harmful effects of radiation, and repeat catheterizations are more common because of improved survival for many complex heart defects. Furthermore,

the increasing complexity of interventions has resulted in longer procedures. For these reasons, the ALARA (as low as reasonably achievable) concept should be an important part of the catheterization team's approach [79]. Centers have demonstrated significant reduction in radiation dose exposure by implementing strategies that remind the team to limit radiation exposure. These strategies are simple to implement such as warning the interventionalist when certain threshold levels are approaching. Other strategies to decrease exposure include (1) using of lower frame rates and less cineangiography – cineangiograms deliver radiation rates approximately 15 times per frame higher than fluoroscopy [81], (2) keeping the image intensifier as close to the patient as possible, (3) keeping arms out of the image (i.e., arms up) as they do not need to be radiated and the added tissue density will trigger Automatic Exposure Control (AEC) and increase radiation, and (4) using collimators to limit volume of tissue exposed and to decrease scatter [79]. It is also important for the anesthesia team to limit personal radiation exposure. Radiation exposure is reduced by fourfold for every doubling of distance from the x-ray tube; therefore, distance from the x-ray tube is the best defense. By convention, the x-ray tubes are positioned behind the patient and to the patient's right, but when these tubes are rotated for different angiographic incidences, they may be placed in closer proximity to the anesthesia team. Finally, it should be mandatory to use radiation shields and to ensure that lead is fitted appropriately and checked frequently for defects (which are often not visible externally). In addition, any worker in a radiation environment should wear a dosimeter to monitor the cumulative radiation exposure, and these should be worn on the outside of any shielding garment.

Magnetic Resonance Imaging (MRI)

Echocardiography has long been the mainstay of noninvasive diagnostic imaging in children with congenital heart disease (CHD) with computerized tomography and cardiac catheterization as adjuncts. Magnetic resonance imaging offers an entirely different and unique modality in diagnosis and assessment of congenital heart disease. Unlike the brain or other solid organs, the heart is a dynamic structure, and MRI can be used to examine it in terms of flow, volume, and function. A major advantage of MRI is the ability to assess the volume and mass of asymmetrical ventricular shapes, especially the right ventricle, which is not well evaluated with echocardiography [82]. Cardiac MRI is also very reproducible.

Simply, an MRI machine creates a magnetic field that aligns protons in the nucleus of hydrogen molecules in the tissues. It then incorporates radiofrequency (RF) pulses to systemically alter the alignment of this magnetic field. The relative movement of the atomic nuclei is captured by the scanner, and two- or three-dimensional images can be created. Recent developments in electrocardiographic-gated MRI has permitted image acquisition to be triggered by the patients ECG, avoiding motion artifacts and allowing cine sequencing of cardiac structures. Magnetic resonance angiography can be used to determine blood flow, chamber volumes, and cardiac outputs. There are two units used to describe the magnet strength, tesla and gauss (one tesla equals 10,000 G). Most medical MRI machines are now 3.0 T strength, but cardiac MRI machines tend to be smaller (1.5 T) because the stronger magnets can magnify flow artifacts and so reduce image clarity. The advantage of a lower magnet strength is increased safety for indwelling metallic objects such as artificial valves or stents.

In addition, the anesthesiologist has a role in safety. Equipment must be MRI compatible, and monitoring is often limited. Direct patient observation is not always possible, and the airway is not immediately accessible. The American Society of Anesthesiologists recently published a practice advisory on anesthetic care for MRI [83]. The task force stated that all anesthesiologists should have general safety education on the unique physical environment of the MRI scanner and that they should collaborate with the radiologist and MRI staff to develop safety-training programs.

In general, children under 8 years of age require general anesthesia. In addition, image quality for cine, angiography and delayed enhancement imaging, is assured by breath holding, which therefore requires endotracheal intubation and neuromuscular blockade. A breath hold may last as long as a minute, and so it is recommended to pre-oxygenate prior to an end-expiration breath hold. One hundred percent oxygen can be continued to promote apneic oxygenation. However, some centers do promote free breathing [84].

Neonates and infants represent a unique age-related risk in the MRI scanner. Negative changes in vital signs have been numerously reported [85–87]. In addition, patients with renal failure are at risk of nephrogenic systemic fibrosis following gadolinium administration [83]. Overall, anesthesia has been reported as safe [88, 89] despite some considerable challenges. Most metallic surgical implants, such as sternal wires, surgical clips, and interventional devices, do not present a danger in a 1.5 T magnet, and image disturbance is minimal. There is no recommended minimum time interval between surgery and MRI, although it is recommended to wait 6 weeks after implantation of a device that could be dislodged (endovascular and intracardiac devices) before exposing the patient to the MRI [90]. The ASA task force stated that pacemakers or implanted cardioverter defibrillators are generally contraindicated for MRI due to issues such as pacing artifacts, reed switch closure, generator movement or displacement, pacing changes, and temperature increases [83]. However, in a recent prospective nonrandomized study, it was demonstrated that with appropriate precautions, MRI can be performed safely in patients with selected cardiac devices. The authors concluded that because changes in device variables and programming may occur, electrophysiological monitoring during MRI is essential [91]. Intravenous access must be appropriate for the intended study. Injection of contrast medications (typically gadolinium) requires a large bore IV preferably in the antecubital fossa, in preference to the hand. Also more than one IV access point may be required to prevent bolusing of concomitant drugs. Adenosine used in the MRI stress test for assessment of perfusion is administered as an infusion for several minutes before the rapid injection of contrast material. An inadvertent bolus dose of adenosine will cause predictable rhythm disturbance but has also been associated with bronchospasm in known asthmatics [92]. Equally, dobutamine is used in the MRI stress test to increase contractility and so review function and potential wall motion abnormalities. Additional IV access should be placed for the dobutamine infusion. As for airway management, consequent to the need for breath holding, tracheal intubation is typically desirable over laryngeal airway devices. It is physically awkward but possible to perform laryngoscopy on the MRI table, bearing in mind only MRI-compatible devices are used. However, the difficult airway must be handled differently. The ideal MRI suite should include an induction room where complex airway management (e.g., fiber-optic intubation) can be safely performed without fear of magnetic interference. Furthermore, the care provider must remember that the airway is not accessible with the patient in the scanner, and management of emergent scenarios, such as laryngospasm, should be planned for.

Anesthesia Equipment for the MRI: The practice advisory published by the ASA states that MRI patients should be monitored in a manner consistent with the ASA Standards for basic anesthetic monitoring. However, the report noted that the anesthesia provider must ensure the monitor is MRI compatible and that the monitoring may be limited. For example, electrocardiograms are notoriously limited due to superimposed voltages from blood flow in the magnetic field, and even though temperature is a critical issue in MRI, no reliable tool for monitoring temperature is currently available for clinical use. Cabling must be ideally fiber optic, which will decrease the risk of cable burns. Increasingly wireless monitoring devices are being utilized, emphasizing the remoteness of the patient to the anesthesiologist. Even an MRI-compatible anesthesia machine requires an extended breathing circuit which results in

additional weight and drag, dead space, and increased compressible circuit volume, which can affect ventilation, particularly in small infants. Capnography and respiratory gas analysis is necessary, but again, long sampling lines result in delayed data capture. In addition to the above, pipeline medical gases, appropriate scavenging, and suction along with adequate electrical outlets and lighting must be available. Alarms must be visible alarms (over audible) because of the ambient noise and the need for care providers to wear ear protection. Total intravenous anesthesia is a popular choice of anesthesia for many reasons. Scavenging of exhaust gases is often not possible, and breath holding for multiple sequences will interrupt an inhalational anesthetic. Traditionally, this has been performed with ultra long infusion lines passed through and out of the immediate MRI arena to a non-MRI-compatible infusion device. Some infusion devices are not only MRI incompatible, but programming is adversely affected by the magnet. At the time of writing this chapter, there are only two FDA-approved infusion devices currently available in the United States, for example, Medrad and MRidium.

Finally, the anesthesiologist should be aware of the concept of "quenching," the rapid, almost explosive, boil-off of liquid helium (coolant), due to a system fault or as a deliberate action to shutdown the magnetic field, which can create an hypoxic environment, for example, in the advent of a fire. However, it is a potentially lethal hazard due to asphyxiation in oxygen-deficient atmospheres. Oxygen sensors should be located in the scanning room and relayed to the control room, and anesthesia providers working in MR should be familiar with the emergency procedures in the event of a quench being necessary. The Association of Anaesthetists of Great Britain and Ireland Guidelines last updated their guidelines in May of 2002 (http://www.aagbi.org/pdf/mri.pdf.). The authors did not recommend that the anesthesia provider remain in the scan room during the MRI procedure. Not only because of the risk of hypoxia during a quenching but also because of the unknown effects of prolonged exposure to magnetic fields. The effects on the unborn fetus are, for example, unknown. The 2007 guidelines from the Department of Health in the UK recommend that pregnant staff do not remain in the scan room while scanning is underway due to concerns of acoustic noise exposure and other risks, such as heat exposure, to the fetus [93]. Finally, an MRI scan is a relatively time-consuming procedure in areas that are typically isolated and distant sites. Transport of critically ill patients becomes an issue of risk benefit. Children from the intensive care suite are at a notable increase risk not only in the scanner itself [94] but during intra-hospital transport. The typically remote location of the MRI facilities will also result in a delayed response of emergency teams and equipment availability.

Conclusion

As discussed throughout this chapter, modern-day pediatric CCL perform complex and invasive procedures on critically ill patients. An engaged and educated anesthesia team is a vital part to the successful outcome of these procedures.

Anesthetic Considerations for Children with Congenital Heart Disease Undergoing Non-cardiac Surgery

41

Lawrence I. Schwartz, Richard J. Ing, and Mark D. Twite

Abstract

Children with congenital heart disease are at increased risk for adverse events during noncardiac surgery. It is essential that the anesthesiologists caring for these children have a comprehensive understanding of the underlying physiology and the impact this has on the delivery of anesthesia. Specific problems such as pulmonary hypertension, cyanosis, heart failure, pacemakers, and endocarditis prophylaxis are reviewed in this chapter. Specific anesthetic considerations for patients who have palliated single ventricle physiology or have received a heart transplant are also discussed.

Keywords

Anesthesia • Arrhythmias • Bacterial endocarditis prophylaxis • Cyanosis • Fontan palliation • Heart failure • Heart transplant • Noncardiac surgery • Pulmonary hypertension • Single ventricle anatomy

Introduction

Congenital heart disease (CHD) has an incidence of 1 in 125 live births, and it is estimated that 30 % of these children will require noncardiac surgery with anesthesia during the first year of life [1]. Examples of procedures where anesthesia may be required are cardiac catheterization, radiological imaging including cardiac MRI, peripherally inserted central line placement, and general surgical procedures. Despite these additional operative hurdles, it is currently estimated that 90 % of these children will survive to adulthood [1, 2].

Children with congenital and acquired heart disease are at an increased risk of cardiac arrest and death while undergoing noncardiac surgery. Single ventricle lesions are the most common congenital heart defects in patients who have a cardiac arrest during noncardiac surgery [3–6]. In children with complex CHD, intraoperative hemodynamic instability during noncardiac surgery is independently associated with single ventricle lesion prior to stage 2 palliation, patients

undergoing more invasive procedures, and those patients receiving preoperative inotropes, angiotensin-converting enzyme (ACE) inhibitors, or digoxin [6]. Other factors increasing the risk of cardiac arrest include younger age, noncardiac surgical emergencies, and unrepaired congenital heart lesions [7]. The underlying mechanisms leading to cardiac arrest in children with CHD having noncardiac surgery are most likely related to an acute deterioration in myocardial function as a consequence of poor myocardial oxygen delivery or primary myocardial disease [8]. The risk of cardiac arrest in patients with CHD undergoing cardiac surgery is even higher than the same group undergoing noncardiac surgery, but there is no increase in mortality. This suggests that a dedicated team of pediatric cardiac anesthesiologists working together with other congenital cardiac specialists in a specialist center may best look after patients with complex CHD [9].

Noncardiac surgeons may be unfamiliar with the pathophysiology of complex CHD. It is essential therefore that the anesthesiologist understands the pathophysiology of the cardiac disease, conducts a careful preoperative evaluation, fully prepares for the case including the possibility of cardiac arrest, and adopts an appropriate balanced anesthetic technique [10]. This chapter discusses specific risks in patients with CHD undergoing noncardiac surgery.

Pulmonary Hypertension

Pulmonary hypertension is defined as a mean pulmonary artery pressure (mPAP) of greater than 25 mmHg at rest and a pulmonary vascular resistance index (PVRI) of greater than 3 Wood units meter squared [11]. Children with pulmonary hypertension will require cardiac catheterization to establish hemodynamic measurements, rule out associated disease states such as pulmonary vein stenosis, and to test vasoreactivity of the pulmonary vascular bed to short-acting drugs such as inhaled nitric oxide (iNO). Additional cardiac catheterizations will then be necessary to monitor the response to therapy. Children with pulmonary hypertension are at significantly increased risk for perioperative cardiac arrest for both noncardiac surgery and during cardiac catheterization [12, 13]. Children with suprasystemic pulmonary hypertension have the greatest perioperative risk for a pulmonary hypertensive crisis and cardiac arrest. The first event in a pulmonary hypertensive crisis is an acute increase in pulmonary vascular resistance (PVR). The trigger for this may be a noxious stimulus, hypoxia, or an elevation in arterial carbon dioxide levels from hypoventilation. This acute rise in PVR causes right ventricular pressure overload and an increase in wall stress. This leads to poor coronary perfusion and right ventricular ischemia which may then worsen right ventricular function and cause a shift of the interventricular septum and subsequent decrease of left ventricular preload. This ventricular interdependence in turn leads to a decrease in aortic root pressure and a fall in coronary perfusion pressure and eventually biventricular failure [14]. The immediate treatment of a pulmonary hypertensive crisis includes administering 100 % oxygen and moderate hyperventilation to decrease alveolar carbon dioxide levels, both of which will decrease PVR [15]. Ventilation should be optimized in such a way as to avoid alveolar overdistension, which will increase arterial pressure in the lungs but maintain adequate positive end-expiratory pressure to prevent alveolar collapse. Any metabolic acidosis should be promptly corrected, as PVR is directly proportional to blood pH. Pulmonary vasodilators should be administered such as iNO. Cardiac output (CO) should be supported as necessary with phenylephrine and volume to maintain coronary perfusion pressure. Finally, it is important to ensure that patients receive adequate analgesia with fentanyl to blunt any sympathetic mediated increase in PVR.

Cyanosis

Chronic cyanosis may affect every organ system in the body primarily via two mechanisms: hyperviscosity and dysfunction of the endothelium. The first response of the body to hypoxia is an increase in erythropoietin levels with

a subsequent increase in the number of circulating red blood cells. This is an attempt to deliver more oxygen to the tissues without increasing cardiac output. However, as blood viscosity rises, blood flow through the microcirculation becomes impaired. When hematocrit levels exceed 65 % the high blood viscosity may actually decrease oxygen delivery to the tissues. The management of hyperviscosity in adults with cyanotic congenital heart disease is controversial, but limited data suggests that phlebotomy may be beneficial to reduce the symptoms of hyperviscosity such as headache, dizziness, and fatigue [16]. However, the resulting iron deficiency results in microcytic erythrocytes that are less deformable for passage through the microcirculation and may further increase the risk for veno-occlusive events. It is essential therefore to avoid prolonged fasting in cyanotic children who should receive clear fluids up to two hours prior to surgery or have intravenous fluids started preoperatively.

Patients with chronic cyanosis and associated polycythemia develop coagulation abnormalities that make them more prone to bleeding. This increased bleeding tendency is attributed to various hemostatic defects including thrombocytopenia, shortened platelet lifetime, suppressed platelet aggregation due to platelets which have already been activated as well as platelet microparticles, and deficiency of clotting factors such as von Willebrand factor [17, 18]. Hyperviscosity directly affects the vascular endothelium due to increased shear stress which results in nitric oxide and prostacyclin release which may modify the balance between vasodilators and vasoconstrictors and affect systemic endothelial function [19]. Dysfunction of the endothelium is central to the pathogenesis of many conditions, including hypertension and cardiac failure [20].

Chronic hypoxia also affects myocardial gene expression, upregulating genes associated with apoptosis and remodeling, and downregulating genes associated with myocardium contractility and function [21]. This reprogramming of the cyanotic myocardium may be responsible for the increased susceptibility of cyanotic children to ischemia and reoxygenation injury during CPB repair of the congenital heart defect.

It is important to remember that end-tidal carbon dioxide monitoring underestimates arterial blood carbon dioxide levels in cyanotic children and that these children have a decreased respiratory drive response to hypoxia [22]. This blunted hypoxic response in conjunction with opiate medication may result in profound hypoxia. Careful postoperative monitoring is therefore essential.

Heart Failure

Heart failure is characterized by decreased cardiac output (CO) and increased systemic or pulmonary venous pressures resulting from ongoing increased pressure or volume load on the heart, or chronic hypoxemia and decreased oxygen supply. Patients with heart failure present with tachypnea, tachycardia, poor perfusion, feeding difficulties, failure to thrive, and pulmonary and/or systemic venous congestion. Cellular damage and myocyte death lead to further progression of the disease. While heart failure in children is rare, it is common in children with CHD. Up to 20 % of patients with repaired congenital heart disease experience congestive heart failure [23]. CHD is the primary cause of heart failure during infancy, while cardiomyopathies and arrhythmias are more likely to cause heart failure in older children [24].

The pathophysiologic process of heart failure starts with myocyte injury due to congenital myopathy or underlying structural disease. This initial injury results in a reduction in CO, which then leads to two major compensatory mechanisms. The first is an increase in catecholamine secretion in an attempt to increase contractility and increase systemic vascular resistance. The second mechanism is an increase in the activity of the renin-aldosterone-angiotensin system leading to water retention and increased preload. While these responses are the body's attempt to improve cardiovascular stability, they ultimately promote worsening of heart failure. Enhanced catecholamine leads to further myocyte injury, dysfunctional intracellular signaling in response to beta-adrenergic stimulation, and ultimately myocyte death. The elevation of both aldosterone

and angiotensin II promotes cardiac fibrosis and apoptosis [24]. At the organ level, changes in cardiac wall stress lead to a mismatch of myocardial oxygen delivery and consumption. In some patients, alterations to cardiac geometry lead to atrioventricular valve insufficiency, placing an additional volume load on the heart.

Pediatric patients with heart failure often present for diagnostic testing and surgical interventions. Providing safe anesthesia to these patients is challenging and complex. Pediatric patients with heart disease are at an increased risk of adverse outcomes and cardiac arrest associated with anesthesia [4, 9, 25]. Patients with heart failure are at even greater risk [26]. Careful preparation and an understanding of the cardiovascular state of the patient are vital to achieving the best possible anesthetic outcome.

Preoperative Considerations

The preoperative evaluation must start with a detailed history, which should include an assessment of the patient's current clinical state relative to his/her baseline. Exercise tolerance, feeding history, and growth patterns will provide a picture of the patient's cardiovascular status. Prior anesthesia history, medications, ECG, imaging studies, and laboratory values should be reviewed. Direct communication between the anesthesiologist and the patient's cardiologist is often very helpful. The cardiologist can provide insight into the patient's severity of illness including recent changes in cardiovascular status. The anesthesiologist will have detailed knowledge of the planned procedure and its anesthetic requirements. This preoperative conversation can prove invaluable in selecting the most appropriate procedure and anesthetic for the patient [24]. When evaluating patients with heart failure for anesthesia, concerns arise from both the heart failure and its treatment. Diuretic therapy, ACE inhibition, and beta-blockade are all mainstays of outpatient heart failure management. The effects of these drugs coupled with preoperative fasting can lead to significant intravascular hypovolemia. In the setting of myocardial disease, even patients presenting with a normal exam and vital signs may experience acute hypotension and a large decrease in preload and CO following induction with venodilating anesthetic agents [24]. Inpatients with heart failure are often critically ill and are at an even greater risk of adverse events from anesthesia. Patients may be intubated and receiving mechanical ventilator support in an attempt to decrease metabolic demand. They are often maintained on continuous intravenous inotropic agents, such as milrinone, epinephrine, dobutamine, and dopamine. These medications place patients at risk for arrhythmia and decrease the ability to escalate support in the face of further cardiovascular deterioration. Additionally, critically ill patients may require mechanical circulatory support in order to overcome an acute exacerbation or "bridge" the patient to heart transplantation.

Anesthetic Considerations

When providing anesthesia for children with heart failure, it is essential to avoid any exacerbation of low cardiac output (CO) and maintain adequate systemic perfusion. Ventricular end-diastolic and atrial pressures are commonly elevated, and CO is sensitive to the adequacy of atrial and ventricular filling [27]. Although cardiac work may be reduced and CO improved by reducing systemic vascular resistance, subendocardial perfusion and contractility may be compromised if coronary perfusion is reduced [27]. Cardiopulmonary interactions associated with elevated left atrial pressure are complex but important to consider when caring for heart failure patients. As a general rule, positive pressure ventilation will reduce the cardiac transmural pressure gradient and decrease myocardial work. The decrease in cardiac work better balances myocardial oxygen supply and demand and improves CO.

Patients with heart failure are at significant risk because inducing the necessary level of anesthesia requires medications that may cause the hemodynamic changes that should be avoided. Changes in hemodynamic status due to the effects of anesthetic agents are likely to be poorly

tolerated and can cause a spiraling drop in CO leading to cardiac arrest. However, inadequate anesthetic depth is also dangerous because an increase in sympathetic tone can increase systemic vascular resistance and worsen heart failure [27]. The overall goal is to provide a balanced anesthetic with an appropriate level of anesthesia while minimizing the cardiovascular depressant effects of the anesthetic drugs.

Induction and maintenance of anesthesia poses a significant risk to CHD patients suffering from heart failure. Many of the intravenous and inhaled anesthetic agents can lead to hypotension, reduced myocardial perfusion, and further depression of myocardial contractility. Many of the intravenous and inhaled anesthetic agents can lead to hypotension which may result in reduced myocardial perfusion and further depression of myocardial contractility. A balanced anesthetic technique, with the careful titration of anesthetic drugs, will help maintain cardiovascular stability. Despite the best preparation and careful administration of anesthesia, children with heart failure are at risk for circulatory collapse and cardiac arrest. The anesthesia provider who elects to care for this very challenging patient population must be prepared to provide aggressive cardiopulmonary resuscitation. Medication and equipment must be readily available for resuscitation, as should additional personnel. Inotropic infusions should be easily available, but prophylactic initiation of these infusions is generally not indicated. Patients with end-stage heart failure may decompensate to the point of requiring mechanical circulatory support. Institutions caring for these children should have a successful ECMO program in place, and anesthesia providers should be knowledgeable of how to activate their program and participate in bringing these patients on to mechanical circulatory support.

Arrhythmias and Pacemakers

Patients with CHD are more likely to have a cardiac rhythm disturbance requiring implantation of a pacemaker and/or internal cardioverter/defibrillator (ICD). The indications for permanent pacemaker placement include (1) advanced second- or third-degree AV block associated with symptomatic bradycardia, heart failure, or low CO; (2) symptomatic sinus node dysfunction; (3) postoperative advanced second- or third-degree AV block that is not expected to resolve or persist at least 7 days after cardiac surgery; (4) congenital third-degree AV block with a wide QRS escape rhythm or ventricular dysfunction; and (5) congenital third-degree AV block with bradycardia [28].

The most common congenital heart lesions associated with the need for a pacemaker are repaired tetralogy of Fallot, transposition of the great arteries, single ventricle lesions post-Fontan completion, congenital conduction disorders, and surgeries involving the interventricular septum [29].

Patients with implanted cardiac devices present for a myriad of surgical interventions. Prior to induction, the preoperative evaluation should include gathering information on the type and manufacturer of the device, the functional capability, and the patient's dependency on the device [30].

Once the procedure has begun, electromagnetic interference (EMI) with radiofrequency waves of 50–60 Hz can disrupt the function of the pacemaker/ICD. Sources of EMI include electrocautery, therapeutic radiation, transthoracic defibrillation, radiofrequency ablation, shock wave lithotripsy, MRI, nerve stimulators, muscle fasciculation, shivering, and large tidal volume ventilation [31, 32]. Implanted cardiac devices which are affected by EMI may cause inappropriate triggering or overpacing, inhibition of pacemaker triggering, asynchronous pacing, an inappropriate shock from an ICD, electrical discharge to the myocardium, and arrhythmias and patient burns.

While technological advances, such as bipolar leads, insulation, and noise protection programming, have made modern devices less susceptible to EMI, adverse events have not been eliminated. Using bipolar diathermy can reduce the risk of patient injury further. The cutting mode creates less EMI than coagulation. It is advisable to use short, intermittent, irregular bursts of diathermy.

The diathermy pad should be grounded, with excellent skin contact, and maximize the distance from the implanted device. It is always recommended that electrical current should not cross the implanted device. The American Society of Anesthesiologists recommends that if there is significant risk of EMI in a pacer-dependent patient, the device should be reprogrammed to asynchronous pacing. ICDs should be turned off, and external-defibrillating pads placed on the patient. Standard monitors should be used [30]. Alternative means of temporary pacing should also be readily available.

Magnets are made primarily for device interrogation, not for emergency use. However, placing a magnet over a pacemaker will switch the mode to asynchronous pacing. The manufacturer of the device determines the default rate, which may not be high enough to provide appropriate CO for a given patient. The magnet may also decrease the function of the pacemaker with a waning battery life. When applied to an ICD, the magnet will turn off the anti-tachycardia function and will not alter the pacemaker settings [29]. Best anesthesia practice is to have the pacemaker interrogated prior to surgery with the necessary adjustments made in consultation with the cardiologist.

The three most common causes of pacemaker failure are lead failure, generator failure, and a failure to capture. Preoperative interrogation should detect the first two causes [29]. While commonly used anesthetic drugs are not believed to directly affect pacemaker function, the result of anesthesia can do so. Hyperkalemia, acidosis, alkalosis, hypothermia, hyperglycemia, hypovolemia, bleeding and transfusions, hypoxemia, and myocardial ischemia can all affect lead thresholds and cause failure of the pacemaker to capture [31].

Finally, the anesthesia provider must maintain vigilance throughout the perioperative period. Reprogramming a device preoperatively does not guarantee protection from damage during the procedure. The implanted cardiac device must be reinterrogated and programmed as necessary in the immediate postoperative period. Patients should receive appropriate observation and monitoring in order to assure proper device function.

Preexisting Medications

Patients with CHD, whether unrepaired or repaired, are often managed with one or more medications, which are not routinely used in children without heart disease (Table 41.1). These drugs are used to decrease preload, augment contractility, decrease afterload, prevent thrombosis, and control heart rate and rhythm. An understanding of these drugs, their effects, and their interactions with anesthesia is necessary in order to formulate and deliver a safe and effective anesthetic. If changes are needed to the patient's medical regimen, they should be discussed and reviewed with the patient's cardiologist.

Endocarditis Prophylaxis

Infective endocarditis (IE) although rare is a potentially devastating condition. However, with the decline in rheumatic heart disease and improved outcomes, congenital heart disease (CHD) has become the leading risk factor in pediatric IE [33].

The pathophysiology of IE in CHD patients is multifactorial but dependent on valvular or mural endocardial damage and bacteremia. The pathway includes endothelial injury, which promotes platelet and fibrin deposition leading to nonbacterial thrombotic endocarditis. A transient bacteremia provides the source for bacterial adherence and proliferation within the vegetation. Patients with cyanotic heart disease and those with shunts and foreign materials implanted provide the milieu for this process to occur. Patients with CHD associated endocarditis carry a high risk of thromboemboli including stroke, long-term antibiotic therapy, additional surgery, as well as death.

Prevention of endocarditis from surgical procedures has been a high priority for decades, and the American Heart Association (AHA) has

Table 41.1 Commonly prescribed medications, their actions and anesthetic considerations in children with congenital heart disease

Drug	Mechanism of action	Impact of anesthesia
Diuretics		
Furosemide	Na^+-K^+ cotransport inhibition at the loop of Henle	Hypovolemia, electrolyte imbalance
Hydrochlorothiazide	Na^+-Cl^- transport inhibition at distal convoluted tubule	Hypovolemia, electrolyte imbalance
Spironolactone	K^+-sparing, inhibit aldosterone	Hyperkalemia
Digoxin	Cardiac glycoside, inotropic agent, inhibits Na^+-K^+ ATPase to increase intracellular Ca	Digoxin toxicity: vomiting, CNS changes, bradycardia, cardiac dysrhythmia
Anticoagulant		
Aspirin	Irreversibly inhibit platelet function	Increased bleeding risk, GI hemorrhage
Warfarin	Inhibit vitamin K-dependent synthesis of clotting factors	Increased internal and surgical bleeding risk
Vasodilators		
Captopril, enalapril	Angiotensin-converting enzyme (ACE) inhibition	Reduce SVR and BP, neutropenia, proteinuria, rash
Amlodipine	Smooth muscle relaxation	Profound decrease SVR, decrease contractility, slow cardiac conduction
Beta-blockers Propranolol, atenolol, metoprolol, carvedilol	Beta-adrenergic receptor blockade used to control abnormal rhythms and decrease myocardial work	Decrease HR and contractility, bronchospasm
Pulmonary hypertension medications		
Sildenafil	PDE-5 inhibition	Pulmonary vasodilation
Bosentan	Inhibits endothelin-1 binding	Anemia, hepatic dysfunction
Epoprostenol	Prostacyclin derivative	Continuous IV med, very short half-life, disruption can be life threatening

been making recommendations since 1955. Prior to 2007, the recommendations for antibiotic prophylaxis were based on expert opinion, but little evidence. In 2007, the AHA published revised guidelines for the prevention of infective endocarditis. There are several rationales for the current revision. First, infective endocarditis is an uncommon but life-threatening disease, and prevention is preferable to treatment. Second, certain underlying cardiac conditions predispose to IE. Third, bacteremia with organisms known to cause IE commonly occurs in certain invasive procedures. Fourth, antimicrobial prophylaxis was proven to be effective in animal experiments. Finally, there is no clear evidence that antibiotic prophylaxis prevents infective endocarditis associated with dental, respiratory tract, gastrointestinal, or genitourinary surgery [34]. It is thought that transient bacteremia is much more likely to occur during routine activities of daily living, such as tooth brushing, than during invasive procedures and that optimal oral hygiene may be more important than antibiotic therapy. In addition, the exceedingly few cases of IE that may be prevented by antibiotic prophylaxis are outweighed by the risk of adverse drug reactions and the development of highly drug-resistant organisms [34] (Table 41.2). The current guidelines have restricted the routine use of antibiotic prophylaxis to invasive dental procedures in patients who have both a high risk of developing infective endocarditis and the most risk of devastating outcomes (Table 41.3). The most common organisms causing infective endocarditis are Streptococcus and Staphylococcus species.

Table 41.2 This table outlines the cardiac population in which it remains currently recommended to treat with antibiotic prophylaxis. Except for the conditions listed, antibiotic prophylaxis is no longer recommended for any other form of CHD

Cardiac conditions associated with the highest risk of adverse outcome from endocarditis for which prophylaxis during dental procedures is recommended
Prosthetic cardiac valve or prosthetic material used for cardiac valve repair
Previous infective endocarditis
CHD
Unrepaired cyanotic CHD, including palliative shunts and conduits
Completely repaired CHD with prosthetic material or device, whether placed by surgery or catheter intervention, during the first 6 months after procedure
Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or device
Cardiac transplantation recipients who develop cardiac valvulopathy

Adapted from Wilson et al. [33]

Table 41.3 Recommended antibiotic regimens for dental procedures from the 2007 AHA guidelines.

Regimens for dental procedures		Single dose 30–60 min prior to procedure	
Situation	Agent	Adult dose	Pediatric dose
Oral	Amoxicillin	2 g po	50 mg/kg po
Unable to take oral medications	Ampicillin	2 g IM/IV	50 mg/kg IM/IV
	or		
	Cefazolin or ceftriaxone	1 g IM/IV	50 mg/kg IM/IV
Allergic to penicillin or ampicillin	Cephalexin[a]	2 g po	50 mg/kg po
	or		
	Clindamycin	600 mg po	20 mg/kg po
	or		
	Azithromycin or clarithromycin	500 mg po	15 mg/kg po
Allergic to penicillin or ampicillin and Unable to take oral medication	Cefazolin or ceftriaxone	1 g IM/IV	50 mg/kg IM/IV
	or Clindamycin	600 mg IM/IV	20 mg/kg IM/IV

IM intramuscular, *IV* intravenous
[a]Cephalosporins should not be used in an individual with a history of anaphylaxis, angioedema, or urticaria with penicillins or ampicillin

Antibiotic prophylaxis is thus focused on those bacteria. No published data has linked respiratory tract procedures with infective endocarditis. Therefore antibiotic prophylaxis is recommended only in patients who are having a respiratory tract procedure in which the respiratory tract mucosa is violated, such as tonsillectomy and adenoidectomy. Antibiotic prophylaxis is not appropriate for bronchoscopy, unless the airway mucosa is incised [34]. The administration of prophylactic antibiotics solely to prevent endocarditis is no longer recommended for patients who undergo genitourinary or gastrointestinal tract procedures, including diagnostic endoscopy and cystoscopy. If there are surgical indications for antibiotic use, it is reasonable to include drugs that will also cover for endocarditis [34].

Recent studies in the United States and Europe reveal that the despite the new guidelines and decrease use of prophylactic antibiotics, there has been no increase in the incidence of endocarditis in the general population or in patients with CHD [35, 36]. Future recommendations for the

prevention of endocarditis will be based on the continued gathering and analysis of data.

Single Ventricle Patients

Patients with single ventricle anatomy (SVA) undergo multiple-staged cardiac surgeries and by definition are palliated to a Fontan circulation. The surgeries are often referred to by the names of the surgeons who first popularized the specific operation: stage I (Norwood), stage II (Glenn), and stage III (Fontan) [37–39]. Each palliative stage creates a unique circulatory physiology associated with specific anesthetic challenges.

Stage I Norwood palliative surgery is completed soon after birth creating a stable source of pulmonary and systemic blood flow. **Stage II** palliative surgery comprises a bidirectional cavopulmonary anastomosis or modified Glenn operation, which is completed at 4–8 months of age [37]. This surgery connects the superior vena cava (SVC) to the pulmonary arteries. The operation prevents volume overloading of the systemic ventricle. The aortopulmonary shunt (classic Norwood) or the RV-PA conduit (Sano variation) is taken down, thus removing systemic forces from the pulmonary vasculature and reducing the risk of pulmonary hypertension. **Stage III**, the final palliative surgery, is the total cavopulmonary anastomosis, commonly referred to as a modified Fontan procedure. The procedure, usually completed at 2–3 years of age, comprises an anastomosis of the inferior vena cava (IVC) to the pulmonary arteries with or without an atrial fenestration. This third operation fully separates the pulmonary and systemic circulations into a series circuit leaving a single systemic ventricle without a dedicated ventricular chamber to pump blood directly to the lungs. The pulmonary blood flow is considered passive because no ventricle pumps blood to the lungs. The circuit depends on the residual kinetic energy in the venous system, after the blood has initially traversed through the systemic circulation, in order to maintain pulmonary blood flow [40].

For the anesthesiologist, it is important to ascertain where the child is in the progression of the three-staged palliative surgeries before anesthesia is embarked upon for noncardiac surgery [41]. Each surgical procedure creates a distinct form of cardiovascular physiology. Patients may benefit from being cared for in centers experienced with complex CHD. Appropriate monitoring is essential to delivering a safe anesthetic. Standard EKG, blood pressure cuff, pulse oximetry, gas analyzer, and capnography are mandatory. It may be necessary to place an indwelling arterial catheter under local anesthesia prior to induction of anesthesia in older children with poor myocardial reserve. However, in young children, most arterial cannulas are inserted after the induction of anesthesia. Transesophageal echocardiography may be helpful to guide therapy when there is hypotension and poor myocardial function under general anesthesia [42, 43].

Stage I Anesthetic Considerations

Children with single ventricle lesions who have undergone stage I but not stage II palliation are at increased risk of cardiac arrest during anesthesia for noncardiac surgery. Patients with hypoplastic left heart syndrome (HLHS) are considered to have the highest risk for noncardiac surgery [44]. After noncardiac surgery, 18 % of stage I palliated HLHS patients are reported to require intensive care unit admission, have a postoperative complication rate of 50 %, and a mortality rate of 19 % [41, 45, 46]. This highlights the need for experienced cardiac anesthesia providers to provide anesthesia for noncardiac surgery in single ventricle patients in established cardiac centers. In the authors' institution, all patients with HLHS and a stage I Norwood palliation undergoing noncardiac surgery are admitted to the intensive care unit for recovery or postoperative management.

Approximately 48 % of children with HLHS develop dysphagia and 9–26 % have gastroesophageal reflux disease (GERD) [47]. Furthermore, 3–45 % of these children have been found to have laryngopharyngeal dysfunction [48]. These complications increase mortality and

morbidity and contribute to failure to thrive [49]. The unique physiology of the Norwood procedure, particularly in those patients palliated with a Sano shunt, causes diminished splanchnic blood flow after meals. This renders the bowel at risk for ischemia [50–52]. Anesthesiologists are often called to assist with aerodigestive work-ups including a rigid and flexible bronchoscopy and upper gastrointestinal endoscopy. Gastrointestinal surgery following the Norwood procedure often consists of placing a gastrostomy tube and laparoscopic Nissen fundoplication [6, 45, 53, 54].

The anesthetic challenges of caring for the patient with a single ventricle lesion for noncardiac surgery include maintaining intraoperative CO and, at the same time, balancing the pulmonary and systemic blood flow. These patients have prolonged hospital admissions and multiple intravenous access attempts invariably result in difficult peripheral intravenous access, further exacerbated by dehydration due to preoperative fasting and the use of diuretics. The anesthesiologist should always be prepared for intraoperative acute patient collapse. Rarely, this may be due to systemic-to-pulmonary artery shunt occlusion, which may require emergent intervention in the cardiac catheterization laboratory and/or placement on ECMO [55].

Stage II Anesthetic Considerations

Following the cavopulmonary anastomosis, all superior vena cava blood returning to the lungs has first to traverse the cerebral blood vessels. To ensure adequate oxygenation, the anesthesiologist should not decrease cerebral blood flow by causing hypocapnia and should maintain adequate pulmonary blood flow by ensuring that the PVR remains low. Hypercarbia and acidemia should not be allowed to develop as both increase the PVR. High ventilation pressures causing increased distension of the alveoli should also be avoided as this will limit alveolar blood flow. In the common atrium, the mixing of oxygenated blood returning from the pulmonary veins and deoxygenated blood returning from the IVC, results in peripherally measured oxygen saturations around 80-85%. Stage II Glenn cavopulmonary anastomosis patients have been shown to tolerate anesthesia better than stage I Norwood patients as evidenced by a decreased complication rate and less intensive care admissions [41].

Stage III Anesthetic Considerations

Following the total cavopulmonary anastomosis or Fontan completion, single ventricle patients are typically no longer cyanosed since all venous return passes through the lungs. There may be a 5–10 % deoxygenated portion of blood that bypasses the lungs through the atrial fenestration, but this helps ensure a good ventricular preload and maintains CO. Fontan patients generally do well with noncardiac anesthesia [41]. The anesthetic management principal for Fontan physiology depends on ensuring an adequate transpulmonary pressure gradient [56]. If SVC or IVC obstruction occurs, pulmonary blood flow will be limited. If the pulmonary venous pressure is high because of a high LVEDP, AV valve stenosis or regurgitation, or loss of sinus rhythm occurs, the pressure gradient decreases and there will be poor forward blood flow through the lungs. Low CO associated with hypotension and hypoxia quickly ensues. Spontaneous ventilation augments passive pulmonary blood flow and is preferred for the Fontan patient as long as hypercarbia does not develop [41]. If intubation and ventilation are required, then ventilation with peak airway pressures below 20 cm H_2O and mean airway pressures less than 10 cm H_2O, with a long expiratory time, optimize passive pulmonary blood flow. An adequate preload is required and SVR should be maintained to optimize coronary perfusion. These patients are at risk for perioperative thrombosis due to low flow and venous stasis of blood. Preoperatively, it is important to check if anticoagulants are part of the medical regimen as this could preclude the use of neuraxial analgesia because of the increased risk of hematoma.

By late childhood or adolescence, many single ventricle patients with a Fontan circulation may have developed cardiac complications including valve stenosis, valve regurgitation, aortic arch stenosis, arrhythmias, or ventricular dysfunction. Systemic complications associated with the Fontan circulation include congestive hepatopathy, the development of pulmonary venous and arterial collaterals, protein-losing enteropathy, plastic bronchitis, coagulopathy, and thromboembolic disease [57]. These complications occur in 11 % of children from 1 to 25 years of age and are time related. They generally present after 8 years following completion of the Fontan [58]. Plastic bronchitis, a diagnosis often requiring urgent bronchoscopy, is a challenge for the anesthesiologist because of the Fontan circulation, and it is often associated with decreased myocardial function. Conservative treatment strategies, such as inhaled and oral corticosteroids, bronchodilators, mucolytics, antibiotics, inhaled tissue plasminogen activator, and heparin, have often failed when the Fontan patient presents for urgent bronchoscopy to remove bronchial casts [59, 60].

Frequently, children with single ventricle palliation will require a period of recovery in a cardiac intensive care unit following noncardiac surgery. Many patients have comorbidities such as hypertension, seizure disorder, renal or hepatic insufficiency, hematologic abnormalities, and respiratory disease, which require management by multiple providers.

Heart Transplant Patients

The first "successful" pediatric heart transplant was in 1967 in an 18-day-old baby who survived 6 h [61]. Today, the average survival is 18 years for infants, 15 years for school aged children, and 11 years for teenagers [61]. With improvements in perioperative and postoperative care, particularly in immunosuppressive therapy, patients receiving heart transplants are surviving longer. Pediatric patients often survive into adulthood, and they may present for a myriad of noncardiac surgeries requiring anesthesia. Understanding the physiology of the transplanted heart and its complications is paramount to delivering a safe and effective anesthetic.

Table 41.4 Physiology of the transplanted heart

Elevated filling pressures
Low normal left ventricular ejection fraction
Restrictive physiology
Increased afterload
Afferent denervation
Silent ischemia
Altered cardiac baro- and mechanoreceptors
Efferent denervation
Resting tachycardia
Impaired chronotropic response to stress
Electrophysiology
Sinus node dysfunction
Abnormal AV node conduction
Shift from B1 to B2 receptors

Adapted from Schure et al. [60]

The transplanted heart is a denervated organ and, therefore, does not respond to neuronal reflexes the way a normal heart will. An elevated resting heart rate reflects the loss of vagal tone, and drugs such as atropine and glycopyrrolate may not have their usual effect. The transplanted heart will offer a blunted response to physiologic stress. It is dependent on an intact Frank-Starling mechanism in order to increase stroke volume in response to preload and stimulation for endogenous circulating neurohormones. The denervated heart will remain responsive to direct-acting sympathomimetic agents such as epinephrine, norepinephrine, and dobutamine, but it will be unresponsive to indirect-acting agents such as dopamine and ephedrine. There are case reports of profound bradycardia and cardiac arrest following administration of neostigmine [61] (Table 41.4).

The prevention and management of rejection are a primary goal of posttransplant medical treatment. Approximately one-third of children experience at least one episode of acute rejection during the first year following heart transplant [36]. The incidence begins to decline after 3 years, reaching 12 % between 5 and 10 years [61]. Recipient CD4 T-cells recognize foreign

Table 41.5 Medications prescribed, mechanism of action, and anesthetic considerations in patients with a transplanted heart

Immunosuppressive agents	Mechanism of action	Adverse effects
Calcineurin inhibitors	Inhibit transcription and production of IL-2	Hypertension, renal dysfunction, neurotoxicity, diabetes, hyperlipidemia, posttransplant lymphoproliferative disease (PTLD)
Cyclosporine, tacrolimus (FK506)		
Antiproliferative agents	Inhibit T-cell and B-cell proliferation	Bone marrow suppression, nephrotoxicity
Azathioprine, MMF		
Corticosteroids	Nonspecific anti-inflammatory	Growth and glucose metabolism
Mono-/polyclonal antibodies	Depletion of T-cell line	Infection, PTLD
OKT3/ATG		
IL-2 inhibitors	IL-2 receptor antibodies	
Basiliximab, daclizumab		
Target of rapamycin protein inhibitors	Immunosuppressive and antiproliferative. Work synergistically with calcineurin inhibitors	Hyperlipidemia, wound healing, proteinuria
Sirolimus		

antigen in the donor heart, triggering T-cell activation, interleukin-2 secretion, and activation of monocytes/macrophages, B-cells, and cytotoxic CD8 cell. Prevention and ongoing suppression of these processes are the fundamental concept governing immunosuppressive therapy [61]. Several classes of drugs, including broad-spectrum anti-inflammatory drugs, are available to help achieve this goal. While the use of these drugs has allowed for improved survival, they also produce their own set of challenges (Table 41.5).

Patients suffering from rejection may present with symptoms and signs of heart failure including poor feeding, failure to thrive, dyspnea, and fatigue. They may also exhibit dysrhythmias and nonspecific signs such as fever. The diagnosis is made on clinical signs, echocardiographic evidence of ventricular dysfunction, and endomyocardial biopsy [61]. Knowledge of a patient's rejection status and ventricular function is essential prior to induction of anesthesia.

Cardiac allograft vasculopathy is a leading late cause of death after heart transplant [62]. At 10 years, 34 % of children have CAV, with the onset influenced by age at transplantation [61]. Freedom from CAV posttransplant is higher in infants and younger children than in adolescents [61]. The diagnosis is made in the catheterization suite, often using intravascular ultrasound to detect intimal thickening. Disease can be widespread and distal lesions may not be amenable to therapy. It is vital to maintain adequate coronary perfusion pressure during anesthesia.

Renal dysfunction may result from poor CO or, more commonly, from immunosuppressive medications. Renal insufficiency may be severe enough to require dialysis or transplant. While 60 % of adults have severe dysfunction at 10 years posttransplant, only 11 % of children will do so [61]. Approximately 70 % of children will develop hypertension after heart transplant [61]. Many of these children are managed medically with calcium channel blockers or ACE inhibitors.

Immunosuppression leaves these patients susceptible to infection, particularly in the early postoperative period. Patients are at risk for opportunistic infections, and fungal infections from Aspergillus and Candida must be kept in mind. Cytomegalovirus is the most common type of opportunistic infection in heart transplant recipients, and CMV-negative blood is recommended when patients require transfusion.

The preoperative assessment of patients with a transplanted heart includes evaluation of cardiac function and clinical state, rejection status, presence of infection, evidence of cardiac allograft vasculopathy, and medications and their

adverse effects. A review of all cardiology studies (echocardiography, catheterization, angiography, ECG, biopsies) is essential. A review of laboratory studies will reveal abnormalities in renal function, electrolyte imbalance, coagulopathy, and bone marrow suppression. The transplant cardiologist will have detailed knowledge of the patient's clinical history and current state of health. A preoperative discussion with the transplant team is helpful to gain a clear understanding of the patient prior to providing anesthesia.

The anesthetic plan will be dictated by the patient's physical status and the nature of the procedure. Many anesthetic techniques have been employed safely and successfully in children who have had a heart transplant. Prolonged fasting is discouraged, as adequate hydration and maintenance of preload are important to avoid hypotension. Appropriate drug selection and dosing is equally important. Intraoperative hypotension should be treated primarily with fluid resuscitation, and then direct-acting sympathomimetic agents, while maintaining adequate depth of anesthesia.

Oral endotracheal intubation is preferable to the nasal route, in order to avoid infection from nasal flora. Most patients will do well under anesthesia, and the individual patient and surgical indications should dictate invasive monitoring. Strict aseptic technique is mandatory when placing invasive monitors due to the risk of infection in immune-compromised patients. A review of the patient's vascular access history with cardiology and previous anesthetic records will help avoid trauma to vessels, as well as save the anesthesiologist a great deal of time and potential frustration when placing lines in patients with occluded vessels.

Conclusion

Patients with complex CHD are at an increased risk of adverse events while undergoing anesthesia for noncardiac surgery. Patients with single ventricle lesions are at the greatest risk. Specific problems such as pulmonary hypertension, cyanosis, heart failure, arrhythmias, preexisting medications, and infective endocarditis may be encountered. Anesthesiologists caring for these patients must be experienced with the unique cardiac physiology and work closely with the cardiologist looking after these patients to help achieve safe anesthesia and good outcomes.

Databases and Outcomes in Congenital Cardiac Anesthesia Patients

42

David F. Vener

Abstract

Multiinstitutional databases for the collection and analysis of physiologic and outcome data in congenital cardiac anesthesia are in their infancy. This chapter reviews the efforts to date of single-site studies as well as previous efforts to collect data from multiple institutions and reviews the strengths and weaknesses of these approaches. Anesthesia today, even in such a sick population, has become remarkably free of adverse events, and it is necessary to collect data from multiple sites in order to accurately assess anesthesia practice and outcomes in a timely manner. The Congenital Cardiac Anesthesia Society has partnered with the Society of Thoracic Surgeons to develop and implement a dataset that is submitted to a central data warehouse for collation and analysis on a twice-yearly basis. This system takes advantage of the common data elements as well as all of the work done in multi-societal meetings to develop a common nomenclature for procedural and outcome terminology. The results of the first 2 years worth of data harvest are presented as an example of the types of data that can be harvested.

Keywords

Adverse events • Anesthesia • Cardiac • Complications • Congenital • Database • Outcomes • Pediatric

Introduction

Anesthesia for patients with congenital heart disease (CHD) is a frequent occurrence in children's hospitals as well as outpatient surgical centers and clinics worldwide. While many of the procedures are specifically related to the patient's heart defect, it is also common for these patients to undergo diagnostic and therapeutic interventions unrelated to their heart defect. Multiple investigations have now shown that this patient population is particularly vulnerable to anesthesia-related complications both in the cardiac operating rooms and in other locations [1–4].

In the last decade, Children's Hospital Boston and the Mayo Clinic have published their results

of anesthesia-related cardiac arrest in congenital heart disease patients [1, 3, 33]. Odegard et al. at Children's Hospital Boston reported on 5,213 cardiac surgical patients cared for over a 6-year period between January 2000 and December 2005 in the cardiac operating rooms, during which they observed 41 episodes of cardiac arrest related to anesthesia in 40 patients for an overall frequency of 0.79 %. Faculty at the Mayo Clinic in Rochester, MN, reviewed the incidence of perioperative cardiac arrest in 92,881 children undergoing all types of surgery at their facility from November 1988 through June 2005. Four thousand two hundred and fourty two of those patients were undergoing cardiac surgery during that 17-year period. They found that the incidence of cardiac arrest was 2.9 per 10,000 patients in the noncardiac procedures compared to 127 per 10,000 in the cardiac surgical group. Anesthesia was found to be the primary cause of the arrest in only 7.5 % of all the 80 recorded cardiac arrests. Within the 80 patients who suffered cardiac arrests under anesthesia, however, 88 % occurred in patients with a history of congenital heart disease, regardless of the type of surgery being performed – a testament to the critical nature of these patients regardless of the procedure being performed. Anesthesia-related outcomes or adverse events other than those leading to cardiac arrest are not discussed in either of these reviews.

A major problem with single-site analysis, critically important as it is, is that the nature of anesthesia practices and the personnel involved can vary dramatically over the time frame necessary to accumulate sufficient data. For example, through the 1990s, halothane was a commonly used inhalational agent in pediatric anesthesia, while it was largely replaced by sevoflurane in the 2000s. Halothane was a frequent culprit in anesthesia-related cardiac arrest due to its direct myocardial depressant effects on both inotropy and chronotropy. For pediatric anesthesia practitioners, the Peri-Operative Cardiac Arrest (POCA) Registry was one of the first multisite studies examining the etiology and incidence of cardiac arrests in children. The registry, which was active from 1994 and 2005, was a voluntary reporting survey which compiled extensive data concerning cardiac arrests in patients less than 18 years of age. Participating institutions agreed to provide the POCA investigators with detailed information any time a cardiac arrest, defined for their purposes as the initiation of chest compressions or death, occurred. Independent examiners then determined whether the cardiac arrest was due to anesthesia-related factors versus non-anesthesia elements such as surgical manipulation. At various times, the POCA registry had between 58 and 79 participants, ranging from free-standing pediatric hospitals to pediatric units located within larger adult institutions. Comparing the two Peri-Operative Cardiac Arrest (POCA) Registry results from the initial publication in 2000 to the update published in 2007 clearly illustrates the effect of the change in medication from halothane to sevoflurane [4, 5]. In the 2000 report, containing data collected from 1994 and 1997, medication-related cardiac arrests accounted for 37 % of the reported arrests, while the results from 1998 and 2004 showed a medication-related incidence of 18 %, which the authors largely ascribed to the decline in halothane usage during this time period.

At its conclusion, the POCA registry had collected information on 373 anesthesia-related total cardiac arrests. One hundred and twenty seven of the 373 (34 %) patients determined to have an anesthesia-related event had congenital or acquired CHD. Ramamoorthy et al. examined the POCA data specifically to determine the effects of CHD on arrest etiology and outcomes [2]. They found that children with underlying CHD (127 of the 373 patients) were both sicker than their non-CHD counterparts and more likely to arrest from cardiovascular-related events. Fifty four percent of the arrests reported in the POCA registry in children with CHD occurred outside of the cardiac ORs, while 26 % were from cardiac ORs and 17 % in the cardiac catheterization labs. The lesion most associated with cardiac arrest was "single ventricle," while those most likely to have the highest mortality were aortic stenosis and cardiomyopathy – the former can be very difficult patients to resuscitate once the arrest has occurred, while the latter is associated

with a significant incidence of sudden cardiac death [6, 7]. Because the POCA data did not have sufficient information about the total numbers of procedures performed on children less than 18 years of age at the reporting institutions, the investigators could not determine an accurate incidence of arrest. Analysis by Ramamoorthy et al. of the POCA data led to their recommendation that those involved in the care of these children understand the physiology of CHD, particularly those patients with unrepaired or partially palliated single ventricle as well as the pharmacodynamics of anesthetic agents in patients with impaired ventricular function [2].

Outside of pediatric cardiac anesthesia, there are at least two major multisite collection efforts ongoing utilizing Automated Anesthesia Information Systems (AIMS) data. The American Society of Anesthesiology's Anesthesia Quality Institute has developed a National Anesthesia Clinical Outcomes Registry, while the Department of Anesthesia at the University of Michigan has developed the Multicenter Perioperative Outcomes Group. Both systems utilize a complete download of de-identified physiologic and anesthetic data from their participating centers. This data harvest can then be "mined" extensively to determine relationships between anesthetic management strategies and physiologic readings and subsequent outcomes [8–10].

Multi-Societal Collaboration

Extensive efforts have been carried out over the past decade to develop a common language for international usage in congenital heart disease patients [35]. As congenital heart programs developed over the years, cardiac lesions and their treatments took on a wide variety of names reflecting the embryologic origin of the affected anatomy, the final appearance of the anatomy, and frequently an eponym for the name of the person most associated with first describing either the lesion itself or its surgical repair – thus, a central shunt, a "Melbourne" shunt, and a "Mee" shunt all describe variations on a surgical procedure providing systemic blood flow to the pulmonary arterial system. In 2001, a group of physicians from the Society of Thoracic Surgeons Congenital Heart Database Committee (STSCHD) and the European Association of Cardiothoracic Surgeons (EACTS) began meeting annually through 2005. Their work has resulted in the creation of the International Pediatric and Congenital Cardiac Code (IPCCC), which has standardized the nomenclature for congenital cardiac malformations and the procedures associated with their repair [11]. Subsequently, an international group of specialists from pediatric cardiac surgery, cardiology, anatomists, anesthesiologists, cardiac intensive care specialists, and government representatives have continued to meet regularly to agree on definitions of lesions, their surgical and cardiovascular repair, and the associated complications [12–17, 34]. Without this dictionary of terminology, it would be impossible to develop and implement databases both nationally and internationally. The IPCCC has now been incorporated into upcoming revisions of the American Medical Associations Current Procedural Terminology (CPT) and the International Classification of Diseases (ICD) and is freely available to interested users at www.ipccc.net.

Congenital Cardiac Anesthesia Society

The Congenital Cardiac Anesthesia Society (CCAS) was incorporated in 2005 as an affiliate of the Society for Pediatric Anesthesia. Its membership is open to anesthesiologists worldwide who either care for or have an interest in patients with congenital cardiac defects. Among its primary goals, the CCAS has committed to developing a multisite database covering anesthesia-related information in patients undergoing surgery or procedures in and out of the cardiac surgical suites, including noncardiac surgery on patients with congenital heart disease (CHD) [38]. After exploring a number of options, the CCAS chose to partner with the Society of Thoracic Surgeons' Congenital Heart Surgery Database (STSCHSD) because of the enormous amount of shared data elements as well as the

STS's long history of successful implementation of their databases. The STSCHSD now collects data from over 100 of the approximately 120 surgical programs in the United States who provide congenital cardiac surgery, and it is discussed further in another chapter in this text [18]. From January 2007 to December 2010, the STSCHSD collected information on 111,354 patients, with an overall discharge mortality of 3.5 % during this time period [19]. Because of a "shared" patient population, the collaboration between the two societies is a natural fit. As part of the agreement, the STS for the first time allowed the collection of data from noncardiac surgical and cardiology procedures occurring in patients with a history of congenital heart defects – which, given the findings of the POCA analysis by Ramamoorthy et al., is one of the major areas where anesthesia-related morbidity occurs.

The goal of the CCAS–STSCHSD collaboration is to provide a more "real-time" picture of the state of anesthesia care for these patients as well as outcomes information related to the incidence of anesthesia complications beyond cardiac arrest. Single-site analysis of this patient population requires years of data collection because of the relatively small number of cases at any one institution. Multisite data collection will allow investigators to collect and analyze data from a much larger patient population and report the results back to the CCAS membership and participating institutions in a timely manner [14, 20].

The CCAS–STS Collaboration: Mechanisms

The STS data is harvested semiannually in the Spring and Fall. The Spring harvest, typically occurring in mid-March, captures and reports data on a calendar-year basis, while the Fall harvest does so on an academic July–June calendar. Programs may choose to report their data at one or both of the harvests, though most appear to only submit data annually, and "backfilling" of data from previous years is allowable and encouraged. The requirements and forms for becoming a participant in the database are available online via the STS [21]. Because transmission of potential Private Health Information (PHI) is involved in the process, it is necessary for a business agreement to be in place prior to data submission in order to be compliant with the Health Insurance Portability and Accountability Act (HIPAA) of 1996 Privacy and Security Rules.

Groups submitting data for the anesthesia portion of the STSCHSD are responsible for paying a flat $3000 per annum, regardless of the number of anesthesiologists participating or the quantity of cases submitted. This fee is in addition to the surgical participation fee. The CCAS negotiated a flat fee with the STS because the traditional fee mechanism that STS had utilized, a charge for each surgeon and an additional charge per case submitted, would potentially discourage groups from participating because of the high annual costs. There are typically significantly more anesthesiologists providing care in a given program to children with CHD than there are surgeons, as many institutions utilize their cardiac anesthesiologists to cover "remote" locations such as cardiac catheterization labs, intensive care units, and diagnostic and interventional radiology suites as well as to care for CHD patients undergoing noncardiac procedures. At other locations, the cardiac anesthesia care team is an integral part of the overall anesthesia staffing, and many physicians may rotate only intermittently into the cardiac operating rooms. At Texas Children's Hospital in Houston, Texas, for example, there are currently twelve cardiac anesthesiologists and five congenital heart surgeons. In addition to the three cardiac ORs, the cardiac anesthesia group is responsible for three cardiac catheterization labs, cardiac ICU coverage, and one radiology site, and many of the cardiac anesthesiologists have significant research and/or administrative obligations outside of their clinical time. Additionally, there are several more anesthesiologists in the general anesthesia division with extensive cardiac experience who routinely provide care for cardiac patients having noncardiac procedures in the inpatient and outpatient operating rooms. Each of these physicians must sign the business

agreement before their data can be submitted. It was felt that a fixed fee approach would encourage greater participation and enrollment of patients, especially among those being cared for outside of the cardiac operating rooms by not financially penalizing institutions for reporting on this critical information.

It is necessary to have the appropriate software to collect and transmit the data to the Duke Clinical Research Institute (DCRI), the data warehouse and processing center for the STSCHSD. All STS-approved vendors for the STSCHD are required to include the anesthesia data elements as part of their software package, so there should be no additional fees associated with that element of the data management. Some programs have chosen to utilize locally developed software not commercially available in order to retain access to data collected prior to their participation in the STSCHD. These programs must follow the same guidelines as commercial products and undergo the same data validation and testing.

The most expensive component of any database is the manpower involved in accurately collecting and entering the data. Data entry may be completed by surgeons, anesthesiologists, cardiac perfusionists, nurses, research assistants, or any combination of the above. In some institutions, the data is entered directly into the software; some collect the data on paper records for later entry, while still other sites abstract the data from the records postoperatively. Regardless of how the data is entered, it is critical that it be audited regularly for both completeness and accuracy. Data auditing in the STSCHSD occurs at multiple stages: individual reporting institutions are responsible for performing internal quality checks to ensure the quality of the data; later, when the data is transmitted to DCRI during the harvest period, it undergoes additional checks to scrub the data of logic errors (such as a date of birth or hospital discharge after the date of surgery) or missing data elements. Every data harvest window is followed by a 2-week period of time when DCRI reports back to the submitting program all the data "errors" and gives them an opportunity to correct and resubmit their data. Finally, the STS performs on-site auditing of five programs per year by a trained audit team consisting of a congenital heart surgeon and data personnel. The audit teams verify that all surgical cases are being submitted and that the appropriate data, including morbidity and mortality, are accurate. One additional layer of data verification has also been instituted to capture long-term outcomes. Where possible using probabilistic matching, the STSCHD data is being linked to administrative records such as the Social Security Master Death Index and individual state death registries [22, 23]. Beginning in 2011, an additional program is audited remotely via computer to ensure that the data being submitted is an accurate accounting of both procedures and outcomes. The anesthesia data is not being audited separately at this time as various programs are working out the mechanics of their anesthesia data entry and the extent to which they will submit data. Ideally, all patients with CHD are being entered at a given site, but for a combination of factors including manpower and training, some sites are currently only entering the cardiac operating room cases, while others are including the cardiac catheterization lab patients but not other hospital locations. Regardless, in order to submit the anesthesia data, the cardiac surgical program at the submitting hospital must be a participant in the STSCHSD.

CCAS–STS Collaboration: Data Reporting and Analysis

Anesthesia departments participating in the CCAS–STS collaboration receive their reports back approximately 2 months after the close of data submission in the Spring and Fall. The report consists of two sets of data: the site-specific data and the national values. Uses for the data include tracking personnel activity, complication occurrences, medication usage statistics, time to extubation, and other important variables. Participants do not receive information about other locations except in the context of the national values. This precludes a site from directly comparing their outcomes against another individual

site. The business agreement between the sites and the STS explicitly forbids this sort of site-to-site comparison, and programs in the past have received warning letters for attempting to utilize STS data in marketing that misrepresents programmatic outcomes versus competing programs in the same city or region. The anesthesia report is developed by members of the CCAS Database Committee and represents an abstract of the submitted data elements felt important to report, such as types of medications, monitoring modalities, airway management, and complications. Data is broken down into three sections: an overall anesthesia report, a section specific to cardiac operating room cases (both on-pump and off-pump), and a section on noncardiac OR cases such as from the cardiac catheterization lab, radiology, and other locations.

All sites "own" their own data at all times and are free to conduct whatever research or publications on it that they desire (with appropriate IRB approval). Sites are also welcome to request from DCRI-specific data element information from the national data. These data requests are broken down into "minor" and "major" requests. Any requests for data from the overall database are routed through the STS' Access and Publications Committee, which includes a representative from the CCAS. Minor requests are typically handled at the discretion of the committee chair and require very little data analysis and are provided at no charge, while major data requests, including any request for information that might be used for publication, are vetted by the entire committee for the appropriateness and logic of the query, and the final publication must be approved by the committee prior to publication to ensure the appropriateness of the data utilization.

Major data requests may include complex multivariant analysis incorporating thousands of data records or other analyses which require significant time for DCRI or STS personnel to prepare. DCRI and the STS have the option of assessing fees associated with a major data analysis which is then passed along to the site that requests the information. The CCAS negotiated with the STS to include these major data requests to be at no charge, assuming they are "reasonable."

CCAS–STS Collaboration: Dataset Management

The CCAS–STS collaboration went "live" on January 1, 2010, after several years of development and programming. The dataset in use through December 1, 2012, is available through the STS website [24]. The data specified for collection is reviewed on a triennial basis, with the next version scheduled to be released for use on January 1, 2013. As users have gained some experience with the database, changes have been made to "bundle" some drug categories and simplify data entry, while expanding other drug categories such as pulmonary vasodilators, antifibrinolytic, and procoagulant medications. The CCAS Database Committee has been in communication regularly to facilitate these changes and communicate them to the STSCHSD committee. Efforts have also been made to eliminate the redundancy of data entry between the surgical side of the dataset and the anesthesia portion. For example, blood component usage and near infrared spectroscopy data are currently residing in both areas but will henceforth only be in the anesthesia section to simplify data entry. Once finalized and released to the software vendors, the updated dataset will also be released on the STS website for prospective users to examine.

CCAS–STS Collaboration: Results

Through the Spring 2012 harvest, including data from January 2010 through December 2011, the CCAS–STSCHSD efforts collected patient information from 29 programs of the 31 that paid the anesthesia participation fee. These programs were diverse in both geographic location and in case volume. A total of 20,226 discrete records had been submitted for 24 months since the inception of the project on January 1, 2010, covering a wide spectrum of surgical types and ages (Table 42.1). The Spring 2012 data includes data from 1,486 patients who were coded as having anesthesia for "noncardiac, non-thoracic procedure on a cardiac patient with cardiac anesthesia." These cases will include everything

Table 42.1 STS congenital anesthesia results (1 Jan 2010–31 Dec 2011)

Number of records	*N/% of total*
Cardiovascular surgery	*13,796/68.20 %*
CPB cardiovascular	10,029/72.70 %
No CPB cardiovascular	3,227/23.39 %
Support devices (ECMO, VAD with/without CPB)	540/3.91 %
Cardiology cath lab	*3,354/16.60 %*
Diagnostic procedures	615/18.33 %
Interventional procedures	1,665/49.64 %
Electrophysiology procedures	1,074/32.02 %
Other (thoracic, noncardiac/ non-thoracic on CV patient)	*3,076/15.20 %*
Age of patient at time of procedure	
Neonatal (0–30 days)	3,662/18.1 %
Infant (31 days–1 year)	5,669/28.0 %
Children (>1 year– <18 years)	8,371/41.4 %
Adult (>18 years)	1,459/7.2 %

Table 42.2 STS congenital anesthesia results (1 Jan 2010–31 Dec 2011)

Adverse event		
None/missing	*19,805*	*97.90 %*
Any adverse event	*411*	*2.10 %*
Dental injury	2	0 %
Respiratory arrest	11	3 %
Difficult intubation/reintubation	66	16 %
Stridor/subglottic stenosis	32	8 %
Inadvertent extubation	14	3 %
Endotracheal tube migration	10	2 %
Airway injury	7	2 %
Arrhythmia – CVL related	6	1 %
Myocardial injury – CVL related	0	0 %
Vascular compromise – CVL related	20	5 %
Pneumothorax – CVL related	1	0 %
Vascular access (>1 h)	87	21 %
Hematoma	4	1 %
Inadvertent arterial puncture	44	11 %
Intravenous/intra-arterial air embolism	1	0 %
Bleeding – regional anesthesia site	1	0 %
Inadvertent intrathecal puncture	0	0 %
Local anesthetic toxicity	0	0 %
Neurologic injury – regional anesthesia related	0	0 %
Anaphylaxis/anaphylactoid reaction	15	4 %
Nonallergic drug reaction	13	3 %
Medication administration (wrong drug)	8	2 %
Medication dosage (wrong dose or time)	8	2 %
Intraoperative recall	1	0 %
Malignant hyperthermia	0	0 %
Protamine reaction	15	4 %
Cardiac arrest unrelated to surgery	40	10 %

Airway compromise – TEE related	28	7 %
Endotracheal extubation – TEE related	8	2 %
Patient transfer event	4	1 %
Neurologic injury – positioning related	11	3 %

from radiologic procedures to bronchoscopies to general surgical procedures such as a Ladd's procedure on a patient with heterotaxy. The overall anesthesia-related adverse event rate was 2.1 %, with vascular access taking more than 1 h being the highest reported complication (0.4 %) followed by unexpected difficulty with intubation or reintubation (0.3 %). Cardiac arrest not due to surgical manipulation occurred in 40 cases (0.2 %). The full range and incidence of complications reported to date is shown in Table 42.2. Because the reporting is voluntary and there is currently no audit process in place for anesthesia, there is no way to verify the accuracy or completeness of the data, and there is a likely bias toward underreporting. With sufficient time and funding, however, it is hoped that anesthesia involvement will become part of the STS audit process. Another mechanism for ensuring data entry and completeness would be the integration of AIMS information similar to the Multicenter Perioperative Outcomes Group or the NACOR data [8, 9]. This data could be filtered appropriately and fed directly into STS-compliant software, eliminating much of the legwork required currently to manually enter data and largely eliminate the inherent bias involved in selective reporting of cases or underreporting.

Difficult Intubation

A recent large review of intubation in 11,219 pediatric patients from Germany showed that patients undergoing cardiac surgery were associated with a significantly higher rate of difficulty with laryngoscopy visualization (grade III/IV laryngoscopy view with an age-appropriate Macintosh blade) [25]. The Spring 2012 CCAS–STS anesthesia data showed a self-reported incidence of "difficult intubation or reintubation" of 47 cases out of 13,256 cardiac surgical records (0.4 %), which appears to be lower than that reported in previous case series [26].

Arterial and Venous Line Placement and Complications

Patients undergoing congenital heart surgery can be particularly difficult to obtain both peripheral and central venous and arterial access due to their need for repeated access both in the hospital and the cardiac catheterization lab. Many of these patients have had thrombosis in major vessels over the course of their treatments or repeated access causing scarring or collateral formation. As a result, line placement intraoperatively can take a significant amount of time after induction of anesthesia and may require surgical placement of lines such as radial or ulnar arterial catheters. Additionally, both central venous and arterial lines are associated with a significant number of complications which may impact both patient morbidity and mortality as well as adding to hospital length of stays, including vessel injury and thrombosis, myocardial injury, catheter-related blood stream infections, arrhythmia, and chylothorax [27–31]. The CCAS–STSCHSD data tool collects information on many of these events, particularly those occurring in the perioperative period such as venous or arterial occlusion, hematoma formation, arrhythmias, or other complications. Additionally, a "complication" category of difficulty with line access requiring more than 1 h after induction of anesthesia is included to try and document the incidence of this event.

Future Developments and the Unique Patient Identifier

Data management and interpretation will be a critical component in providing CCAS members with accurate information about the current state of anesthesia care and provide direction for future research. It is hoped that the CCAS–STS collaboration will serve as a model for incorporating other specialties into the dataset with the goal of creating a "cradle-to-grave" model. Because cardiac patients may see multiple providers at multiple locations over their lifetime, the STSCHSD developed a unique patient identifier based upon the patient's last name, date of birth, social security (where available), and mother's last name. This confidential alphanumeric identifier, which can be calculated at any treating site, can then be used to track an individual patient across multiple care locations and time as well as linking it to the administrative databases such as the Social Security Master Death File [36]. Duke University's IRB, which covers the research activity at DCRI, has reviewed the ongoing submission of PHI to the STSCHSD and found it to be within the guidelines of HIPAA-related law, as has outside counsel retained by the STS to evaluate the process [32]. Nonetheless, not all programs however are able yet to provide access to this level of Protected Health Information because of HIPAA-related concerns. Many IRBs, whose permission is required, have balked at this, despite the presence of a signed business contract. Commercial vendors supporting the STSCHSD have included functionality in their software to "strip" or de-identify the PHI from patient records prior to transmission for those programs unable to share the data with DCRI. It is only through this process however that physicians will be able to determine accurately the long-term mortality and morbidity associated with these complex procedures [37]. For example, a patient with hypoplastic left heart disease may undergo at least three cardiovascular surgical procedures and numerous nonsurgical procedures prior to age 4 at multiple facilities. If they happen to suffer a major morbidity or mortality after discharge from the

hospital at any time, the institution(s) where the procedures were performed may have no way to record this data, yet it would come through using linkage to the federal or state administrative data. Alternatively, if the patient undergoes a procedure at Hospital A and then is subsequently admitted to Hospital B due to complications or the need for revision, then the patient is included in two separate datasets, and any mortality or morbidity would be ascribed to Hospital B, despite the original surgery and its ensuing problem being performed at the first hospital. The UPI is an attempt to control for this and present a more accurate picture of the time course of various heart defects and their repairs.

Conclusion

Children undergoing repair of congenital heart defects are among the sickest population treated by anesthesiologists. The incidence of complications such as cardiac arrest related to anesthesia is proportionally much higher, the difficulties associated with airway and venous access are well known, and the time and money spent on their care far outweigh their numbers. To date there have been no systematic reviews of their anesthetic care and the associated complications. The CCAS database in conjunction with the STSCHSD marks the first real-time picture of the "state of the art" for anesthesia practitioners. This information will potentially help guide future care as well as provide better information for the parents and patients.

Mechanical Aspects of Pediatric Cardio Pulmonary Bypass

43

Scott Lawson, Cory Ellis, Craig McRobb, and Brian Mejak

Abstract

Cardiopulmonary bypass during cardiac surgery provides a safe, reliable platform for cardiopulmonary support. For the surgeon, a motionless, bloodless operative field is critical to complete a successful cardiac repair.

Patients undergoing cardiac surgery are at risk of major organ system sequelae due to numerous physiologic insults from the artificial surfaces and conditions resulting from cardiopulmonary bypass circuitry. Some of these insults include hemodilution, hypothermia, exposure to foreign materials, non-pulsatile flow, and nonphysiologic shear stresses. Patients may experience systemic inflammatory response syndrome and coagulation derangement that can lead to major organ dysfunction and clinical bleeding. Understanding these conditions allows for the clinician to ameliorate these effects and provide improved outcomes in this delicate patient population. This chapter will overview the mechanical aspect of cardiopulmonary bypass in children.

Introduction

The history of cardiopulmonary bypass (CPB) began nearly 60 years ago in the pediatric congenital heart population. In 1953, Dr. John Gibbon used his homemade heart-lung machine (HLM) to perform the first complex cardiac surgical procedure, an atrial septal defect repair [1]. That first CPB circuitry was extremely large and complicated, requiring 14 units of whole blood to prime. This early experience with cardiac surgery resulted in very high mortality and Dr. Gibbon did not continue to perform cardiac surgery with the new device. However, Dr. Walter Lillehei, 1 year later, did report a successful series (63 % survival) of open-heart cardiac repairs utilizing the cross-circulation technique [2]. Later, Dr. John Kirklin refined the earlier design of Gibbon's HLM and published a series of 8 children to correct cardiac defects with a 50 % survival rate [3]. The Gibbon-Mayo pump oxygenator and circuit needed 5–11 units of whole blood to prime and its use could be very unpredictable and adventurous.

Extracorporeal technology has evolved into an extremely safe and effective procedure which has saved many thousands of lives with survival rates approaching 100 % in some cardiac procedures [4]. Despite this exponential increase in quality of CPB technique and technology, its effects upon patients are still relatively poorly understood.

Historically, the operator of the HLM was someone who happened to work in the research laboratory or assisted in the operating room. These courageous individuals had to learn to run the HLM through trial and error which often lead to critical mistakes and harm to patients. In the current era of extracorporeal technology, formal perfusion training programs exist and the clinical perfusionist is a highly trained and dedicated professional within the cardiac surgical team [5]. Safety and communication are of supreme importance as cardiac surgical teams strive to improve survival and decrease morbidity, especially neurological complications. Cardiovascular perfusion can be defined as a profession that combines technical expertise and medical knowledge [6].

This chapter will add to the reader's knowledge basic notions of artificial mechanical support and its impact upon pediatric patients; it reviews current equipment, management techniques, and technologies used for pediatric CPB.

Basic Physiology of Cardiopulmonary Bypass

The point of CPB is to provide a safe, reliable platform for cardiopulmonary support during cardiac surgery. For the surgeon, a motionless, bloodless operative field is critical to complete a successful cardiac repair.

Pediatric patients undergoing cardiac surgery are at risk of major organ system sequelae due to numerous physiologic insults from the artificial surfaces and conditions resulting from CPB circuitry. Some of these insults include hemodilution, hypothermia, exposure to foreign materials, non-pulsatile flow, and nonphysiologic shear stresses. Patients may experience systemic inflammatory response syndrome and coagulation derangement that can lead to major organ dysfunction and clinical bleeding.

CPB circuits are constructed of artificial material which activates many inherent biological

systems designed to protect the body from foreign invaders [7]. Blood component exposure to foreign materials results in a systemic inflammatory response [8] and the severity of this response is directly correlated to amount of foreign surface area and the length of time on CPB [9]. Current CPB circuits can be equal to or exceed the surface area of a neonate's body surface area. In contrast, an adult CPB circuit may be only 20 % of an adult's body surface area. Therefore, pediatric patients are at higher risk of CPB sequelae.

In addition to the activation of these inflammatory mediators, the coagulation system is commonly deranged due to a range of hemostatic defects resulting from cardiac surgery and CPB [10]. This can be a result of the circuit's prime volume, contents, and shear stresses encountered as blood is exposed to the foreign surfaces and nonphysiological pressures and pathways. Significant strides have been made to ameliorate the sequelae of CPB via circuit surface modification [11], pharmacologic intervention [12], and various new techniques, all of which will be reviewed later in this chapter. It is now understood that in infants undergoing low-to-moderate complexity cardiac surgery, the contribution of inflammatory mediator production to postoperative morbidity is relatively limited [13].

In addition to exposure to foreign surfaces, the blood is placed under nonphysiologic stresses as it travels through an extracorporeal circuit. Shear stress is defined as the force applied by flowing liquid to its boundary [14]. There is a complex interaction of biomechanical forces, and more specifically shear stress, derived by the flow of blood and the vascular endothelium. The transmission of hemodynamic forces throughout the endothelium leads to biophysical, biochemical, and gene regulatory responses of endothelial cells to hemodynamic shear stresses [15]. Shear stress is commonly encountered within the extracorporeal circuit as blood flows through artificial surfaces, into oxygenation devices, which use turbulence to increase the oxygenator's efficiency, and via techniques such as vacuum-assisted venous drainage (VAVD) [16].

Hemodilution is widely used in CPB to reduce the need of banked blood products. Prime constituents for pediatric CPB often include electrolyte-balanced crystalloid solutions, heparin, mannitol, and sodium bicarbonate. If the patient is less than 10–12 kg, then the use of packed red blood cells and human plasma are often added. The degree of hemodilution varies widely from institution to institution and varies dependant on the size of the patient undergoing CPB. It is rare for a neonatal CPB circuit to be primed without the use of banked blood products due to the large discrepancy between the patient's body surface area and the CPB circuit's surface area. As the degree of hemodilution increases, the hematocrit level decreases. Although controversial, it has become generally accepted in pediatric patients that a hematocrit level of approximately 30 % is optimal [17]. Generally, hemodilution can have deleterious effects and caution needs to be employed to ensure that a patient not become too anemic [18]. A calculation to determine the extent of hemodilution can be used to predict a post-CPB hematocrit:

$$HctCPB = \frac{(\mathrm{BVpt})(\mathrm{HCTpt})}{(\mathrm{BVpt}) + TPV}$$

where HctCPB = the mixed Hct (TPV + BVpt), BVpt = patient's blood volume (weight [kg] estimated blood volume [ml/kg]), TPV = total priming volume, and HCTpt = starting hematocrit of the patient [19].

The following equation estimates the amount of red blood cells needed to achieve a desired hematocrit once on CPB:

$$\begin{aligned} Added\ RBCs\,(ml) = {} & (BVpt + TPV)\,(Hct\ desired) \\ & - (BVpt)\,(Hctpt) \end{aligned}$$

where added RBCs = milliliters of packed RBCs added to the prime volume, BVpt = patient's blood volume, TPV = total priming volume, Hct desired = the desired hematocrit on CPB, and Hctpt = starting hematocrit of the patient.

Table 43.1 Recommended CPB flow rates for different sized patients. CPB flow rate suggestions for different sized patients. (Flow rates should ultimately be based on patient parameters such as SvO_2, MAP, lactate levels, rSO_2, and acid/base balance from arterial and venous blood gas values)

Patient weight (kg)	CPB flow rate (ml/kg/min)
2–7	120–200
7–10	100–175
10–20	80–150
>20	50–75

Adequacy of perfusion on CPB has been historically based upon a recommended flow rate derived from the patient's body weight and the maintenance of efficient organ perfusion as determined by venous saturation (SvO_2), arterial blood gas values, acid/base balance, and whole body oxygen (O_2) consumption (Table 43.1) [20]. More recently, other parameters have been reported to aid in the evaluation of perfusion adequacy such as regional cerebral O_2 saturation (rSO_2) using near-infrared spectroscopy (NIRS) technology and whole body lactate measurement [21, 22]. Any given extracorporeal oxygenator is designed to transfer O_2 at a fixed set of standards set by the Association for the Advancement of Medical Instrumentation such as hematocrit, temperature, and flow rate. The manufacturer will then set a "maximum rated flow" for the device, based on its performance. Generally, the smaller the membrane surface area of the device, the lower the maximum rated flow recommendation for that device. Less membrane surface area allows for lower priming volumes and foreign material surface area, which is advantageous for pediatric patients.

The mean arterial pressure (MAP) is an important parameter to monitor while on CPB. While a given flow rate and O_2 transfer for a patient and device, respectively, is important, the MAP must also be maintained. Maintenance of the patient's systemic vascular resistance (SVR) is very important to end-organ perfusion. Maintaining the vascular tone of a patient on CPB is achieved with pharmacologic intervention. Once the CPB flow rate is optimal and the oxygenator is performing adequately, the SVR may be manipulated using pharmacologic intervention. Phenylephrine (Neo-Synephrine) is a common vasoconstrictor and Forane (isoflurane), a commonly used anesthetic inhalation agent used during CPB, acts as a vasodilator. These are first-line agents commonly used while on CPB; if these interventions are inadequate, then stronger agents may be considered and consultation with the cardiac anesthetist is warranted.

The use of non-pulsatile flow on CPB is common. Although there are advocates for pulsatile flow, when reviewing the subject, there are equal numbers of reports that describe no advantage to its use [23]. It is technically very difficult to reproduce a physiological pulsatile waveform with artificial devices. It also makes CPB pumps more complicated and expensive which has led most practitioners to adopt non-pulsatile perfusion devices for routine use.

Hypothermia is a very useful tool in pediatric cardiac surgery. By lowering the core temperature of a patient undergoing CPB, the metabolic rate of the patient is lowered which has a protective effect for all major organ systems. Hypothermia also allows for decreasing the CPB flow rate, which helps to give the surgeon a bloodless operating field.

Anticoagulation and its reversal is another extremely important facet of cardiac surgery requiring CPB. The activated clotting time (ACT) has long been the standard for monitoring of anticoagulation status during CPB [24]. It is generally agreed that an ACT of >480 seconds is required while on CPB to maintain adequate anticoagulation [25]. However, the ACT assay has inherent problems as it can be prolonged in patients who are hypothermic, thrombocytopenic, and hemodiluted. All of these situations are routinely encountered in pediatric patients who require CPB [26]. The initial heparin dose is often derived from the patient's body weight, routinely 400 units/kg. However, some caregivers use a heparin/protamine titration to evaluate if a patient is resistant or sensitive to heparin and can give an initial heparin dose that reflects the patient's metabolic response to the latter. If an inadequate amount of heparin is received,

a patient may experience clotting of the extracorporeal surfaces (this can be mild to catastrophic depending on the amount of clotting within the CPB circuit), antithrombin III (AT3) deficiency, thrombocytopenia, disseminated intravascular coagulation (DIC), and increased bleeding post-CPB [27].

A potential problem with heparin administration is the occurrence of heparin-induced thrombocytopenia and thrombosis (HITT). The incidence of HITT in children is approximately 1 % [28]. This potentially lethal problem is often initially suspected due to a sudden thrombocytopenia occurring several hours after the onset of heparin therapy. An HITT assay should rapidly be evaluated, and if positive, the patient should be anticoagulated with a direct thrombin inhibitor such as argatroban or bivalirudin, and the heparin therapy should be ceased [29, 30].

After CPB, heparin must be reversed so that normal hemostasis may occur. To achieve hemostasis post-CPB, a protamine dose at a 1:1 ratio with the amount of heparin given during CPB is administered [31]. An ACT should then be evaluated to determine if additional protamine is required. Once the ACT is normalized, any additional bleeding should be considered either surgical or a coagulopathy.

CPB Equipment: The Anatomy of an Extracorporeal Circuit

HLM Consoles

The HLM consoles used for CPB generally consist of four to five individual pumps. The first and most important pump is the arterial pump head. This is the device which provides pressure and flow to the patient. The arterial pump may be a roller head pump or a centrifugal pump. A roller head pump consists of the hardware, a mechanical machine with two rollers that rotate against a fixed U-shaped back wall. A length of plastic tubing, generally polyvinyl chloride, is placed into the raceway of the roller pump. The rollers are adjusted so that they will pinch the tubing wall together against the roller and the back wall of the raceway. A positive displacement of fluid then occurs as the rollers rotate around the raceway. A stroke volume is generated and the amount of the stroke volume is dependant upon the length of tubing in the raceway and the diameter of the tubing in the raceway. The flow generated from this pump is also dependant on the revolutions per minute (RPM) of the roller pump (Fig. 43.1). The roller pump will pull blood from a venous reservoir and push it through an oxygenator to achieve gas exchange and then continue onto the patient. The adjustment, or occlusion, of the roller on the tubing against the back wall of the raceway must be precisely set: if the occlusion is too loose, then the flow value will be falsely elevated (most roller pump consoles have computerized calculations based on the RPMs of the pump and the diameter of the tubing to calculate a blood flow), and if the occlusion is too tight, the formed elements in the blood will be damaged and hemolysis may ensue. A centrifugal pump is also commonly used as the arterial pump in CPB circuits. This type of pump utilizes centrifugal force to generate pressure and blood flow. The hardware consists of an electrical driver which

Fig. 43.2 Photograph of a centrifugal blood pump (Courtesy of Sorin Group, Mirandola, Italy)

spins a magnet or group of magnets. The disposable, sterile piece consists of a plastic housing which contains magnets and impellers or cones. The hardware side magnets couple with the disposable side magnets and when the whole apparatus spins, an area of low pressure is generated in the center of the device and areas of high pressure exist on the outer edges of the spinning device. An inlet port is mounted at the center of the disposable piece and a dedicated outlet port on the outer portion. The spinning device is essentially a constrained vortex which generates flow and pressure (Fig. 43.2). The remainder of the HLM console consists of at least three or four roller pumps, one of which serves to deliver cardioplegia (CPG) solution to the heart, once the cross-clamp has been applied. The remaining two to three roller pumps are used for sterile field suction. One is a dedicated left heart vent and the other one or two roller pumps are used as handheld suction devices to harvest sterile blood from the surgical field once the patient has been systemically heparinized. The remainder of the HLM console often has computer-controlled servoregulation from pressure transducers or safety monitoring devices. In-line blood gas monitors are often present on the HLM console (Fig. 43.3) along with Forane vaporizers, O_2 flowmeter, and blender to control the fraction of O_2 to be delivered.

Fig. 43.3 Photograph of a typical heart/lung machine (Courtesy of Sorin Group, Mirandola, Italy)

Recently, mast-mounted HLM consoles (Fig. 43.4) have become available for pediatric centers. These types of consoles have the roller pumps mounted on remote arms which can be

Fig. 43.4 Photograph of a mast-mounted heart/lung machine (Courtesy of Sorin Group, Mirandola, Italy)

configured in a wide variety of ways to reduce the distance from the patient. This shorter distance from the patient results in shorter tubing line lengths and decreased overall prime volume and surface area of CPB circuits [32].

Oxygenators (Artificial Lungs)

Many factors are weighed when choosing an oxygenator for pediatric cardiopulmonary bypass. There are currently seven different oxygenators (Table 43.2) on the market in the United States. When selecting an oxygenator, one must account for required flow rates, prime volumes, pressure drop, heat exchanger efficiency, air handling capabilities, and surface coatings. Patient age and O_2 demands must also be accounted for when selecting an oxygenator. This is one of the biggest differences between adult and pediatric cardiopulmonary bypass. Figures 43.5 and 43.6 are examples of pediatric oxygenators.

Most oxygenators' fibers are constructed of microporous polypropylene (Fig. 43.7). The process of gas transfer occurs when the O_2-rich gas on the inside of the fibers traverses to the outside of the fibers into the deoxygenated blood, due to the large diffusion gradient. The reverse process occurs for CO_2 removal from blood in the oxygenator. Anesthetic gas such as isoflurane can be breathed into the oxygenator's gas line to maintain levels of sedation and pressure. Integral heat exchangers made of stainless steel or polyurethane can warm and cool the blood to achieve core temperatures suitable for the individual patient's needs. New generation oxygenators have arterial line filters (ALF) wrapped around fiber bundles eliminating the need for a separate device. The integrated ALF oxygenator has demonstrated the ability to remove microemboli effectively and eliminate the need to CO_2 flush circuits before priming [33]. Venous reservoir features are important when selecting an oxygenator as well. Filters (33–64 μm) in the reservoirs can remove air [34] and particulate matter and act as a defoaming agent. With the increased usage of vacuum-assisted venous drainage (VAVD), a pressure relief valve on or in the reservoir housing is an important safety feature greatly reducing the chances of reservoir over-pressurization or excessive negative pressurization [35].

Filtration

Many aspects of CPB, such as surgical technique, perfusionist technique, and cannula design [36], contribute to the presence of gaseous microemboli (GME) in the circuit. Arterial line filters have been effective devices to remove microemboli [37]. They are designed with computational flow dynamics to expel emboli via a purge line and incorporate polyester screen filters ranging in size from 20 to 40um, to block matter from reaching the patient. Few centers (2 %) choose not to utilize ALFs as a means to reduce prime and/or cost of surgery [38]. The emergence of new generation oxygenators with integrated filters should eliminate this argument.

Leukocyte-reducing filters are another type of filter designed to reduce leukocyte counts during CPB in an attempt to attenuate the systemic

Table 43.2 Oxygenators currently available in the USA (ALF – arterial line filter). Information on pediatric oxygenators currently available in the US market. ALF – arterial line filter

Oxygenator	Manufacturer	Prime volume (ml)	Maximum flow rate (ml/min)	Integrated ALF (Y/N)

inflammatory response. However, their usage is not widespread in the pediatric population due to conflicting adult studies showing benefits in outcomes [39].

Pre-bypass filters are designed to remove debris from CPB circuitry encountered from manufacturing. Improved modern-day manufacturing has greatly reduced particles and impurities in CPB disposable equipment and solutions, but has not eliminated them. Pre-bypass filter sizes that range from 0.2 to 5.0 μm are employed during circuit priming. Filters 0.2 μm in pore size need only 5 min of usage to remove 100 % of microemboli greater than 0.1 μm, and 91 % of microemboli smaller than 0.1 μm [40].

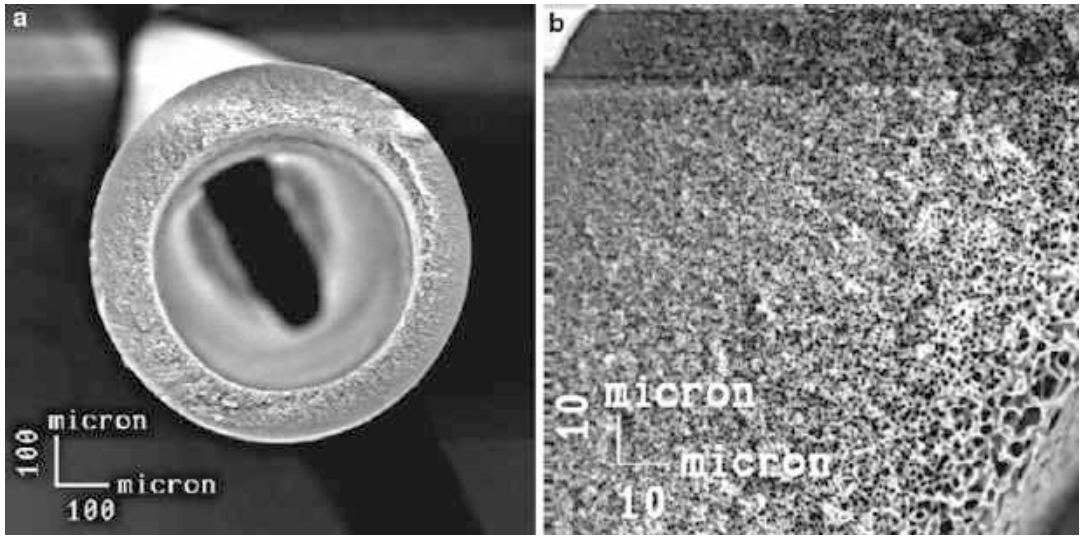

Fig. 43.7 Scanning electron microscopic photograph of a microporous hollow fiber typically used for CPB oxygenators

Vacuum-Assisted Venous Drainage

Vacuum-assisted venous drainage (VAVD) has allowed for the downsizing of the length and diameter of venous tubing therefore reducing prime volumes. VAVD is the method of applying a regulated vacuum on a sealed venous reservoir to increase the negative pressure within the venous reservoir. Perfusionists may replace the force of gravity with vacuum or exceed it, if deemed necessary. This technique has made it possible to use smaller venous lines and position reservoirs higher/closer to the operating field [41]. As stated earlier, the use of a pressure relief valve is necessary to avoid accidents such as negative or positive pressure buildup in the reservoir. Minimal vacuum must be used to avoid excessive GME entrainment in the venous line which can overload the oxygenator and filter's ability to remove air [42]. Figure 43.8 is an example of a VAVD suction regulator.

Fig. 43.8 Photograph of a VAVD regulator (Courtesy of Boehringer Ingelheim, Ridgefield, CT)

Circuit Tubing

The size of tubing selected for CPB circuits depends highly on the flow requirements of the patient. Commonly used tubing diameters in neonatal/pediatric bypass are 3/16, 1/4, and 3/8 in. (Table 43.3). Tubing and circuit components can be treated with heparin- or non-heparin-based coatings. These coatings

Table 43.3 Priming volume and flow rates of different sizes of CPB tubing. Information on the different internal diameters of tubing routinely used for pediatric CPB circuits. I.D. = internal diameter

Tubing size (I.D.)	Prime vol. (ml/ft)	Max. art. flow rate (ml/min)	Max. ven. return rate (ml/min)
1/8 in.	2.4	<450	250–300
3/16 in.	5.4	<1,300	500–650
1/4 in.	9.6	<3,000	1,200–1,600
3/8 in.	21.6	>5,000	4,000–4,500
1/2 in.	38.4	N/A	>5,000

Fig. 43.9 Photograph of cannulas commonly used for CPB (Courtesy of Sorin Group, Mirandola, Italy)

were first introduced as a means to reduce heparin usage [43] but never gained widespread acceptance for that practice. Many studies were conducted on surface coatings such as the one by Deptula et al. [44] who demonstrated a decreased blood usage, improved postoperative lung function, and reduced the time spent in the intensive care unit. A recent meta-analysis by Fitzgerald (Fitzgerald D, personal communication, October 5, 2011) on adult CPB literature dating back to 1970 yielded 115 randomized controlled studies of which 74 showed coated circuits appearing to be beneficial in reducing the inflammatory response.

Cannulas

Cannulas act as the interface between the patient and the CPB circuit allowing for diversion of venous blood from the patient to the CPB circuit and the return of arterialized blood back to the patient (Fig. 43.9). Cannulas, inserted by a cardiovascular surgeon, are selected according to the size and flow demands of each patient. The arterial cannulas are generally placed in the ascending aorta and may be advanced up to the innominate artery for selective cerebral perfusion for aortic arch surgeries [45]. Special circumstances such as reoperations may dictate the cannulation of a femoral, carotid, or axillary artery for access for CPB. Venous cannulas are placed in the right atrium or in the inferior vena cava and the superior vena cava depending on the procedure to be performed. During reoperations, the femoral vein or right internal jugular may be cannulated for venous access, but these serve as only emergency temporary measures to support patients as such sites frequently cannot provide adequate venous drainage for surgical exposure. During bypass, the CPB circuit becomes an extension of the patient's native circulation. The venous and arterial cannula provides vascular access on a large scale and almost immediate opportunities for both rapid volume infusion and drug administration.

CPB Management and Techniques

The majority of patients undergoing CPB are cooled and warmed as a part of a cardiac procedure. The extent to which a patient is cooled or warmed depends on a number of factors including both surgical procedure and surgeon's preference. The content of dissolved gas and changes in the solubility of those gasses in blood can pose a problem with rapid changes in temperature

from both cold to warm, as well as warm to cold. Gaseous micro-emboli can be formed as a result of temperature gradients greater than 12 °C during warming [46]. Strict adherence to a maximum temperature gradient of 10 °C should be observed during both cooling and rewarming of pediatric patients with the CPB circuit.

Efforts by pediatric perfusionists and manufacturers have been made to reduce priming volumes of pediatric devices due to the immense hemodilution of the small patient. Performing techniques prior to initiating CPB, such as retrograde autologous priming (RAP), can further reduce hemodilution and transfusion requirements [47]. Retrograde autologous priming is the process of replacing crystalloid in the circuit with the patient's own blood prior to or during initiation. Debate exists on whether to use fresh whole blood or reconstituted blood (red blood cells and fresh frozen plasma). Only 7 % of North American centers utilize fresh whole blood [38, 48] possibly because it can be difficult to obtain and priming with fresh whole blood has been associated with an increased length of stay in the ICU and increased perioperative fluid overload when compared to reconstituted blood [48].

Many institutions are trending to higher hematocrit levels during CPB on pediatric patients. This practice can lead to a more aggressive use of packed red blood cells in the pediatric patient population. Nonetheless, measures are still being employed to reduce donor exposure. The practice of modified ultrafiltration (MUF) can raise hemoglobin levels following termination of bypass and reduce postoperative transfusions [49]. Modified ultrafiltration will be discussed in detail later in this chapter. Forty-nine percent of North American pediatric centers [38, 48] use autotransfusion devices to collect shed operative field blood for later reinfusion. These cell savage devices produce a washed RBC product with a highly packed red cell mass (hematocrit levels are generally 46–66 % depending on the device) [50]. These devices are excellent at removing plasma-free hemoglobin, potassium, and heparin; however, operators must be aware they also expel much of the platelets and clotting factors as well. Autotransfusion devices may be used to wash banked blood before administering it to the bypass circuit to protect the patient from the harmful by-products of an aged unit of banked blood [51].

Ultrafiltration

Ultrafiltration (UF) is the removal of intravascular fluid and low molecular weight substances under a hydrostatic pressure gradient across a semipermeable membrane. Ultrafiltration techniques have been used in cardiac surgery since 1976 [52] and the use of an UF device in pediatric cardiac surgery requiring CPB has become widespread, due to profound hemodilution that occurs as a result of the crystalloid prime volume of the CPB circuit. Recent advances that aimed at reducing the prime volume of CPB circuits (neonatal oxygenators, VAVD, autologous priming, amongst others) have decreased the necessity of priming with blood for pediatric patients and reduced donor exposures for neonates. The incentive to decrease the need for blood usage is the elimination of its deleterious effects and reduction of costs associated with transfusions. Along with the previously mentioned advances, the knowledge that hemodilution caused by a crystalloid prime can quickly be reversed with an UF device has helped spur the march of progress towards completely bloodless pediatric cardiac surgery for even the smallest patients [53]. Even when a blood prime is used, an UF device has multiple functions in pediatric CPB. These include washing of the blood in the CPB prime (pre-CPB balanced ultrafiltration – PreBUF), reversal of non-prime-related hemodilution caused by the addition of crystalloid solutions during CPB (irrigation, CPG, maintenance volume – conventional ultrafiltration – CUF), inflammatory mediator removal (zero-balance ultrafiltration – ZBUF; modified ultrafiltration – MUF), lowering of serum potassium (dilutional ultrafiltration – DUF), and post-CPB circuit salvage techniques.

Certain drugs may be removed or concentrated by UF. One of the most important to

consider in the pediatric CPB patient is heparin. Unfractionated heparin has a molecular weight range of 3,000–30,000 daltons (d) with a mean of 15,000d [54]. Since many UF devices used for CPB have a pore size greater than this, heparin molecules may be removed by UF. However, others have reported a possible concentrating effect of UF on heparin levels, potentially as a result of interactions of negatively charged heparin molecules with proteins [55]. This unpredictability makes it important to closely monitor the patient's anticoagulation level, especially when large volumes of ultrafiltrate are to be removed.

Cardioplegia/Myocardial Protection

Many operations for congenital heart defects require direct visualization and intervention inside the heart for correction. Placing the patient on CPB diverts most of the blood around the heart and lungs, but does not create a completely bloodless nor motionless field. Operating on a motionless heart has two main advantages: ease of surgical correction compared to operating on a beating heart and prevention of the heart from ejecting air that may be entrained through an open cardiac chamber. The use of CPG allows for the safe cessation of cardiac function during cardiac repairs.

One aspect of what is referred to as a myocardial protection strategy is the use of CPG. A poor myocardial protection strategy can subvert the benefits of an otherwise perfect surgical correction. Cardioplegia is a term used for a solution that causes electromechanical arrest which prevents or attenuates myocardial ischemia/injury during aortic cross-clamping. This solution is often delivered cold so that it causes a hypothermic as well as a chemical arrest, and significantly reduces myocardial O_2 demand allowing the heart to tolerate longer periods of ischemia. Electromechanical arrest accounts for an approximately 90 % reduction in myocardial O_2 consumption [56].

In order to isolate and arrest the heart, an aortic cross-clamp (XCL) is placed across the ascending aorta. By itself, clamping of the ascending aorta on a patient with a warm beating heart immediately stops coronary blood flow creating myocardial ischemia and eventually myocardial tissue necrosis. To prevent this, CPG is infused into the coronary arteries via the ascending aorta (between the XCL and the aortic valve) immediately after placement of the XCL.

If an operation requires a long period of myocardial arrest, repeated doses of CPG may be necessary to help maintain myocardial hypothermia and electromechanical arrest and to resupply the myocardium with O_2 and substrates during the arrest period. The range of reported CPG administration strategies includes giving CPG continuously, to giving a single dose for prolonged arrest periods [57, 58].

Once myocardial arrest is no longer required, the XCL is removed and coronary blood flow is restored. With the resumption of coronary blood flow, the CPG is washed out of the coronary circulation, the myocardium rewarms, membrane channels and pumps resume normal function, O_2 and high-energy stores are replenished, and the heart often begins to beat spontaneously.

Despite the use of CPG and hypothermia, the heart is still susceptible to injury from ischemic-reperfusion [59]. Techniques to attenuate the degree of injury include reducing ischemic times, monitoring of electrical activity, achieving uniform hypothermia, and the use of systemic hypothermia and O_2 radical scavengers.

It is important to consider differences between the pediatric and adult myocardium. Intracellular mechanisms of calcium regulation in the pediatric myocardium function at decreased levels compared to mature hearts [60]. Until the myocardium matures, it relies more heavily on the movement of calcium across the cell membrane for excitation-contraction coupling. A pediatric myocardial protection strategy must take this sensitivity to calcium overload after an ischemic insult into consideration.

In order to provide an ideal CPG solution, additives in combination with the arresting agent are included in the solution. Some common additives include a buffer to counter the decrease in pH that occurs during myocardial ischemia.

A substrate such as glucose is often added to provide an energy source for any ongoing metabolism during the arrest period and also serves as an oncotic agent. In addition to glucose, albumin and mannitol are commonly used as oncotic agents [61]. Low levels of calcium are present to prevent calcium-related injury once coronary blood flow is restored. Magnesium and lidocaine have been used in some CPG formulas acting as membrane-stabilizing agents [62].

Electromechanical arrest of the myocardium in a flaccid diastolic state is achieved by targeting different points in the excitation-contraction coupling pathway using a variety of additives. The mechanisms of action of these additives include depolarizing agents, polarizing agents, and modified depolarizing agents. The most common solutions rely on hyperkalemia to achieve electromechanical arrest. The mechanism of action is a diastolic arrest caused by depolarization of the cell membrane (high extracellular K^+ and high intracellular Ca^+) that causes the membrane to be unexcitable [56].

Along with the mechanism of action and CPG composition, other variables that comprise a CPG strategy include the route of administration, CPG temperature, ratio of CPG to blood, and frequency of administration.

It is important that CPG is delivered uniformly throughout the myocardium. In order to achieve this, multiple routes of administration may be necessary. A catheter is placed in the ascending aorta proximal to the XCL and CPG solution is pumped into the ascending aorta. As long as the aortic valve is competent, the aortic root fills with CPG. As the aortic root pressure increases, the CPG is forced into the coronary ostia where it perfuses the coronaries in an antegrade fashion. In the presence of aortic valve insufficiency, antegrade CPG may not be effective, as the solution may flow retrograde across the aortic valve into the left ventricle. In this case, distention of the left ventricle is a concern as there is a clamp on the ascending aorta and the heart is likely fibrillating and unable to eject. A vent placed in the left ventricle and/or surgical manipulation of the heart may be necessary to prevent myocardial injury from distention. An "antegrade only" approach may not perfuse all available myocardial capillaries [63]. Retrograde or direct coronary ostial CPG delivery may be necessary in the presence of aortic valve insufficiency to achieve an adequate myocardial arrest. A retrograde CPG catheter (Fig. 43.10) can be placed and CPG delivered directly into the coronary sinus. The CPG perfuses the coronary circulation retrograde from the coronary veins into the arteries and out the coronary ostia. The catheter has an inflatable balloon that helps keep it in place and to prevent CPG from flowing into the right atrium. A pressure monitoring port on the catheter is used to measure the pressure in the coronary sinus. The coronary sinus pressure is usually maintained <40 mmHg during delivery to prevent rupture [64].

Debate and research continue on what is the ideal solution for pediatric myocardial protection. Composition of CPG solutions can range from almost all blood to all crystalloid. Common blood: CPG ratios currently used for pediatric cardiac surgery are 4:1 and 1:4.

Deep Hypothermic Cardiopulmonary Bypass with or Without Total Circulatory Arrest

Profound hypothermia (core body temperature <22 °C) is utilized to protect the patient's major organs if total circulatory arrest is required [65, 66]. The use of deep hypothermic circulatory arrest (DHCA) has been widely reported for children in need of complex aortic arch repairs [67–69]. Kirklin and collaborators [70] reported a maximum safe period of DHCA to be 30–45 min even though the precise time period is considered to be unknown. Concerns linger regarding impact to the individual undergoing this technique as well as society in general. Subtle, detectable neuropsychiatric injury may occur in a significant percentage of these patients [67]. Due to the concerns of neuropsychiatric injury during DHCA, Pigula and colleagues described a technique to significantly decrease the DHCA time required for neonatal aortic arch reconstruction thereby

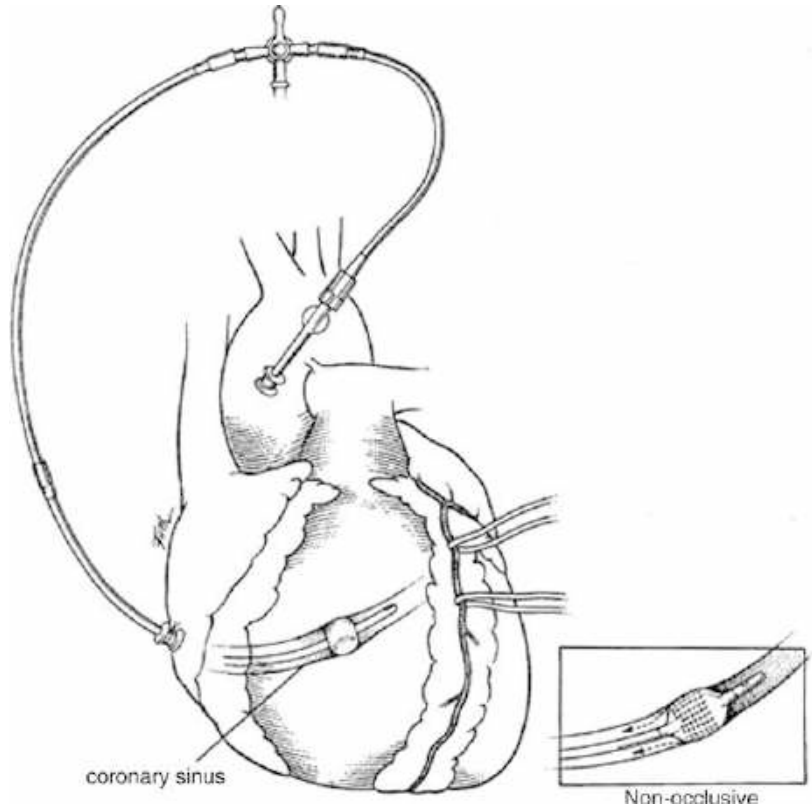

Fig. 43.10 Illustration of retrograde cardioplegia catheter placement

reducing the risk of psychomotor deficits [71]. Regional low-flow cerebral perfusion (RLFP) via the modified Blalock shunt conduit can be performed at 18 °C. This technique allows for antegrade perfusion to the cerebral vasculature while maintaining a bloodless operative field for the surgeon to repair the transverse aortic arch. It has been shown that the preservation of energy substrates can be achieved, in an animal model, at cerebral flows as low as 10 ml/kg/min [72]. However, Pigula, in a clinical report, stated that reacquisition of the baseline relative cerebral blood volume index occurs consistently at approximately 20 ml/kg/min, and that this flow rate showed a strong clinical correlation with NIRS signals [73]. Conversely, there have been several reports illustrating confounding effects of RLFP. Scheller and colleagues showed altered neuronal Golgi morphology when using RLFP vs. DHCA [74], Skaryak showed greater pulmonary dysfunction when using RLFP vs. DHCA [75], and Visconti found no neurodevelopmental outcome difference at 1 year between the two techniques [76]. These inconsistent reports of RLFP have led some to a second option to reduce DHCA times. Intermittent perfusion during DHCA has been described as flowing approximately 50 ml/kg/min for 1 min every 15 min of DHCA time [77]. This technique showed significant recovery of cerebral metabolism over uninterrupted DHCA.

The management of CO_2 during CPB for repairs that require DHCA has been widely investigated [78, 79]. Two different strategies have emerged: pH stat (temperature corrected) and alpha stat (temperature uncorrected) blood gas management. The strategy of pH stat is measurement of the CO_2 level in blood at a given temperature. When cold, this usually means that extrinsic CO_2 needs to be added to the sweep gas of the CPB circuit. Alpha stat strategy uses a mathematical algorithm to reflect the CO_2 content in the blood at 37 °C. Alpha stat technique results in little or no extrinsic CO_2 being added to

the CPB circuit. The clinical difference between the techniques is that patients receiving pH stat blood gas management have more CO_2 in the blood which causes cerebral vasodilatation. In pediatric patients requiring DHCA, this increased blood flow to the brain results in improved cerebral protection as the brain is evenly cooled and thereby better protected once CPB blood flow is ceased. Skaryak and collaborators [80] reported that a combination of pH stat and alpha stat "crossover" management offers the optimal strategy. The crossover technique is described as using pH stat management during cooling allowing for increased cerebral blood flow. Then, just prior to DHCA, the use of alpha stat management is employed to blow off excess CO_2 and increase the blood pH so that the brain's environment is more physiologic during the period of DHCA. During rewarming, alpha stat management is continued until off CPB. As reported by Groom et al. [38], a majority of pediatric centers use this pH stat/alpha stat crossover strategy.

CPB Monitoring

In order to safely operate the HLM and provide adequate cardiopulmonary support to the patient, a number of parameters are routinely monitored. These include venous reservoir level and air bubble detectors, CPB circuit pressures and temperatures, blood gas and saturation sensors, flowmeters, and anticoagulation monitoring.

A number of different temperatures are monitored during pediatric CPB. These include arterial and venous blood temperatures, CPG solution temperatures, water bath temperatures, and patient temperatures (bladder, rectal, nasopharyngeal). The primary means of controlling a patient's temperature during CPB is through the use of heat exchangers and heater/cooler devices. Close monitoring of blood and water and patient temperatures allows avoidance of both extreme temperature gradients and cerebral hyperthermia. Monitoring of CPG solution temperature assures CPG is delivered at precise temperatures. Monitoring of multiple patient temperatures can also assist with assuring adequate perfusion of all areas of the body and can help identify problems such as arterial cannula malposition, aortic dissection, as well as anatomic concerns (vascular shunts, aortic coarctation).

A number of different pressures are routinely monitored during pediatric CPB. These include CPB circuit pressures and patient blood pressures. Since blood is being pumped through the circuit, often with a roller pump, it is important that pressures in the circuit are maintained in a certain range. Monitoring of circuit pressures allows the pumps on the HLM to be servoregulated to prevent over-pressurization and catastrophic rupture of circuit components or overly negative pressures which can cause tubing collapse and/or air entrainment. Common sites for pressure monitoring on the CPB circuit include the arterial line (post-oxygenator), post-arterial pump (pre-oxygenator), the CPG circuit, and the venous reservoir.

Arterial line pressure (ALP) is a very important parameter to monitor particularly when using a roller pump. A high arterial line pressure can represent a malposition of the arterial cannula (aortic dissection, cannula against the aortic wall, etc.), a malpositioned aortic cross-clamp, a cannula that is too small for the desired pump flow, a kinked arterial line or cannula, or a clotting oxygenator. A low arterial line pressure can help diagnose an under-occluded roller pump, a kink in the CPB circuit pre-pump, excessive shunting from the arterial line (i.e., CPG pump, shunt line with VAVD, open AV bridge), and a clotted oxygenator (if measured post-oxygenator).

Cardioplegia circuit pressure is monitored while delivering CPG solution. The CPG pump can be servoregulated to prevent circuit rupture due to high pressure, prevent over-pressurization of the patient's coronary circulation, or to prevent pulling air across the oxygenator in the case of low arterial line pressure. The CPG line pressure can also be used to guide CPG delivery rates.

Venous reservoir pressure is monitored either directly from the venous line or from a port on

the reservoir. Monitoring of this pressure is a particularly important safety technique when using assisted venous drainage techniques (i.e., VAVD) with a sealed venous reservoir. Reservoir pressurization can lead to an air embolus traveling up the venous line and into the patient with potential catastrophic results [81].

Usage of flowmeters in pediatric CPB is particularly important since even a small shunting of pump flow can result in a patient being underperfused. Typical CPB circuit shunts include arterial filter purge lines, manifold lines (for drawing blood samples and administering drugs), and shunting blood through an ultrafiltration device. Noninvasive ultrasonic flowmeters can be placed on the arterial line of the CPB circuit at a point distal to any of these shunts, thus providing an accurate measurement of blood flow to the patient. Flowmeters can also be used on the venous line of the circuit to help optimize vacuum pressure with VAVD, determine if cannula adjustments result in improved venous return, and to help balance arterial flow with venous return [82].

Monitoring patient NIRS values, MAP, central venous pressure/left atrial pressure, patient temperatures, and laboratory values during CPB is extremely critical in providing safe, effective CPB support. Adult studies report that CPB impairs cerebral autoregulation. Some anesthetics, such as isoflurane, further impair autoregulation during CPB [83]. Pediatric-specific autoregulatory ranges are even less clear [84]. Numerous preoperative, intraoperative, and postoperative factors place children at risk of neurologic injury while undergoing surgical repair of cardiac disease. Injuries sustained during bypass or in the immediate postoperative period can have long-lasting sequelae. Some of these neurologic insults can be decreased through modulating inflammation, hypothermia, and other perfusion techniques. Despite these improvements in CPB protocols, it still carries significant risk of neurologic damage. Using NIRS monitoring to detect impending or ongoing cerebral ischemia can enable care providers to adjust clinical parameters to better support cerebral metabolism in real time.

Future Directions

The future of pediatric CPB will undoubtedly continue towards reductions in the systemic inflammatory response from CPB systems. This may involve the development of new polymers which mimic the native human endothelium, smaller components of the CPB circuit that will yield a much smaller foreign surface area, and pharmacologic interventions that may ameliorate the inflammatory effects of foreign material that the blood comes in contact with. As extracorporeal technology continues to evolve, CPB circuitry will become smaller and less inflammatory to better serve the neonatal cardiac patient.

Fetal cardiac surgery has been investigated and may show promise in preventing simple cardiac anomalies from becoming severe neonatal cardiac defects [85]. Fetal cardiac surgery with CPB is complicated and currently is not considered to be feasible for widespread adaptation [86]. However, fetal cardiac surgery is on the horizon and may become feasible as extracorporeal technology and cardiac surgical techniques become more advanced and refined for this delicate patient population.

Systemic Inflammatory Response to Cardiopulmonary Bypass in Pediatric Patients and Related Strategies for Prevention

44

Tara Karamlou and Ross M. Ungerleider

Abstract

Cardiopulmonary bypass in pediatric patients is associated with generalized activation of both innate and acquired immunity. The systemic inflammatory response occurs in response to multiple nonphysiologic stimuli. Activation of the inflammatory response involves an intricate cascade which results in pronounced amplification that affects nearly every end-organ system. These processes have a direct role in commonly encountered postoperative complications and can lead to significant morbidity following repair of congenital heart defects. This chapter will discuss the systemic inflammatory response related to cardiopulmonary bypass and measures that attempt to modulate this phenomenon.

Introduction

Cardiopulmonary bypass (CPB) in pediatric patients is associated with generalized activation of both innate and acquired immunity [1–7], and this phenomenon is exaggerated at the extremes of age [3]. The systemic inflammatory response to CPB occurs in response to multiple nonphysiologic stimuli, including exposure of blood elements to foreign surfaces, nonpulsatile perfusion, periods of relative hypoperfusion, alterations in temperature (especially hypothermia), and ischemia-reperfusion injury.

Defining the "systemic inflammatory response" within the context of pediatric CPB is challenging given that consensus guidelines published by the American College of Chest Physicians/Society of Critical Care Medicine (ACCP/SCCM) in 1992 described a final common pathway in adults, elucidated by a variety of insults [8]. According to these guidelines, two of the following manifestations must be fulfilled for the diagnosis: (1) body temperature higher than 38 °C or lower than 36 °C, (2) heart rate more than 90 beats per minute, (3) respiratory rate more than 20/min or $PaCO_2$ less than 32 mmHg, and (4) leukocyte count more than 12,000 cells/mm^3 or less than 4,000 cells/mm^3, or the presence of more than 10 % neutrophils. Owing to the difficulties extrapolating this initial

definition to particular subsets of patients, a more recent iteration was proposed [9]. The 2001 definition [9] is a hierarchical model, termed *PIRO*, that stratifies patients according to their ***p***redisposing conditions, the nature and extent of the ***i***nsult, the nature and magnitude of the host ***r***esponse, and the degree of concomitant ***o***rgan dysfunction.

Activation of the inflammatory response involves an intricate cascade which results in pronounced amplification that affects nearly every end-organ system. Neutrophils, which are the primary effector cells, become primed; complement and kallikrein-kinin systems are subsequently and systematically stimulated; inflammatory (and anti-inflammatory) cytokines are generated; and platelets are activated, subsequently covering the surface of the extracorporeal circuit resulting in microembolic events, further coagulation disturbances, and thrombocytopenia[2–17]. These processes have a direct role in commonly encountered postoperative complications and can lead to significant morbidity following repair of congenital heart defects. Multiple studies [2–6, 12–21] have demonstrated elevation of inflammatory mediators, myocardial dysfunction, capillary leak syndrome, acute lung injury, coagulopathies, and multiorgan failure[2–6, 12–21]. However, the precise contribution of CPB to these deleterious sequelae is more difficult to ascertain. Patients and procedural factors might play a variable role in inciting the post-CPB inflammatory response, and neither the occurrence nor the degree of postoperative sequelae is uniform [22]. Furthermore, recent evidence suggests that ischemia-reperfusion may play an increased role in the inflammatory cascade, especially concerning the cerebral and myocardial microcirculations. Caputo and colleagues [18] have published data suggesting that oxygen-mediated injury is implicit in myocardial injury (especially in cyanotic neonates) and also contributes to hepatic and neuronal injury.

Despite the multifactorial nature of the systemic inflammatory response following cardiac surgery in pediatric patients, developing techniques to ameliorate post-CPB injury are of considerable interest. Specific strategies aimed at reducing the deleterious systemic effects of CPB discussed in this chapter include pharmacologic agents (steroids), circuit coating, temperature modification, and use of ultrafiltration. The chapter will conclude with substantial discussion of a promising avenue of research and development pursued in our laboratory using circuit miniaturization and avoidance of allogeneic blood transfusion to improve post-CPB outcomes.

The Systemic Inflammatory Cascade

The inflammatory response to CPB has been extensively characterized elsewhere [1–22]. It is complex, incited by the exposure of blood to foreign surfaces, wide fluctuations in temperature, and ischemia-reperfusion injury. Though the majority of "contact activation" is attributed to the extracorporeal circuit interface with blood components, other commonly used adjuncts also contribute to post-CPB inflammation, including the use of cardiotomy suction and intracardiac venting. Patient-dependent factors including extremes of age and the presence of certain congenital defects further contribute to the wide range of systemic effects manifest in pediatric patients following CPB. In general though, several broad pathophysiologic categories can be defined as follows: (1) complement activation; (2) initiation of coagulation, fibrinolytic, and kallikrein cascades; (3) neutrophil activation with degranulation and proteolytic enzyme release; (4) oxygen-derived free radical production; (5) endotoxin and cytokine release; and (6) nitric oxide (NO), endothelin-1 (ET-1), and platelet-activating factor (PAF) production by "primed" endothelial cells [23–37] (Fig. 44.1). The sequential activation of these cascades coupled with extensive interactions result in a sustained and amplified systemic inflammatory response syndrome (SIRS) [21, 29–32].

Currently Used Strategies to Reduce Inflammation

Steroids

Glucocorticoids blunt neutrophil upregulation; inhibit the expression of adhesion molecules produced by the activated endothelial cells,

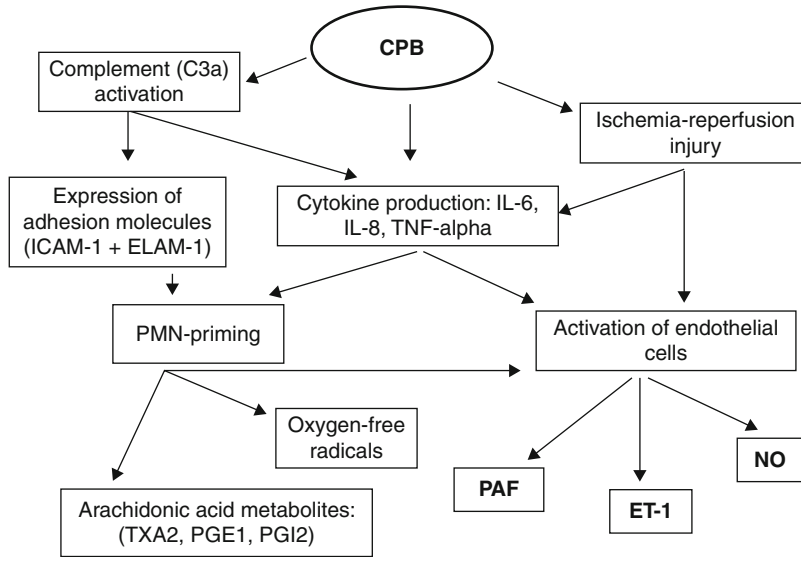

Fig. 44.1 Schematic representation of the biologic mechanisms responsible for the inflammatory response to cardiopulmonary bypass. The cascades are shown in sequential order, but significant redundancy and interactions exist between each arm. The cumulative result of these events is tissue injury and organ dysfunction. *CPB* cardiopulmonary bypass, *ICAM-1* intracellular adhesion molecule-1, *ELAM-1* endothelial-leukocyte adhesion molecule-1, *PMN* polymorphonuclear leukocyte, *TXA2* thromboxane A2, PGE_1 prostaglandin E1, PGI_2 prostacyclin, *PAF* platelet-activating factor, *ET-1* endothelin-1, *NO* nitric oxide, *IL* interleukin, *TNF* tumor necrosis factor

including endothelial-leukocyte adhesion molecule-1 (ELAM-1) and intercellular adhesion molecule-1 (ICAM-1); and therefore reduce diapedesis of leukocytes into injured areas [34–37]. In keeping with their pharmacologic mechanisms of action, steroid administration did appear to have salutary effects on post-CPB outcomes in earlier studies. Ungerleider's group [38, 39] has extensively studied the timing of steroid administration and found that premedication with methylprednisolone (Solumedrol®) 30 mg/kg 12 h preoperatively is beneficial relative to isolated administration in the pump prime. Bronicki and colleagues [40] demonstrated that preoperative administration of dexamethasone (1 mg/kg) intravenously 1 h before the pump run in children produced an eightfold decrease in interleukin-6 and a threefold decrease in tumor necrosis factor-alpha (TNF-α), which improved convalescence. However, more recent studies, including a randomized controlled trial in 76 neonates, have not shown corticosteroids to be beneficial in improving clinical metrics [35, 40–42]. Pasquali and colleagues [19] used a national database to study 46,730 patients aged 0–18 years undergoing congenital heart surgery, 54 % of whom received corticosteroids. These authors found that steroid administration did not reduce neither mortality nor length of mechanical ventilation. Patients receiving steroids had longer hospital length of stay, a greater prevalence of infection and need for insulin use, than nonsteroid recipients. Similarly, a recent meta-analysis [42] also failed to demonstrate any benefit in clinical outcomes with glucocorticoid use. Critics of these negative studies point out that steroid administration protocols were not standardized or even known (as in the study by Pasquali et al.) and therefore may have missed a true effect. It is also possible that changes in circuitry (with biologic coating, oxygenator miniaturization, smaller surface area from decreased circuit size, to cite a few examples) may have an influence in the manifestations of systemic inflammation in the more current era. However, the effect of steroids provided in large doses at least several hours prior to exposure to

the extracorporeal circuit has been shown to reduce the expression of inflammatory mediators, and anecdotal experience by several experts suggests that they remain an important consideration for neonatal and infant CPB.

Ultrafiltration and Leukocyte Reduction

Leukocyte filtration during CPB was initially tested in animals in the early 1990s and subsequently used in humans undergoing cardiac surgery [43]. Ultrafiltration can be broadly classified into two types: conventional ultrafiltration, which is carried out during the entire period of CPB (whether dilutional in which volume is added to the CPB circuit to permit greater levels of ultrafiltration, or otherwise), and modified ultrafiltration (MUF), which is conducted at the termination of CPB. Ultrafiltration of a blood prime prior to the institution of CPB (pre-bypass ultrafiltration, or BUF) is commonly performed at many centers as well. Whether performed in combination or alone, these ultrafiltration methods have been found to lower postoperative morbidity following pediatric CPB [44–48]. In particular, ultrafiltration lowers serum levels of pro-inflammatory cytokines, reduces the rise in total body and lung water following CPB in pediatric patients, and shortens the duration of mechanical ventilation relative to unfiltered control CPB [22]. However, the optimum ultrafiltration method is still debated for several reasons: (1) there is wide variation in the performance of ultrafiltration (type, endpoints, volume of ultrafiltrate); (2) patient characteristics (age, diagnosis, cyanotic or acyanotic lesions) and procedural characteristics (use of deep hypothermic circulatory arrest, temperature, myocardial protection, operative time) are heterogeneous; (3) easily measureable parameters such as cytokines have not consistently translated into linear improvements in durable clinical outcomes; (4) ischemia-reperfusion injury can be mediated initially by other effector cells, and thus occur independent of neutrophil participation [18, 20, 32]; and (5) the removal of certain anti-inflammatory cytokines, such as interleukin-10, may actually produce deleterious effects [18, 22, 49]. Furthermore, each method has unique benefits and drawbacks which complicate decision-making. MUF produces greater levels of hemoconcentration but requires additional exposure to the extracorporeal circuit. In contrast, conventional ultrafiltration does not lengthen the duration of CPB but can only moderately hemoconcentrate [50, 51]. A recent randomized trial of 60 infants undergoing biventricular repair by Williams et al. [22] reported no difference in clinical outcomes among infants receiving either MUF, dilutional conventional ultrafiltration, or both methods. Two recent reviews of ultrafiltration following cardiac surgery concluded that the results of published studies are conflicting and further investigations are necessary to delineate the best method in pediatric patients [22, 33, 50]. Not surprisingly, greater volumes of ultrafiltrate (greater than 104 ml/kg in neonates) appear to improve efficacy, and accordingly, the adequacy of ultrafiltration strategies should be assessed based on a meaningful increase in both hematocrit and arterial blood pressure [51–53]. Some studies may have demonstrated a negative or inconsequential effect of MUF simply because the MUF was not adequately performed.

Biocompatible Coated Circuitry

Heparin-coated circuits and more recently poly-2-methoxyethyl-acrylate (PMEA) coating may attenuate inflammation following infant CPB. Jensen and colleagues showed that the use of a heparin-coated perfusion system reduced fibrinolytic activity following bypass in a prospective randomized trial of 40 children [54]. A similar reduction in C-reactive protein and complement levels with PMEA-coated circuitry was demonstrated by Ueyama et al [55]. in a prospective randomized study comparing heparin-coated, PMEA-coated, and conventional circuits.

Despite the use of these strategies, organ dysfunction remains a significant problem in infants after the use of hypothermic low-flow CPB or deep hypothermic circulatory arrest [16, 30, 31].

Modification of Perfusion Temperature

Hypothermia has been widely used to provide end-organ protection during periods of ischemia [56–58]. The main rationale for body cooling is to reduce metabolic rate sufficiently to allow greater matching between oxygen consumption and delivery. Early studies in pediatric patients demonstrated a systemic anti-inflammatory benefit with lower perfusion temperatures, though salutary effects were been elucidated in the brain parenchyma, where increased white cell activation within the cerebral microcirculation, both histologically and in serum, correlated in linear fashion with increased CPB temperature [56, 59]. Based on studies in adult patients undergoing coronary artery bypass graft operations that demonstrated improved neurologic and myocardial function with normothermic CPB, however, attention was refocused on investigation of the impact of perfusion temperature [18, 56]. Several recent studies have reported either small improvements in measured outcomes [18] or no impact of perfusion temperature on outcomes following pediatric CPB [56, 60]. Caputo and colleagues [18] performed a randomized trial of 59 children undergoing correction of simple congenital heart disease into either a hypothermic (28 °C) strategy or a normothermic strategy (37 °C). Though inflammatory mediators increased in both groups, normothermic CPB produced less myocardial oxidative stress, as measured by troponin I and 8-isoprostane release, compared to hypothermic CPB. Unfortunately, the reduced levels of apparent myocardial injury in this study did not translate into measureable clinical benefits. Stocker and colleagues [56] similarly found that systemic cooling to moderate hypothermia (24 °C) produced no benefit in either short-term clinical outcomes (duration of mechanical ventilation, ICU or hospital length of stay) or serum markers of acute inflammation.

Miniaturized Circuitry and a Bloodless Prime

The deleterious effects of allogeneic blood transfusions are well characterized and include transmission of blood-borne diseases, immunomodulation in cancer patients, and the risk of alloimmunization precluding organ transplantation [20, 21, 32, 61, 62]. Recently, though, the potent pro-inflammatory effects of blood usage have been elucidated [20, 21, 32, 61–63]. Silliman and colleagues have shown that blood transfusion is a major risk factor for postinjury multiorgan system failure, especially in certain susceptible patients, including trauma patients, infants, and those exposed to cardiopulmonary bypass [64, 65]. Silliman et al [65]. have also shown that the risk of transfusion related morbidity is highly correlated with the duration of blood storage.

The neutrophil has been implicated as a primary effector cell in the pathogenesis of transfusion-mediated hyperinflammation [63–67]. The plasma from stored red blood cells directly primes PMNs for cytotoxicity, prompting the release of lytic enzymes (sPLA2, superoxide (O_2-), and elastase) [32, 63–67]. Additionally, recent studies have documented delayed apoptosis of neutrophils in patients receiving blood transfusions [47, 68–71]. Unfavorable sequelae may be further magnified by current treatment paradigms used in congenital heart surgery. Fresh whole blood, often used in the conduct of infant CPB, was associated with increased fluid overload and longer ICU length of stay in a recent randomized study of 200 pediatric patients [72]. In addition, the general reticence to accept a hematocrit <30 % despite evidence that a hematocrit of 25 % is adequate leads to unnecessary transfusion [20, 21, 32].

In addition to the contribution of homologous blood products, inflammation has also been associated with the use of large prime volumes and circuit surface area in animal models [20, 21, 32, 73–75]. Wabeke and colleagues [74] employed vacuum-assisted venous drainage in a rabbit model of CPB and showed that the use of a smaller prime (90 vs. 330 ml) normalized resistance in the peripheral microcirculation. Hanley's group [75] also showed improved

placental hemodynamics and decreased C3a and lactoferrin levels with the use of a miniaturized bypass circuit in an ovine fetal model.

Although small feasibility studies in neonatal piglets have shown that avoidance of blood can be achieved in infant CPB by a sufficient reduction in circuit size [20, 21, 32], few clinical studies have been reported. Fukumura and colleagues [76] used a low-volume prime in conjunction with dilutional ultrafiltration in 19 neonates with transposition of the great arteries undergoing arterial switch operation. The miniaturized circuit reduced postoperative water gain, improved systolic blood pressure, and reduced ventilatory time. Koster and colleagues [77] used a miniaturized circuit of 110 ml for repair of congenital heart defects in 13 consecutive neonates (weight 1.7–4.1 kg), demonstrating that their circuit allowed asanguineous priming in 6 patients. Reduction in inflammatory mediators was similarly shown by Fromes et al [78]. who incorporated biocompatible components into a minimal extracorporeal circuit in adult patients.

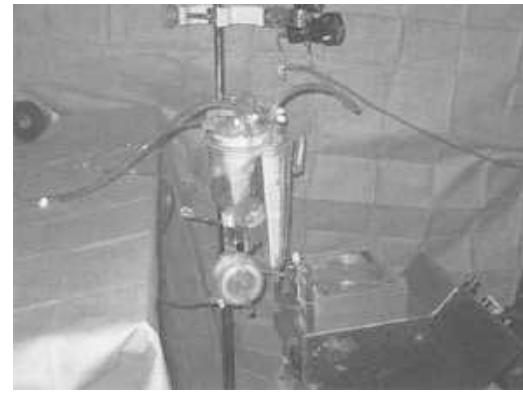

Fig. 44.2 Photograph of the miniaturized cardiopulmonary bypass circuit. A single-roller pump head is stationed immediately adjacent to the operating table to minimize tubing lengths. To improve venous drainage, an additional roller head (out of picture) is used in conjunction with the pictured regulator to provide vacuum-assisted drainage at -20 mmHg. A left ventricular vent drains into the reservoir to prevent left ventricular distension in the presence of aortic insufficiency, sometimes experiences when using the low-flow strategy. The oxygenator has a prime volume of 47 ml, the smallest commercially available. For an asanguineous prime, heparin, sodium bicarbonate, fentanyl, and albumin to a total volume of 50 ml are used to prime the oxygenator only. Immediately on cannulation the circuit and reservoir are retrograde primed and bypass initiated

Reducing Systemic Inflammation with a Miniaturized Circuit

This author's group developed a miniaturized circuit with a total priming volume of 109 ml to determine whether reduction in circuit size and avoidance of blood reduces inflammation following hypothermic low-flow CPB in a neonatal piglet model [20, 21, 32]. The circuit devised for this experiment consisted of a reconfigured pump console that was placed immediately adjacent to the experimental subject, a Polystan infant oxygenator requiring a 52 cc prime, and 3/16' tubing throughout (Fig. 44.2). Vacuum-assisted venous drainage was employed to augment venous return, and there was no arterial filter. Sixteen neonatal piglets (3–5 kg) were divided into three groups based upon the prime constituents: group 1 ($n = 5$) underwent CPB using a conventional circuit (175 ml) primed with fresh blood, group 2 ($n = 5$) underwent CPB using a conventional circuit (175 ml) primed with blood harvested 6 days prior to use, and group 3 ($n = 6$) underwent CPB using a miniaturized circuit (109 ml) to achieve an asanguineous prime. The blood was harvested from donor swine using sterile technique and stored in CPD bags at 4 °C. The piglets were placed on CPB (100 ml/kg/min), cooled to 18 °C and then underwent continuous CPB (50 cc/kg/min) for 30 min. The piglets were then rewarmed to normothermia and weaned from CPB. Serum TNF-α and right ventricular and pulmonary function parameters were measured before and after CPB. Neutrophil priming activity in the fresh and aged donor blood was also assessed.

The results are summarized in Table 44.1. In addition, TNF-α was lower in the miniaturized circuit group (group III) (1465 ± 397 pg/ml) than in the groups receiving blood (3940 ± 77 pg/ml), $P = 0.004$. Neutrophil priming activity, measured by superoxide production, was significantly

Table 44.1 Post-cardiopulmonary bypass (CPB) parameters ($n = 16$). Group I animals received a conventional circuit primed with fresh blood. Group II received a conventional circuit primed with stored blood. Group III animals received a miniaturized circuit and crystalloid prime

higher in aged blood (3.71 ±.55 nmol/min) than in fresh blood (1.89 ± 0.15 nmol/min), $P = 0.02$.

In summary, in a neonatal swine model, the use of a miniaturized circuit and an asanguineous prime reduced TNF-α, improved right ventricular and pulmonary function, and reduced fluid sequestration. Our findings may be partly explained by increased neutrophil priming activity, which is related to the duration of blood storage.

Conclusions

CPB in pediatric patients incites a robust systemic inflammatory response, which contributes to important postoperative morbidity following repair of congenital heart defects. The inflammatory response is a multifactorial and complex cascade that begins with activation of vascular endothelium in response to contact of blood elements with foreign surfaces. The cascade is initiated primarily by neutrophils and involves both the complement and coagulation cascades. End-organ function is impacted in an unpredictable manner, but certain patient subsets (cyanotic lesions) and organs (brain, myocardium) appear to be at increased risk. Strategies to reduce the post-CPB inflammatory response are numerous and include pharmacologic, mechanical, and physiologic manipulation instituted during all phases of perioperative care.

Neuroprotection Strategies During Cardiopulmonary Bypass

45

Yoshio Ootaki and Ross M. Ungerleider

Abstract

The conduct of operative procedures for repair of congenital cardiac defects has evolved over time. Initially, intracardiac operations were performed with the aid of profound hypothermia and circulatory arrest. Over time, bypass and surgical techniques improved, obviating the need for deep hypothermic circulatory arrest for all but the most complex surgical procedures. Since the beginning, congenital cardiac diseases and the surgical intervention for these defects have been associated with neurologic dysfunction. The perioperative period has often been associated with the complication of neurologic injury, although it has become quite clear that the perioperative period is only one small point in time in which neurologic injury can occur. However, several important variables and techniques used for the management of congenital cardiac defects may help prevent neurologic injury. This chapter overviews some of the strategies utilized for neuroprotection.

Introduction

Since the inception of congenital cardiac surgery, there has been an association between repair of complex cardiac defects and neurologic injury. What has also become evident is that there is a clear association between congenital cardiac defects and neurologic anomalies, regardless of the corrective cardiac surgical procedures. Because of the known association of congenital heart diseases (CHD) and their subsequent repair with neurologic injury, techniques used to facilitate surgical correction have been implicated as causal for neurologic injury. One such technique, deep hypothermic circulatory arrest (DHCA), has been particularly implicated in the development of neurologic injury. DHCA is a technique that involves the complete cessation of systemic and cerebral blood flow (CBF) at hypothermic temperatures to facilitate complex

cardiac repairs. Impaired neurologic recovery has become causally linked to cerebral ischemia sustained during DHCA. Considerable time and energy has consequently been spent reducing or eliminating periods of cerebral ischemia during cardiopulmonary bypass (CPB) through the use of several perfusion techniques, including antegrade selective cerebral perfusion (SCP), retrograde cerebral perfusion (RCP), circulatory arrest with intermittent perfusion (IP), and normothermic/mild hypothermic full-flow bypass. All techniques have advantages as well as limitations.

Evidence is gradually accumulating to suggest that numerous nonsurgical factors predispose to the initiation and progression of brain injury in the neonatal period. The incidence of neurologic injury in the treatment of CHD has not been affected by the surgical and cardiopulmonary bypass techniques designed to avoid DHCA. Furthermore, multivariable regression analyses studying the entire neonatal period demonstrate that intraoperative factors account for less than 20 % of the variance in neurologic dysfunction [1]. An understanding of these risks, together with the particular vulnerability of the immature brain, is therefore necessary to continue the pursuit of improved neurologic outcomes following infant cardiac surgery.

Preoperative Factors Influencing Neurologic Outcome

Prematurity as an independent cause of perinatal brain injury is of enormous importance. More than 40 % of premature newborns (<34 weeks gestational age) may show neurodevelopmental delay associated with white matter injury, ventriculomegaly, or intraventricular hemorrhage [2]. This significant morbidity is primarily due to the particular vulnerability of the immature human brain to hypoxic, chemical, and inflammatory injuries. Developing white matter (WM) appears especially at risk and specific "temporal windows" of this susceptibility to injury are now being recognized. The most dangerous period is preterm at 32–34 weeks' gestation, and injury in this window results in cystic necrosis and gliosis in the periventricular WM regions, resulting in periventricular leukomalacia (PVL). Nevertheless, this window of vulnerability has been shown to extend later into gestation and the early post-term period. The fact that many infants born with complex CHD exhibit microcephaly and developmental immaturity has led some authors to speculate that they display the same vulnerability, extending well into the neonatal and perioperative period [3, 4].

Recent magnetic resonance imaging (MRI) studies have confirmed that 29 % of neonates showed abnormal brain MRI findings before congenital heart surgery and 38 % of neonates showed new abnormal MRI findings after congenital heart surgery [5]. In neonates with hypoplastic left heart syndrome (HLHS), 23 % of patients demonstrated preoperative ischemic lesions in MRI, and 73 % of neonates demonstrated new or worsened ischemic lesions after surgery [6]. Another MRI study showed that PVL was seen in 54 % of neonates (age <30 days) after cardiac surgery compared with 4 % in infants (age >30 days) [7]. Magnetic resonance spectroscopy (MRS) revealed abnormal brain metabolism in neonates with CHD [5, 8], which might reflect impaired brain development in utero. From 41 autopsy studies in infants with HLHS, microencephaly was found in 27 % of patients, and immature cortical mantle was found in 21 % of patients [9]. From 52 autopsy studies in patients with CHD, brain anomalies were seen in 71 % of patients [10]. The association of prematurity and CHD patients with white matter injury is corroborated by these studies.

Mortality and morbidity after cardiac surgery have been studied in patients with CHD associated with genetic disorders (e.g., trisomy 21, deletion 22q11) [11–13]. However, there are few studies examining the neurodevelopmental outcomes in children with CHD and genetic disorders who underwent cardiac surgery. Gaynor and associates [14] reported that the presence of a genetic syndrome was an important predictor of neurodevelopmental delay after

repair of tetralogy of Fallot. They also reported [15] the impaired neurodevelopmental outcome after cardiac surgery in infants associated with genetic syndromes. Other genetic factors such as apolipoprotein E genotype were recognized as risk factors of central nervous system injury after infant cardiac surgery [16].

Perfusion Technique

Strategies for the conduct of cardiac surgical procedures have evolved. Every technique has a role in the safe conduct of a cardiac surgical procedure, and there is clear preference among surgeons regarding these strategies.

Deep Hypothermic Circulatory Arrest (DHCA)

DHCA involves the complete uninterrupted cessation of CPB flow after a period of perfusion cooling to a predetermined target temperature – usually below 22 °C. The advantages of DHCA include the ease and simplicity of cardiopulmonary bypass combined with unparalleled clarity in a surgical field free of blood and ancillary equipment. In addition, it is worth considering that DHCA may involve a relatively shorter exposure to CPB than continuous perfusion techniques. The "ideal" maximally protective temperature has not been established but should offset potential harmful consequences of severely nonphysiologic temperatures against the necessary reduction in cerebral metabolic oxygen consumption. A typical target temperature of between 16 °C and 20 °C has emerged through anecdotal practice. For prolonged (>40 min) exposure to circulatory arrest, it is generally recommended that cooling duration should be for a minimum of 20 min, and the head should be packed in ice for the entire ischemic period to prevent cerebral rewarming from ambient room temperature throughout the period of circulatory arrest.

After the reinstitution of CPB, rewarming is initiated by removing the ice and warming the CPB perfusate. Particular attention should be paid to the temperature gradient, which should not exceed 10 °C between venous and arterial blood, during rewarming because there is a real risk of liberating dissolved gases in the form of air emboli, which are recognized to result in microvascular obstruction. It is widely accepted that rewarming should be more gradual, over a minimum period of approximately 30 min, to prevent rebound hypothermia once separated from CPB.

Considerable energy has been spent attempting to identify the minimum "safe" duration of DHCA, the threshold beyond which the hazard for sustaining neurologic dysfunction begins to rise significantly. Based on experimental and clinical studies, this period appears to be approximately 40 min.

The observed link between cardiac surgery and neurologic injury was historically interpreted as a causal link to DHCA. Experimental studies were energetically undertaken to investigate the effects of DHCA on cerebral physiology and neuronal injury. Cerebral reperfusion anomalies (no-reflow) are a consistent feature of DHCA and have been interpreted as an indicator of poor neurologic outcomes, although this link has not been well established. Nevertheless, interventions that alleviate no-reflow including steroids [17], leukocyte filtration [18], platelet-activating factor antagonism [19], circuit miniaturization [20], and intermittent perfusion [21] are all considered to be beneficial to subsequent recovery.

In the 1990s, several groups used histologic models in neonatal piglets to confirm that DHCA initiated diffuse neuronal death throughout the cerebral cortex, basal ganglia, and hippocampus [22–25]. However, these models required lengthy (60–120 min) uninterrupted DHCA and the animals frequently received no cardiorespiratory support postoperatively. The relevance of these studies to the modern application of DHCA is therefore dubious. Nevertheless, DHCA has progressively fallen out of favor with many surgeons who have adopted novel continuous perfusion techniques.

The Boston Circulatory Arrest Trial represents an impressive attempt to examine the impact of DHCA on neurologic outcome in a carefully controlled prospective manner and provides the best insight into "safe" durations of DHCA on functional outcome. The investigators chose to study patients with D-transposition of the great arteries who underwent an arterial switch operation [26]. This diagnosis is associated with an extremely low incidence of noncardiac anomalies, and because patients should have essentially normal hemodynamic physiology after a successful arterial switch operation, they are ideally suited for studying neurologic outcomes. After randomizing patients to surgical repair using either uninterrupted DHCA or deep hypothermic continuous low-flow CPB (50 mL/kg/min), the children have been subsequently followed up to 8 years with detailed neurodevelopmental assessments. Overall, despite lengthy DHCA durations (mean 52 min), the children did not perform significantly worse in Wechsler academic achievement tests, neuropsychological testing, or speech and language development when compared with children exposed to continuous low-flow CPB. More importantly, both groups of children faired significantly worse than age-matched controls, supporting the idea that factors other than cerebral ischemia in the perioperative period are important. Careful analysis of the impact of uninterrupted DHCA duration on neurodevelopmental outcome implied a threshold of approximately 41 min, beyond which the risk of permanent cerebral injury is significantly elevated [27]. This is consistent with earlier observational and anecdotal reports suggesting a "safe" threshold for uninterrupted DHCA of 45 min [28]. At present, there is no clinical evidence to suggest that DHCA for durations shorter than this are associated with greater neurologic impairment than any other CPB strategy. Nevertheless, few topics inspire more contentious debate [29] than differences between perfusion strategies for the repair of congenital cardiac defects.

Regional/Selective Cerebral Perfusion (SCP)

The relation between reduced cerebral metabolic oxygen consumption and hypothermia prompted the notion that greatly reduced cerebral flow rates during CPB might nevertheless provide sufficient oxygenated blood to prevent accumulation of anaerobic metabolic products. Therefore, the concept of low-flow CPB emerged in the early 1990s [30] to reduce cerebral ischemic injury while avoiding some of the technical incumbencies of full-flow CPB. Experimentally, low-flow CPB is usually administered at a rate of 50 mL/kg/min through the aorta [31], delivering approximately 40–50 % normal cerebral blood flow (CBF). In clinical practice, low-flow CPB is more frequently administered through a cannula inserted in the innominate artery (or a prosthetic graft anastomosed to the innominate artery), and therefore, this is more accurately regional or SCP (selective cerebral perfusion). Further confusion arises because 50 mL/kg/min to the cerebral circulation actually represents quantitatively normal CBF. Nevertheless, despite being quantitatively normal overall, regional distribution of CBF during regional perfusion abnormalities may still result in no-reflow phenomena [32]. This may be because CBF at hypothermia is pressure dependent rather than flow dependent [33].

Continuous low flow and SCP are associated with preservation of cerebral energy stores [30], improved cerebral reperfusion [20], improved histologic outcome, and improved neurologic function [34] when compared with prolonged (60–120 min) uninterrupted DHCA in the experimental setting. However, these extremely prolonged DHCA durations represent significant departure from clinical practice, and therefore the relevance of these observations is doubtful. No direct experimental comparisons between continuous perfusion techniques and DHCA in the range 0–40 min have been made. The only randomized clinical trial conducted on this subject failed to demonstrate a significant

advantage through the use of continuous cerebral perfusion [26]. Several groups have examined the impact of flow rates on histologic outcome. At deep hypothermia, Jonas' group concluded that any flow rate between 10 and 50 mL/kg/min was adequate to prevent histologic injury and maintain baseline cerebral oxygenation (as determined using NIRS) [35]. Flow rates below 25 mL/kg/min at moderate hypothermia (25 °C) resulted in both histologic injury and cerebral tissue oxygenation falling below the baseline 55 %. At mild hypothermia, however, all the low-flow strategies resulted in histologic and functional injury [35]. Loepke and associates also failed to detect histologic abnormalities after prolonged deep hypothermic low-flow CPB at 25–50 mL/kg/min, but at rates as low as 5 mL/kg/min, the resulting injury in the neocortex, basal ganglia, and hippocampus was mild [36]. Despite overall cerebral tissue oxygenation remaining above baseline during hypothermic low-flow CPB, regional perfusion abnormalities do occur, which gives rise to the potential for regional cerebral ischemic injury. Consequently, no-reflow may occur following low-flow CPB, although less consistently and to a lesser extent than DHCA [20].

Retrograde Cerebral Perfusion (RCP)

Retrograde cerebral perfusion (RCP) was first used as a method to flush out massive air embolism during cardiopulmonary bypass (CPB) [37]. This method was introduced as a means to improve cerebral protection during DHCA in 1990 [38]. Since then, RCP has been successfully used mainly in adult thoracic aortic surgery as an adjunct to DHCA to enhance cerebral protection [39]. Mechanisms with which retrograde cerebral perfusion may accomplish neuroprotection include the flushing of air and atheromatous embolic material from the cerebral circulation, the maintenance of cerebral hypothermia, and the provision of nutritive cerebral flow [40]. However, its effect is controversial [41].

RCP has also been applied to the pediatric population [42, 43]. However, RCP has not been widely used in the pediatric population possibly due to wide acceptance of DHCA and to the technical difficulty for cannulation of the SVC in neonates in order to provide RCP. [44].

Intermittent Perfusion (IP)

Analogous to the wisdom behind the administration of blood cardioplegia intermittently, in the late 1990s the concept of IP emerged [21]. Experimental studies demonstrated that ultrastructural abnormalities sustained during uninterrupted circulatory arrest could be avoided by intermittently perfusing at full pump flows for 2 min every 20 min. Experimental studies have indicated that IP reduces cerebral no-reflow and reduces the astroglial ultrastructural changes associated with DHCA [21]. Many surgeons who employ DHCA have embraced this concept either by adhering to a predetermined IP regimen or otherwise more commonly by administering brief periods of systemic flow at convenient interludes in the surgical procedure. The required rate of systemic flow during the period of IP necessary to prevent the increase of harmful metabolic products has recently been shown to be approximately 80 mL/kg/min [45]. Cerebral oximetry can provide a guide for IP strategy during the surgery [46]. The clinical impact of IP protocols on functional neurologic recovery has not been formally characterized.

The introduction of IP strategies has raised the suggestion that cooling to deep and profound hypothermic temperatures may not be necessary. Target temperatures in the region of 20–25 °C (moderate hypothermia) have several theoretical advantages. The most obvious are the shorter durations required for cooling and rewarming and therefore potentially shorter overall durations of CPB. In addition, the neurologic and systemic inflammatory consequences of very low temperatures have not been clearly delineated. These authors have made preliminary attempts to

study circulatory arrest with IP at 25 °C. Because of the higher core temperatures, it was chosen to adopt briefer cycles of ischemia and reperfusion: 2 min reperfusion after every 10 min ischemia. After favorable experiences in animal studies, this practice has now been transferred to the clinical setting by taking one step further. After cooling to 25 °C, full-flow CPB is maintained at this temperature, and we arrest the circulation only when absolutely necessary as dictated by the surgical procedure, thus producing a strategy that is more like continuous perfusion with intermittent circulatory arrest rather than circulatory arrest with intermittent perfusion. To further protect the brain from ischemia, the head is packed with ice until rewarming is commenced and exposure to intermittent periods of circulatory arrest is no longer necessary. Anecdotally, this novel concept of moderate hypothermia with intermittent circulatory arrest is extremely well tolerated with short cooling and rewarming durations and detectably smoother weaning from CPB. This practice has yet to be formally studied, but these experiences lead to suggest that this may be a useful compromise.

Normothermic/Mild Hypothermic Full-Flow Bypass

Several groups have recently advocated the use of normothermic CPB strategies for the repair of complex CHD on the empirical assumption that it represents a more "physiologic" and less inflammatory state [47–50]. Caputo and associates reported lower troponin levels following normothermic CPB, although when adjusted for duration of aortic cross-clamp, this observation was no longer significant [50]. Moreover, levels of activated complement C3a and IL-6 and IL-8 were not different than levels after more conventional CPB strategies. This same group also reported that normothermic CPB is associated with similar renal impairment in children compared with hypothermic CPB [51]. However, the study group consisted of relatively older children (more than 3 years old), and the inflammatory response after the normothermic CPB was not investigated. Pouard and associates similarly reported lower levels of troponin, and a nonsignificant trend toward shorter intensive care stays with normothermic CPB [50]. Ly and associates reported their experience with normothermic CPB using selective cerebral perfusion for aortic arch repair [52]. They reported that all patients were free from neurologic symptoms and at follow-up were growing and developing normally.

However, the long-term benefits and the cerebral effects of using normothermic CPB have not been assessed, and there is a significant body of evidence to suggest that normothermic temperatures may not be advantageous. Normothermic selective cerebral perfusion did not reduce postoperative neurological dysfunction in some reports [53]. Higher CPB temperatures are associated with leukocyte activation and elevated numbers of rolling and adherent leukocytes on intravital microscopic evaluation of the cerebral circulation [54]. Furthermore, normothermic temperatures require high flow rates, which increase the risk of microemboli and increase left heart return and the need for suction. This results in impaired intracardiac surgical exposure. Therefore, despite considerable opinion and debate, the subject of normothermic full-flow CPB is largely a matter of personal preference with no proven benefit.

Acid–Base Management

The role of CO_2 management in CPB has been studied extensively both in animal models and in prospective randomized trials in pediatric patients [55, 56]. Two different blood gas management strategies have been advocated based on the effect of CO_2 on arterial and intracellular pH at hypothermic temperatures: *α-stat strategy* maintains a pH of 7.40 measured without mathematic correction for temperature effects, whereas *pH-stat* uses a nomogram-based mathematic correction for the alkalotic effects of hypothermia. Using pH-stat strategy, CO_2 is added to

maintain a temperature corrected pH of 7.40. The addition of CO_2, however, lowers the intracellular pH, resulting in impaired intracellular enzymatic function. In addition, the loss of electrochemical neutrality is rendered more problematic because at hypothermic temperatures, the normal buffering systems (NH^{3-}, HCO^{3-}) become ineffective. At hypothermia, buffering capacity is limited to negative charges of the amino acids composing intracellular proteins. The amino acid histidine, which contains an α-imidazole ring, is the most important buffer at hypothermic conditions. The principal advantage of α-stat strategy, therefore, is in preserving intracellular electrochemical neutrality, maintaining appropriate intracellular pH, and improving the efficacy of intracellular enzymatic function [57]. During moderate hypothermia, selecting one blood gas management strategy over the other appears less critical, because brain intracellular pH differences are small [58, 59]. During deep hypothermia (with or without DHCA), the addition of CO_2 during active brain cooling could potentially improve the distribution of the cold perfusate to deep brain structures.

Alpha-stat strategy became the preferred approach in many centers based on experimental findings suggesting that α-stat preserved cerebral autoregulation and maintained coupling between flow and metabolism down to low cerebral perfusion pressures to near 20 mmHg [60]. The experimental data was, in part, supported by trials in adult patients demonstrating improved cognitive outcomes with α-stat management [61, 62]. These data were never confirmed in the pediatric population, however.

Virtual epidemics of choreoathetosis following a switch in perfusion protocols from pH-stat to α-stat prompted a reinvestigation of the optimum blood gas strategy. Several studies suggested that pH-stat management enhances the distribution of extracorporeal perfusate to the brain and may help cool the brain more thoroughly and rapidly [63, 64]. Although improved cooling was seen in these studies, metabolic recovery after circulatory arrest was shown to be impaired suggesting that the acid load induced by pH-stat had a negative effect on enzymatic function after cerebral rewarming. A prospective clinical trial of α-stat versus pH-stat at Boston Children's Hospital demonstrated decreased morbidity and a trend toward decreased mortality in infants randomized to pH-stat management [55]. Numerous clinical and laboratory studies from other centers in recent years have confirmed the advantages of the pH strategy for pediatric bypass [65–70]. The group at Duke in 2000, based on their experimental work in a neonatal piglet model [63], advocated a combined blood gas management strategy using pH-stat during cooling, followed by α-stat management before initiation of circulatory arrest. The authors of this study hypothesized that such a successive strategy would allow the beneficial effects of more uniform cooling along with avoidance of intracerebral acid load during rewarming.

On the basis of the collective body of experimental and clinical evidence, these authors would advocate the use of pH-stat management for hypothermic CPB in infants, at least during the period of perfusion cooling. Current trends to reduce the degree of hypothermia, shorten the duration of circulatory arrest, and prolong the time allocated for rewarming may reduce the relative importance of one management strategy versus another.

Transfusion

Hemodilution and Circuit Miniaturization

Hemodilution during CPB was initially introduced to reduce allogeneic blood requirement in combination with the large early CPB circuits. In addition, hemodilution was proposed to improve flow in the microcirculation. In past decades, standard practice would involve lowering the hematocrit during CPB to 25 % or even as low as 20 % [71]. However, severe hemodilution is a problem not only for red cell-dependent

gas transport but also for platelet and humoral factor-dependent coagulation and protein-dependent intravascular oncotic pressure. The threshold for "unacceptable" hematocrit is not clearly defined, but several studies indicate that oxygen delivery, tissue blood flow, and clinical outcome may only be affected at levels below 14–17 % for extended periods of time [72, 73].

Circuit miniaturization is another method to reduce allogeneic blood requirement as well as CPB inflammatory response. Wabeke and associates employed vacuum-assisted venous drainage (VAVD) in a rabbit model of CPB and showed that the use of a smaller prime (90 vs. 330 mL) normalized resistance in the peripheral microcirculation [74]. Hanley's group showed improved placental hemodynamics and decreased C3a and lactoferrin levels with the use of a miniaturized bypass circuit in an ovine fetal model [75]. Supported by these effects of miniaturization of the CPB circuit, a more aggressive reduction of the CPB circuit size has also been shown to perform well in the clinical field. Fukumura and associates used a low-volume prime in conjunction with dilutional ultrafiltration in 19 neonates with transposition of the great arteries undergoing arterial switch operation [76]. The miniaturized circuit reduced postoperative water gain, improved systolic blood pressure, and reduced ventilatory time. Reduction in inflammatory mediators was similarly shown by Fromes and associates who incorporated biocompatible components into a minimal extracorporeal circuit in adult patients [77]. Koster and associates reported a significant reduction of transfusion in neonatal open-heart surgery using miniaturized CPB circuit, which consisted of 110 mL of priming volume [78]. They performed cardiac surgery in neonates without blood transfusion in 6 out of 13 patients. This same group reported using a miniaturized CPB circuit with which they safely performed cardiac surgery without transfusion in 17 out of 23 neonates. However, the neurologic outcome for their patients is still unclear from these trials and assessment of the clinical benefits has yet to be undertaken.

Transfusion Strategies

Jonas' group undertook a randomized clinical trial comparing hemodilution to hematocrits of 20 % or 30 % in patients with cardiac surgery less than 9 months of age [79]. Intraoperative data were comparable but psychomotor development scores were significantly worse in the lower hematocrit group. However, mental development scores were not different, nor were the incidences of abnormal neurologic examinations. Newburger and associates undertook randomized clinical trial of hemodilution to a hematocrit value of 25 % versus 35 % in infant cardiac surgery [80]. There were no major benefits or risks between two groups. Psychomotor Development Index and Mental Development Index scores at 1 year also did not show any significant differences, although these values were lower compared with normal age group.

Several animal studies have revisited the issue and increasingly suggest that higher hematocrits (30 %) are preferable [81–83]. Not only is tissue flow and metabolism improved, but leukocyte and endothelial cell activation is also reduced [82]. The evidence is not firm enough to categorically advocate one category over the other, but a gradual shift away from lower hematocrits toward a target hematocrit on CPB of 25–30 % (and higher) is occurring.

Anti-inflammatory Agents

Steroids

Many clinical and laboratory studies have suggested that corticosteroid usage improves the postoperative course after CPB [17, 84, 85]. These salutary effects have mainly included a reduction in myocardial injury with improved cardiac output and decreased pulmonary edema [85, 86]. Glucocorticoids blunt neutrophil upregulation; inhibit the expression of adhesion molecules produced by the activated endothelial cells, including endothelial-leukocyte adhesion molecule-1 (ELAM-1)

and intercellular adhesion molecule-1 (ICAM-1); and therefore reduce diapedesis of leukocytes into injured areas [87, 88]. Whether exogenously administered corticosteroids provide enhanced neuroprotection following DHCA is more controversial [89]. A study by Schubert and associates showed no attenuation of neuronal injury following 120 min of DHCA in a neonatal piglet model using 30 mg/kg of methylprednisolone administered 24 h before surgery [90]. In fact, these authors showed both increased rates of necrotic neuronal cell death and apoptosis at 6 h following separation from CPB. In contrast, Langley and associates demonstrated improved recovery of CBF following 60 min of DHCA in their neonatal piglet model wherein methylprednisolone (30 mg/kg) was administered at 8 h and 2 h before surgery [17]. Given the disparate experimental findings, it is not surprising that current steroid administration practices (type, dosing, route, and timing) during the conduct of pediatric open-heart surgery are highly variable [91]. Ungerleider's group [17, 85] has extensively studied the timing of steroid administration and found that premedication with methylprednisolone (Solu-Medrol) 10 mg/kg 12 h preoperatively is beneficial relative to isolated administration in the pump prime. Bronicki and associates demonstrated that preoperative administration of dexamethasone (1 mg/kg) intravenously 1 h before the pump run in children produced an eightfold decrease in IL-6 and a threefold decrease in TNF-α, which improved convalescence [84].

A multicenter randomized trial recently underwent to assess the effect of single dose or double dose of methylprednisolone [92]. The interleukin-6 level was reduced in the double dose group; however, double dose methylprednisolone was associated with higher serum creatinine and poorer postoperative diuresis. There was no clinical difference between two groups such as duration of mechanical ventilation and intensive care unit and hospital stay. The Toronto group recently demonstrated that double dose methylprednisolone reduced duration of mechanical ventilation, intensive care unit stay, and hospital stay in children undergoing high-risk cardiac surgery [93]. Given the lack of consensus regarding-steroid administration and the wide variations in practice among large centers in North America, it is clear that a multicenter clinical trial to investigate the potential impact of corticosteroids, patient selection, and their optimum administration is indicated.

Aprotinin

Aprotinin is a serine protease inhibitor that inhibits kallikrein and plasmin, resulting in suppression of multiple systems involved in the inflammatory response, including inhibition of factor XII, bradykinin, and anaphylatoxins, as well as activation of leukocytes and platelets [94]. Although no longer available, the effects of aprotinin are noteworthy and included in this chapter both for historical relevance and to indicate the extraordinary influence aprotinin (and perhaps future similar preparations) can have on outcome in infant cardiac surgery. Aprotinin has known efficacy in reducing the bleeding diathesis that frequently accompanies the use of CPB. Costello and associates reported reduced operative closure time and blood product exposure in a matched prospective study of 36 patients less than 6 months of age [95]. It is possible, given the deleterious effect of blood product exposure and extended operative time, that aprotinin may exert a beneficial effect in pediatric CPB. Accordingly, aprotinin has shown promise in reducing capillary leak, reducing biochemical markers of inflammation, and improving myocardial recovery following CPB [96]. Aprotinin has also been shown to result in more rapid recovery of cerebral energy metabolism following DHCA in animal models and is associated with a decrease in neurologic complications of patients undergoing coronary artery bypass grafting [97]. Jonas' group demonstrated improved neurologic function after deep hypothermic CPB in piglet survival models [98].

However, concern regarding the safety of aprotinin arose from observational studies showing an association between the drug and increased rates of cardiovascular and cerebrovascular complications, renal failure, and short- and long-term mortality in adults [99, 100]. Although several studies in pediatric populations showed aprotinin did not show significantly increased mortality or morbidity [101–103], aprotinin was suspended from clinical use after the report from the Blood Conservation Using Antifibrinolytics in a Randomized Trial (BART) [104]. It is unclear whether adult aprotinin safety data are relevant to pediatric populations undergoing open-heart surgery.

Ultrafiltration

Leukocyte filtration during CPB was initially tested in animals in the early 1990s and subsequently used in humans undergoing cardiac surgery [105]. When leukocyte filters are incorporated into the extracorporeal circuit, total leukocyte count and CD18-mediated neutrophil adhesion are significantly attenuated compared to control patient groups, but this has not translated into clinical benefit. In particular, parameters of myocardial and lung function, including respiratory index, blood PaO_2, spirometry, pulmonary vascular resistance, and myocardial-bound creatine kinase (CK-MB) levels, were not affected by the use of a leukocyte filter [106, 107]. Equivocal findings, however, are difficult to interpret because ischemia-reperfusion injury can be mediated initially by other effecter cells and therefore occurs independent of neutrophil participation [108].

Intraoperative ultrafiltration, using a conventional or modified approach, has been reported to reduce the rise in total body water following CPB in pediatric patients, as well as the duration of mechanical ventilation [109]. Modified ultrafiltration has the advantage of filtering only the patient's extracellular blood volume and results in more rapid recovery of ventricular function [110], reduced brain injury [111], and less postoperative blood loss, although blood transfusion rate did not change [112, 113]. Similar to the data with leukocyte depletion, reduction of inflammatory markers with ultrafiltration have been inconsistent and have not provided durable clinical benefit, likely because many factors including choice of filter and pore size, the hemofiltration rate, and the timing of the procedure importantly influence outcome [114]. In addition, the removal of certain anti-inflammatory cytokines, such as IL-10, may actually produce deleterious effects [115].

Monitoring

Near-Infrared Spectroscopy (NIRS)

NIRS is an FDA-approved noninvasive optical technique that can provide continuous real-time assessment of microcirculatory oxygenation at the patient's bedside. Biological tissues are relatively transparent to near-infrared light (700–900 nm). Within this range of optical wavelengths, oxygenated and deoxygenated hemoglobin have different absorption spectra. The attenuation of light from the emitter is detected and from this, a value for the tissue (cerebral) oxygen saturation (rSO_2) can be calculated. This is the same principle by which pulse oximetry works, except that pulse-oximetry measures the pulsatile arterial component. NIRS instead provides a "weighted average" of the tissue circulation: 75–85 % of the signal is contributed by the venules. Because mixed venous saturations (SvO_2) vary according to cardiac output, NIRS potentially can provide real-time information about both tissue oxygenation and tissue perfusion. Deciphering the relative contribution of each of these components (hemoglobin oxygen saturation and blood flow) is not possible from the NIRS calculation alone. Although isolated values are therefore not especially helpful, its use as a trend monitor has been shown to be useful for identifying abrupt changes in tissue oxygen delivery that should be addressed to minimize ischemic injury. NIRS has been applied both in the operating room while on CPB as well as pre- and postoperatively in the intensive care unit.

In the operating room, NIRS can be used to identify regional perfusion anomalies (e.g., by misplaced cannulae) either by revealing abnormally low values or otherwise through asymmetric readings between bilateral monitors [116]. This latter circumstance is presently a matter of contention [117] because significant bilateral disparity (>10 %) has been reported within individuals in whom no injury was sustained [118]. In one case, the bilateral cerebral NIRS readings were significantly different throughout the procedure (including preoperatively) and were resistant to repeated interventions aimed at improving the lower reading [119]. Because no injury was sustained, the inference is that considerable variations exist within individual patients, and therefore, the value of using bilateral monitors is currently not fully understood.

Alternatively, NIRS can be utilized during periods of reduced CPB flow or circulatory arrest to indicate the point at which tissue levels of oxygenation have fallen to a threshold that might be injurious (generally considered to be 20 % below baseline [117]. Once this point is reached, intervention can be directed toward restoring tissue oxygenation (temporarily increasing pump flow rate or intermittently perfusing the brain. Of course, the central premise behind this practice is that by intervening on the basis of NIRS readings, clinical neurologic outcome is improved. Evidence is accumulating to corroborate this practice: Kurth and associates reported that low intraoperative NIRS values may predict worse neurologic recovery [120]. Austin's group reported that by intervening at threshold levels, recovery can be improved [121].

NIRS monitoring of patients with congenital heart defects in neonates provides continuous, noninvasive, real-time assessment of regional perfusion in intensive care units. Phelps and associates reported that low regional cerebral oxygen saturation by NIRS had a strong association with subsequent adverse outcome after first stage Norwood operation [122]. Johnson and associates reported that NIRS monitoring reduced use of controlled ventilation before first stage Norwood operation [123]. In this subset of patients, optimization of the pulmonary to systemic flow ratio is critical. NIRS monitoring is becoming an important role to manage those critical patients.

NIRS has been extensively studied in animal and human models for decades. Interpretation of the signals for clinical benefit is still controversial [124, 125]. There is clearly the need to more formally assess the issue in a prospective controlled manner in addition to clarifying normative values and trends.

Venous Oximetric Catheter

Continuous cardiac output and mixed venous oxygen saturation monitoring has been widely used in adult cardiac surgical patients [126]. However, the use of venous oximetric catheters was limited in neonates or infants mainly due to vessel size. In 2002, Tweddell and associates reported routine clinical use of continuous superior vena cava oximetry (SvO_2) in patients undergoing a first stage Norwood operation [127]. The use of continuous SvO_2 monitoring allowed for early identification of decreased cardiac output [128]. Several validation studies showed good correlation with actual blood gas oximetry [129–131]. Baulig and associates reported that SvO_2 monitoring did not accurately reflect actual blood gas oximetry when the values were below 70 %, which is usual after palliative surgery for congenital heart defects [132], but it seemed to be a useful tool providing an accurate trend of continuous central venous oxygen saturation. Although Marimón and associates reported that there was no strong correlation ($r = 0.58$) between cranial NIRS and SvO_2 measurements [133], more objective values might be helpful to make correct decisions in a more timely manner for very critically ill patients [128].

Hoffman and associates reported that venous gas saturation should be maintained more than 30 % to avoid anaerobic metabolism [134]. Crowley and associates reported that 18 min of central venous saturations less than 40 % measured by continuous SvO_2 is associated with

major adverse events [135]. Further investigation of SvO_2 will be needed as a potential target parameter in high-risk pediatric patients to minimize the risk of major adverse events.

Summary

The conduct of cardiac surgical procedures for the treatment of congenital cardiac defects has evolved significantly over the last 60 years. Despite this, there remains an important risk of neurologic injury. Several variables and techniques described above may significantly improve the understanding and decrease the prevalence of neurologic injury in the periprocedural period for treatment of complex cardiac defects.

Monitoring of the Cardiac Patient

George Hoffman and Stuart Berger

Standard Monitoring Techniques in the Pediatric Cardiac Intensive Care Unit

46

Ryan J. Butts, Thomas Bao Do, and Andrew M. Atz

Abstract

Bedside monitoring is a vital component of any intensive care unit. It is often what separates intensive care versus non-intensive hospitalization. The vast amount of invasive and noninvasive monitoring techniques alert the patient's care team to changes in the physiological state of the patient and assess the response to interventions. Pediatric patients with heart disease are at risk for significant morbidities and mortalities, especially in the immediate postoperative period. Therefore, close monitoring is paramount to delivering the best care in this population. This chapter outlines the most common techniques of monitoring critically ill pediatric cardiac patients. It will explore not only the information gained from each modality but also discuss its limitations. How each modality can help direct care with examples specific to children with heart disease is discussed.

Introduction

Preoperative and postoperative management of children in the Cardiac Intensive Care Unit (CICU) is dependent upon close monitoring of the patient. Intensive monitoring serves multiple purposes in the intensive care unit. It helps describe the current physiological state of the patient, guides and assesses the effectiveness of therapeutic interventions, and alerts the medical team to changes in physiological state of the patient. The ideal monitor is reliable, has low morbidity, is cost-effective, responds quickly to hemodynamic changes, and provides important information. Invasive monitoring of systemic blood pressure and right and/or left atrial pressures are routine in the CICU and are paramount to making clinical decisions in the postoperative period. Noninvasive monitoring of systemic oxygen saturation, heart rate, ECG, respiratory rate, and systemic blood pressure are equally important. Newer noninvasive monitoring techniques, such as near-infrared spectroscopy, are now nearly universally employed. There is not one ideal bedside monitoring technique that can fully describe the patient's physiologic state; therefore, the challenge to the cardiac intensivist, cardiologist, and cardiac surgeon is to synthesize the large amount of information obtained from all the differing monitoring techniques to properly assess and treat the patient.

Noninvasive Monitoring

Noninvasive monitoring modalities can often help discern the hemodynamic state of the patient while reducing the risk of infection, thrombosis, or other important morbidities. These techniques do not directly measure hemodynamics and therefore are not often used alone in the immediate postoperative or critically ill patient. However, many patients outside the immediate postoperative period can be managed successfully with noninvasive monitoring alone. Newer noninvasive monitoring techniques such as near infrared spectroscopy (NIRS) and pulse oximetry that is more accurate at lower oxygen saturations often provide invaluable data and may help decrease the need for invasive or laboratory monitoring.

Physical Exam

One of the most important, but often overlooked, methods of bedside patient monitoring is frequent physical exams by health-care providers. The exam can be detailed or focused based upon a patient's problem. The physical exam will often direct the physician in ordering the next line of diagnostic tests. In the cardiac ICU, cardiac and respiratory exams will help delineate the etiology of hypoxia in congenital heart disease. The lack of a shunt murmur in an acutely hypoxic patient with a Blalock-Taussig shunt may indicate acute shunt thrombosis or worsening pulmonary hypertension versus an unchanged murmur in a patient with unequal breath sounds which indicates atelectasis or endotracheal tube mainstem placement. Therefore, the physical exam remains a vital part of patient assessment and monitoring in the cardiac intensive care unit.

ECG Monitoring

All patients in a cardiac intensive care unit should be placed on telemetry. It should be readily accessible to all providers near the bedside for review, while password protected remote access allows for off-site monitoring. Continuous ECG monitoring through telemetry provides invaluable data such as prompt recognition of arrhythmias, monitoring of heart rate trends, and early recognition of myocardial ischemia.

Arrhythmias are common in pediatric patients after cardiac surgery and in patients with advanced heart failure and may confer a worse prognosis [1–3]. Early recognition and treatment of arrhythmias can prevent circulatory collapse. One of the most common postoperative arrhythmias is junctional ectopic tachycardia (JET), especially after Fontan procedure or intervention around the membranous ventricular septum [3–5].

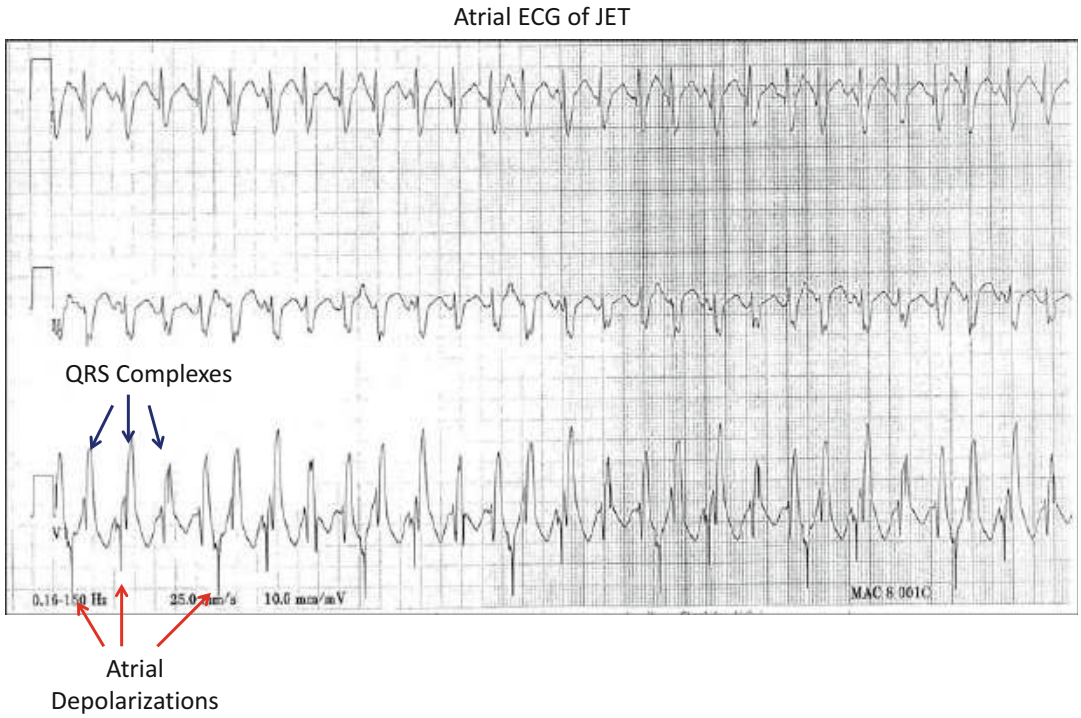

Fig. 46.1 Atrial ECG of postoperative tetralogy of fallot repair. V1 is connected to temporary a-pacing wire. Lead I and II are traditional surface leads. In V1, atrial depolarization show up sharp, narrow deflection (*red arrows*). The QRS complex is wide, however, it is the same as a baseline ECG obtained immediately postop, therefore making JET the diagnosis instead of Vtach

Even though JET may not be much faster than the underlying sinus rhythm, the loss of coordinated atrial contraction and ventricular filling can be enough to significantly decrease cardiac output. This is the case as the ventricle is often relatively noncompliant after cardiopulmonary bypass and surgery and therefore is often more dependent upon atrial contraction for adequate preload. Close attention to the ECG tracing to notice the absence of p-waves is very important. It is often difficult to see p-waves on neonates immediately after surgery even if they are in sinus rhythm. Alternating the leads until the p-wave is best seen is often necessary as well as performing standard 15-lead EKGs. If the presence of sinus rhythm cannot be ascertained with traditional telemetry and a 15-lead EKG, in the postoperative patient with temporary atrial pacemaker wires, an ECG with the atrial leads can help determine the exact timing of atrial depolarization (Fig. 46.1).

The long-term monitoring of heart rate trends can help provide information about the overall condition of the patient [6]. A gradual change from sinus tachycardia to a normal rate for age indicates that a patient's hemodynamic state has begun to improve, and vice versa. Heart rate trends can also help determine adequacy of sedation in nonverbal patients. In the absence of pacing, a lack of long-term heart rate variability can help identify patients with an incessant tachycardia, such as PJRT. For patients in sinus rhythm, the absence of long-term variability is a poor prognostic sign [7]. Review of long-term heart rate trends may help identify arrhythmias that have rates that would be considered normal for age, such as sinus node reentrant tachycardia or slow atrial flutter with 2:1 conduction. For reentrant tachycardias, review of the heart rate trends will often show instantaneous increases in heart rate instead of a gradual change. Combining long-term heart rate trends with trends in other

vital signs such as blood pressure and oxygen saturation will greatly aid in understanding the hemodynamic situation of a patient.

Pulse Oximetry

In 1974, the first pulse oximeter was developed by a Japanese engineer [8]. Since 1975, the use of pulse oximetry has become routine for all intensive care unit patients as well as all cardiac ward patients. In single ventricle heart disease, systemic oxygen delivery may be compromised by a lack of pulmonary blood flow or by an excess of pulmonary flow at the expense of systemic blood flow. A single-ventricle patient after a systemic to pulmonary artery shunt can have either of these situations, and the pulse oximeter can easily help differentiate the two. A rapidly decreasing systemic oxygen saturation can often be the first sign of shunt thrombosis [9].

The pulse oximeter provides instant feedback to the clinician on the effectiveness of interventions. For example, if a patient is considered to be having a sudden increase in pulmonary vascular resistance leading to systemic desaturation, after the initiation of inhaled nitric oxide, the clinician does not need to wait for an arterial PaO2 to confirm improvement. Pulse oximetry monitoring in the pre-ductal position (right upper extremity) as well as post-ductal position (lower extremity) can provide important clinical information, especially in the preoperative neonate with congenital heart disease. Particular lesions where pre- and post-ductal monitoring can be helpful are coarctation, aortic stenosis, and transposition of the great arteries. Physiological states and cardiac anatomy which leads to shunting of blood from the pulmonary artery to the aorta have the potential of creating a difference between the pre-ductal saturation versus the post-ductal saturation. This is often called "differential" cyanosis. The presence and degree of differential cyanosis help describe the patient's physiological state.

While pulse oximetry is incredibly helpful, intensivists must be aware of its limitations. The pulse oximeter works by emitting a 660 and 940 nm infrared light. The 660-nm wavelength is absorbed by deoxyhemoglobin, and 940-nm wavelength is absorbed by oxyhemoglobin [10, 11]. The pulse oximeter then calculates the percentage of oxyhemoglobin by obtaining the ratio of light absorbed in the two different wavelengths [8]. Therefore, the pulse oximeter does not measure carboxyhemoglobin or methemoglobin, the latter of which may be important in patients on inhaled nitric oxide for a prolonged period of time [12, 13]. If carboxyhemoglobin or methemoglobin is of particular concern to the clinician, co-oximetry should be sent.

Especially important in congenital heart disease, the accuracy and precision of the pulse oximeter decreases at lower oxygen saturations especially in patients with dark pigmentation [14–18]. Therefore, variations recorded by pulse oximetry in a patient with cyanotic heart disease may actually reflect the limitations of the instrument and not actual variations in patient systemic saturations. Also important in the CICU is the potential for irregular rhythms and tachyarrhythmias to cause inaccurate readings [19]. Severe tricuspid regurgitation or any condition that leads to exaggerated venous pulsations also can cause spuriously low saturation readings as the venous pulsations may be misread as arterial pulsations [20]. Newer generation pulse oximeters may improve these inaccuracies and thus would be very helpful in patients with cyanotic heart disease [21]. The clinician should ensure that the variations in pulse oximetry readings actually represent the patient's systemic saturation before making management decisions. The accuracy of pulse oximetry is compromised by motion of the limb being monitored, excessive light interference, severe anemia, and methylene blue administration [22–25]. It is very common for motion artifact or light interference to cause a spuriously low oxygen saturation value [26, 27]. Also, low perfusion state from low cardiac output or excessive vasoconstriction will also impair the accuracy of pulse oximetry [28, 29]. The newer generation devices mentioned before with signal extraction algorithms may perform better in these states [30].

While pulse oximetry has an important role in the CICU, it has had unintended consequences. Pulse oximetry has led to more interventions,

as evidenced by the more frequent use of prostaglandins in patients with transposition of the great arteries in the era of routine pulse oximetry usage [31]. Therefore, the clinician should be knowledgeable in the other methods of measuring oxygen delivery and content as well as the limitations of pulse oximetry before making clinical decisions.

Near-Infrared Spectroscopy

Near-infrared spectroscopy (NIRS) was introduced over 35 years ago, but only recently over the past decade has it been routinely used as a monitoring tool in the perioperative management of patients in the CICU to evaluate regional tissue perfusion [32–34]. The underlying principal behind NIRS is the intrinsic ability of light in the near-infrared spectrum (optimally 700–1,100 nm) to penetrate through normal tissue a few centimeters deep. There are three compounds with regard to NIRS monitoring that absorb light in this spectrum: oxyhemoglobin, deoxyhemoglobin, and cytochrome-c oxidase. A modification of the Beer-Lambert law of optics is then employed to measure the concentration of a desired substance based on the absorption of light with two different wavelengths. Thus, a NIRS device is able to noninvasively display an accurate estimation of capillary-venous oxyhemoglobin saturation (rSO_2) of blood flow to the local tissue area, whether it be the brain (cerebral NIRS) or abdominal organs (somatic NIRS).

It has been shown that cerebral rSO_2 in healthy, well-perfused patients is about 70 % [35, 36]. In patients with cyanotic congenital heart disease, cerebral rSO_2 can be expected to range between 46 % and 57 % [37]. Therefore, perturbations in NIRS values from a patient's established "normal" value over time can be interpreted as a change in the metabolic supply and demand of the region sampled and, accordingly, can help predict global circulatory function.

There have been multiple studies aimed at establishing the validity of NIRS values against more established, invasive measures of local venous oxyhemoglobin saturation as well as studies analyzing the utility of NIRS in pediatric cardiac patients. Earlier studies of NIRS showed good correlation in regional oxyhemoglobin saturation between cerebral NIRS and jugular bulb venous saturation [38–40]. In the CICU setting, it has been shown that in patients with hypoplastic left heart syndrome before Norwood palliation, cerebral and somatic rSO_2 values were similar, reflecting similar oxygen extraction across different vascular beds of these patients with decreased systemic perfusion [41]. More recent studies have used multivariate models to show correlation between cerebral and somatic NIRS with direct measures of mixed venous oxygen saturation in patients after stage 1 Norwood palliation [42]. Others have carried this further by investigating cerebral NIRS values in the postoperative period of Norwood palliation patients to find an association between low NIRS readings and future adverse outcomes [43]. Thus, multisite continuous NIRS monitoring has now become nearly universal along with other more established hemodynamic monitoring systems in postoperative cardiac and critically ill patients at risk for multiorgan dysfunction.

Noninvasive Blood Pressure Monitoring

The measurement of noninvasive blood pressure (NIBP) is incredibly common and important in the CICU. For the less critically ill patient, NIBP can be adequate to help measure perfusion pressure without the morbidities associated with invasive arterial lines. NIBP of multiple extremities can also be used to help monitor for coarctation of the aorta or to help determine the quality of coarctation repair [44]. The most accurate method of noninvasive blood pressure monitoring is through auscultation of the first Korotkoff sound and resolution of sound through a stethoscope while deflating a sphygmomanometer. However, this is rarely performed due to the relative labor intensity required. Therefore, the majority of noninvasive blood pressure monitoring occurs through automated blood pressure cuffs. These devices have multiple limitations that need to be considered when interpreting.

Automated blood pressure cuffs work by measuring oscillations in the artery as the pressure in the cuff is decreased. These measured oscillations are then used to calculate a systolic, diastolic, and mean blood pressure. Therefore, these measurements are calculated values, not directly measured values, and do not always correlate with auscultatory blood pressures [45]. In addition, because the cuff is detecting oscillations, movement of the measured limb can lead to erroneous measurements. Also, this technique may take upwards of 20–30 s to determine a blood pressure. In particularly unstable patients, this time delay may not be clinically acceptable. Acute swings in blood pressure can often lead to the inability of automated cuffs to determine an accurate blood pressure. It is also very important for the correct blood pressure cuff size to be used. The air bladder portion of the cuff should cover 80–100 % of the circumference of the measured limb. The length of the cuff should cover approximately 2/3 of the distance between the two closest joints (i.e., 2/3 the distance from the shoulder to elbow when measuring blood pressure in the arm and 2/3 from hip to knee when measuring in the thigh). A significant limitation of noninvasive blood pressure readings in the CICU setting is that it is less reliable in critically ill neonates [46].

Invasive Monitoring

Arterial Blood Pressure

Continuous blood pressure monitoring is essential in the postoperative management of patients in the CICU. This is accomplished by peripheral or central arterial cannulation and has the added benefit of providing access for arterial blood gas and laboratory sampling.

Common sites for arterial cannulation include the radial, femoral, and, in newborns, umbilical arteries. Consideration should be given for not only the site of arterial cannulation but also the side of the body. The right rather than left radial artery is chosen if blood flow to the left arm is deemed interrupted or an arterial waveform is anticipated to be unreliable in a patient with coarctation repair with a subclavian flap. Some institutions keep a Foley catheter in place for as long as a femoral line is present to minimize the risk of infection from urine contamination. Though this practice may not be universally accepted across all institutions, it does highlight a potential for further research into the multiple areas of possible infection introduction in patients in the CICU. In addition, preservation of the femoral arteries by limiting the number and length of time they are cannulated is considered in a patient that is expected to undergo multiple catheterizations. As opposed to intermittent, noninvasive blood pressure readings from a cuff, continuous monitoring via an arterial catheter in the postoperative patient is indispensable. It is more reliable and accurate and allows the bedside clinician to not only visualize an unexpected precipitous rise or fall in blood pressure but also to appreciate a less subtle trend and make expedient management decisions before the patient's clinical status deteriorates [47, 48].

There is a wealth of information pertaining to a patient's clinical condition that can be gleaned with proper analysis of the arterial waveform. A dampened upstroke of the waveform could be due to coarctation of the aorta or aortic stenosis but can also be associated with poor ventricular function/contractility. Alternatively, a waveform with a quick rising upstroke is a reflection of good ventricular myocardial contractility. One must also be aware that the peak systolic pressure is different depending on catheter location. The peak systolic pressure of a central artery such as the aortic arch can be 8–10 mmHg lower than a peripheral artery such as the radial or posterior tibial [49].

An acute or gradual change in pulse pressure (difference between the systolic and diastolic pressures) can also provide vital information about the patient's clinical status. In the immediate postoperative period, an acutely narrowed pulse pressure should alert the clinician to investigate a state where the stroke volume may be low, such as the possibility of worsening pericardial

effusion leading to tamponade. Conversely, a widened pulse pressure can be due to diastolic runoff from aortic insufficiency or in patients after placement of a systemic to pulmonary artery (e.g., Blalock-Taussig) shunt.

Even with continuous arterial monitoring in the CICU setting, diastolic blood pressure trends are often overlooked and underappreciated as an important hemodynamic parameter that can herald impending and potentially irreversible changes to ventricular function. For example, in a patient with a Blalock-Taussig shunt and systemic vasodilation leading to decreasing diastolic pressure, coronary blood flow is compromised due to depressed coronary perfusion pressure (difference between diastolic and right atrial pressures).

Like any other invasive line left in the body, one must be cognizant of the potential for immediate and long-term complications such as vessel thrombosis, bleeding, nerve injury, and infection when an arterial catheter is placed and maintained for a prolonged period [50, 51]. The incidence of local infection and bacteremia, although low, is a concern whenever a catheter or line is left in place for a prolonged amount of time [52, 53]. It has been shown that an important factor in vessel thrombosis is the catheter caliber in relation to vessel size [54]. Thus, the smallest possible arterial catheter should be used to adequately monitor blood pressure continuously for the shortest amount of time as possible. Furthermore, patients on a heparin drip should have it turned off a few hours before catheter removal to minimize the risk of prolonged bleeding and to assist in proper hemostasis at the catheter exit site. Nevertheless, complications from a peripheral or central arterial catheter are low and the benefits of accurate, continuous blood pressure monitoring in a patient in the CICU, especially during the immediate postoperative period, far outweigh the risks.

Central Venous Pressure

Central venous pressure (CVP) monitoring is routine in postoperative patients in the CICU to assist the bedside clinician in evaluating a patient's clinical status, but it also serves as a means of long-term venous access and for the delivery of continuous drip medications or total parenteral nutrition. CVP monitoring can be accomplished via a centrally placed catheter originating from the internal (IJ) or external jugular (EJ), subclavian, femoral, or, in neonates, the umbilical veins. These catheters are commonly placed at the bedside by the intensive care physician (commonly via a modified Seldinger technique, with or without ultrasound guidance), whereas a right atrial (RA) or left atrial (LA) line is inserted by the cardiothoracic surgeon intraoperatively [55]. When placed at bedside, proper positioning of the catheter tip is confirmed by a chest roentgenogram. A catheter originating from an upper body vein (e.g., jugular or subclavian) should have its tip situated at the superior vena cava-right atrial junction, which will give a more accurate measure of central venous pressure and oxygen saturation than a catheter originating from the lower body veins such as the femoral vein [56]. No matter where the central venous catheter is placed or its site of origin, CVP monitoring and the vascular access it provides in the immediate postoperative period is paramount in the ongoing management of CICU patients following cardiopulmonary bypass who may have large fluid shifts and rapidly changing hemodynamics.

Interpretation of the CVP tracing will not only assist the bedside clinician in the evaluation of a patient's fluid status but also helps to characterize common postoperative dysrhythmias. A normal CVP tracing has three positive deflections or waves. The *a* wave is due to right atrial contraction (seen immediately after the *p*-wave on the ECG), the *c* wave is caused by the deflection of a closed tricuspid valve upwards into the right atrium during ventricular contraction, and the *v* wave is due to right atrial filling. There are also two negative deflections called the *x* descent, corresponding to the pulling action of ventricular myocardium on the tricuspid valve away from the right atrium, and the *y* descent, which occurs as blood enters the right ventricle upon opening of the tricuspid valve. Thus, an absent *a* wave represents the absence of or ineffective atrial contraction (e.g., atrial fibrillation), whereas

"cannon" *a* waves reflect atrial contraction against a closed tricuspid valve seen frequently in postoperative dysrhythmias with loss of atrioventricular synchrony, such as junctional ectopic tachycardia [57].

Normal CVP values in a patient with congenital heart disease range anywhere from 3 mmHg to 8 mmHg. A lower value may represent volume depletion, whereas an elevated value could be a reflection of either poor ventricular function after cardiopulmonary bypass or volume overload. Certainly one must first investigate whether the reading is accurate by ensuring that there exists no malfunctioning equipment or improper catheter position (e.g., catheter tip in the ventricle or against a chamber wall) and that the patient's position has not changed since a higher reading (patient's position is higher relative to the transducer) or an erroneously low reading (patient's position is lower than the transducer) may be due to a change in the patient's bed height [58]. In addition, an understanding of the patient's specific cardiac anatomy and previous surgical interventions will dictate the range of acceptable "normal" CVP values (i.e., baseline CVP readings from an IJ catheter in a patient after the Fontan procedure are more elevated than in a patient after VSD closure with good biventricular function). Furthermore, the IJ pressure in a patient with a cavopulmonary anastomosis reflects pulmonary artery pressure, and if an atrial line is also present, the pressure difference between these two is a reflection of the transpulmonary gradient.

Shifting hemodynamics in a postoperative patient can often be represented by the RA or LA pressure tracings which are a reflection of the right or left ventricular end-diastolic pressures (EDP), respectively. Ventricular EDP is a function of the interplay between ventricular function, afterload, volume status, and ventricular compliance. An elevated RA tracing could be a representative of worsening ventricular function or, in the immediate postoperative period, may be the first sign of a pericardial effusion or poor post-cardiopulmonary bypass ventricular compliance. Conversely, a depressed RA pressure reading could be the result of ongoing blood loss or other forms of intravascular volume depletion. However, in a well-perfused patient several days after surgical repair, a decreasing RA pressure tracing from a higher level to a more normal range is most commonly a reflection of improving ventricular function and overall hemodynamics, thus a likely indication that further monitoring is no longer needed. Therefore, readings from a central venous line are not interpreted by the bedside cardiac intensivist in isolation but rather considered as one piece of a complex, evolving puzzle along with pertinent background information (patient's cardiac anatomy, surgical procedure, etc.) and other existing hemodynamic parameters (HR, BP, SaO_2, etc.) to arrive at a clear picture of the patient's clinical status.

Pulmonary Artery Pressure and Cardiac Output

Though a much less frequently utilized monitoring technique in the pediatric CICU than in the adult CICU, pulmonary artery (PA) pressure monitoring remains a vital tool in the postoperative assessment of cardiac patients. The PA catheter is commonly placed via a transthoracic approach by the surgeon directly into the PA or through the right ventricular infundibulum after surgical repair. Alternatively, it can be placed by entering the right atrium and advanced across the tricuspid and pulmonary valves (Fig. 46.2). This approach allows for future retraction of the catheter into the right atrium (RA) for central access when PA pressure monitoring is no longer deemed necessary, while also having a theoretical benefit of decreased risk of bleeding upon removal of the catheter as the RA exit site is under lower pressure than the PA or right ventricle. They can also be placed by anesthesiologists or bedside intensivists via the internal jugular vein, external jugular vein, or, less commonly, the femoral vein using balloon-assisted catheters [59]. When present, PA catheters allow for a number of principal measures of cardiac function such as mixed venous oxygen saturation (SvO_2) and cardiac output/index.

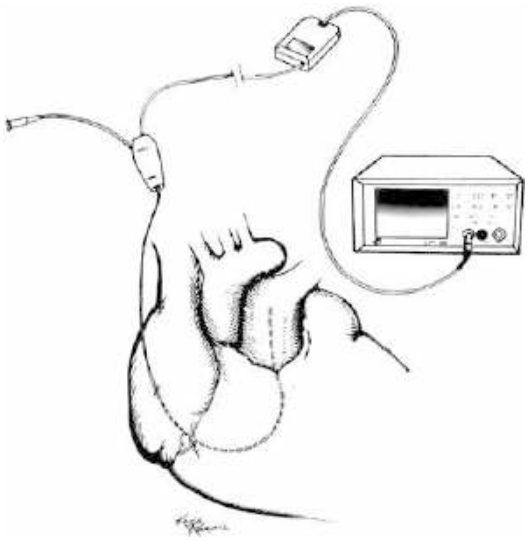

Fig. 46.2 Illustration of pulmonary artery catheter entering the right atrium, advanced across the tricuspid and pulmonary valves, and with the tip located in the main pulmonary artery

Although oxygen saturations from blood sampled at the superior vena cava is often perceived as a SvO_2, a true SvO_2 value is derived from blood drawn from the pulmonary artery. A well-perfused patient with an arterial oxygen saturation of 100 % should have a SvO_2 of about 75 %. SvO_2 itself is dependent on a number of factors such as cardiac output, metabolic demand (oxygen consumption), hemoglobin concentration, and arterial oxygen saturation. Thus a normal SvO_2 is an indication of sufficient oxygen delivery and satisfactory global tissue perfusion. A fall in SvO_2 should prompt the bedside clinician to further explore its etiology by evaluating the patient's cardiac function, hemoglobin, and arterial oxygen saturation or investigate whether the patient has an acute increase in metabolic demand.

The PA catheter can also be used to directly measure cardiac output via thermodilution [60, 61]. With a thermistor at the catheter tip located in the PA, saline with a known volume and temperature is injected into the RA. After the thermistor senses a change in temperature of the blood, calculation of cardiac output is achieved by generating a temperature change versus time curve. The area under the curve is the cardiac output. Thermodilution only works if there are no intracardiac shunts. Since the PA catheter exclusively measures cardiac output of the right heart, this can only equal left heart cardiac output if no intracardiac shunts exist.

Although thermodilution remains the gold standard in the measurement of cardiac output in the CICU, there are now several methods of indirect, relatively less, or noninvasive measures of cardiac output such as ultrasound Doppler techniques and arterial pulse contour analysis [62, 63]. By using Doppler ultrasound to calculate arterial blood flow velocity via the frequency shift of reflected ultrasound waves at the ascending aorta, a simple calculation of cardiac output is made by multiplying this arterial blood flow velocity with the vessel's cross-sectional area (obtained by 2D echocardiography) [64]. This method can certainly produce inaccurate measurements, mainly from imprecise determination of vessel area and flow velocity, and furthermore, the measured cardiac output is smaller than that measured by thermodilution because it does not take into account coronary blood flow.

Arterial pulse contour analysis is a relatively recent modality to measure cardiac output by calculating stroke volume from the assessment of the arterial pulse pressure wave [65]. The validity of this method has been recognized in adults and more recently in postoperative congenital heart disease patients as an accurate continuous monitor of cardiac output [66, 67]. However, the benefit of having a continuous beat-to-beat monitor of cardiac output by arterial pulse contour analysis is offset by the unfortunate fact that it must be routinely calibrated and compared against another concurrent method of cardiac output measurement such as transpulmonary thermodilution.

Mechanical Ventilation Monitoring

Positive pressure mechanical ventilation is a life-sustaining technology in patients with end-stage heart failure, complex heart disease, or recent cardiac surgery. While positive pressure

ventilation can be life sustaining, it can often have deleterious effects on hemodynamics that should be considered in any ventilation strategy. Due to positive pressure increasing intrathoracic pressure and therefore increasing central venous pressure, patients with passive pulmonary blood flow, such as Fontan patients, exhibit improved hemodynamics once extubated [68]. It is therefore imperative for cardiac intensivists to pay close attention to all available information regarding pulmonary mechanics while managing cardiac disease.

While a patient is mechanically ventilated, the ventilator provides important, clinically relevant information to the cardiac intensivist. In volume control mechanical ventilation, including pressure-regulated volume control, peak inspiratory pressure is variable. Increasing inspiratory pressure indicates decreasing pulmonary compliance. Acute increases in airway pressure can be from patient agitation, new pneumothorax, airway obstruction, bronchospasm, or a multitude of other causes. Nonetheless, sudden unexpected changes in increased airway pressure should be investigated and treated promptly. More gradual increases in inspiratory pressure in the cardiac intensive care unit often represent the development of pulmonary edema or pleural effusions. Pulmonary edema often develops after long cardiopulmonary bypass times in the operating room or the need for large amounts of blood products to counteract bleeding and is reflective of total body fluid overload combined with increased inflammation associated with bypass. Pulmonary edema can also develop in cardiomyopathies, ventricular dysfunction, systemic atrioventricular valve regurgitation, or stenosis. Pleural effusions often develop in patients with high central venous and right atrial pressures. As rising inspiratory pressure can alert the cardiac intensivist to an underlying problem, it can also help gauge the response to therapeutic interventions. Lowering of inspiratory pressures indicate improved pulmonary compliance and can aid in deciding the appropriate time for extubation.

The use of end-tidal carbon dioxide ($ETCO_2$) monitors has become routine in the pediatric CICU as their size has decreased and thus minimizing the added dead space [69]. $ETCO_2$ uses an infrared light source that is passed through a small gas chamber. Infrared light is absorbed by CO_2. A light receptor on the end of the gas chamber measures the amount of infrared light that passes through the chamber and uses the information to calculate the partial pressure of CO_2 passing through the chamber [70]. This provides instantaneous measurements that can be displayed in graphic waveforms, capnography, and, in a numeric form, capnometry. This information can often be displayed on integrated bedside monitors. $ETCO_2$ monitors are frequently used in the mechanically ventilated patient; however, they are also a proven method of monitoring in a spontaneously breathing pediatric patient via nasal cannula [71].

$ETCO_2$ in healthy patients is an accurate estimate of arterial CO_2, with a typical difference between arterial CO_2 and $ETCO_2$ of1-4 mmHg. An elevated gradient between $ETCO_2$ and arterial CO_2 indicates increased dead space ventilation. Above normal dead space, ventilation may be from ventilation-perfusion mismatch (V/Q mismatch). In the pediatric CICU, V/Q mismatch can be caused by residual cardiac lesions, especially areas of pulmonary artery stenosis; decreased pulmonary blood flow, such as shunt stenosis or pulmonary hypertension; or inefficient ventilation, which can be caused by pulmonary edema, pleural effusions, or atelectasis. Notably, right to left shunts, whether intracardiac (ASD, VSD), extracardiac (pulmonary AVMs), or surgically created (Fontan fenestration), will lead to an increased gradient between the $ETCO_2$ and $PaCO_2$ [72]. Increasing gradients between $ETCO_2$ and $PaCO_2$ are often the first physiological sign of impending shunt thrombosis, preceding decreasing systemic desaturation [73].

$ETCO_2$ monitoring helps alert the cardiac intensivist to physiological changes in the patient. Due to $ETCO_2$ monitoring providing instantaneous information that can be accurately measured over a prolonged period of time, the direction of $ETCO_2$ (increase vs. decrease) and timeframe of change (acute vs. gradual) can help the physician determine likely causes for change (Table 46.1). Gradual increases in $ETCO_2$ are

Table 46.1 Changes in $ETCO_2$ and possible etiologies

	Direction of change	
Time of change	Increase	Decrease
Acute	Resolving "tet" spell	Shunt thrombosis
	Resolution of shunt thrombosis	Pulmonary embolus
	Increase in pulmonary blood flow	ETT occlusion
Gradual	Hypoventilation	Improved pulmonary compliance
	Oversedation	Fever reduction
	Awakening from sedation	Increasing sedation

often a result of hypoventilation, such as from oversedation, or increased CO_2 production (awakening from sedation). Acute increases in $ETCO_2$ in the pediatric CICU are often from increases in pulmonary blood, such as relieving dynamic pulmonary obstruction during a hypercyanotic "tet" spell or relief of partial shunt thrombosis. Acutely decreasing $ETCO_2$ should alert the cardiac intensivists to problems that would lead to acutely decreased pulmonary blood flow (i.e., shunt thrombosis, pulmonary embolus, or decreased cardiac output), hyperventilation from agitation, obstruction in the endotracheal tube, or a sudden increase in V/Q mismatch (spontaneous pneumothorax, mucous plugging). However, gradual decreases in $ETCO_2$ can be from improving ventilation (i.e., improvements in pulmonary compliance), gradual increasing dead space ventilation (worsening pulmonary edema), or decrease in CO_2 production (resolution of fever or increasing level of sedation). Sudden loss of an $ETCO_2$ waveform can be from extubation, sudden loss of pulmonary blood flow (shunt thrombosis or cardiac arrest), or disconnection from the ventilator. If an arterial line is not present, $ETCO_2$ monitoring can assist the intensivist in assessing the adequacy of chest compressions during resuscitation. If chest compressions are inadequate, $ETCO_2$ will be very low or absent as there will not be adequate pulmonary blood flow.

As with all monitoring techniques, understanding basic physiology helps in the analysis of $ETCO_2$ monitors. In short, it is reflective of both the heart's ability to facilitate the transfer of CO_2 via blood to pulmonary vasculature, the pulmonary vasculature's ability to distribute CO_2 to the alveolus, and the ability of the lung/airway to exhale CO_2. $ETCO_2$ is a powerful tool for the cardiac intensivist and, when used in combination with other monitoring variables, can alert the intensivist to changes in the patient's physiological state, guide differential diagnosis for etiologies of change, as well as provide immediate feedback on the effectiveness of interventions.

Non-invasive Monitoring of Oxygen Delivery

47

George M. Hoffman, Nancy S. Ghanayem, and James S. Tweddell

Abstract

The major advantage that a cardiovascular system confers to an organism is the sustained transport of large amounts of substrate to support high levels of cellular energy production through aerobic metabolism. While the proximal and distal steps of oxygen transport involve diffusion from alveolus to pulmonary capillary and from systemic capillary to mitochondria, the most common life-threatening disorders of oxygen delivery result from circulatory disorders and failure of adequate oxygen delivery to individual organ beds to meet metabolic demand. Oxygen economy, expressed as the difference or ratio of oxygen consumption to oxygen delivery, has a critical value, below which tissue oxygen tension and venous oxygen saturation is so low that aerobic metabolism cannot be supported. Oxygen economy has typically been computed from invasive measures of arterial and mixed venous blood. Truly mixed venous blood is available only from the pulmonary artery with anatomically normal circulation, and thus determination of oxygen economy from invasive measures may be technically challenging in children and sometimes actually impossible. Although blood from the superior vena cava can be a close

approximation of mixed venous blood, this still requires central venous cannulation with its attendant risks and limitations. Since different tissues have different ratios of blood flow and metabolism, a mixed venous blood sample reflects the flow-weighted average of heterogeneous regional circulations and thus may be relatively insensitive to circulatory disorders which affect the distribution of vascular resistance and blood flow. Thus, invasive mixed venous blood sampling, although a standard measure of oxygen economy, has significant limitations. The use of organ-specific regional blood flow monitoring can open a window on these circulatory vulnerabilities and guide interventions to maintain adequate organ blood flow and oxygenation, with evidence for improved outcomes. This chapter will review the theoretical and practical aspects of alternative methods of measuring oxygen economy, with an emphasis on near-infrared spectroscopy (NIRS).

Introduction

The major advantage that a cardiovascular system confers to an organism is the sustained transport of large amounts of substrate to support high levels of cellular energy production through aerobic metabolism. While the proximal and distal steps of oxygen transport involve diffusion from alveolus to pulmonary capillary and from systemic capillary to mitochondria, the most common life-threatening disorders of oxygen delivery result from circulatory disorders and failure of adequate oxygen delivery to individual organ beds to meet metabolic demand. In a wide variety of conditions, progressive multiorgan failure and death follows quantitatively from a period of oxygen transport deficiency (Fig. 47.1) [1]. Oxygen economy, expressed as the difference or ratio of oxygen consumption to oxygen delivery, reaches a critical value (the anaerobic threshold) below which tissue oxygen tension and venous oxygen saturation is so low that aerobic metabolism cannot be supported (Fig. 47.2) [2]. Oxygen debt, calculated as the cumulative area below the anaerobic threshold, is a quantification of hypoxia with predictive value greater than measures of cardiac output (Fig. 47.3) [3, 4].

Oxygen economy has typically been computed from invasive measures of arterial and mixed venous blood. Truly mixed venous blood is available only from the pulmonary artery with anatomically normal circulation, and thus determination of oxygen economy from invasive measures may be technically challenging in children and sometimes actually impossible. Under many conditions, blood from the superior vena cava can be assumed to be a close approximation of mixed venous blood [5], but this still requires central venous cannulation with its attendant risks and limitations. Since different tissues have ratios of blood flow and metabolism, a mixed venous blood sample reflects the flow-weighted average of difference regional circulations and thus may be relatively insensitive to circulatory disorders which affect

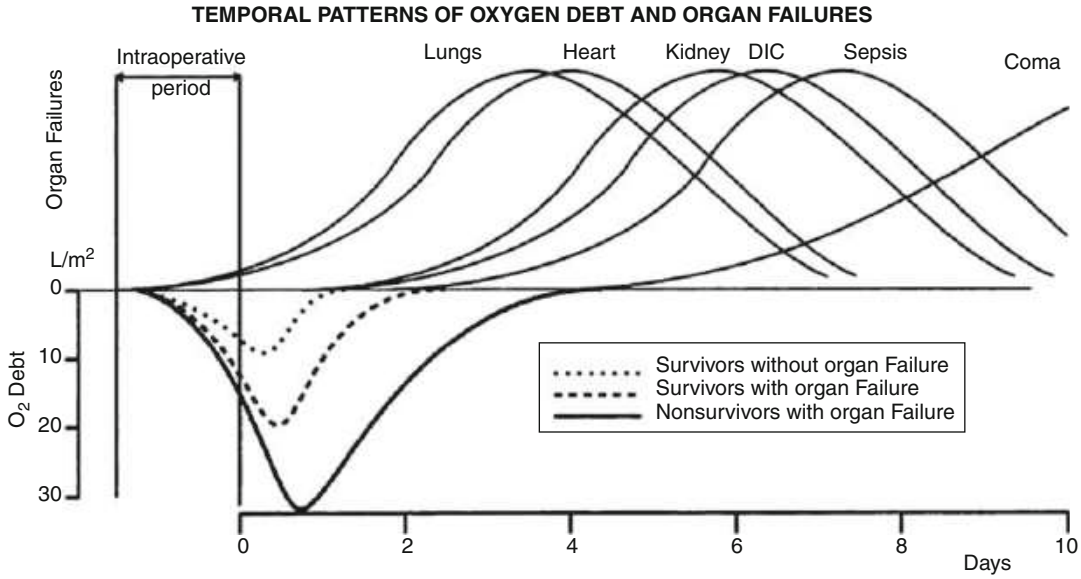

Fig. 47.1 Stereotypic patterns of oxygen economy and subsequent organ failure and death, in adults undergoing high-risk surgery. Perioperative oxygen economy was calculated hourly from invasive measures of O_2 delivery, compared to preoperative baseline values. All patients experienced a decrease in intraoperative oxygen delivery, which recovered to baseline within 12 h in patients with uncomplicated outcomes. The cumulative oxygen deficit was larger in patients with complications and largest in non-survivors. End-organ failures followed the resolution of oxygen transport deficiency (From source [1], with permission)

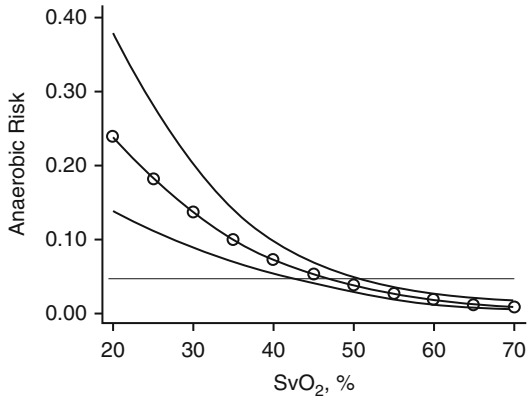

Fig. 47.2 The risk of anaerobic metabolism rises as superior vena cava oxygen saturation (SvO_2) falls. In neonates following palliation of hypoplastic left heart syndrome, the anaerobic threshold occurs at an SvO_2 in the 30–40 % range (From source [2], with permission)

the distribution of vascular resistance and blood flow. Thus, invasive mixed venous blood sampling, although a standard measure of oxygen economy, has significant limitations. Moreover, oxygen availability to the mitochondria will more closely be reflected by regional venous oxygen tension, and the flow-weighted mixture of regional venous blood makes a mixed venous oxygen measurement insensitive to significant regional oxygen deficits [6].

Neonates with significant congenital cardiac disease experience multiple threats to adequate cellular oxygen delivery, before, during, and after corrective or palliative surgery, with or without deliberate intraoperative alteration of blood flow required to complete the surgical procedure [7–12]. Factors that can reduce whole-body systemic oxygen delivery include pulmonary-systemic flow tradeoff that can occur in all neonates with ductal patency and which may be exaggerated with pharmacologic maintenance of ductal patency beyond the first few days of life, inefficiency of unpalliated or partially corrected cardiac anatomy, functional myocardial limitation following hypoxia-ischemia, anemia, and altered hemoglobin-oxygen transport function from stored blood. Increased metabolic demand for oxygen can result from

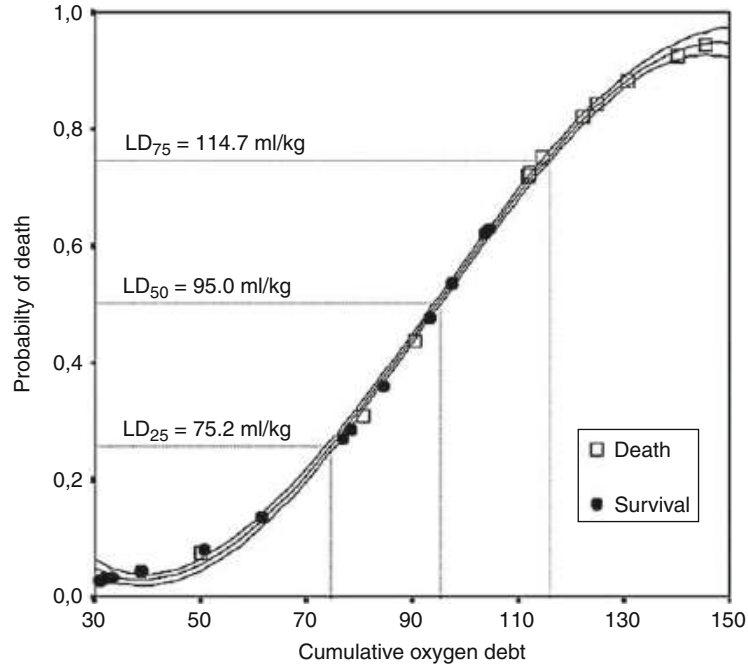

Fig. 47.3 Cumulative oxygen deficit, calculated from the anaerobic threshold, is highly predictive of mortality. An oxygen deficit of 95 ml/kg, corresponding to about 20 min of oxygen consumption, is the LD50 (From source [3], with permission)

inefficient cardiac anatomy, inotropic support, pain, cold stress, respiratory disease, wound healing, infection, and the inflammatory state that often is exaggerated following surgery and cardiopulmonary bypass in neonates. Even when whole-body supply–demand relationships appear adequate, regional, organ-specific supply–demand relationships can be impaired. The increasing use of organ-specific regional blood flow monitoring can open a window on these vulnerabilities and guide interventions to maintain adequate organ blood flow and oxygenation, with evidence for improved outcomes [6, 9, 10, 13–17]. This chapter will review the theoretical and practical aspects of alternative methods of measuring oxygen economy, with an emphasis on near-infrared spectroscopy (NIRS).

Heterogeneity of the Circulation

Systemic blood flow is divided among organs according to differences in regional resistance. Factors affecting regional resistance include local autoregulatory mechanisms that serve to couple flow to metabolism, autonomic influences on resistance, mainly via postganglionic sympathetic nerves, and nonspecific global effects mainly mediated through cytokines and hormones. These three major effects are superimposed dynamically to create a locoregional resistance environment. The network of whole-body locoregional circulations thus compete with each other for blood flow and determine what caregivers think of as systemic vascular resistance. Importantly, knowing both total cardiac output and perfusion pressure (aortic minus central venous pressure) will allow determination of total systemic resistance but will not provide direct information about the distribution of blood flow among regional (organ) circulations. Since the uptake of oxygen from hemoglobin by mitochondria follows from diffusion down concentration gradients that are determined by supply and demand, the regional venous oxygen saturation (rSO_2) can be utilized as a circulation measure by application of the Fick relationship for regional circulation as $\mathbf{rSO_2 = SaO_2 - rVO_2/rDO_2}$.

Historical Perspective and Technologic Development of NIRS

Organ-specific oxygen monitoring with near-infrared spectroscopy (NIRS) in the clinical arena became practical less than two decades ago with the development of reflectance devices that could estimate the ratio of oxygenated to total hemoglobin in the monitored tissue field, without reliance on complex calibration procedures necessary to derive absolute concentrations [18]. While reports of relationships of cerebral desaturation to neurologic outcomes came early in adults [19] and children [20], the lack of standardized technology limited generalization of these findings. A large study [21] showing a positive outcome impact of interventions to improve cerebral oxygenation based on multimodal neurologic monitoring with NIRS, transcranial Doppler, and electroencephalography highlighted the potential to improve neurologic outcomes in infants and children undergoing cardiac surgery. The commercial availability of versatile NIRS devices (Somanetics 3100A and 4100A) opened the door to more widespread adoption of the technology [21–23], such that use of NIRS in the perioperative care of neonates and children undergoing cardiac surgery is the standard at many centers worldwide [6, 17, 24, 25].

The fundamental challenge in validation of NIRS oxyhemoglobin saturation measurement (rSO2) is that the field of measurement is regional, diffuse, and internally heterogeneous, such that there is no single place to obtain blood that will be equal to the NIRS field. This obstacle is usually surmounted by characterizing the field as lying between the arterial and venous points and by modeling the field saturation from arterial and regional venous measures. Both the anatomic and optical properties of tissue make recovery of photons from arteries less likely than from capillaries or veins, and thus the rSO_2 will be close to the regional vein saturation [26]. The spatial resolution of continuous-wave reflectance NIRS results from the underlying physical principles that predict the average light path in a scattering medium to follow a circular path, resulting in a measurement depth of about one-half the source-detector distance. Further resolution is provided by coupling a short- and long-distance source-detector array and subtracting the short/shallow signal, effectively focusing the measurement in deeper tissue with very good accuracy [26, 27]. The relationship between cerebral rSO_2 and jugular bulb venous saturation is much stronger in small heads than in large heads [26, 28–30].

Devices with a 4 cm source-detector distance can monitor organ-specific oxygenation of the brain, kidney, and mesentery particularly well in small subjects, thus being especially suited to monitoring regional circulation in neonates and infants [29]. Refinements to spatially resolved NIRS have included the use of laser light sources to reduce variability in emission spectra (CAS Medical) [31], the use of additional wavelengths to remove more nonheme absorbers, and the use of additional light paths (Nonin Medical) [32]. All devices show good trending performance, with competitive advantage depending on the specific monitoring circumstance [33, 34].

Regional hyperemia will result in greater regional oxygen delivery and rSO_2 will rise; the converse will occur with ischemia. This relationship can be mathematically stated by the regional Fick principle, such the regional blood flow $(RBF) = k/(SaO_2\text{-}rSO_2)$. Thus, the regional arterial-venous difference is inversely related to blood flow when hemoglobin and organ oxygen demand are constant. Consideration of both the rSO_2 and the $SaO_2\text{-}rSO_2$ difference will help interpretation. The fractional regional oxygen extraction has also been characterized as $fOE = (SaO_2\text{-}rSO_2)/SaO_2$ [35].

While the brain was the organ of interest driving development of clinical NIRS technology with devices offering two probes for bilateral cerebral monitoring, the clinical scope of monitoring has more recently been broadened to non-cerebral, somatic fields including skeletal muscle, renal (flank region), and mesenteric (anterior abdominal wall) regions [29]. The utility of simultaneous multiple-site monitoring has

Table 47.1 Measured and derived noninvasive oxygen parameters with salient applications

Parameter	Common abbreviations	Application, limitations
Arterial oxygen saturation by pulse oximetry	SpO_2	Approximation of arterial saturation. Close agreement (±3 %) at high saturation; poorer agreement (±6 %) at $SpO_2 < 80$ % [96–98]
Regional, tissue, or capillary-field saturation by NIRS	rSO_2, SfO_2, StO_2, ScO_2	Measure of regional ("field," tissue, capillary) saturation; approximation of regional venous saturation, with moderate agreement (±6–11 %) over a wide dynamic range; better in smaller patients [26, 32, 99, 100]. Normal ranges have been defined [45]
Cerebral oxygen saturation	rSO_2C; ScO_2C	Related to jugular bulb saturation, cerebral blood flow, cerebral dysfunction, and neurologic outcomes in a wide range of experimental and clinical conditions
Renal (somatic) oxygen saturation	rSO_2R, rSO_2S, ScO_2S	Related to renal vein saturation [44] and renal function in neonates, infants, and small children [81, 82]
Mesenteric (somatic) oxygen saturation	rSO_2mes, rSO_2S, ScO_2mes	Related to feeding intolerance and NEC [85, 86]; related to SvO_2 and lactate in postoperative neonates [89]
Regional oxygen extraction by NIRS and pulse oximetry	$\Delta arSO_2 = SpO_2 - rSO_2$ $FtOE = (SaO_2\text{-}rSO_2)/SaO_2$	Inversely related to blood flow/metabolism ratio by Fick principle. FtOE (cerebral) related to cerebral outcome [35]
Somatic-cerebral rSO_2 difference	$\Delta rSO_2SC = rSO_2S - rSO_2C$ $\Delta rSO_2RC = rSO_2R - rSO_2C$	Multisite index of regional flow redistribution. Related to shock and organ dysfunction [48]
Somatic-cerebral ratio	$rSO_2S/C = rSO_2S/rSO_2C$	Index of regional flow redistribution. Related to necrotizing enterocolitis [88]
Model SvO_2	Linear combination of multiple rSO_2 measures from cerebral and somatic sites	Predictive of SvO_2 [101] and lactate [55]

been highlighted in reports of cerebral and somatic monitoring during selective perfusion of the cerebral bed *in lieu* of total circulatory arrest during profound hypothermia for complex neonatal arch reconstructions [36–38] and during repair of aortic coarctation [39]. These descriptive studies revealed not only distinct patterns of regional oxygenation evident during selective perfusion of different regional beds in the intraoperative management sequence but also the feasibility of a noninvasive device to function as a continuous monitor of organ blood flow and circulatory physiology. Although much of the published material is physiologically mechanistic or descriptive, increasing evidence reveals a relationship of both cerebral and somatic oxygenation to various outcomes [6, 16, 17, 40, 41]. A summary of noninvasive oxygen parameters appears in Table 47.1.

Descriptive Physiology of Multiple-Site NIRS

The organ specificity of multiple regional NIRS monitoring sites has been described by vascular cannulation and occlusion procedures in piglet models and human neonates and infants, with good evidence that a large portion of the signal is organ specific, especially in infants less than 10 kg [29, 42–44]. By comparing the change in regional rSO_2 during isolated renal or mesenteric artery occlusion to the change during global ischemia (cardiac arrest) in piglets, we estimated that renal and mesenteric contributions to the optical rSO_2 signal were 51 and 65 %, respectively, thus validating the organ specificity of regional measures [42]. The observed changes in organ oxygenation during global ischemia

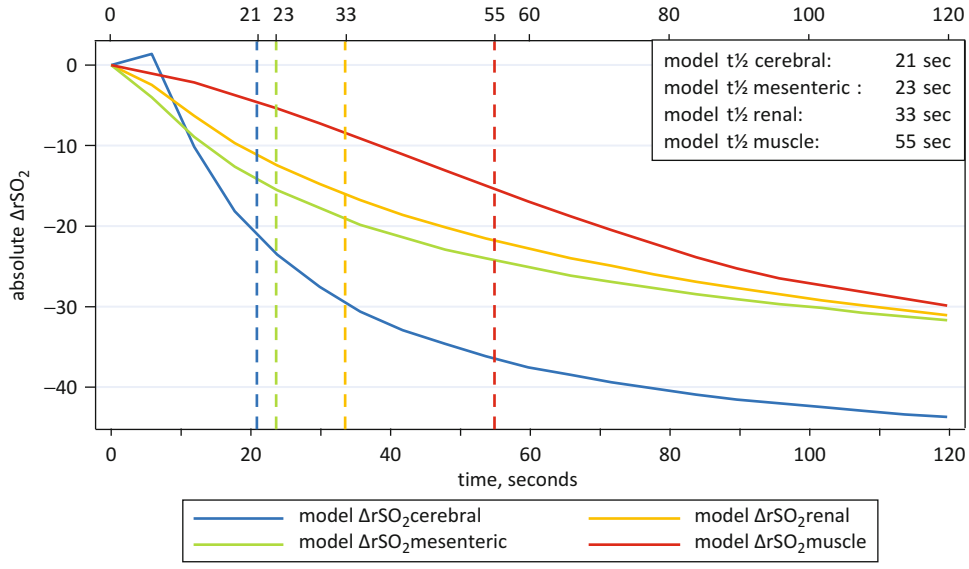

Fig. 47.4 NIRS-derived desaturation curves from cerebral, mesenteric, renal, and skeletal muscle beds in isoflurane-anesthetized neonatal piglets during conditions of normothermic global ischemia induced by acute cardiac arrest. Data are expressed as the absolute change in regional saturation (rSO_2) from baseline. Cerebral tissue has the most rapid desaturation during global ischemia, reflecting the highest ratio of oxygen consumption (From source [43], with permission)

were related to the described flow/metabolism ratios of organs in the resting, anesthetized animal, with the most rapid desaturation occurring in the cerebral bed (Fig. 47.4) [43]. These normothermic desaturation kinetics recapitulate the relative sensitivities of the brain, intestine, and kidney to ischemia and their contributions to long-term morbidity in the critically ill infant.

In normal newborns over the first 5 days of life, the average cerebral rSO_2 was 78 % and average renal rSO_2 was 87 % [45]. The cerebral and particularly somatic-renal rSO_2 show high short-term variability as dynamic measures, reflecting changes in blood flow related to activity, blood oxygen and carbon dioxide levels, and sympathetic tone (Fig. 47.5). The difference between somatic-renal and cerebral rSO_2 in this normal population was 9 %, an index of the relative distribution of blood flow between cerebral and somatic beds. The renal rSO_2 exceeded the cerebral rSO_2 in 24/25 of these normal neonates, reflecting the relatively high blood flow to metabolism ratio in the kidney that renders it susceptible to injury when sympathetic tone is high. These NIRS-derived indices of regional oxygenation are congruent with measures derived from regional vein sampling during cardiac catheterization and with measures of tissue oxygen tension in different organs derived from invasive oxygen electrode microsampling [46, 47].

The pattern of regional oxygenation is state dependent under normal conditions and can indicate the presence of circulatory abnormality when sampled over time. In unpalliated neonates with HLHS maintained on prostaglandin infusion, a wide arterio-regional difference across the renal bed (average 24 %) provided evidence of somatic hypoperfusion and a goal for management [7]. Both the somatic and cerebral arterio-regional differences normalized after palliation [48], when the neonates were managed with inotropic and vasoactive agents targeting an SvO_2 greater than 50 %, as previously described and with excellent outcome [9]. The observed

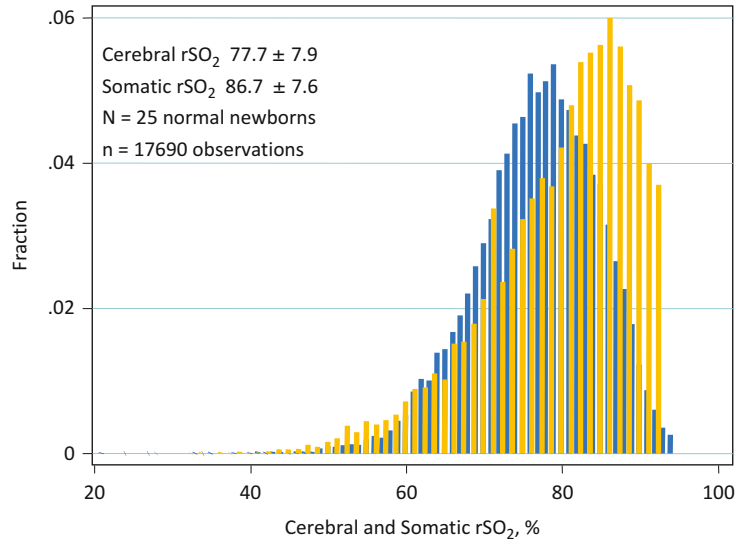

Fig. 47.5 Normal values for cerebral and somatic (renal) regional saturation (rSO_2) measures, derived from 25 normal newborns over the first 5 days of life. Individual measures were obtained at 10-S intervals over a 5-h period that included resting and feeding. The cerebral extraction was 20 %, and the somatic was 11 %, with an average somatic-cerebral rSO_2 difference of 9 %. Although highly dynamic in the short term, the pattern of average somatic rSO_2 exceeding average cerebral rSO_2 was observed in 24/25 neonates, and there were no consistent or important changes in either measure in the transition from resting to feeding (From source [45], with permission)

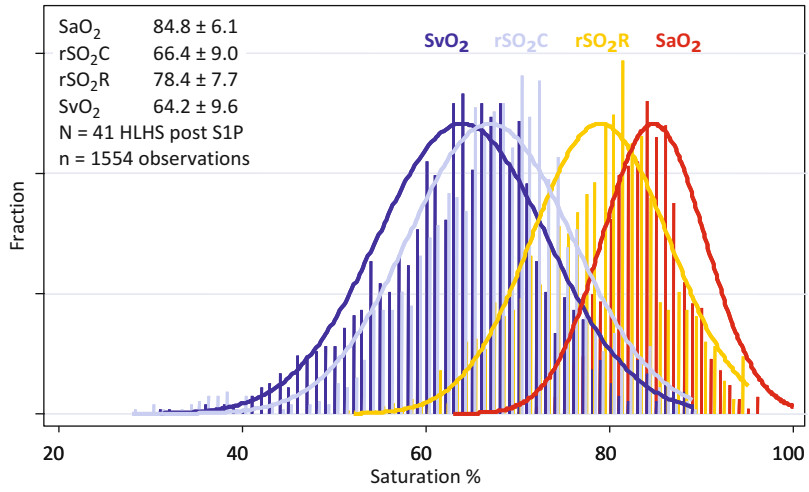

Fig. 47.6 Invasive and noninvasive measures of systemic and regional oxygenation in neonates following stage one palliation of hypoplastic left heart syndrome while supported with mechanical ventilation and inotropic support. Although the arterial blood is desaturated, the relative profile of arterial, somatic, and cerebral saturations is close to that observed in normal newborns, with cerebral extraction of 18 % and somatic extraction of 12 % (From source [48], with permission)

pattern of arterial-cerebral and arterial-somatic saturation differences, which are inversely proportional to regional blood flow/metabolism, are remarkably similar in normal newborns and in our postoperative S1P population (Fig. 47.6). The observed regional oxygenation profile in normal newborns and preoperative and postoperative HLHS is summarized in Table 47.2.

Table 47.2 Regional oxygenation by pulse oximetry (SaO_2), cerebral (rSO_2C) and renal somatic (rSO_2R) NIRS in normal newborns [45], and patients with hypoplastic left heart syndrome before [7] and after [48] stage one palliation. Derived parameters are somatic-cerebral rSO_2 difference (ΔrSO_2RC), arterial-cerebral difference ($\Delta arSO_2C$), and arterial-somatic difference ($\Delta arSO_2R$). Somatic hypoperfusion is evident before palliation by a wide $\Delta arSO_2R$ and a small somatic-cerebral difference (ΔrSO_2RC). Although the absolute SaO_2 and regional rSO_2 after palliation is lower than normal newborns, the regional blood flow parameters, as reflected by arterial-regional differences, are normalized

Parameter	Normal ($N = 25$, $n = 17{,}690$)	HLHS pre-S1P ($N = 47$, $n = 1{,}831$)	HLHS post-S1P ($N = 41$, $n = 1{,}554$)
SaO_2	98 ± 4	92.3 ± 5.4^a	84.8 ± 6.1^a
rSO_2C	77.7 ± 7.9	66.8 ± 8.5^a	66.4 ± 9.0^a
rSO_2R	86.7 ± 7.6	68.4 ± 8.8^a	78.4 ± 7.7^a
ΔrSO_2RC	9.0 ± 8.9	$1.6 \pm 9.4^{a, b}$	11.9 ± 9.4
$\Delta arSO_2C$	20.3 ± 7.9	25.1 ± 9.0	18.2 ± 8.6
$\Delta arSO_2R$	11.2 ± 7.6	$23.5 \pm 9.1^{a, b}$	6.3 ± 7.3
SvO_2			64.2 ± 9.6

Goal-Directed Global Hemodynamic Management with Multisite NIRS

Evidence is strong for improved outcome in evolving shock states in adults and children by incorporation of global oxygen balance measures such as quasi-mixed venous saturation (SvO_2) [5, 49]. Because NIRS measures of hemoglobin saturation (rSO_2) are close to the regional venous saturation, a relationship between rSO_2 and SvO_2 is expected. Several studies have revealed that, under certain conditions, the cerebral rSO_2 and SvO_2 from the superior venal cava are correlated, since the cerebral venous drainage is the dominant contributor to SVC flow in the resting state [50, 51]. Likewise, Doppler studies of the SVC are correlated with cerebral rSO_2 [52]. However, the mixed SvO_2 is a flow-weighted average of all regional venous saturations, and thus multisite NIRS monitoring might reveal a more reliable indicator of changes in SvO_2. These authors found that a linear combination of cerebral and somatic rSO_2 best fit the changes in SvO_2 in the acute perioperative period (Fig. 47.7) [6, 17, 53].

Monitoring multiple-site regional NIRS rSO_2 permits rapid, continuous, and noninvasive estimation of SvO_2, an indicator of whole-body oxygen economy which is related to the development of shock [2], and targeting of which can improve outcome [9, 54]. This multiple-site NIRS approach can provide a similar predictor of biochemical shock as SvO_2. In the acute postoperative period following neonatal and infant cardiac repairs, somatic NIRS rSO_2, from both the anterior abdominal (mesenteric) and dorsolateral (renal) regions, was highly related to blood lactate levels [89]. In a study of postoperative infants undergoing both single-ventricle palliation and two-ventricle repairs, the average cerebral and somatic rSO_2 was found to be highly related to blood lactate levels, with the best fit a log-linear relationship [55] (Fig. 47.8).

These authors found a similar relationship between renal-somatic rSO_2R and biochemical shock following stage one palliation of hypoplastic left heart syndrome, but a stronger, nonlinear relationship for the somatic-cerebral rSO_2 difference, ΔrSO_2RC (Fig. 47.9). This relationship indicates that the risk of biochemical shock in the early postoperative period rises as the renal-somatic bed becomes less well perfused compared to the brain, indicated by a fall in the ΔrSO_2RC from the normal value of about 10 %. It was postulated that contamination from arterial saturation, and some patient-specific optical properties, affecting NIRS rSO_2 are reduced when the difference between two sites is derived and that the altered somatic hypoperfusion that most frequently accompanies low cardiac output states is thus more accurately detected by signals

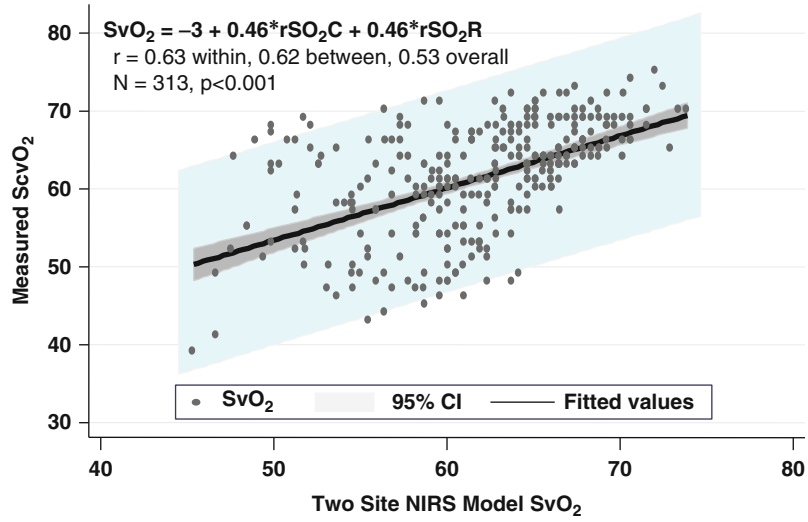

Fig. 47.7 Simultaneous measures of cerebral and somatic rSO_2, and optically measured saturation from the superior vena cava, in neonates following stage one palliation of hypoplastic left heart syndrome. A linear combination of both cerebral and renal rSO_2 best fit the SvO_2, with approximately equal weighting of cerebral and somatic sites (Adapted from source [53], with permission)

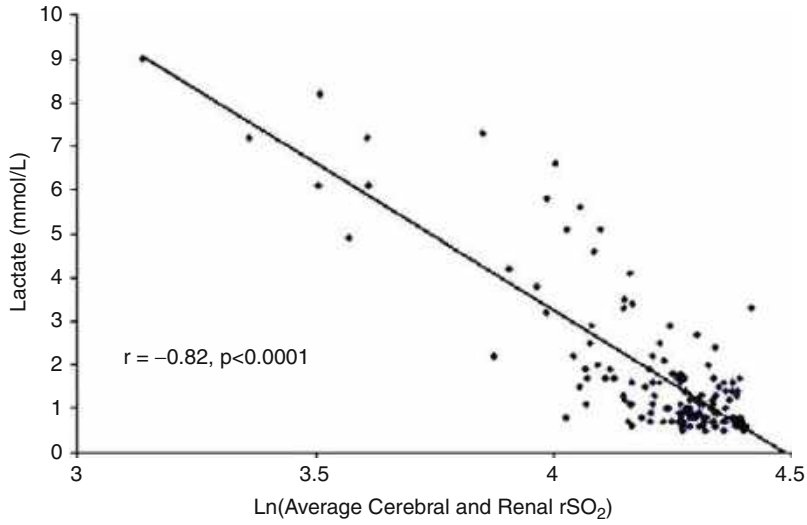

Fig. 47.8 A linear combination of cerebral and somatic rSO_2 was highly related to blood lactate concentration in infants and children following two-ventricle corrective surgery (Modified from source [55], with permission)

that compare relative blood flow/metabolism relationships in different tissue regions. In a high-risk population of neonates following single-ventricle palliation, the risk of biochemical shock, multiple organ dysfunction, and mortality were each related to reduction in the somatic-cerebral rSO_2 difference (Fig. 47.10) [56]. The rapid, continuous, noninvasive, and therefore low-risk application of cerebral and somatic NIRS to provide hemodynamic assessment has led to a recent consensus recommendation as useful in the critically ill single-ventricle infant at high risk for, or being resuscitated from, shock [17, 57, 58]. NIRS monitoring is unique in offering a window into tissue oxygen status even when blood flow is non-pulsatile (as with extracorporeal circulatory assist devices) or when circulation is critically impaired or absent in the peri-arrest/arrest situation. Continuous-noninvasive estimation of adequacy of cardiac output is practical with a monitoring strategy that includes pulse oximetry and cerebral/somatic NIRS in patients at risk for shock and with complex circulatory physiology from uncorrected or

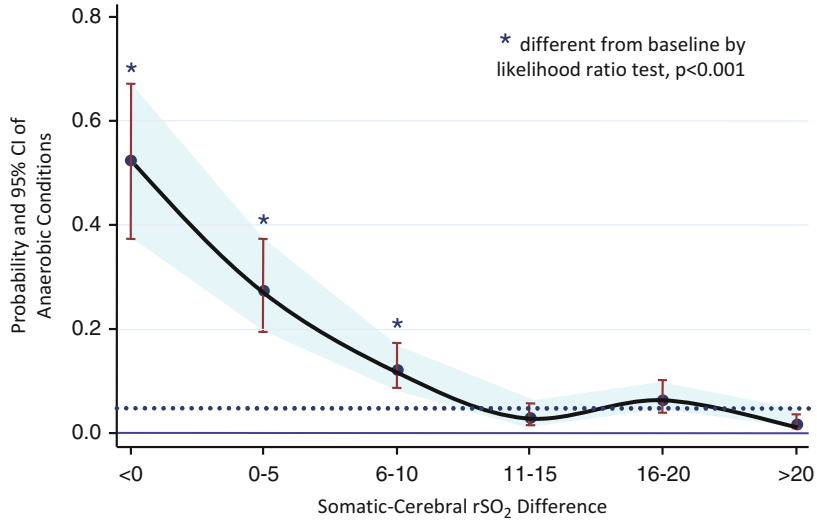

Fig. 47.9 The risk of development of biochemical shock, defined by falling base excess of more than −4 mEq/L/h, is highly related to somatic hypoperfusion as measured by the difference between somatic and cerebral rSO_2 in neonates following stage one palliation of hypoplastic left heart syndrome. The somatic-cerebral difference was a more reliable predictor of shock than the somatic measure alone; see text for details (Adapted from source [56], with permission)

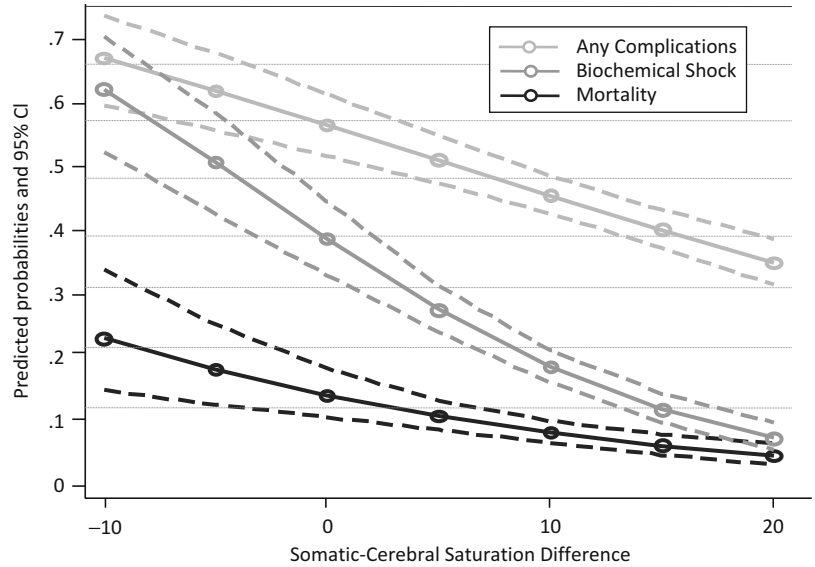

Fig. 47.10 Redistribution of blood flow away from somatic regions results in a narrowing of the difference between somatic and cerebral rSO_2. This regional saturation pattern is predictive not only of biochemical shock but of multiple organ dysfunction and death in neonates following stage one palliation of hypoplastic left heart syndrome (From source [56], with permission)

palliated congenital heart disease, allowing dynamic assessment of circulatory states that complement the invasive information typically obtained only during a snapshot in the cardiac catheterization laboratory. Using this two-site approach, the early detection and goal-directed treatment of shock is possible without invasive monitoring. In employing this approach, we have

reduced the incidence of biochemical shock in our intensive care unit by a factor of three [15, 48].

Patients undergo a range of physiologic stressors in the intraoperative period and in other stressful conditions, including: agitation and anxiety; drug-induced alterations in myocardial performance, vascular tone, and autonomic balance; changes in venous return with blood loss, positive pressure ventilation, positioning, and table tilting; changes in autonomic tone with surgical stimulation; direct manipulation of the lungs, heart, and blood vessels; interruption of blood flow by clamping the aorta to exclude lower body during coarctation repair or interruption of blood flow to the heart during procedures on cardiopulmonary bypass (CPB); cardiac arrest induced either deliberately during deep hypothermic conditions (DHCA) or as an unintended consequence of the convergence of the preceding factors. Although surgical procedures requiring anesthesia have relatively minor changes in standard parameters such as arterial saturation and blood pressure, blood pressure may be maintained at the expense of blood flow when autonomic activation or exogenous vasoactive drugs cause an increase in systemic vascular resistance and intraoperative normalization of standard parameters does not adequately prevent complications [59]. The use of venous oximetric indicators, either directly by SvO_2 or indirectly by NIRS, provides a window on circulation by the continuous use of the Fick principle to estimate regional and whole-body blood flow/metabolism ratios.

Cerebral Oxygenation and Function

Despite the induction of profound hypothermia to reduce metabolism, prolonged cardiac arrest during neonatal cardiac surgery is associated with higher likelihood of reduced neurodevelopmental performance [60]. A large body of literature is directed at characterizing the changes in cerebral oxygenation by NIRS during cardiopulmonary bypass (CPB), hypothermia, and deep hypothermic circulatory arrest (DHCA), to help identify risk conditions and drive treatment to improve outcome. Animal data clearly reveal a normothermic NIRS threshold for cerebral metabolism and cellular disruption that inflects sharply as cerebral oxygenation falls below 40 % [61]. Cerebral injury following normothermic cerebral hypoxia to the 30–40 % range by NIRS shows a time-dose dependency that results in behavioral and histologic abnormality when maintained for more than 1 h [62]. The degree of hypothermia utilized on CPB may profoundly alter the relationship between cerebral saturation and injury, with competing effects on cerebral metabolism and oxygen availability [63–66], and the changes in pH, flow rate, and hemoglobin concentration introduce many interacting supply and demand-side factors that threaten organ function. In piglets undergoing CPB, NIRS could detect cerebral hypoxic conditions produced by alterations in cerebral blood flow, hemoglobin concentration, temperature, and pH management, and the degree of cerebral desaturation produced by combination of these conditions was directly related to cerebral injury, with a threshold near 55 % at 26 °C [67–69].

During DHCA, the brain can continue to utilize oxygen that is present in stagnant blood in capillaries to meet metabolic demand. The rate of hemoglobin desaturation during DHCA will thus be related to continued utilization of oxygen, and a reduction in the rate of desaturation would represent a decrease in brain oxygen uptake. Although an absolute rSO_2 threshold for injury during DHCA has not been identified, the duration of DHCA beyond the point at which oxygen uptake falls, a point termed the "nadir" even though it is not the lowest point, is highly related to injury [68, 70]. Once the nadir has been identified by NIRS, preparations to reperfuse the brain can be planned to avoid conditions likely to cause injury [71].

The initial findings by Kurth [20] and Austin [21] of a relationship between intraoperative cerebral desaturation and postoperative neurologic outcome have recently been characterized in more formal studies on humans. Although techniques for surgical repair, cardiopulmonary bypass, and physiologic support

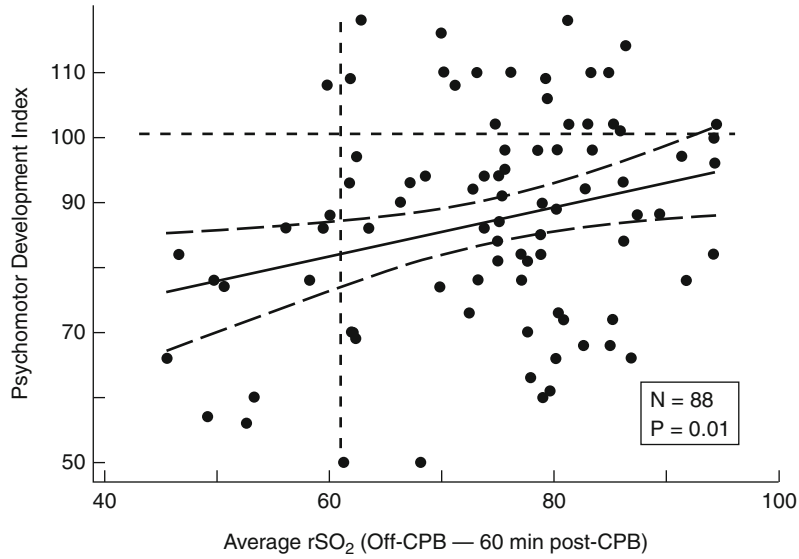

Fig. 47.11 Cerebral rSO_2 in the immediate post-CPB warm period, with a relationship between lower rSO_2 (<60 %) and reduced psychomotor performance at 15 months of age (From source [40], with permission)

have evolved over the past decade such that some of the conditions that may induce cerebral injury can be reduced by programmatic, not patient-specific, strategies, evidence from the recent era [40, 72] points to cerebral desaturation during normothermia immediately following CPB as a marker for, and potential cause of, cerebral injury, detected both by neuroimaging and neurodevelopmental testing during the second year of life (Fig. 47.11) [40].

Following hypothermic cardiopulmonary bypass, cerebral rSO_2 can remain low (Fig. 47.12). This early postoperative cerebral vulnerability occurs despite normalization of other hemodynamic parameters (Fig. 47.13), showing little relationship to blood pressure when maintained in a normal range, moderate relationship to SaO_2, and stronger relationship to SvO_2 (Fig. 47.14) [23, 71, 73]. These authors have preliminary work suggesting that prolonged, profound hypothermia and pH-stat conditions, regardless of occurrence on CPB, antegrade perfusion, or DHCA, will alter cerebral autoregulation and vasoreactivity for many hours postoperatively and that modification of pH conditions during antegrade perfusion might ameliorate this postoperative condition [74]. Prolonged cerebral desaturation following S1P for HLHS has been identified as a risk factor for both MRI changes and reduced neurodevelopmental performance, with critical thresholds in the 45–55 % range (see Fig. 47.15) [16, 75]. Because of the variability in the limits of cerebral autoregulation during development [76, 77], between individuals [78], and in conditions of critical illness [74, 78–80], these authors have adopted a monitoring strategy in the cardiac intensive care unit that includes cerebral and somatic NIRS monitoring in nearly all patients.

Somatic Oxygenation and Organ Function

The relationship between organ blood flow, oxygenation, function, and injury is complex, with disease-specific, pharmacologic, and autonomic influences, but hypoxic-ischemic injury remains a significant factor in renal and mesenteric injury in neonates [6, 56, 81]. Postoperative renal dysfunction, expressed as the ratio of current creatinine to the preoperative value, peaks on postoperative day 2 or 3. In the postoperative single-ventricle neonate, with low systemic perfusion on the basis of myocardial dysfunction and aortopulmonary runoff, blood pressure had no relationship to the creatinine peak. In this patient

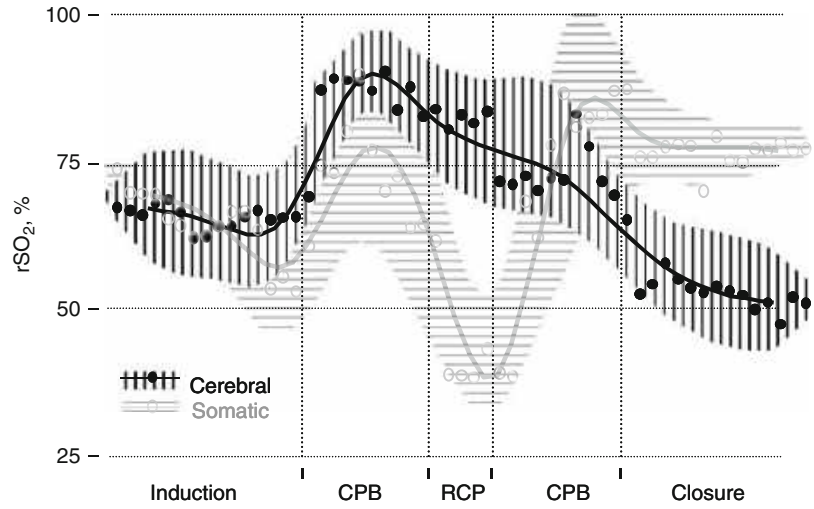

Fig. 47.12 Cerebral and renal-somatic saturations (rSO_2) were measured during stage one palliation of hypoplastic left heart syndrome utilizing hypothermic cardiopulmonary bypass (*CPB*) and antegrade regional cerebral perfusion (*RCP*) for arch reconstruction. Cerebral rSO_2 was maintained during CPB and RCP, while somatic rSO_2 revealed the severe perfusion deficit during RCP. Following separation from cardiopulmonary bypass, cerebral rSO_2 was difficult to maintain above 50 % (From source [38], with permission)

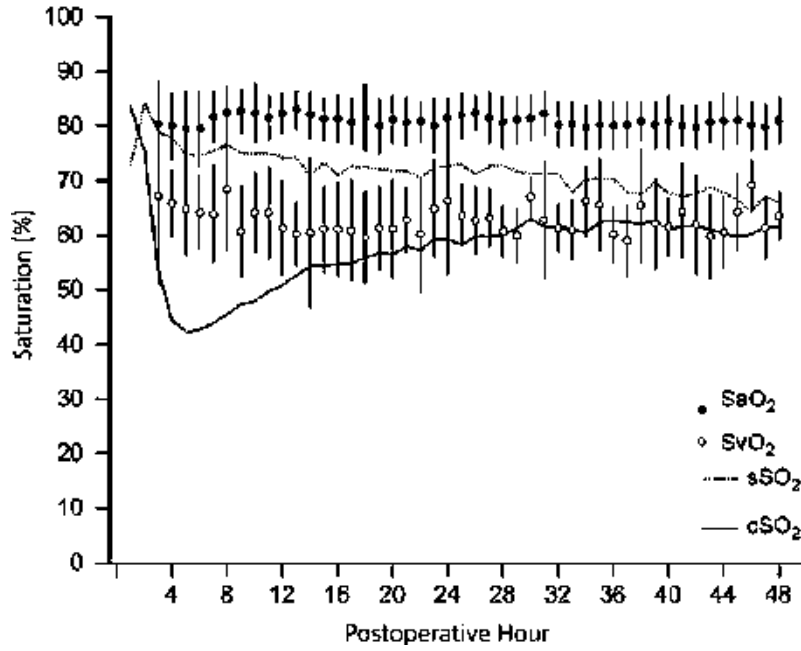

Fig. 47.13 In neonates following stage one palliation hypoplastic left heart syndrome, an early postoperative period of cerebral desaturation was observed despite improving global hemodynamic measures, emphasizing the vulnerability of the cerebral circulation (From source [73], with permission)

population, it was found that renal-somatic rSO_2 on the first postoperative day is the best predictor of the peak in creatinine rise on postoperative day 3, with a 50 % risk of acute kidney injury (AKI, doubling creatinine) if the renal-somatic rSO_2 was less than 60 % (Fig. 47.16) [82]. These findings were recently corroborated in another center, with a fourfold increased risk of AKI when renal-somatic rSO_2 was less than 50 % for 2 hours [81]. In sepsis, there is evidence for both

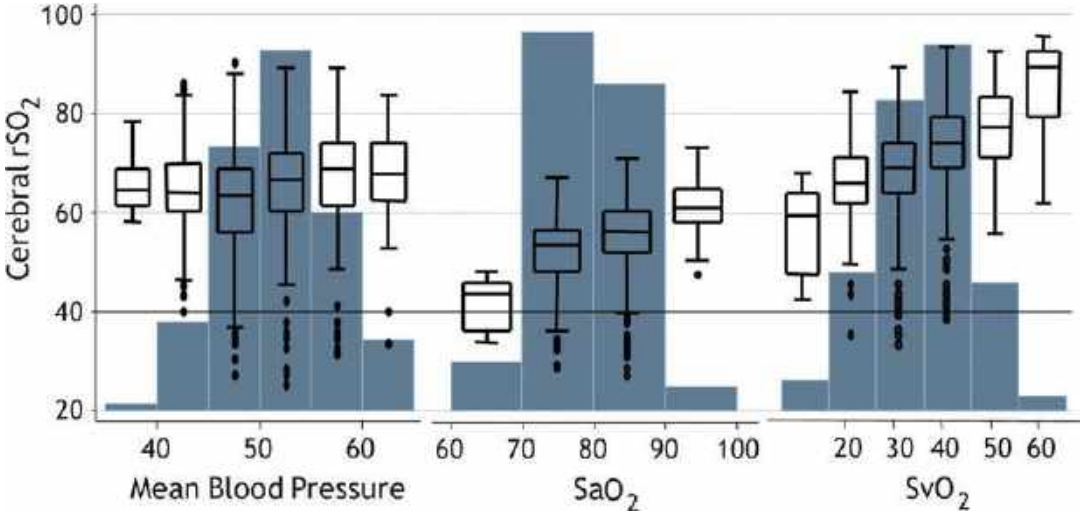

Fig. 47.14 In neonates following stage one palliation of hypoplastic left heart syndrome, significant cerebral desaturation (less than 50 %) occurred despite normal or acceptable levels of arterial saturation or blood pressure. Cerebral desaturation was not observed when SvO_2 was above 50 % (From source [23], with permission)

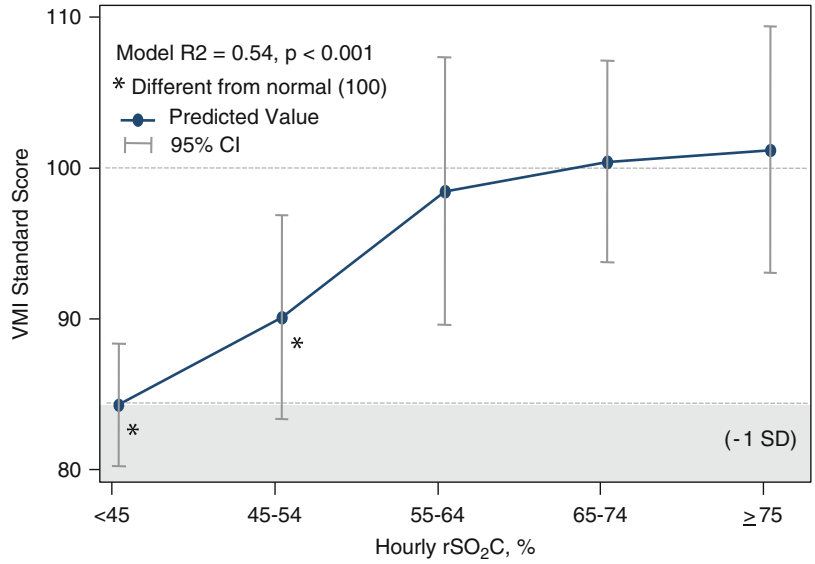

Fig. 47.15 Cerebral desaturation detected by NIRS following neonatal palliation of hypoplastic left heart syndrome was associated with poorer performance on neurodevelopmental assessment at 4–5 years of age (Adapted from [16], with permission)

hypoperfusion and hyperperfusion as components of renal injury, and this potentially protective renal vasodilatation is prostacyclin dependent and impaired by indomethacin and related drugs [83]. Renal tubular function is highly oxygen dependent, and reduction in renal oxygenation is a significant risk factor for renal dysfunction [84]. Renal vein saturation is approximated by a local NIRS probe in neonates and small infants [44], and thus goal-directed therapy that includes normalizing somatic-renal NIRS might be expected to reduce renal ischemic injury [17, 56].

Vascular resistance in the mesenteric vascular bed, as in the renal, is under intense control by the sympathetic nervous system and is a source of potentially catastrophic injury in newborns.

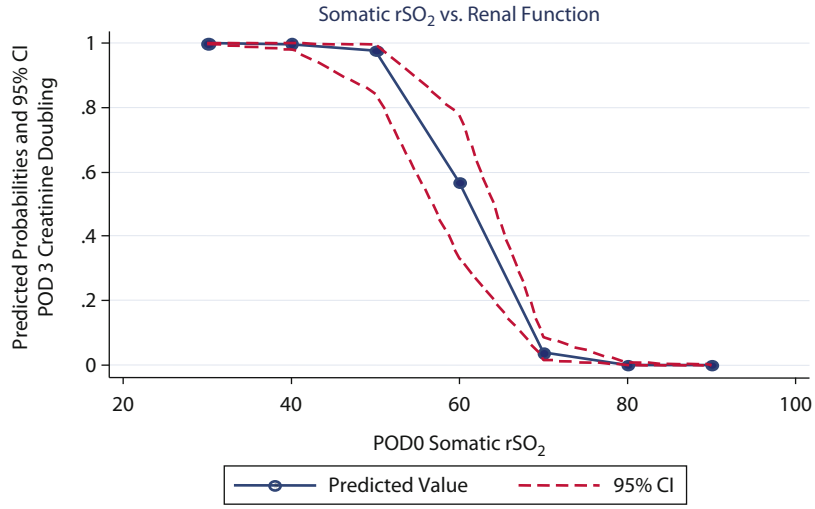

Fig. 47.16 Somatic-renal saturation (rSO_2R) measured on the first day following stage one palliation of hypoplastic left heart syndrome was predictive of the peak creatinine observed 2 days later. The risk of acute kidney injury, defined as a doubling of creatinine from preoperative baseline, was 50 % with a somatic rSO_2R less than 60 % for 1 hour (From source [82], with permission)

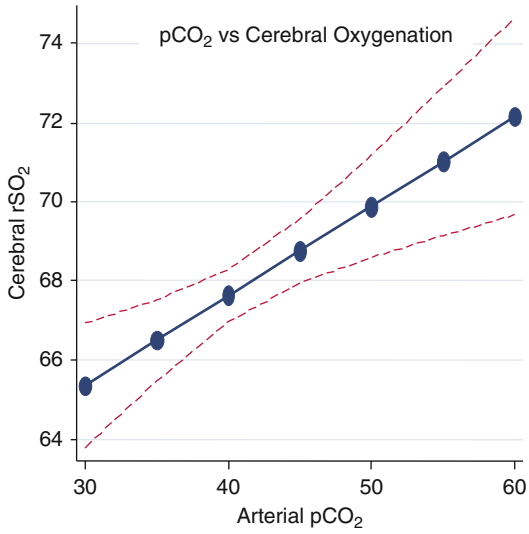
Animal data suggest that both mesenteric and renal circulations show similar responses to ischemia as monitored by NIRS, and the specific choice of somatic probe site is perhaps less important for monitoring global hemodynamics [43]. As distinct from normal newborns who do not demonstrate renal-somatic desaturation with feeding [45], frequent renal-somatic desaturation has been observed in newborns who have feeding difficulties [85, 86] and under conditions of stress [87]. Placement of a NIRS probe on the lower anterior abdominal wall provides a window on the mesenteric circulation, specifically, and has revealed an increased risk of necrotizing enterocolitis in premature infants [88] and a close relationship to lactate and SvO_2 in the post-cardiac surgical neonate [89]. In premature infants with large persistent patent ductus arteriosus (PDA), the mesenteric circulation may be at particular risk, and in this population, the abdominal NIRS saturation was lower than in preterm infants without a large PDA [90].

The distribution of blood flow between pulmonary (Qp) and systemic circulations (Qs) in the newborn with transitional circulation, large PDA, or complex congenital heart disease is dynamic. Just as the presence of a right-to-left shunt can be diagnosed by arterial desaturation, a left-to-right shunt can be detected by somatic desaturation. Modulation of pulmonary vascular resistance by manipulation of blood gas parameters is a frequent intervention strategy, but the arterial saturation alone is an inadequate determinant of Qp/Qs. With estimation of SvO_2 by two-site NIRS, a continuous estimate of Qp/Qs can aid in the assessment and treatment of newborns with complex anatomy and physiology. Although pulmonary vascular resistance can be increased by hypoxic gas mixtures and hypercapnia, only the latter increases systemic and cerebral oxygenation [91, 92].

While the effect of hypercapnia to evoke cerebral vasodilatation is well established, the effects on other aspects of regional perfusion are less clear. In single-ventricle neonates, with potential for carbon dioxide-induced changes in both Qp/Qs and cerebrovascular resistance, we found evidence for a tradeoff of cerebral and renal circulation, such that hypercapnia resulted in a reduction in renal blood flow that mirrored the cerebral increase (Fig. 47.17) [93]. These regional flow measures are typically derived from static snapshot measures during cardiac catheterization or with Doppler ultrasonographic examinations that do not characterize the patient's physiology under changing conditions. Monitoring cerebral and somatic NIRS provides a continuously available noninvasive measure of potential changes in cardiac output distribution



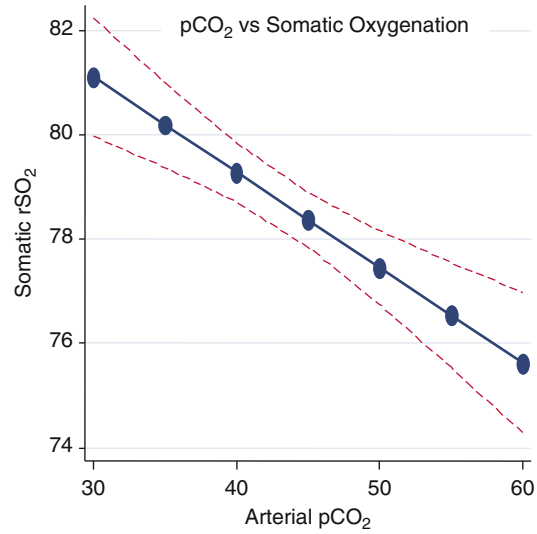


Fig. 47.17 Changes in arterial carbon dioxide tension (pCO_2) can alter the distribution of regional vascular resistance and blood flow. In neonates following stage one palliation of hypoplastic left heart syndrome, an increase in pCO_2 causes an increase in cerebral blood flow and oxygenation, but this is mirrored by a reduction in renal-somatic blood flow and oxygenation (From source [93], with permission)

with changing ventilator strategies, vasoactive drug infusions, induction or withdrawal of sedation, other common medical interventions, or feeding and physical activity [94, 95].

Summary

Organ-specific regional venous oxygen saturation monitoring with NIRS can approximate global SvO_2 for outcome relationships and as a target for goal-directed intervention. The additional information about organ-specific oxygenation and blood flow shows good relationship to organ function. Increasing evidence supports the validity of regional NIRS measures of oxygen saturation as estimates of organ-specific blood flow in the monitored field, with relationship to organ-specific and global hemodynamic state and outcomes. This information can also provide continuous diagnostic information in the cardiac neonate, with complex blood flow patterns, myocardial performance issues, and variable and bidirectional shunting. The venous-side information provided by NIRS is especially helpful during times of high-risk acute intervention or complex physiologic derangement, and the continuous-noninvasive characteristics permit more longitudinal application and assessment of physiology in challenging and dynamic conditions [94].

Biomarkers in Pediatric Cardiology and Cardiac Surgery

48

Angela Lorts, David Hehir, and Catherine Krawczeski

Abstract

Biomarkers are used in clinical medicine for early and rapid diagnosis of a disease state and to monitor therapeutic intervention. Innovative technologies have uncovered novel genes and gene products that have emerged as clinically relevant biomarkers. The discovery, validation, and clinical use of several biomarkers, such as the troponins and natriuretic peptides, have revolutionized diagnosis and management in the field of cardiology, leading to significant improvement in outcomes over the last few decades in diseases such as acute coronary syndrome. Although biomarker discovery in the areas of brain and kidney injury has lagged behind, significant work in the discovery and validation of biomarkers for acute brain injury and acute kidney injury (AKI) in pediatric heart patients is ongoing, with promising new biomarkers.

Keywords

Acute kidney injury • Biomarker • Brain injury • Cardiac surgery • Cardiopulmonary bypass • Glial fibrillary acidic protein • Heart failure • Interleukin-18 • Kidney injury molecule-1 • L-type fatty acid-binding protein • Natriuretic peptides • Neuron-specific enolase • Neutrophil gelatinase-associated lipocalin • Pediatric • S100B • Troponin • Ubiquitin C-terminal hydroxylase-1

Introduction

A "biomarker," or biologic marker, is a measureable substance produced by the body and used to diagnose or determine a biologic state. Most biomarkers used in clinical medicine are genes, proteins, or other chemical substances that are expressed or induced in disease, allowing for early and rapid diagnosis and subsequent therapeutic intervention. Although no biomarker is "ideal," clinically applicable biomarkers should have a number of desirable characteristics. First, they should be noninvasive and easy to measure at bedside or in a standard clinical laboratory, using easily accessible samples such as blood or urine. Biomarker measurements should be rapid and reliable. Biomarkers should be highly sensitive to facilitate early detection with a wide dynamic range and established cutoff values that allow for risk stratification, therapeutic response, and prognostication. Additionally, they should exhibit strong biomarker performance on statistical analysis, including accuracy testing by receiver-operating characteristic (ROC) curves and newer analytic techniques such as the Net Reclassification Index. Lastly, biomarkers should be specific for the disease state, enable identification of varying etiologies of the disease, and correlate with disease severity and outcomes, which would allow monitoring of the disease and response to therapeutic interventions.

Innovative technologies such as functional genomics and proteomics have uncovered novel genes and gene products that have emerged as clinically relevant biomarkers [1]. Genomics, the study of the genetic makeup of a species, gained popularity in the 1990s with the Human Genome Project. The advent of the microarray, or DNA chip, allows investigators to efficiently search through thousands of genes simultaneously, looking for genes that may produce proteins that could serve as biomarkers of disease. Proteomics is the study of the structure and function of proteins. Proteins can be studied with a variety of methods, including gel electrophoresis, immunoblotting, mass spectrometry, and enzymatic or metabolic assays. Each method is used to determine different types of information and each has strengths and limitations. Advancing technologies have radically improved the speed and precision of protein identification and measurement.

Using these technologies, the discovery, validation, and clinical use of several biomarkers, such as the troponins and brain natriuretic peptides (BNP), have revolutionized diagnosis and management in the field of cardiology, leading to significant improvement in outcomes over the last few decades in diseases such as acute coronary syndrome. Although biomarker discovery in the areas of brain and kidney injury has lagged behind, significant work in the discovery and validation of biomarkers for acute brain injury and acute kidney injury (AKI) is ongoing, with promising new biomarkers.

Biomarkers for Myocardial Injury

Definition and Pathophysiology

There are multiple etiologies of cardiomyocyte injury in children, such as volume/pressure overload due to unrepaired congenital heart disease, ischemia/reperfusion associated with cardiopulmonary bypass, or myocardial injury due to systemic illness. Myocardial stress leads to a string of events resulting in cardiomyocyte stretch, synthesis of multiple peptides and hormones, and ultimately cellular death/necrosis and the subsequent release of cellular contents. Cell death leads to the secretion of inflammatory mediators and neurohormones from cardiomyocytes, infiltrating white blood cells and neighboring fibroblasts. Markers of necrotic cardiomyocytes can then be detected in serum and used as a marker of myocardial disease.

An abundance of published literature and ongoing research exists dedicated to discovery of the "perfect" biomarker of cardiac failure. To date, there are hundreds of proposed candidates but only a few of these markers, troponins and natriuretic peptides, have undergone the "test of time" and are useful in clinical practice. Nevertheless, despite the proven benefit of following

trends in these established cardiac biomarkers, elevations do not fully demonstrate the etiology or the pathophysiology of the disease state. The current practice in adult heart failure medicine is to use biomarker levels as a diagnostic modality, to assist in the titration of medical therapy and to predict the need for a surgical intervention [2]. These biomarkers are utilized less frequently in children, presumably due to the smaller number of heart failure patients and the multitude of causes of heart failure in pediatrics.

Established Cardiac Biomarkers

Natriuretic Peptides

The natriuretic peptides are one of the most common biomarkers followed in the adult heart failure population. These peptides are produced by the heart and the vascular endothelium in response to atrial stretch. Serum levels are therefore positively related to cardiac filling pressures and inversely related to ventricular function. Myocardial dysfunction leads to the release of natriuretic peptides which influence fluid balance and systemic vascular resistance. The precursor protein is a 134-amino acid proBNP that is released from storage granules, which undergoes posttranslational modification, resulting in the 76-amino acid N-terminal proBNP (NT-proBNP) and the 32-amino acid molecule BNP. In adult heart failure patients, serum NT-proBNP and BNP levels have been shown to correlate with the New York Heart Association (NYHA) class and are used to predict adverse outcomes and estimate disease severity [3]. Both biomarkers have been proven to be useful in risk stratification of adult heart failure patients. As a general guideline, 90 % of young and healthy adults will have a BNP level lower than 25 pg/ml and an NT-proBNP level of less than or equal to 70 pg/ml [4].

The significance of serum levels of the natriuretic peptides as markers of cardiac disease was first published in 1994 [5]. The original studies were followed by prospective studies in the emergency department that described the use of BNP as a means to distinguish respiratory difficulties due to cardiac disease versus noncardiac causes. Subsequent studies, performed in the acute setting, strengthened the conclusion that BNP is a sensitive and specific diagnostic marker of cardiac failure. Additional studies have shown that BNP levels are not only diagnostic but also prognostic. Higher BNP levels correlate with a greater risk of mortality and recurrent heart failure [3].

Associations between plasma BNP concentrations and prognosis suggested that targeting biomarker levels with therapy may be more effective than current strategies. The Christchurch group published early data that demonstrated that therapy guided by serial measurements of NT-proBNP produced better outcome than therapy guided by clinical exam alone [6]. Since that time, there have been several studies evaluating the use of hormone-guided therapy to improve outcomes, but only a minority of the studies have shown a statistically significant benefit to this approach [2].

There has been much debate in the adult literature about the relative roles of BNP or NT-proBNP. There is a paucity of studies evaluating one against the other, but those studies that have been completed do not show a wide variation in utility. The important difference is that BNP has a half-life of approximately 20 min while NT-proBNP has a longer half-life of about 1–2 h. NT-proBNP is much more stable in room air after being drawn [7]. There remains debate regarding the use of the two levels in renal failure, and it may be that one is superior to the other in this scenario.

Although BNP testing has become standard of care in the adult setting, data to support the use of BNP testing in pediatrics are limited. As with many therapeutics and monitoring devices, data are extrapolated from the adult population for use in pediatrics. This is complicated by the fact that pediatric normal values are age dependent and many of the patients that would benefit from BNP testing have structurally abnormal hearts. BNP levels are extremely high in the first week of life (approximately 60–90 pg/ml), and levels vary depending on how rapidly the pulmonary artery pressure falls [8]. After the neonatal

period, BNP values in normal children are similar to adult values. Initial pediatric studies to determine utility focused on the use of BNP levels to predict cardiac versus pulmonary causes of neonatal respiratory distress [9]. Although the plasma BNP level was not a confirmative test, it was found to have a high sensitivity for rapidly ruling out serious cardiovascular problems in infants with respiratory distress. Recognizing that serious cardiovascular disease in a neonate could be devastating, and the current literature is not conclusive, clinical decisions should not be made on this single laboratory value. In a study by Mir et al., 31 children with congestive heart failure, as defined by the modified Ross criteria, were enrolled and N-BNP levels were measured [8]. These levels were found to be higher than the normal age-matched population and correlated with ejection fraction and clinical symptoms. Subsequently additional studies were published to evaluate natriuretic peptide levels in various pediatric populations, including neonates with patent ductus arteriosus [10], doxorubicin-induced cardiomyopathy [11], and myocardial dysfunction associated with Duchenne muscular dystrophy (DMD) [12]. These studies all suggested a positive correlation of BNP or N-BNP levels to disease severity and prognosis. Interestingly, the peptide levels were not found to be a sensitive marker for early detection of systolic dysfunction in children with DMD but an increased level in these patients did predict a poor prognosis [12].

In 2006, a study from Price et al., which examined BNP levels in 53 children with chronic left ventricular (LV) dysfunction, showed that BNP testing may be useful in the outpatient setting of chronic heart failure patients [13]. This study found that there was a large range of BNP levels in children with LV dysfunction with some children having normal levels ($<$30 pg/ml). Moreover, BNP concentrations predicted 90-day composite end point of death, hospitalization, or listing for transplant. A BNP concentration of $>$300 pg/ml, in particular, appeared to be a strong discriminator of patient morbidity and mortality. More recently, a prospective study was performed in children to diagnose cardiovascular disease in children [14]. The study was designed to determine if BNP testing could be a frontline test to diagnose cardiac disease in the acute care setting. The study validated the use of BNP measurements to diagnose significant cardiovascular disease in the pediatric patient. The cutoffs offering optimal accuracy were 170 pg/ml from birth to 7 days of age and 41 pg/ml for those neonates older than 7 days to the age of 19 years. The post hoc analysis in the Pediatric Carvedilol Trial suggested a threshold of $>$140 pg/ml for predicting adverse outcomes in children with known heart failure [15]. These cutoffs are different than published and company-recommended cutoffs of 80–100 pg/ml for adults. From the data available in children with structurally normal hearts, it is reasonable to conclude that following BNP levels is effective in guiding therapy and predicting prognosis; however, the number of patients included in the pediatric studies is extremely small when compared to the large prospective adult trials that have been performed.

The studies reviewed were done in patients with structurally normal cardiac anatomy. There have been data to support the use of BNP levels as a marker of volume overload in left-to-right shunts (atrial and ventricular septal defects and patent ductus arteriosus), and recently, experience with BNP monitoring in patients with complex single-ventricle physiology has been published. In these studies of children with single-ventricle physiology, BNP levels were higher after the first palliative surgery [16]. This finding is consistent with the proposal that single-ventricle children have the larger volume load prior to their Glenn operation (or second stage palliation). These studies also found that children with a single right ventricle had higher BNP levels than those children with a single left ventricle [17]. This study suggests that a BNP threshold of 45 pg/ml should be used in monitoring the onset of HF in this subset of patients, despite the stage of palliation they have undergone.

In summary, adult data support the use of BNP values to determine the degree of circulatory compensation in adult patients and the response of these patients to treatment. The pediatric data

do not yet rival the adult data but are supportive of the use of BNP levels as adjunct tools to the management of children with heart failure in both the acute and outpatient setting.

Cardiac Troponins

Biochemical markers of cardiac damage are used extensively in the adult population, primarily for the diagnosis and management of acute myocardial infarction (AMI). Progress in biomarker discovery has advanced the field from nonspecific marker monitoring (creatine kinase) to creatine kinase MB and cardiac troponins (cTnI and CTnT).

As part of the complex myocardial sarcomeric unit, the troponins' primary function is to control the interactions between the thick (myosin) and thin (actin) filaments. The troponin complex is made up of 3 subunits: troponin C is the calcium-binding subunit, troponin T is involved in the attachment to the thin filament, and troponin I serves to inhibit the actin-myosin cross-bridge formation. There is a developmental isoform switch from fetal cTnI to an adult form anywhere from 9 months to 2 years of age. Despite the developmental difference in cTnI, cTnT levels are clinically useful in all age. Importantly, cTnI and cTnT are cardiac specific and in all ages they represent myocardial disease [18]. Testing for cTnI and cTnT can be interchangeable with very few exceptions. Both biomarkers are detected about 4 h after injury and may peak initially due to membrane rupture and peak again later when the myocyte undergoes necrosis. The cTnT appears to be detected in the serum longer (10–14 days) than its counterpart cTnI (7 days) [18].

Clear differences due exist between the normal values of pediatric and adult troponin testing. It has been shown that newborns have higher troponin levels at baseline than the average adult [19]. This is theorized to be due to physiologic changes that occur at delivery versus programmed cell death that may occur during this period.

The majority of research on cardiac troponins has been in AMI. The rarity of AMI in children has hindered the ability to study troponin levels in children following coronary events, but there are other conditions that result in troponin release. In pediatrics, troponin levels have been shown to be useful in diagnosing myocarditis [20], evaluation of the extent of a cardiac contusion, predicting operative timing in congenital heart disease [21], detecting rejection in transplant patients [22], and monitoring for anthracycline toxicity [23]. Troponin levels are used commonly to assist with the diagnosis of viral myocarditis. The etiology of a newly diagnosed dilated cardiomyopathy is difficult to determine with standard diagnostic procedures. Myocardial biopsy, although the gold standard, has a low sensitivity rate since a small piece of the myocardium is being tested. An elevated troponin in these children, in addition to history and physical findings, suggests an acute viral myocarditis and less likely a chronic dilated cardiomyopathy. The likelihood of a viral process becomes important when the patient is decompensating and may need to be listed for transplantation and supported with a mechanical assist device. If a viral process with acute cardiomyocyte damage is suspected, different strategies may be taken to support the patient to allow for recovery.

Cardiac troponins have been proven to be useful markers of cardiac damage in the adult population, and with published pediatric values, the levels will become more and more useful in children. As these assays become more sensitive and the pediatrician becomes more comfortable with interpretation of the results, they become utilized to assist in making a cardiac diagnosis.

Emerging Biomarkers for Myocardial Injury

The adult biomarker literature has been abundant with multiple candidates for markers of cardiac disease, but to date, the only biomarkers routinely measured are the few summarized above. Other potential biomarkers of cardiac failure include:

1. Inflammatory markers: C-reactive protein has been shown to be a predictor of heart failure-related mortality in the adult population [24]. In children, there has been one study that collected multiple inflammatory markers – TNF-α and TNF-α receptor, and

hsCRP – and found that elevations correlated with more severe left ventricular dilation and dysfunction.
2. Copeptin: This marker, C-terminal portion of pro-vasopressin, has been associated with HF mortality in two large adult studies. In both studies, copeptin was shown to be a stronger predictor of mortality than either BNP or NT-proBNP [25].
3. Galectin-3: This protein is produced by macrophages and is elevated in adults with acute heart failure. De Boer et al. found that doubling of galectin-3 levels after heart failure hospitalization was associated with an increased risk of mortality and heart failure readmission [26].
4. Growth-differentiation factor 15: This protein is a member of the TGF-β pathway and may play a role in cardioprotection during ischemia/reperfusion. The adult data that exists reveals a correlation between serum levels and mortality in adult patients that have acute coronary syndrome [27].
5. Matrix remodeling proteins: Ventricular remodeling is closely linked to the production of collagen and the breakdown of the matrix. There is extensive literature on the complex remodeling pathway and the value of measuring blood levels of the matrix metalloproteinases and their inhibitors in the adult heart failure population [28].
6. Interleukin receptor ST2: This receptor binds to IL-33 (a cytokine synthesized by fibroblasts and directly involved in fibrosis and remodeling) and may represent the myocyte-extracellular matrix relationship that occurs during pathologic remodeling. Elevated levels of this soluble receptor are predictive of mortality long term and at 1 year after diagnosis [29].

Biomarkers of Brain Injury

Definition and Pathophysiology

Serum biomarkers of brain injury are promising adjuncts to current multimodal neuromonitoring strategies in the care of the CHD patient in the operating room and intensive care unit. Biomarkers of brain injury can be classified as diagnostic, monitoring, surrogate, and stratification [30]. Each type has a potential role in the care of the perioperative CHD patient and may improve existing diagnostic and prognostic abilities. Currently available neuromonitoring techniques include near-infrared spectroscopy (NIRS), electroencephalogram, transcranial Doppler ultrasound, and emboli detection and classification quantification. In addition, standard physiologic data, the physical exam, and neuroimaging are important tools for diagnosis and prognosis of central nervous system (CNS) injury. However, each of these modalities suffers from specific limitations in the perioperative pediatric population, including size and space limitations, the need for specialized personnel and interpretation, a lack of validation, and low sensitivity and specificity for brain injury. It has become well recognized that multimodal neuromonitoring offers the greatest potential for accurately detecting and preventing neurologic sequelae of surgery with CPB [31, 32]. While not currently widespread in clinical practice, serum biomarkers of brain injury will complement existing neuromonitoring modalities due to ease of measurement (blood draw), with relatively inexpensive, rapid, and standardized analysis techniques (bedside or clinical lab testing) and central nervous system specificity. In addition, the ideal biomarker of brain injury will be sensitive to early brain injury and relatively resistant to the effects of cardiopulmonary bypass (CPB) including hemolysis, inflammation, renal insufficiency, and hepatic dysfunction.

Neurologic impairment remains prevalent in patients undergoing CPB for the repair of CHD, with rates of serious acute neurologic injury estimated at 4–8 % and long-term neurodevelopmental abnormalities found in up to 40–50 % of school aged children [33, 34]. The periods of greatest vulnerability for CNS injury appear to be the operative and anesthetic phases as well as the early postoperative course in the ICU [32]. Brain injury may result from hypoxemia-ischemia, inflammation, embolism, and other vascular accidents. This is due to altered cerebral perfusion,

the effects of deep hypothermic circulatory arrest (DHCA), loss of autoregulation, impaired hemodynamics following weaning from CPB, and the effects of anesthetics and inotropic medications [32]. The incidence of CPB-related brain injury may be modified by genetic predisposition, preoperative physiologic state, cardiac lesion, cerebrovascular anatomy, and cerebral protection strategies employed during and after surgery. In addition, there is evidence that patients with CHD may be at increased risk for brain injury throughout their lives. This includes the preoperative phase; patients with complex congenital heart disease are known to have a high incidence of preoperative brain abnormalities and injury [35]. This is likely multifactorial in nature, due to abnormal fetal cerebral blood flow patterns, associated syndromic features, and postnatal susceptibilities resulting from cyanosis, hypotension, and embolic injury [36].

As therapeutic interventions for brain injury improve, early detection and intervention is paramount. Brain injury following CPB may be diagnosed many days after the injury, obviating the possibility of specific treatment in many cases. A critical need is the identification and/or confirmation of acute stroke, embolism, or intracranial hemorrhage in the sedated perioperative patient who is too unstable for transfer to CT or MRI. Biomarkers may help identify the patient with ongoing ischemia or perfusion deficits in the operating room or intensive care unit who would benefit from immediate corrective intervention and subsequent neuroprotective management strategies. In addition, they may have prognostic value in identifying those patients with subclinical disease in the postoperative period who would most benefit from early intervention rehabilitation therapies. It is likely that a "biomarker array" will be more powerful than any single biomarker at detection and monitoring of brain injury in CHD patients. This is due to varying biochemical properties, kinetics of release and elimination, and varying specificity for the different types of brain injury (i.e., diffuse hypoxia vs. focal hemorrhage or stroke). While previously studied biomarkers such as S100B and neuron-specific enolase (NSE) have not been widely adopted into clinical practice due to their limitations, brain biomarker research has experienced a resurgence due to the application of neuroproteomics [37]. Emerging biomarkers such as glial fibrillary acidic protein (GFAP) and ubiquitin C-terminal hydroxylase-1 (UCH-L1) promise improved specificity for brain tissue and complementary biochemical properties which may lead to a greater clinical role in the future.

Current and Potential Biomarkers of Brain Injury

S100B

S100B is the most widely studied biomarker of brain injury in the setting of CPB. S100B is a cytosolic glial-derived protein that can be detected in serum and cerebral spinal fluid by enzyme-linked immunosorbent assay (ELISA). Although its specific function in the body is not known, it is thought to be involved in glial cell growth and activation. It is encoded on the long arm of chromosome 21 and consists of two monomeric subunits. Its half-life has been reported at 25–60 min, and elimination is not influenced by mild to moderate renal dysfunction [30]. S100B increases in patients undergoing CPB almost immediately and typically reaches its peak level at the end of CPB [38]. This trend has been replicated in pediatric populations [39]. In most patients, S100B decreases rapidly to baseline following CPB, but in some patients there may be a second, lower, peak. In addition, patients with altered cerebral blood flow patterns exhibit preoperative elevation of S100B, with lower postoperative levels, implying resolution of ongoing cell damage following repair of CHD.

An elevation of serum S100B is associated with higher mortality and worse neurologic outcome after traumatic brain injury, cardiac arrest, and in adults following CPB. Vos found that S100B $>$ 1.13 ng/mL was associated with increased mortality following traumatic brain injury in adults (100 % sensitivity, 41 % specificity) [40]. In pediatric patients following cardiac arrest, S100B had a higher initial peak and

remained elevated in those who died, with a level of 0.7 μg/L or greater providing 63 % sensitivity and 76 % specificity for death [41]. However, S100B levels did not correlate with neurologic outcome in survivors in this study. Georgiadis measured S100B in 190 adults undergoing coronary artery bypass surgery with CPB, finding S100B levels > 1.4 μg/L 24 h after CPB highly predictive (80 % positive predictive value) of postoperative stroke, stupor, or coma [42]. LeMaire found much higher levels of S100B in 39 adults undergoing thoracic aorta repair utilizing circulatory arrest [43]. Patients with postoperative neurologic events ($n = 3$) had higher S100 B levels than those with neurologically intact survival (7.17 ± 1.01 vs. 3.63 ± 2.31 μg/L; $p = 0.013$). The authors suggest a threshold level of 6 μg/L be used for prediction of significant neurologic injury in the early postoperative period, in contrast to the level of 1.4 μg/L found in the Georgiadis study. This difference highlights the difficulty generalizing thresholds of S100B useful for predicting neurologic injury when making comparisons between studies and various patient populations.

S100B has failed to gain widespread clinical acceptance due to a number of limitations. While clearly expressed at high levels in glial cells, S100B can also be found in extracerebral sources such as fat, muscle, and marrow. It is likely that the very high post-CPB peak in S100B is the result of extracerebral contamination, with one investigator attributing greater than 80 % of the variability in this peak level to nonneuronal sources [44]. The expression of S100B is age dependent with levels highest in the neonatal period therefore complicating its interpretation in neonates undergoing CPB, who are thought to be at highest risk for CNS injury [45]. There is variability in assay specificity with no universal standards which limits inter-study comparison and generalizability [30]. In addition, the conflicting results of studies assessing the association of S100B with short- and long-term cognitive and neurodevelopmental functioning limit its potential use as a surrogate or monitoring biomarker [42]. However, most studies to date have focused on the prognostic value of the early high peak. Given the likely contamination of S100B during bypass and the work by Georgiadis, Topjian, and others demonstrating the increased power of the later elevations in predicting outcomes, perhaps future studies should focus on the predictive power of S100B 24–48 h following CPB and the importance of a delayed decay curve. Lardner examined this problem by evaluating neurologic outcomes in 43 children undergoing CPB, finding those with an elevated S100B level 48 h after CPB to have an OR of 33.9 for neurologic injury ($p < 0.03$, 95 % CI 1/39−827) [46].

Neuron-Specific Enolase (NSE)

NSE is a cytosolic protein found in neurons and neuroendocrine tissues [30]. Along with S100B, it has been extensively studied in the neonatal population at risk for hypoxic injury, as well as head trauma, cardiac arrest, and CPB [42]. The normal function of NSE is to catalyze the conversion of 2-phospho-D-glycerate to phosphoenolpyruvate in the glycolytic pathway. NSE increases upon initiation of CPB in a manner similar to S100B, returning to baseline within 24–48 in most patients [42]. Elevated NSE has been associated with poor outcomes following trauma, cardiac arrest, and seizures [47]. The importance of elevated NSE following CPB remains controversial. Georgiadis found elevated NSE to have 79 % specificity for the composite outcome of stroke, stupor, or coma in adults following surgery with CPB but concluded it to be inferior to S100B as a biomarker. The utility of NSE as a biomarker in CPB suffers from its contamination from hemolysis and extracerebral sources. It is relatively neuron-specific but has been detected in neuroendocrine tissues and in neuroendocrine tumors [48].

Glial Fibrillary Acidic Protein (GFAP)

GFAP is a structural protein found almost exclusively in astrocytes. It is an intermediate filament protein and is the main structural protein of the cytoskeleton of glial cells. Following brain injury, GFAP expression is upregulated in the brain due to reactive gliosis and can be detected in serum and CSF as a result of glial cell

death [49]. GFAP has been studied extensively and found to be elevated in patients following stroke, traumatic brain injury, and cardiac arrest [50, 51].Vos found GFAP (OR 8.82) to have the strongest predictive ability for poor neurological outcome in patients following severe traumatic brain injury, when compared with S100B (OR 5.12) and NSE (OR 3.95) [52]. An elevated GFAP (>0.1 ng/dL) at 12, 24, and 48 h following cardiac arrest has also been shown to correlate with poor neurological outcome at 6 months postarrest [53]. In the subset of patients receiving therapeutic hypothermia following cardiac arrest, a significant association was found between elevated GFAP and poor 6-month neurologic outcomes, suggesting that GFAP could be used to monitor the effect of neuroprotective interventions. A particularly attractive attribute is its ability to distinguish between intracranial hemorrhage and disuse hypoxia/ischemia [50]. In a study of 205 adults presenting to emergency rooms with symptoms of stroke, GFAP was significantly more elevated in those with intracranial hemorrhage versus ischemia (1.91 μg/L vs. 0.08 μg/L; $p < 0.001$) [54]. Using a cutoff of 0.29 μg/L, GFAP demonstrated a sensitivity of 84.2 % and specificity of 96.3 % for hemorrhage versus ischemia. GFAP has not been studied extensively in the CPB population, and no studies exist in children following cardiac surgery.

Ubiquitin C-Terminal Hydroxylase-1 (UCH-L1)

UCH-L1 is a highly abundant neuronal protein with very little extra-CNS expression. In the field of histopathology, UCH-L1 has been used as a marker for neurons due to its high specificity [55]. In disease and in health, it is involved in the regulation and processing of excessive, misfolded, or oxidized proteins which are entering the ATP-dependent proteasome pathway [55]. Its detection in the serum has been associated with neurodegenerative diseases such as Parkinson's disease [56]. In patients with traumatic brain injury, a higher UCH-L1 level has been associated with lower Glasgow Coma Score, worse functional outcomes, and death [55]. Mondello demonstrated that UCH-L1 elevation correlates with abnormalities on CT scan [57]. An intriguing finding of this study was that in patients with diffuse brain injury by CT, UCH-L1 was significantly higher (1.55 ± 0.18 vs. 1.21 ± 0.15 ng/mL; $p = 0.01$), while in patients with a focal lesion on CT, there was a significant elevation of GFAP (2.95 ± 0.48 vs. 0.74 ± 0.11 ng/mL; $p = 0.03$). In a canine model of DHCA, Arnaoutakis found that serum UCH-L1 levels were elevated 8 h post-CPB to a greater degree in a DHCA group of animals when compared to a CPB group without DHCA, and those with a higher 8-h level had significantly worse functional outcome [56]. Compared with a group who underwent 1 h of DHCA, those who underwent 2 h of DHCA had significantly higher CSF UCH-L1 at 24 h, and functional outcomes were worse. Siman showed an elevation of CSF UCH-L1 in patients undergoing aortic aneurysm repair [58]. Those patients who underwent aortic cross-clamping without DHCA had a significantly higher peak UCH-L1. UCH-L1 has not been studied in a pediatric population, and more investigation is needed into its relationship with neurological injury and outcomes following CPB.

Monitoring of Brain Injury in Mechanical Circulatory Support

Patients requiring extracorporeal membrane oxygenator (ECMO) and ventricular assist device (VAD) support may experience the greatest benefit from the clinical use of biomarkers of brain injury. The incidence of intracranial hemorrhage, stroke, and brain death in patients on ECMO has been reported from 10 % to 52 %, and in those who do suffer acute neurologic injury mortality can be as high as 89 % [59]. Long-term cognitive and neurodevelopmental disabilities are found in as many as 60 % of survivors up to 10 years following ECMO [60]. Neurologic morbidity and associated mortality are particularly high in single-ventricle patients requiring ECMO support [61]. Booth found that 5/6 patients with bidirectional Glenn physiology on ECMO died

and the lone survivor suffered severe neurologic impairment [62].

The use of biomarkers is particularly attractive as a diagnostic screening test and ongoing monitor for acute hemorrhage or stroke following ECMO cannulation in patients with congenital heart disease. These patients may be too unstable to justify a transport to a CT scanner for diagnosis of suspected brain injury. A significant percentage will have an open chest and be deeply sedated and/or muscle relaxed, especially in a postoperative ECMO scenario. Therefore, the index of suspicion for injury must be high to warrant the risk of a complex transport to radiology. Biomarkers offer the ability to serve as an initial screen, to characterize patients into high- or low-risk groups prior to undertaking the gold-standard radiologic test. Gazzolo found that in neonates on ECMO who developed intracranial hemorrhage, S100B was significantly elevated in comparison to controls with no intracranial hemorrhage (2.91 ± 0.91 vs. 0.53 ± 0.15 μg/L; $p = <0.05$) [63]. This elevation was seen on average 72 h before an ultrasound diagnosis was made. In children requiring ECMO for a variety of etiologies, Bembea found GFAP to be significantly higher in those with brain injury (5.9 ng/mL vs. 0.09 ng/mL; $p = 0.04$) and found the odds ratio for brain injury for GFAP > 0.436 ng/mL to be 11.5 (CI 1.3–98.3) [49]. The early detection of neurologic injury through the use of validated biomarkers could have profound therapeutic and prognostic significance to these patients.

Future Directions: Biomarkers of Brain Injury in Pediatric CHD Patients

Biomarkers offer an attractive potential adjunct to current neuromonitoring modalities in the operating room and ICU, but at this time, no individual biomarker possesses suitable evidence for widespread clinical use. Future research should focus on continued novel biomarker discovery through techniques such as proteomics, validation of current biomarkers in a variety of populations, and demonstration of their feasibility and ability to improve patient outcomes. Much like the biomarkers of myocardial injury, it is likely that an array of biomarkers of brain injury with differing properties will improve their predictive power.

Biomarkers for Acute Kidney Injury

Definition and Pathophysiology

Acute kidney injury (AKI) is a common and severe complication of critical illness and is independently associated with adverse outcomes, including prolonged intensive care and hospital stays, diminished quality of life, and increased long-term mortality. Although AKI occurs in a variety of clinical settings, cardiac disease and cardiac surgery are common causes of AKI, second only to sepsis in critically ill patients [64]. The etiology of AKI following cardiopulmonary bypass (CPB) is likely multifactorial. Possible etiologies include ischemia-reperfusion injury, oxidative stress, and activation of the systemic inflammatory response. All of these factors may contribute to global endothelial dysfunction, leading to capillary leak and vasomotor instability. The kidney is particularly sensitive to these effects, and non-pulsatile flow during CPB contributes further to tubular epithelial injury through renal artery vasoconstriction, worsening the ischemia-reperfusion injury. Established risk factors for cardiac surgery-associated AKI are younger age and longer CPB time [65]. Additionally, infants and children undergoing CPB for repair or palliation of cyanotic CHD may be especially vulnerable to developing AKI since many children require multiple surgeries for stepwise repair of complex congenital anomalies.

AKI is a complex disorder with manifestations ranging from a minimal rise in serum creatinine to anuric renal failure. It is characterized by a rapid decline in the glomerular filtration rate (GFR) and by the accumulation of nitrogenous waste products such as blood urea nitrogen and serum creatinine. A conceptual framework for AKI has been proposed [66] which allows understanding of the clinical continuum of the disease, opportunities for improved diagnosis, and areas to target therapeutic

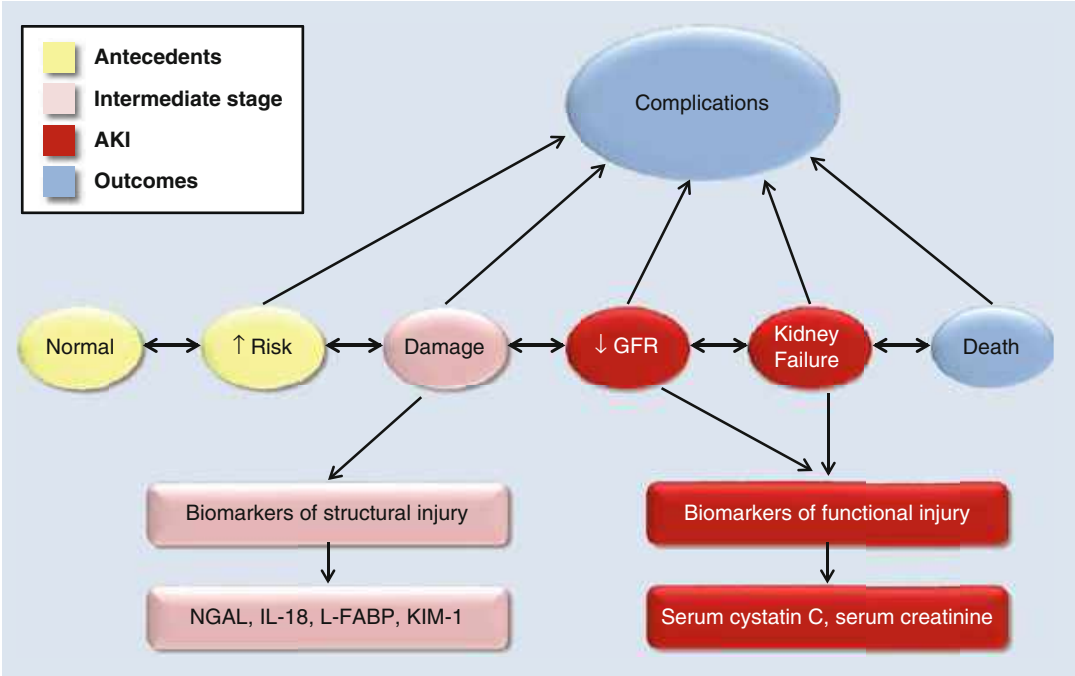

Fig. 48.1 Conceptual model of acute kidney injury (*AKI*) demonstrating spectrum of injury and time course of biomarker elevation (Reproduced from Murray PT, et al. *Clin J Am SocNephrol* 3: 864–868, 2008, with permission)

intervention. Figure 48.1 depicts the stages in the development and potential recovery of AKI. AKI (in red) is defined as a reduction in GFR, which may be diagnosed using biomarkers of functional injury such as serum creatinine or cystatin C. Preceding this stage is "kidney damage," an intermediate state during which structural damage occurs without overt functional injury. Detection of injury at this stage is the focus of emerging biomarkers such as neutrophil gelatinase-associated lipocalin (NGAL) and interleukin-18 (IL-18). It is during this stage of early damage that potentially reversible changes, such as loss of cellular polarity or microvascular perturbations, are detected [67]. Interventions at this stage have been successful at preventing and treating AKI in experimental animal studies. However, once AKI has set in, more severe and irreversible changes, such as cell death and desquamation, occur. Although tubular cells do possess the ability to regenerate and repair after injury, most interventions initiated in this late stage of AKI have been unsuccessful [67].

The Need for Better Markers of AKI

The utilization of biomarkers, in particular troponin, for the rapid diagnosis of myocardial injury, has revolutionized cardiac care, allowing for timely therapeutic interventions and a dramatic decrease in mortality over the past few decades. In contrast, the diagnosis of AKI has continued to rely on functional biomarkers, such as serum creatinine, which is delayed and unreliable in the acute setting. First, serum creatinine concentration is affected by a number of factors, including age, muscle mass, gender, and dietary intake. Second, up to 50 % of kidney function may be lost before serum creatinine even begins to rise. Third, at lower rates of glomerular filtration, tubular secretion of creatinine results in overestimation of renal function. Finally, during acute changes in glomerular filtration, serum creatinine does not accurately depict kidney function until steady-state equilibrium has been reached, which may require several days.

Animal models have contributed greatly to the mechanistic understanding of AKI and support the concept that early intervention and treatment of AKI is more effective [67]. Unfortunately, the translation of these treatments to clinical medicine has met with limited, if any, success. A major reason for this failure is the lack of early markers for AKI, and hence a delay in initiating timely therapy. Delaying potentially effective treatment for AKI until the serum creatinine increases above a threshold level is analogous to beginning definitive treatment in patients with an acute myocardial infarction only after functional evidence of heart failure is seen. A troponin-like biomarker of AKI that is easily measured, unaffected by other biological variables, and capable of both early detection and risk stratification would represent a tremendous advance in the field of critical care medicine. As such, quest for such AKI biomarkers has been an area of intense research [67].

Conventional urinary biomarkers such as casts and fractional excretion of sodium are insensitive and nonspecific for the early recognition of AKI [68]. Other traditional urinary biomarkers, such as filtered high molecular weight proteins and tubular proteins or enzymes, have also suffered from low specificity and lack of standardized assays [69]. Fortunately, the application of innovative technologies such as functional genomics and proteomics to human and animal models of AKI has uncovered several novel genes and gene products that are emerging as AKI biomarkers [70]. The most promising of these are neutrophil gelatinase-associated lipocalin (NGAL), interleukin-18 (IL-18), liver fatty acid-binding protein (L-FABP), and kidney injury molecule-1 (KIM-1).

Emerging Biomarkers for AKI

Neutrophil Gelatinase-Associated Lipocalin (NGAL)

NGAL is a siderophore-binding lipocalin involved in ischemic kidney injury and repair. It is normally expressed at very low levels in several human tissues, including kidney, lungs, stomach, and colon. The gene for NGAL is significantly upregulated in the kidney very early after ischemic injury, and the protein is over-expressed in distal tubule cells [71]. NGAL has been identified as one of the earliest and most robustly induced genes and proteins in the kidney after ischemic or nephrotoxic injury [70] and is easily measured in plasma or urine very early after injury [72, 73]. In a prospective landmark study of 71 children undergoing CPB, AKI (defined as a 50 % increase in serum creatinine) occurred in 28 % of subjects but the diagnosis using serum creatinine was possible only 1–3 days after surgery [73]. In contrast, NGAL measurements by ELISA revealed a dramatic increase in both urine and plasma within 2 h of onset of CPB in those who subsequently developed AKI. Both urine and plasma NGAL were independent predictors of AKI, with an area under the curve for the receiver-operating characteristic (AUC-ROC) of > 0.9 for the 2- and 6-h measurements. These results have been confirmed in several studies in cardiac surgical patients [72, 74] and additional studies have demonstrated elevations in NGAL with other forms of kidney injury, including contrast nephropathy, lupus nephritis, nephrotoxic injury, and delayed graft function in kidney transplants [75–78]. As an iron-transporting protein, NGAL may play a primary role in renal tubular survival and recovery and has been used therapeutically in ischemia-reperfusion injury animal models [77]. NGAL has emerged as the most promising biomarker to date. However, it appears that NGAL is most sensitive and specific in relatively uncomplicated patient populations with AKI [79] and that NGAL measurements may be influenced by a number of coexisting variables, such as preexisting renal disease and systemic or urinary tract infections. In a recent meta-analysis of the published performances of NGAL as a predictive biomarker for AKI after cardiac surgery, the mean AUC-ROC was 0.78 (95 % confidence interval 0.67–0.87) [79]. The mean-derived sensitivity and specificity from these studies are in the 75–80 % range. From the published literature, the derived optimal cutoff value of NGAL for the early prediction of AKI appears to be 150 ng/mL [79].

NGAL is also emerging as a useful early biomarker for therapeutic trials. A reduction in urine NGAL has been employed as an outcome variable in clinical trials demonstrating the improved efficacy of a modern hydroxyethyl starch preparation over albumin or gelatin in maintaining renal function in cardiac surgery patients [80]. Similarly, the response of urine NGAL was attenuated in cardiac surgery patients who experienced a lower incidence of AKI after sodium bicarbonate therapy when compared to sodium chloride [81]. Furthermore, subjects who developed AKI after aprotinin use during cardiac surgery displayed a dramatic rise in urine NGAL in the immediate postoperative period [82], attesting to the potential use of NGAL for the prediction of nephrotoxic AKI. Not surprisingly, NGAL measurements as an outcome variable are currently included in several ongoing clinical trials. The approach of using NGAL as a trigger to initiate and monitor novel therapies, and as a safety biomarker when using potentially nephrotoxic agents, is expected to increase.

Recent studies have also demonstrated the utility of early NGAL measurements for predicting clinical outcomes of AKI. In subjects undergoing cardiac surgery, the 2-h postoperative plasma NGAL levels strongly correlated with duration and severity of AKI and length of hospital stay. In addition, the 12-h plasma NGAL strongly correlated with mortality [72]. Similarly, the 2-h urine NGAL levels highly correlated with duration and severity of AKI, length of hospital stay, dialysis requirement, and death [74]. Perhaps even more interesting is that elevations in NGAL have been shown to correlate with worse clinical outcomes even when serum creatinine remains in the normal range. In a recent meta-analysis of over 1200 patients, those with NGAL elevations but normal serum creatinine (19 % of patients) had significantly longer ICU and hospital lengths of stay, greater need for renal replacement therapy, and higher mortality than those patients with normal NGAL and serum creatinine levels [83]. These NGAL (+), creatinine (−) patients likely exhibited early structural injury to the kidney without functional changes. In this group of patients, NGAL diagnosed 40 % more patients with AKI than creatinine alone and very few patients had elevation in serum creatinine without a prior elevation in NGAL. These results highlight the potential future role of NGAL in changing the definition of AKI.

The NGAL results described thus far have been obtained using research-based ELISA assays, which are impractical in the clinical setting. A major recent advance from the clinical laboratory perspective has been the development of a point-of-care kit for the clinical measurement of plasma NGAL (Triage® NGAL Device, Alere Incorporated). The assay is facile with quantitative results available in 15 min and requires only microliter quantities of whole blood or plasma. In subjects undergoing cardiac surgery, the 2-h plasma NGAL measurement measured by the Triage® Device showed an AUC of 0.96, sensitivity of 0.84, and specificity of 0.94 for prediction of AKI using a cutoff value of 150 ng/mL [72]. Furthermore, a urine NGAL immunoassay has also been developed for a standardized clinical platform (ARCHITECT analyzer, Abbott Diagnostics). This assay is also easy to perform with no manual pretreatment steps, a first result available within 35 min, and requires only 150 µl of urine. Following cardiac surgery, the 2-h urine NGAL measurement by ARCHITECT analyzer showed an AUC of 0.95, sensitivity of 0.79, and specificity of 0.92 for prediction of AKI using a cutoff value of 150 mg/mL [74].

Interleukin (IL)-18

IL-18 is a proinflammatory cytokine that is known to be induced and cleaved in the proximal tubule, and subsequently easily detected in the urine following ischemic AKI in animal models. In a cross-sectional study, urine IL-18 levels measured by ELISA were markedly elevated in patients with established AKI, but not in subjects with urinary tract infection, chronic kidney disease, nephrotic syndrome, or prerenal azotemia [84]. In a subsequent study, urinary IL-18 was found to be significantly upregulated prior to the increase in serum creatinine in patients with acute respiratory distress syndrome who developed AKI [85]. On multivariate analysis, urine IL-18 levels $>$ 100 pg/mg creatinine predicted the

development of AKI 24 h before the rise in serum creatinine, with an AUC of 0.73. Urine IL-18 on the day of initiation of mechanical ventilation was also predictive of mortality in these patients, independent of severity of illness scores and serum creatinine [85].

Both urinary IL-18 and NGAL were recently shown to represent early, predictive, sequential AKI biomarkers in children undergoing cardiac surgery [86]. In patients who developed AKI 2–3 days after surgery, urinary NGAL was induced within 2 h and peaked at 6 h whereas urine IL-18 levels increased around 6 h and peaked at over 25-fold at 12 h after surgery (AUC 0.75). Both IL-18 and NGAL were independently associated with duration of AKI among cases.

In subjects who undergo kidney transplantation, urine IL-18 and NGAL have emerged as predictive biomarkers for delayed graft function (defined as dialysis requirement within the first week after transplantation) [87]. In a prospective, multicenter study of children and adults, both IL-18 and NGAL in urine samples collected on the day of transplant predicted subsequent delayed graft function and dialysis requirement with an AUC of 0.9 for both biomarkers. By multivariate analysis, both urine IL-18 and NGAL predicted the trend in serum creatinine in the posttransplant period after adjusting for age, gender, race, urine output, and cold ischemia time ($p < 0.01$).

Recently published results also suggest that urine IL-18 measurements represent early biomarkers of AKI in the intensive care setting, being able to predict this complication about 2 days prior to the rise in serum creatinine [88]. Early urine IL-18 measurements correlated with the severity of AKI as well as mortality. Thus, urinary IL-18 rises prior to serum creatinine in non-septic critically ill children, predicts severity of AKI, and is an independent predictor of mortality in this heterogeneous group of patients with unknown timing of kidney injury.

IL-18 is more specific to ischemic AKI and largely not affected by nephrotoxins, chronic kidney disease, or urinary tract infections. However, IL-18 measurements may also be influenced by a number of coexisting variables, since renal IL-18 mRNA levels are known to be induced in other disease states such as endotoxemia, immunologic injury, and cisplatin toxicity. Furthermore, plasma IL-18 levels are known to be increased in various pathophysiologic states, such as inflammatory arthritis, inflammatory bowel disease, systemic lupus erythematosus, psoriasis, hepatitis, and multiple sclerosis. The relationships between plasma and urine IL-18 remain largely unexplored.

Kidney Injury Molecule-1 (KIM-1)

Kidney injury molecule-1 (*KIM-1*) was first identified by subtractive hybridization screening as a gene that is markedly upregulated in ischemic rat kidneys [89], a finding that has been confirmed in several other transcriptome profiling studies. Downstream proteomic studies have also shown KIM-1 to be one of the most highly induced proteins in the kidney after AKI in animal models, and a proteolytically processed domain of KIM-1 is easily detected in the urine soon after AKI [90]. Assays for KIM-1 (ELISA and microbead-based) have been developed in research laboratories, but are not commercially available.

In a small human cross-sectional study, KIM-1 was found to be markedly induced in proximal tubules in kidney biopsies from patients with established AKI (primarily ischemic), and urinary KIM-1 measured by ELISA distinguished ischemic AKI from prerenal azotemia and chronic renal disease [91]. Recent studies have expanded the potential clinical utility of KIM-1 as a predictive AKI biomarker. In a case–control study of 40 children undergoing cardiac surgery, 20 with AKI (defined as a 50 % increase in serum creatinine) and 20 without AKI, urinary KIM-1 levels were markedly enhanced, with an AUC of 0.83 at the 12-h time point [92]. In a larger prospective cohort study of 201 hospitalized patients with established AKI, both urinary KIM-1 as well as urinary N-acetyl-β-(D)-glucosaminidase (NAG) were found to be associated with adverse clinical outcomes, including dialysis requirement and death [92]. However, the association between KIM-1 concentrations and the composite end point (dialysis or mortality) was weak (odds

ratio 3.2 for highest vs. lowest quartile) and was not significant after adjustment for covariates.

It is likely that NGAL and KIM-1 will emerge as tandem biomarkers of AKI, with NGAL being most sensitive at the earliest time points and KIM-1 potentially adding specificity at slightly later time points. One advantage of KIM-1 as a urinary biomarker is the fact that its expression seems to be limited to the injured or diseased kidney, and no systemic source of KIM-1 has been described. However, urinary KIM-1 measurements may be influenced by a number of other confounding variables. KIM-1 is induced in the kidney and upregulated in the urine by a large number of nephrotoxins, including cyclosporine, cisplatin, cadmium, gentamicin, mercury, and chromium [93]. Similarly, KIM-1 in the kidney and urine is induced in a variety of chronic proteinuric, inflammatory, and fibrotic disease states in humans.

Liver-Type Fatty Acid-Binding Protein (L-FABP)

Liver-type fatty acid-binding protein (L-FABP) is a 14-kDa intracellular carrier protein normally expressed in the kidney proximal convoluted and straight tubules and involved in the transport of intracellular long-chain fatty acids. Ischemia induces free fatty acid overload in the proximal tubule, which can exacerbate tubule-interstitial disease. L-FABP has been validated in nephrotoxic and ischemic AKI. In a model of cisplatin-induced AKI, increased shedding of urinary L-FABP was seen within 24 h, whereas a rise in serum creatinine was not detectable until after 72 h of cisplatin treatment. In a pilot study in contrast-induced AKI, urinary L-FABP levels were significantly increased prior to the increase in serum creatinine in patients that developed AKI [94]. In a prospective study of 40 children undergoing cardiac surgery, ELISA analysis showed dramatic increases in urine L-FABP from preoperative values 4 h after onset of CPB [95]. Urinary L-FABP measurements may also be influenced by a number of confounding variables. A number of studies have documented increased urinary L-FABP levels in patients with nondiabetic chronic kidney disease, early diabetic nephropathy, idiopathic focal glomerulosclerosis, and polycystic kidney disease. L-FABP is also abundantly expressed in the liver, and urinary L-FABP may be influenced by serum L-FABP levels. As in the case of NGAL, any systemic L-FABP would be freely filtered by the kidney glomerulus, but would be largely reabsorbed by megalin-mediated proximal tubular uptake. Encouragingly, studies have shown that in the presence of chronic renal disease, a reduction in proximal tubular reabsorption results in increased urinary L-FABP excretion, which does not quantitatively correlate with serum L-FABP levels [96]. The estimated contribution of serum L-FABP to urinary L-FABP in chronic kidney disease was only about 3 %, suggesting that serum L-FABP levels do not influence urinary L-FABP levels. Further evidence for this notion has recently been provided in patients who developed AKI post-cardiac surgery, who also developed significant early acute liver injury [95]. In this subgroup, there was a significant increase in serum L-FABP levels at 12 h post-cardiac surgery but not at 4 h. In contrast, urinary L-FABP levels measured in this same subset of patients were dramatically increased within the first 4 h after surgery, while urinary levels at 12 h had actually begun to decline. These findings confirm the dissociation between plasma and urine L-FABP levels in AKI and suggest that increased urinary L-FABP levels at 4 h post-cardiac surgery in AKI patients represent an enhanced shedding of L-FABP from the proximal tubule rather than reflecting increased filtration of high serum levels.

AKI Biomarker Combinations

Since many pathways are involved in the pathogenesis of AKI, it is believed that combinations of biomarkers with different properties may prove most predictive. In a recent study of biomarker combinations in pediatric cardiopulmonary bypass patients, the addition of a urine biomarker "panel," consisting of NGAL, IL-18, L-FABP, and KIM-1, to a clinical model, enhanced the prediction of AKI at 6–24 h after surgery [97]. In this study, biomarkers rose in a predictable pattern in AKI patients, with

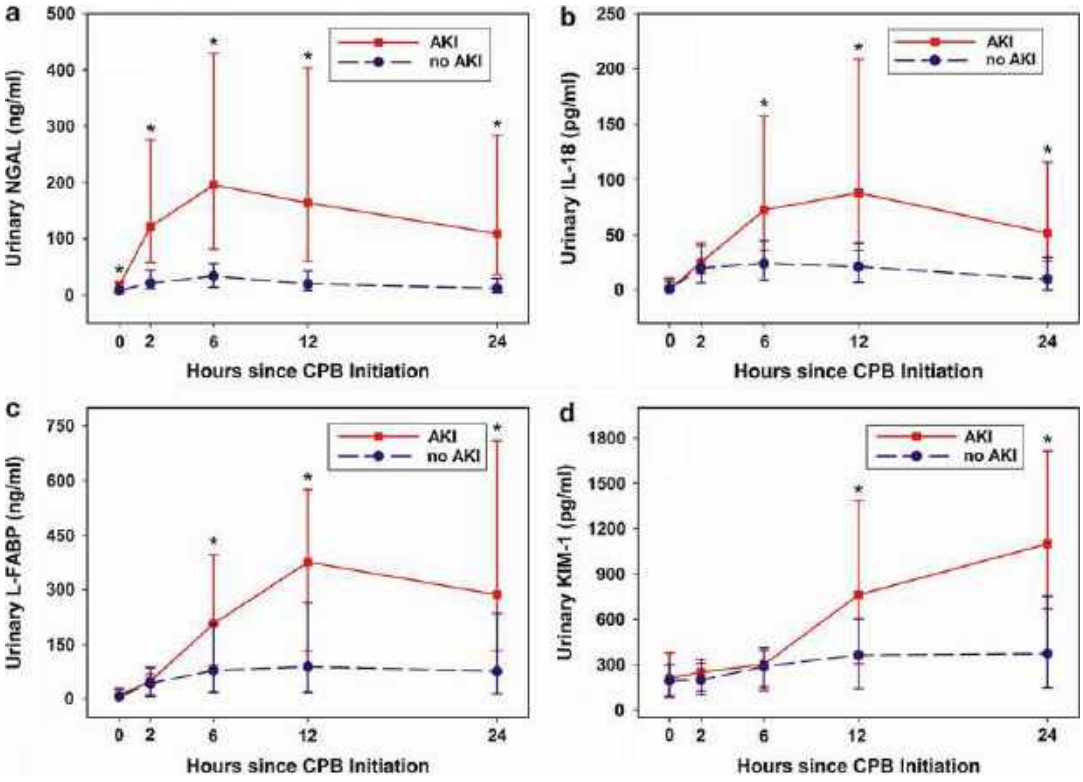

Fig. 48.2 Urine biomarker concentrations by AKI status in pediatric patients after cardiopulmonary bypass. Median and interquartile range (*IQR*) are presented. Statistically significant differences ($p < 0.0001$) in medians between *AKI* and *non-AKI* patients are denoted by *. (**a**) urine NGAL; (**b**): urine IL-18; (**c**) urine L-FABP; (**d**) urine KIM-1 (From Krawczeski CD et al. *J Am CollCardiol* 2011; 58: 2301–2309, with permission)

significant NGAL elevations at 2 h, IL-18 and L-FABP at 6 h, and KIM-1 at 12 h after cardiopulmonary bypass (Fig. 48.2). The importance of determining the temporal sequence of biomarkers is underscored by the four phases of AKI [67]. In the initiation phase during the ischemic insult, intracellular ATP depletion is profound, and generation of reactive oxygen molecules and labile iron is initiated. Vasodilator, ATP-donor, antioxidant, and iron chelation therapies may be especially effective during this phase, and the appearance of NGAL may be used to trigger such therapies. Prolongation of ischemia followed by reperfusion ushers in the extension phase. Tubules undergo reperfusion-mediated cell death, and the injured endothelial and epithelial cells amplify the inflammatory cascades. This phase probably represents a window of opportunity for early diagnosis with intermediate biomarkers, such as L-FABP and IL-18, and active therapeutic intervention with anti-apoptotic and anti-inflammatory strategies. During the maintenance phase, both cell injury and regeneration occur simultaneously. Measures such as growth factors and stem cells that accelerate the endogenous regeneration processes, initiated by later biomarkers with high specificity such as KIM-1, may be most effective during this phase. In the future, the use of "biomarker panels" will likely allow one to pinpoint the timing of injury and assist in selecting appropriately timed therapies.

Future Perspectives in AKI Biomarkers

Although recently discovered biomarkers, most notably NGAL, have been validated as a superior

mechanism of diagnosing AKI earlier than current modalities, little has been done to demonstrate clinical translation of these studies. Although animal data are abundant, there is currently no study that demonstrates that clinical outcomes can be improved by earlier AKI diagnosis. Prospective studies that demonstrate improved outcomes with early targeted therapy are needed. Additionally, since the majority of pediatric AKI studies have been performed in cardiac surgical patients, it is important to confirm results in populations with other mechanisms of kidney injury.

Pediatric congestive heart failure is a particular population that may benefit from earlier diagnosis of AKI. Heart failure patients are at risk for low cardiac output states in which renal blood flow is compromised. Current clinical diagnosis depends largely on serum creatinine and markers of function, including urine output. Recently, the concept of a cardiorenal syndrome (CRS) has been coined to acknowledge the interplay between these organ systems. The CRS has been described as subtypes in which type 1 is AKI caused by worsening cardiac function and type 5 is systemic condition that causes dysfunction of both cardiac and renal systems. Biomarkers that aid in earlier diagnosis of these conditions could be valuable. One of the key consequences of congestive heart failure is fluid overload, and patients who have type 1 CRS have decreased diuretic responsiveness making earlier recognition of AKI important for guiding therapeutic management.

Another area of utility within pediatric cardiology may be among children with heart transplants as these children are typically managed with long-term immunosuppressant medicines that are oftentimes renal toxic. Many of these children have a history of congenital heart disease and may have suffered from AKI due to either history of CPB or low cardiac output states. With administration of nephrotoxic medications, their renal health may be further compromised. These children are particularly vulnerable to acute-on-chronic kidney injury from a variety of mechanisms including prerenal azotemia, sepsis, contrast injury, low cardiac output states, and others. More timely recognition of AKI could direct renal-protecting intervention. Initial studies have been suggestive that KIM-1 can be used as a marker of kidney function and injury in patients with post-cardiac transplantation, although further studies are necessary to be conclusive.

Interestingly, with the established reliability of biomarkers such as NGAL, studies are beginning to use these as *definitions* of AKI rather than merely *predictors*. A recent study looking at fenoldopam during cardiopulmonary bypass as a potential treatment for the prevention of AKI defined a successful therapy as one which restricts elevation of biomarkers [98]. It is logical for future studies to use these biomarkers as measured end points, as they are rapid, inexpensive, and can be standardized.

Among children, recent discovery of novel biomarkers has begun to assist in the diagnosis of myocardial dysfunction and its severity. Trending brain and kidney biomarkers have also allowed for more expedient detection of end-organ dysfunction that may be the result of compromised cardiac output. Monitoring and further understanding of cardiac, kidney, and brain biomarkers will continue to alter the field of pediatric cardiology, and they will be most influential to the perioperative care of these patients. Further validation of biomarkers, demonstration of clinical utility, and expanded commercial availability will likely translate to benefits in the care of children with cardiac disease.

Echocardiography in the ICU

49

Edward Kirkpatrick, Amanda J. Shillingford, and Meryl S. Cohen

Abstract

Echocardiography is a valuable tool used to aid in the management of pediatric patients in the ICU. Echocardiography allows for the assessment of cardiac physiology including cardiac function, pericardial effusions, suspicion for pulmonary hypertension, and cardiac valve integrity. The use of echocardiography for the assessment of mechanical cardiac support and suspected endocarditis is discussed. Echocardiography is particularly suited for the postoperative assessment after cardiac surgery and the unique physiology of single ventricle patients.

Keywords

Diastolic function • Echocardiography • ECMO • Endocarditis • LVAD • Pericardial effusion • Postoperative echocardiography • Pulmonary hypertension • Single ventricle • Systolic function • Valve regurgitation • Valve stenosis

Introduction

Echocardiography has become a mainstay in the cardiovascular assessment of postoperative and critically ill children in the intensive care unit (ICU). The relatively noninvasive nature and bedside portability of echocardiography make this a valuable modality for performing assessments of cardiac anatomy and physiology, diagnosing sources of hemodynamic compromise, and impacting therapeutic options [1]. The American Academy of Pediatrics guidelines for pediatric cardiovascular (CV) centers state that CV intensive care units (ICUs) should have a "pediatric cardiologists capable of performing complete echocardiographic assessments. . .available 24 h a day, 7 days a week" stressing the *essential* use of this modality [2].

TTE Versus TEE

Standard two-dimensional transthoracic echocardiography (TTE) can be performed on almost any patient in the ICU though acoustic windows and imaging planes may be limited by bandages, chest tubes, and an open chest. Transesophageal echocardiography (TEE) is primarily used in the operating room to assess the postoperative repair. However, TEE can also be used safely in the ICU in order to obtain better imaging of the cardiac structures. Neonates and children are almost always intubated for TEE in order to protect the airway, but older children and adults can undergo TEE without intubation. Use of TEE can be limited by the probe size, especially in neonates less than 2.5 kg [3] and in patients with oral airway abnormalities which might warrant the use of an intracardiac echocardiography (ICE) probe (Table 49.1). ICE probes however can only view in a longitudinal plane, therefore limiting cardiac assessment. Most recently a micromini omniplane TEE probe has been developed and utilized in very small infants.

Table 49.1 Contraindications to TEE [4]

Absolute contraindications	Relative contraindications
Perforated viscous	Atlantoaxial disease
Esophageal pathology	Cervical instability
Active upper GI bleed	Prior chest radiation
Recent upper GI surgery	Recent upper GI bleed
	Coagulopathy
	History of dysphagia

Assessment of Systemic Cardiac Output and Myocardial Function

Echocardiography can be utilized to assess and quantify myocardial function and cardiac output (CO). CO is the product of stroke volume (SV) and heart rate: CO = SV × HR. In order to assess ventricular stroke volume, the cross-sectional area at the level of the outflow valve (aortic or pulmonary) orifice is calculated from the measurement of the valve diameter (D) multiplied by the Doppler velocity time integral (VTI) across the outflow tract [5, 6]. VTI measures the area under the curve of a spectral Doppler waveform [5, 6]. The final equation for CO becomes

$$\mathrm{CO} = \pi\left(D^2/4\right) \times \text{Aortic VTI} \times \mathrm{HR}$$

The noninvasive measurement of CO has been found to correlate well with cardiac catheterization-derived CO using thermodilution and Fick measurements ($r = 0.96$ and 0.90, respectively) [6]. Pediatric assessment of Doppler-derived CO has been shown to be most useful with serial tracking rather than absolute values especially related to the complexity of many heart defects [7].

Cardiac function can be assessed by its individual components. The net effect of systolic function is dependent upon cardiac contractility, preload, afterload, and heart rate [5]. Individual assessment of each of these components allows for targeted therapies to augment CO in ICU patients.

Cardiac contractility assessment should be independent of preload or afterload effects [8]. However, the most common way to assess contractility is with fractional shortening (Fs) and ejection fraction (EF) since these methods are reliable and easy to measure. Fs is performed in the long axis or short axis views and measures the dimensions of the left ventricle in systole and diastole. Fs is dependent upon loading conditions and heart rate [9], and direct measurements can be difficult to obtain with poor acoustic windows. Moreover, wall motion abnormalities such as paradoxical septal wall motion (commonly seen following cardiac surgery) preclude the ability to make a measurement of Fs. Normal Fs ranges from 28 % to 44 %:

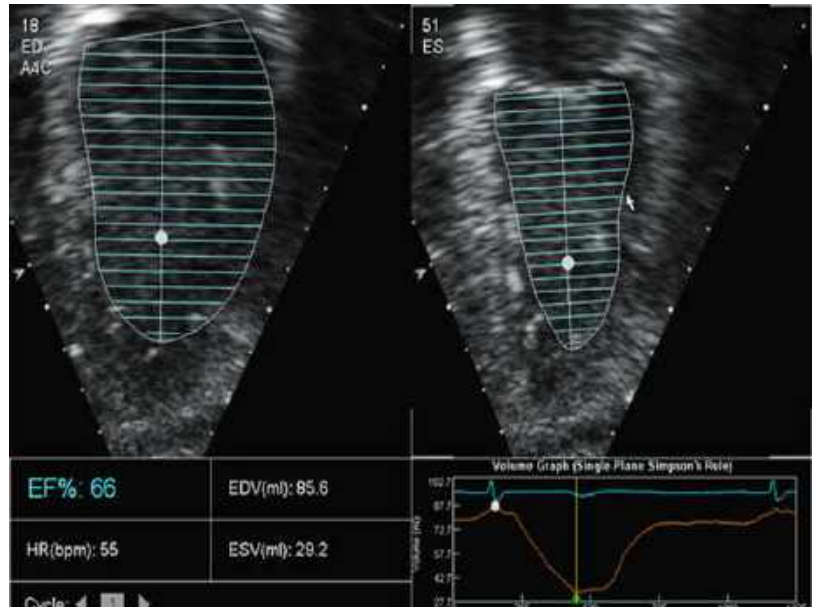

Fig. 49.1 Simpson's rule applied to the left ventricle to calculate EF and ventricular volume

$$Fs = \frac{LV\ diameter\ of\ end\ diastole\ (LVDD) - LV\ diameter\ of\ end\ systole\ (LVSD)}{LVDD} \times 100$$

EF is a measure of the volumetric change in the left ventricle from diastole to systole and is also reported as a percent:

$$\frac{\text{Diastolic volume} - \text{Systolic volume}}{\text{Diastolic volume}} \times 100$$

Like Fs, EF is also load and heart rate dependent [10]. There are multiple ways to calculate EF with one of the most common being a two-dimensional measurement known as the modified Simpson's rule. This method is the most common technique for measuring EF and involves dividing a normal ventricle into discs along the long axis and derives a diastolic and systolic volume in the four-chamber view and/or the two-chamber view (Fig. 49.1). This measurement can be performed quickly with good reproducibility [11]. It has also been shown to have at least modest correlation with cardiac MRI values of EF [12]. Normal EF ranges from 56 % to 78 % in children. Subjective visualization of the contractility of the ventricular walls has also been shown to be a reliable method to estimate cardiac function [13]. This visual evaluation from the four-chamber view has been shown to have a high correlation with Simpson's method ($R = 0.857$) [13]. Other echocardiographic measures of cardiac contractility are described in Table 49.2 [14–15].

Preload

Preload assessment in the ICU setting is important to help determine fluid responsiveness [5]. Echocardiography has been used to assess volume status based on the ventricular diastolic area [16]. However, ventricular diastolic area assessment has not correlated well with wedge pressures. In general, only patients with small end-diastolic areas (evidence of hypovolemia) are likely to have augmented cardiac output

Table 49.2 Measurements of cardiac contractility

Measure	Echo view	Calculation	Pros	Cons
Fractional shortening	Long axis	$\frac{LVDD-LVSD}{LVDD}$	Easy, quick, and reproducible	Dependent upon load conditions and heart rate
	Short axis		Can be visually estimated	
Ejection fraction	Long axis	Multiple	Easy, quick, and reproducible	Load dependent
	Apical 2- and 4-chamber views		Well correlated with MRI	Absolute values likely different from MRI-derived values
			Can be visually estimated	
VcFc	Short axis	$VcFc = \frac{LVDD-LVSD}{LVDD \times LVET\,c}$	Corrected for heart rate	Afterload dependent, difficult to measure in ICU setting
		Normal value is 1.08 ± 0.14 circs/s for children	Used to determine contractility needs per afterload	
dP/dt	Four-chamber view Mitral or tricuspid regurgitation jet needed	Mitral: time for velocity change from 1 to 3 m/s or time to change 32 mmHg	Echo equivalent of true measure of contractility	Need regurgitation signal but does not work with severe regurgitation
		Normal value: >1,200 mmHg/s	Value with serial comparison	Preload dependent

LVDD left ventricular diastolic diameter, *LVSD* left ventricular systolic diameter, *VcFc* velocity of circumferential fiber shortening corrected for heart rate, *LVET* left ventricular ejection time, *dP/dt* change in pressure over change in time

with volume administration [16]. In mechanically ventilated patients, measuring respiratory variation in cardiac output indices can predict fluid responsiveness [17]. Respiratory variation of echo-derived variables, such as Doppler velocities in the ascending aorta (12 % variation), the end-diastolic area (16 % variation), inferior vena cava diameter (18 % variation), and superior vena cava diameter (36 % variation), are also highly predictive fluid responsiveness [17]. In spontaneously breathing patients, passive leg raises may augment right ventricular preload. These changes can then be correlated to changes in cardiac output as measured by aortic valve velocity time integral (VTI). A 10 % increase in VTI suggests the potential to increase cardiac output with a fluid bolus [17].

Afterload

Left ventricular afterload is defined as the opposing force to ventricular fiber shortening during systole [18]. End-systolic wall stress (σes) is an echocardiographic assessment of afterload; it is a measure of peripheral vascular resistance and intrinsic cardiac factors on ventricular contraction [18]. Using Laplace's law, wall stress is proportional to chamber dimension and pressure while inversely related to wall thickness [18]. Meridional wall stress is the most common measure used with the equation

$$wall\ stress\left(\frac{g}{cm^2}\right) = \frac{0.334\,(LV\ pressure) \times LV\ end\ systolic\ diameter\ (LVID)}{LV\ posterior\ wall\ thickness\ in\ systole\ (LVPW)\left[1+\left(\frac{LVPW}{LVID}\right)\right]}$$

Normal values are reported as 64.8 ± 19.5 g/cm^2 [14]. The utility of assessing wall stress is best when used in relation with ventricular contractility. The Vcfc/σes relationship is

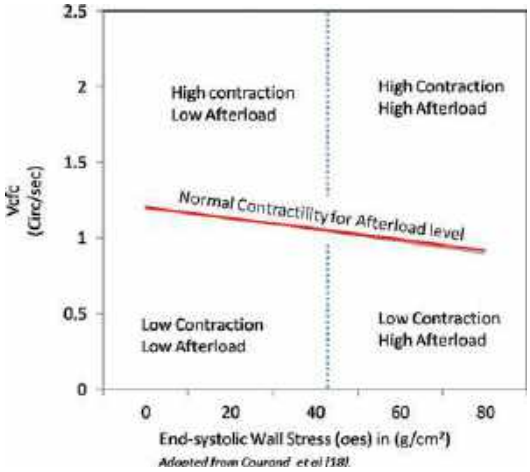

Fig. 49.2 End-systolic wall stress (afterload) versus rate-corrected velocity of circumferential shortening (contractility). Quadrants show areas of over or under compensation of contractility for afterload level

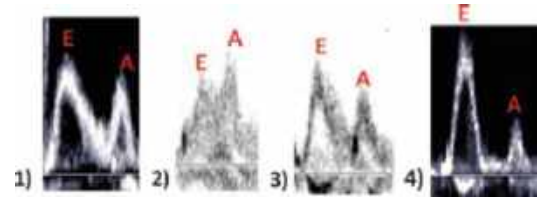

Fig. 49.3 Mitral inflow wave patterns. (**1**) Normal E and A wave ratio ($0.75 < E/A < 1.5$) indicating normal diastolic function. (**2**) E and A wave reversal ($E/A < 0.75$) indicating mild impairment of ventricular relaxation. (**3**) Return of normal E and A ratio (pseudo-normalization) indicating moderate diastolic dysfunction (use DTI to distinguish between normal inflow). (**4**) E> > A wave ($E/A > 1.5$) indicating restrictive physiology

independent of preload and heart rate which allows for the clinical utility of assessing the adequacy of contractility to afterload [19] (Fig. 49.2). Evaluation of systemic vascular resistance (SVR) has been used as a surrogate for afterload. SVR is a mathematical relationship describing peripheral resistance to flow (SVR = mean arterial pressure-central venous pressure/cardiac output). SVR does have some correlation with afterload when experimentally measured together; however, the degree of change in SVR does not have an equal change in afterload and may even have opposing changes under certain inotropic conditions [18]. Changes in aortic Doppler contour can occur in elevated SVR states with a decrease in deceleration time [20]. Right ventricular afterload and pulmonary vascular resistance (PVR) will be discussed in the section "Assessment for Pulmonary Hypertension".

Assessment of Diastolic Function

Abnormal ventricular relaxation creates elevation of atrial and diastolic ventricular pressures which impacts ventricular filling [21]. Diastolic dysfunction should be suspected in susceptible patients (after cardiac surgery, known ventricular hypertrophy, myocardial ischemia, sepsis) with elevation of filling pressures and/or pulmonary edema despite normal systolic function [21]. Doppler assessment of diastolic function is possible with measurements of blood pool characteristics through the atria and ventricles as well as myocardial wall motion velocity in diastole [22]. Changes in inflow patterns can be used to describe the severity of diastolic dysfunction which ranges from mild (impaired relaxation) to moderate with elevated filling pressures to severe with "restrictive filling" [21, 22]. Measurement of mitral inflow Doppler patterns including the early diastolic wave (E wave) and the atrial contraction wave (A wave) provides assessment of the status of ventricular filling [22]. E wave velocity is normally higher than A wave velocity, but this ratio changes with impaired relaxation (Fig. 49.3). The pattern reflects the contribution of atrial contraction to ventricular filling as atrial pressures increase [22]. These patterns can be difficult to recognize in patients with elevated heart rates; fusion of the E and A waves may occur in tachycardia. Further discrimination between levels of diastolic dysfunction usually requires additional assessment of myocardial velocities during diastole using Doppler tissue imaging (DTI) and pulmonary venous inflow patterns. DTI measures the myocardial velocities of the lateral and septal annuli of the mitral valve and has been correlated with diastolic dysfunction. The early diastolic velocity of DTI (E′) decreases with diastolic dysfunction, and the

ratio between the mitral E wave and DTI E′ wave (E/E′) is especially strong at predicting elevated left ventricular filling pressures [1, 22]. Septal annular DTI correlate best with cardiac catheterization-derived measures of LV end-diastolic function [1]. An E/E′ ratio of <8 predicts normal filling pressures, while a ratio >15 predicts elevated pressures [1]. In normal children, the left ventricular E/E′ ratio decreases from infancy to age 5 years, while the right ventricular E/E′ remains constant [23]. Pulmonary venous flow signals normally have a systolic (S) and diastolic (D) wave of near equal velocity. Elevated atrial pressures cause decreased S wave velocity or even reversal such that the D wave is larger than the S wave. Moreover, elevated atrial pressures may result in a separate atrial wave (A wave) that correlates with atrial contraction [24].

Assessment of right ventricular diastolic function is more challenging by echocardiography. The presence of antegrade flow during atrial contraction (diastole) into the main pulmonary artery signifies restrictive physiology manifested as diminished right ventricular diastolic compliance (Fig. 49.4). This pattern has been described in patients after tetralogy of Fallot repair. In patients with tetralogy of Fallot, antegrade diastolic flow has been correlated with improved exercise performance in patients with significant pulmonary regurgitation suggesting that a less compliant right ventricle might be of benefit with this physiology [25]. Other means of measuring diastolic function of the right ventricle including E/E′ and MPI are less reliable.

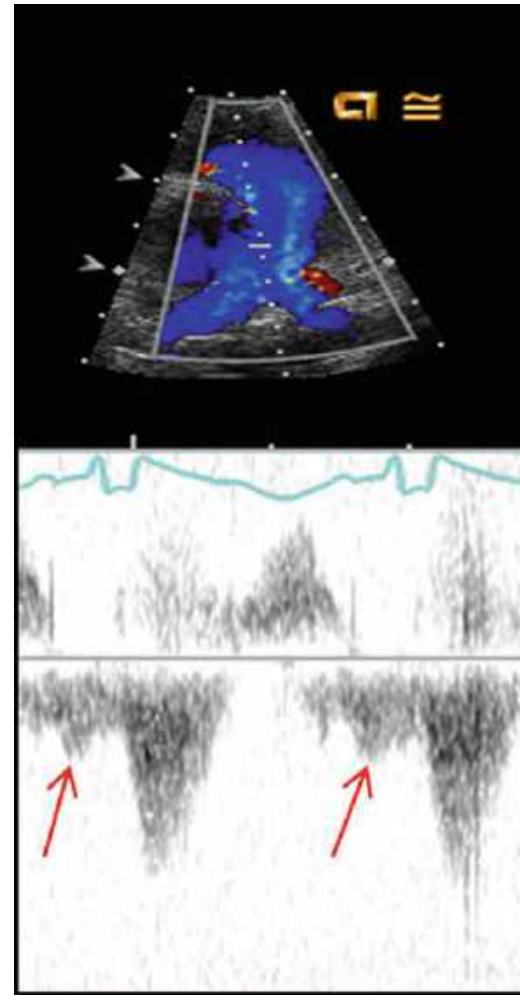

Fig. 49.4 Doppler interrogation of the main pulmonary shows antegrade flow during atrial contraction (*red arrows*)

Assessment for Cardiac Tamponade

Cardiac tamponade occurs as a result of fluid accumulation in the pericardial space that negatively impacts cardiac output. Intrapericardial pressure exceeds cardiac chamber diastolic pressures and impairs ventricular filling resulting in equalization of diastolic intracardiac chamber pressures [26, 27]. Echocardiography is an excellent tool to diagnose cardiac tamponade using two-dimensional (2D) and Doppler assessment. Echocardiography can be used to assess effusion size and location, right atrial collapse, right ventricular diastolic collapse, Doppler velocity changes with respiratory variation (Doppler equivalent of pulsus paradoxus), and lack of inferior vena cava respiratory collapse [26, 28]. Cardiac tamponade may occur within hours after cardiac surgery as a result of bleeding or within 1 or 2 weeks as a result of post pericardiotomy syndrome. Post-pericardiotomy syndrome is an immune-mediated phenomenon whereby serous fluid accumulates around the heart after open heart surgery, most commonly repair of atrial septal defects.

Fig. 49.5 Severe pericardial effusion with atrial and ventricular collapse

Pericardial fluid is seen as a dark echo-free space outside the heart (Fig. 49.5). Effusions are described as global/diffuse if they surround the heart or regional/loculated if they are located in only one area around the heart [29]. Assessment of effusion size requires 2D evaluation in multiple views, namely, parasternal long and short axis, four-chamber, and subcostal views during diastole. Semi-qualitatively, diffuse effusions can be considered small if the sum of the anterior and posterior fluid spaces are <9 mm, moderate if 10–19 mm, and large if >20 mm [29]. Pericardial fluid can also be localized to any individual cardiac chamber and create clinical tamponade that may be missed [27]. Importantly, rapid accumulation of pericardial fluid may result in tamponade with a relatively small effusion. Slower accumulation allows for cardiac compensation such that tamponade may not develop until the effusion is quite large.

Right atrial collapse signifies cardiac tamponade and has been defined as a 30 % inward movement of the right atrium in late diastole or early systole [26]. Right ventricular free wall diastolic collapse is noted to occur in early diastole and persists usually for one-third of the cardiac cycle [26]. Prominent respiratory variation of Doppler flow velocities across the left ventricular outflow tract is an echocardiographic equivalent of pulsus paradoxus [28] (Fig. 49.6). Using the apical views, exaggerated Doppler velocity variation can also be seen across the mitral valve and the aorta [28]. The suprasternal view can image the descending aorta outside the pericardium to provide more accurate assessment of flow variation. A 40 % change between the maximum and minimum velocities heralds tamponade physiology with better sensitivity and specificity than the cardiac wall collapse methods [26]. Lack of inferior vena cava respiratory collapse also supports the finding of cardiac tamponade and is defined as a lack of vessel collapse by at least 50 % with deep inspiration [26]; however, it is less reliable than other methods in young children and cannot be used in patients on positive pressure ventilation. The presence of an atrial level shunt, aortic regurgitation, and pulmonary hypertension will hinder the ability to assess tamponade with echocardiography [26, 28].

Importantly, the value of echocardiography to assess for tamponade physiology can be hindered by the presence of a significant atrial level shunt and aortic regurgitation which will hinder the development of pulsus paradoxus [28]. Pulmonary hypertension will also reduce the sensitivity of all echo findings in tamponade and significantly reduce the accuracy of paradoxical flow variation [26].

Assessment for Pulmonary Hypertension

Pulmonary hypertension (PH) frequently occurs in the setting of congenital heart disease and may negatively affect outcome in patients undergoing cardiac surgery. Other patients at risk for pulmonary hypertension complications include those with preexisting idiopathic PH, persistent systemic shunts, pulmonary vein anomalies, chronic lung disease, left-sided cardiac lesions such as mitral stenosis, and left-sided heart failure. PH is defined as mean pulmonary artery pressure of ≥25 mmHg [30]. There are subclasses of PH based upon the etiology in adults [31] and pediatrics [32], but it is generally due to elevated pulmonary vascular resistance (PVR) or left heart disease resulting in elevated atrial or pulmonary venous pressures [31].

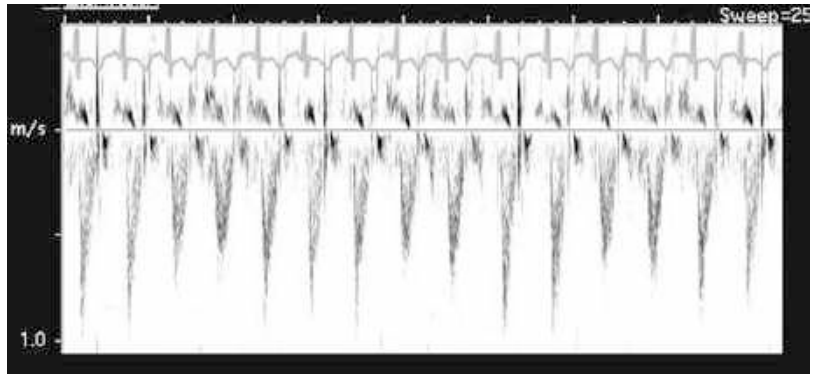

Fig. 49.6 Significant respiratory variation seen on outflow Doppler

Several echocardiographic parameters are used to assess for PH, which rely on having an unobstructed right ventricular outflow tract and absence of pulmonary artery obstruction. The peak tricuspid regurgitation (TR) gradient is the most commonly utilized Doppler-derived parameter to measure pulmonary artery systolic pressure (PASP). The normal estimated PASP is $\leq$30 mmHg [33]. The TR gradient is measured by continuous wave Doppler velocity across the tricuspid valve in line with the regurgitation flow and using the modified Bernoulli equation ($4\times(velocity\ of\ TR)^2$) to convert to a pressure gradient [34]. This pressure represents the gradient between the right ventricle and right atrium; the right atrial pressure (normal 5–10 mmHg) should be added to the derived pressure gradient to give an estimate of RV systolic pressure [35]. A similar method using the pulmonary regurgitation (PR) end-diastolic gradient can be used to estimate end-diastolic pulmonary artery pressure. In older children and adults, inferior vena cava collapse with respiration has been used to estimate right atrial pressure [36]. A >50 % collapse correlates to a right atrial pressure of 10 mmHg, <50 % correlates to 15 mmHg, and no collapse to 20 mmHg [35]. Unfortunately this method has been found to be imprecise and can lead to further error when using echo to estimate RVP [34]. TR and PR Doppler signals must be strong to make accurate measures of velocity. [34]. One study that compared echocardiographic estimates of right ventricular pressure in comparison to direct measurement with right heart catheterization (the gold standard for diagnosis of pulmonary hypertension) found good correlation with PASP ($r = 0.68$–0.71), but the absolute values by echocardiography were $\pm$10 mmHg than the catheter-measured values more than 50 % of the time [34]. It is important to note that hemodynamic conditions are different in the catheterization laboratory and the ICU and may in part account for these discrepancies. Moreover, patients with shunts from the left ventricle to right atrium may have erroneously high measures of RV pressure (since the jet is actually a reflection of LV pressure).

Abnormally elevated RV pressures create observable changes in RV shape, size, thickness, outflow Doppler signal, and function (Fig. 49.7). In a pediatric study of children less than 2 years old, the predictability of these structural changes associated with PH was determined retrospectively with a subsequent catheterization [37]. The presence of RA dilation, RVH, RV dilation, and flattening of the interventricular septum in systole were better positive predictors of the presence of PH if TR was also measurable [37]. Multiple echo findings did not improve results, and the addition of the estimated RAP further decreased the predictive value [37].

European echocardiography guidelines to determine the presence of PH in adults have been developed (Table 49.3).

Pulmonary vascular resistance (PVR) is a catheterization-derived measure of the pressure

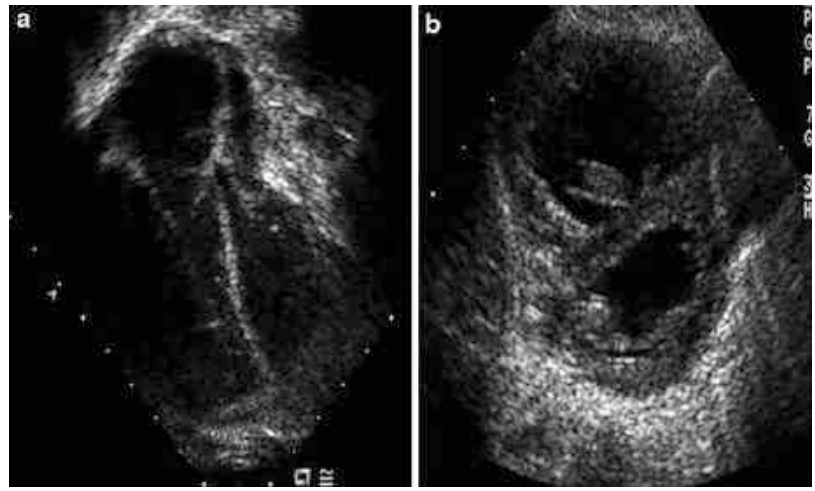

Fig. 49.7 Findings that can be seen in pulmonary hypertension. (**a**) Right atrial and ventricular dilation seen in four-chamber view. (**b**) RV hypertrophy, dilation, and septal flattening seen in short axis view

Table 49.3 Guidelines to evaluate for PH by echo

Presence of PH	TR gradient	2D echo findings
PH unlikely	<2.8 m/s with est. PASP <36 mmHg	No additional findings
Possible PH	TR <2.8 m/s	Additional findings present
Possible PH	TR 2.9–3.4 m/s or est. PASP 37–50 mmHg	No additional findings
PH Likely	TR > 3.4 m/s or est. PASP >50 mmHg	No additional findings necessary

Pressures included estimated RAP of 5 mmHg (Adopted from European Society of Cardiology [37])

drop across the pulmonary bed divided by pulmonary blood flow. Echocardiographic Doppler assessment of the contour across the pulmonary artery may show early deceleration as a result of elevated PVR (resembling a notch in the outflow Doppler contour) but can be an inconsistent finding (Fig. 49.8) [39]. Using Doppler to estimate PVR has been validated with a ratio of TR to VTI of the right ventricular outflow tract of <0.2 indicating a normal PVR <2 Woods units [35]. Deceleration time of the Doppler signal into the branch pulmonary arteries (inflection point time or InT) corrected for heart rate is another measure of high PVR [39]. A significant difference exits between low and high PVR states with an InT value of <5.8 milliseconds suggestive of elevated PVR [39]. Limited studies have found that patients who have a decrease in PVR or PASP (vasoreactive) with oxygen are likely to have a measureable increase in pulmonary blood flow as measured by an increase of the C.O. (or VTI) across the RVOT [40].

Assessment of Valve Regurgitation

Valve regurgitation can be an important consequence of congenital heart disease, an acute occurrence due to infective endocarditis, or a residual post-intervention defect. Color Doppler is used to assess for the presence valve regurgitation [41] and includes visualization of the jet area, its effect on chamber size, and vascular blood flow (Fig. 49.9). Chronic moderate or greater regurgitation may cause chamber dilation, while mild regurgitation generally does not [41]. The vena contracta (VC) is the narrowest portion of the regurgitation jet which correlates with the effective regurgitant orifice of the valve [41]. Size of the vena contracta is usually measured as a diameter and appears independent to flow rate, pressure gradients, and eccentricity of the jet, making it a quick and fairly reliable method to estimate the severity of valve regurgitation [41]. However, this method has been less reliable in children than adults and is limited

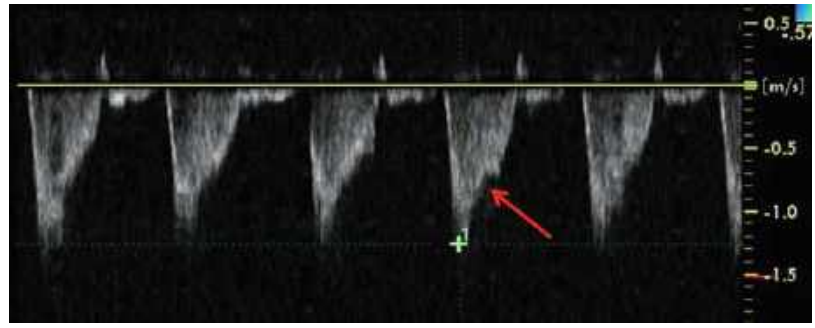

Fig. 49.8 Pulmonary outflow Doppler in PH. *Arrow* shows inflection point of rapid deceleration due to elevated PVR

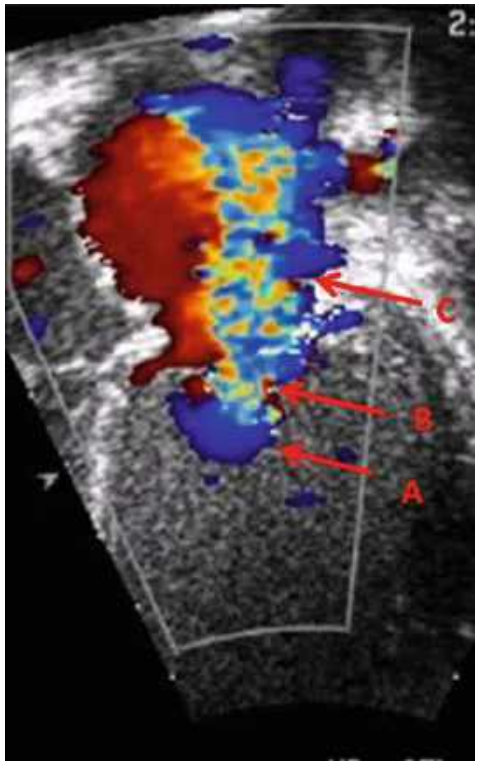

Fig. 49.9 Four-chamber view of mitral regurgitation showing the components of the regurgitant jet: (*A*) convergence zone, (*B*) vena contracta, and (*C*) jet area

when there are multiple jets of regurgitation (a common occurrence in children). The table below (Table 49.4) shows general guidelines for grading regurgitation severity in adults. Limited echo windows impact Doppler resolution, and tachycardia decreases the time needed to develop full jet areas [41]. Eccentric jets, elevated cardiac pressures, poor cardiac function, and unstable hemodynamics affect the regurgitation signal making estimation of severity unreliable [41]. In pediatric echocardiography, subjective assessment of regurgitation based on jet width and jet area in the receiving chamber appears to be most frequently used.

Assessment of Valve Stenosis

Pediatric valve stenosis is usually associated with a congenital abnormality of the valve. Critical stenosis of the pulmonary or aortic valves is defined by the need for prostaglandins to maintain patency of the patent ductus arteriosus to preserve systemic or pulmonary output. Current echocardiography guidelines for valve stenosis utilize Doppler velocities across the valves, evidence of chamber dilation, valve morphology, and calculation of effective valve area to grade severity (Table 49.5) [43]. Estimated valve area can be calculated by the continuity equation:

$$\textit{Effective valve area} = \frac{\textit{Cross sectional area of the LVOT} \times \textit{Velocity aross the LVOT}}{\textit{Velocity across the arotic value}}$$

These criteria are primarily used in adult patients, which must be considered when extrapolating to the pediatric population. In pediatrics, aortic stenosis (AS) has routinely

Table 49.4 Severity of valve regurgitation

Value	Mild	Moderate	Severe
Aortic valve	Regurgitation jet/LVOT <25 %	Regurgitation jet/LVOT 25–64 %	Regurgitation jet/LVOT >64 %
	Faint Doppler signal density by CW	Dense Doppler signal density by CW	Dense Doppler signal density by CW
	Normal LV size	Normal or dilated LV	Dilated LV
	Brief or no DA diastolic flow reversal VC <0.3	Possible diastolic flow reversal in the DA	Holodiastolic flow reversal in the DA
	VC <0.3	VC <0.3–0.6	VC >0.6
Pulmonary valve	Thin jet size with narrow origin	Intermediate jet width	Large jet size with wide origin
	Faint Doppler signal density by CW	Dense Doppler signal density by CW	Dense Doppler signal density by CW
		Normal or dilated RV	Dilated RV
	Normal RV size	VC-not defined	Holodiastolic flow reversal into branch Pas[a]
	VC-not defined		VC-not defined
Mitral valve	Cenral jet area/atrial area <20 %	Cenral jet area/atrial area 20–39 %	Cenral jet area/atrial area <40 %
	Incomplete, faint Doppler signal density by CW	Dense Doppler signal density by CW	Dense Doppler signal density by CW
	Normal atrial size	Normal or dilated atrium	Dilated atrium
	Systolic dominance of pulmonary vein flow by Doppler	Pulmonary vein systolic flow blunting	Pulmonary vein systolic flow reversal
	VC <0.3	VC 0.3–0.69	VC ≥0.7
Tricuspid Valve	Central jet area/atrial area <20 %	Central jet area/atrial area 20–40 %	Central jet area/atrial area <40 %
	Incomplete, faint Doppler signal density by CW	Dense Doppler signal density by CW	Dense Doppler signal density by CW
	Normal atrial size	Normal or dilated atrium	Dilated atrium
	Systolic dominance of hepatic vein flow	Systolic blunting of hepatic vein flow	Systolic flow reversal of hepatic vein flow
	VC-not defined	VC <0.7	VC >0.7

been described by Doppler pressure gradients. In a study of pediatric patients undergoing intervention for AS in the catheterization lab, the need for intervention could be predicted by echo Doppler using a maximal aortic valve gradient of >90 mmHg from the high parasternal view and >50 mmHg mean aortic valve gradient from the apical view with specificities of 94 % and 100 %, respectively [44]. A peak gradient from the high parasternal view ≤55 mmHg predicted no need for intervention 100 % of the time [44]. However, critical AS can result in diminished ventricular function and create a low cardiac output state. This will also decrease the measured gradients across the valve making absolute pressure gradient values unreliable to assess severity. In addition to poor contractility, critical AS by echo will usually show a thickened, dysplastic, uni-commissural aortic valve with limited opening and poor Doppler flow across it. Echo evidence for pulmonary hypertension may be present in AS. Associated lesions such as coarctation of the aorta and VSD need to be ruled out. In pulmonary stenosis, a pediatric study found that mean Doppler gradients better correlated with cardiac catheterization pressure gradients across the pulmonary valve [45]. Using mean pulmonary gradients, intervention was found appropriate for values >50 mmHg [45]. As with AS, critical PS may result in decreased ventricular function, thus making absolute pressure gradient values unreliable to assess severity. Patients with critical PS usually have a PFO or ASD with right to left shunting and significant ventricular hypertrophy. Congenital mitral stenosis can be seen with multilevel left-sided obstruction such as AS and coarctation creating a Shone's complex [46]. The severity of congenital mitral stenosis is generally depicted in terms of mean diastolic gradient [47]. Tricuspid stenosis is rare and can be seen in the postoperative setting after valve repair or VSD closure. AHA guidelines grade tricuspid stenosis as "significant" if it requires intervention [43].

Assessment of Mechanical Support

Mechanical support is commonly utilized in the ICU setting for patients in low cardiac output. This includes patients who present with cardiomyopathy or myocarditis, unremitting ventricular arrhythmias, postoperative ventricular dysfunction, or pulmonary hypertensive crisis. Extracorporeal membrane oxygenation (ECMO) and ventricular assist devices (VADS) can be evaluated by echocardiography to assess for potential device dysfunction. Venoarterial ECMO has a venous inflow cannula in the right atrium and an outflow arterial cannula in the aortic arch [48]. Echo can be used to assess for proper placement of the cannulas as well as flow characteristics [49]. Known position problems for the inflow venous cannula include cannula malposition against the atrial septum, into the coronary sinus or out of the atrium, and into the caval veins; any of these abnormal positions can lead to low flow states and low cardiac output [49]. The arterial cannula can also be misplaced into the subclavian artery leading to poor cardiac output, or it may be aimed toward the aortic valve which can result in valvular damage [49]. In some cases, ventricular dysfunction results in atrial distention which can be visualized on 2D echocardiography. In these cases, atrial decompression may be required by atrial septostomy with or without atrial stent placement. Distended and non-ejecting (as seen by lack of native outflow valve opening) ventricles are at risk for thrombus formation which may be detected by echocardiography [48].

Pulsatile pump VADS have an inflow conduit (usually inserted into the ventricular apex) that sends blood into the pumping chamber which in turn delivers blood to the outflow conduit in the ascending aorta (or main pulmonary artery for right VADS). Both the inflow and outflow conduits have porcine valves [50]. Inflow pump complications are common concerns with VADS. The inflow cannula can be seen in the parasternal long axis and apical four-chamber views (Fig. 49.10). Flow into the cannula should be laminar and

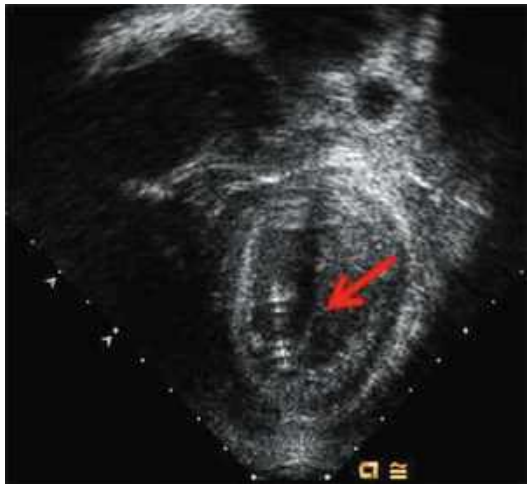

Fig. 49.10 LVAD inflow cannula seen in apical four-chamber view

Fig. 49.11 Bacterial endocarditis seen as vegetation on the mitral valve in the parasternal long axis view. Lesion was accompanied by severe MR

aligned with the inflow tract [51]. Inflow valve regurgitation is seen as a reversal of flow into the ventricle during pump ejection and is usually accompanied by a non-decompressed ventricle and frequent opening of the native semilunar valve [50]. Inflow cannula obstruction is noted by interruption of the inward Doppler flow signal and can be caused by thrombus, cannula misalignment, marked ventricular hypertrophy, or interventricular septal deviation into the cannula [51]. Outflow connection to the ascending aorta can be distorted, and obstruction is suggested by elevated Doppler flow velocities which would be more noticeable with the patient in a seated versus laying position [50]. The outflow cannula is best imaged in the high right parasternal view [51]. Attention should also be made regarding the presence of regurgitation of the other native valves which may affect ventricular decompression [51].

Assessment for Endocarditis

Infective endocarditis (IE) should be suspected in the ICU in pediatric patients that have susceptible risk factors (abnormal heart valves, recent cardiac surgery, intracardiac prosthetic material, and bacteremia). According to the modified Duke criteria, echocardiography can be used as major criteria for the diagnosis of infective endocarditis (IE) if any of the following conditions are met [52] (Fig. 49.11):

1. Oscillating intracardiac mass on the valves, chordae, implanted material, or in the path of turbulent jets
2. Intracardiac abscess
3. New partial dehiscence of a prosthetic valve

Minor echocardiographic criteria for IE include new valvular fenestration, nodular thickening of valves, and the presence of nonmobile lesions [52]. Associated findings with IE include cardiac dysfunction, valve regurgitation, and pericardial effusion [53]. It is important to note that echocardiography (TTE or TEE) can miss IE in up to 15 % of the cases; thus, repeat studies may be necessary [53]. Likewise, false positives can occur in the setting of cardiac tumors, prolapsed valves, and thrombi [53]. Adult studies describe a sensitivity of TTE for detecting IE of only 70 % which is why TEE with a positive predictive value of 90 % is the preferred method to evaluate for IE [54]. However, in pediatrics, a study comparing TTE with TEE found TTE performs much better and has a sensitivity of 86 % for any cardiac findings with 93 % sensitivity for identification of vegetations [54].

Lesion-Specific Postoperative Echocardiography

Targeted echo evaluations of specific structures based on the physiology and type of surgical repair can provide useful information to help guide ICU management in the postoperative period. Echocardiographic assessments of the surgical repair are often made in the operating room with TEE. However, hemodynamic conditions are different under general anesthesia compared to the postoperative state in the ICU; moreover, TEE is limited in its ability to see very anterior or extracardiac structures. Table 49.6 shows common lesions that may exist postoperatively by TEE.

Pulmonary and Systemic Veins

Susceptibility to venous obstruction can occur in several settings including anomalous pulmonary venous return, sinus venosus atrial septal defect, congenital pulmonary vein stenosis, intracardiac baffle procedures, and Glenn and Fontan procedures. Pulmonary veins can be imaged from several echocardiographic views, and multiple views may be necessary in order to assess all four veins. The vena cavae are best imaged from subcostal sagittal views, and the superior vena cava can also be well visualized from suprasternal frontal view and the high right parasternal view. A normal pulmonary venous flow pattern is phasic with systolic and diastolic peaks. Peak velocities of greater than 1 m/s in the pulmonary veins are considered abnormal [56]. Similarly, normal Doppler flow patterns in the superior and inferior vena cava show phasic antegrade peaks in systole and diastole with dominant systolic wave. Importantly, when venous obstruction is present, pulse wave Doppler patterns reveal non-phasic high-velocity continuous flow (see section on "Cavopulmonary Shunts" below).

Ventricular Septal Defects (VSD)

After ventricular septal defect (VSD) closure, residual peri-patch leaks are common [57–59]. Residual VSDs less than 2 mm are generally not hemodynamically significant and often close spontaneously [59], while defects >3 mm can create hemodynamic compromise and may warrant surgical closure [60]. Elevated ventricular pressures may cause underestimation of residual shunt size in the operating room by TEE. In addition, the left ventricle to right atrial shunt jet should be carefully distinguished from the TR jet in order to avoid misdiagnosis of pulmonary hypertension [61, 62]. The best views for imaging these shunts are apical and subcostal frontal. The presence of right to left shunting indicates elevated RV pressure.

Adjacent structures can be affected after VSD repair. Suturing of VSD patch near the area of the septal leaflet of the tricuspid valve or maneuvering through the tricuspid valve may cause distortion of the tricuspid valve and result in tricuspid valve regurgitation [58].

Common Atrioventricular Canal Defect

Intraoperative TEE will identify significant residual atrial or ventricular level shunting,

Table 49.6 Significant postoperative TEE findings (Adopted from Rosenfeld et al. [55])

Lesion	Not significant findings	Possibly significant findings	Significant findings
Residual VSD	Color Doppler jet width ≤3 mm	Color Doppler jet width 3–4 mm	Color Doppler jet width >4 mm
Aortic or mitral regurgitation	VC < 2 mm	VC 2–4 mm	VC > 4 mm
Outflow tract obstruction	Peak gradient ≤20 mmHg	Peak gradient 20–40 mmHg	Peak gradient >40 mmHg
Mitral stenosis	Doppler mean gradient ≤5 mmHg	Doppler mean gradient 5–8 mmHg	Doppler mean gradient >8 mmHg

VC vena contracta

as well as the presence of residual left or right atrioventricular valve stenosis or regurgitation. However, the degree of atrioventricular valve regurgitation is often underestimated in the operating room, and thus follow-up TTE assessments of valve competency may be helpful in the early postoperative period (*see previous section on valvar disease*) [63, 64]. PH can also occur after common atrioventricular canal repair especially in children with Down syndrome. RV pressure assessment should also be performed in these patients.

Valve Repair

Residual valvar stenosis or regurgitation visualized on intraoperative TEE may be altered based on factors related to myocardial function, preload, and afterload in the operating room. Residual regurgitant jets may be eccentric, and visualization and measurement is recommended from multiple echo views. After valve repair or replacement, ventricular function may diminish because of the acute increase in afterload that is inherent to the operation. Postoperative assessment of ventricular performance is important in these patients. Prosthetic valves should be assessed for perivalvar leak or rarely for dehiscence.

Tetralogy of Fallot (TOF)

Patients undergoing TOF repair almost universally have a TEE in the operating room to assess for residual VSD and residual right ventricular outflow tract obstruction and to estimate RV pressure if the TR jet is significant. If a patent foramen ovale is present, direction of flow is helpful to distinguish ventilation concerns from right to left atrial level shunting (due to poor RV compliance). In patients who are relatively tachycardic or hypovolemic, dynamic residual outflow tract obstruction may be overestimated, while VSD shunting can be underestimated in the setting of elevated RV pressures. Branch pulmonary artery hypoplasia is common in TOF, and these vessels are not always well seen by TEE. Residual VSDs can be located in the anterior RV trabecular septum. Preminger et al. termed these defects "intramural" VSDs, which appear to result from suturing the superior edge of the VSD patch to trabeculations rather than the RV free wall [65]. As a result, left to right shunting occurs through the trabeculations from the LV outflow tract into the sinus portion of the RV. These defects are important to recognize as they can enlarge over time [65]. The intramural VSD often requires repair through the aortic valve where it is best identified. In patients with markedly hypoplastic branch pulmonary arteries, the presence of retrograde or continuous flow in the branch pulmonary arteries should raise suspicion for a significant residual collateral vessel.

After TOF repair, patients are at risk for restrictive RV physiology which can lead to low cardiac output syndrome, elevated central venous pressures, and prolonged chest tube drainage. The presence of antegrade flow in the main pulmonary artery with atrial contraction is characteristic of restrictive RV physiology [25] (Fig. 49.3). Lower myocardial performance index (MPI) has also been associated with restrictive RV physiology after TOF repair [66]. Due to abnormal RV compliance, right to left shunting across a residual atrial communication can be seen and may be a source for cyanosis in the postoperative period. This shunting can help avoid low cardiac output in the immediate postoperative period.

Transposition of the Great Arteries (TGA)

The arterial switch operation is presently the preferred surgical repair for patients with transposition of the great arteries (TGA). Many centers utilize intraoperative TEE to assess the repair. Diminished myocardial function and/or regional wall motion abnormalities should prompt additional diagnostic investigations to assess for coronary insufficiency after reimplantation. Color flow in the proximal coronary arteries can be demonstrated by both TEE and TTE; however,

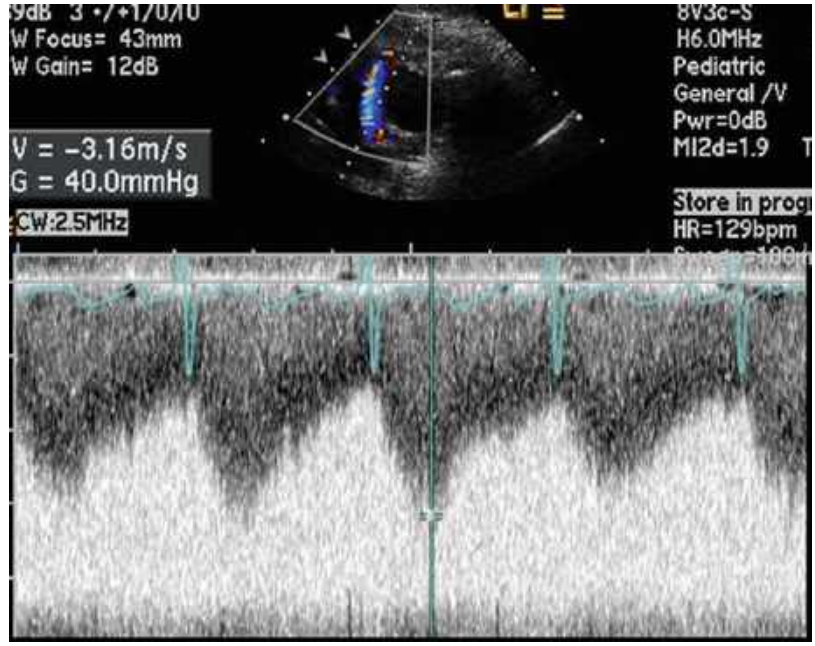

Fig. 49.12 Modified BT shunt with continuous flow pattern throughout systole and diastole in a sawtooth pattern

quantification of flow or detection of distal stenosis is not possible. Supravalvar aortic or pulmonary stenosis rarely results in a need for reoperation, but should be included as part of the postoperative evaluation. Parasternal long axis views will demonstrate the supravalvar aortic region well as well as the supravalvar pulmonary root when the probe is directed anteriorly. Mild neo-aortic regurgitation is common after the arterial switch operation and can worsen in the longer term [67]. Mild supravalvar pulmonary stenosis, including branch pulmonary artery stenosis, is also common after the arterial switch operation. Aortopulmonary collaterals have been described in TGA and can rarely lead to congestive heart failure, respiratory failure [68], and even pulmonary hypertension [69]. While these collateral vessels may be difficult to visualize completely by echocardiography, the presence of left heart dilation or significant retrograde flow in the descending aorta should prompt further diagnostic evaluation. In rare cases, the pulmonary vascular resistance does not decrease after ASO, leaving some patients with chronic PH which often requires medical intervention with pulmonary vasodilators. It is important to distinguish between branch pulmonary artery stenosis and true pulmonary artery hypertension in this cohort after ASO.

Shunts/Single Ventricle

Aortopulmonary shunts are utilized for palliation in single ventricle CHD and provide a reliable source of pulmonary blood flow from the systemic circulation to the pulmonary circulation. Shunt flow can be accessed from multiple views, but suprasternal or high parasternal views provide the best visualization. Color Doppler will demonstrate shunt flow, and narrowing of the color jet near the anastomotic sites or within the shunt may indicate obstruction and should be correlated to the clinical status. For Blalock-Taussig shunts, innominate artery distortion can also occur and this structure should be evaluated if decreased pulmonary blood flow is suspected. Normal Doppler flow in a shunt reveals a continuous flow pattern throughout systole and diastole in a sawtooth pattern (Fig. 49.12). Loss of diastolic flow continuation should raise concern for significant obstruction [70]. In shunted

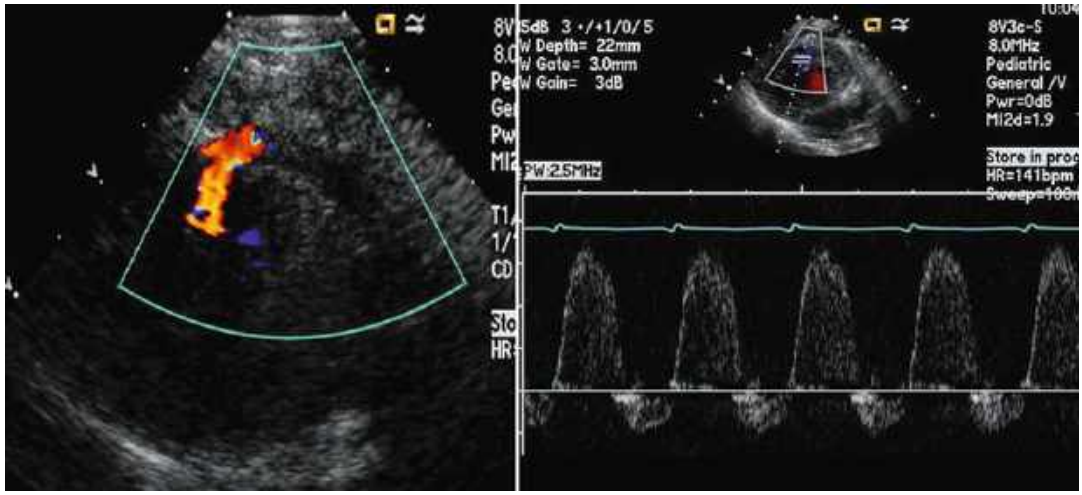

Fig. 49.13 Proximal RV-PA conduit off of RV in a patient with HLHS and corresponding Doppler pattern

patients, Doppler flow patterns in the descending aorta demonstrate holodiastolic flow reversal when normal shunt flow is present. Estimation of a pressure gradient across shunts should be used with caution, particularly in longer shunts, since the modified Bernoulli equation is not valid across a long narrow tube. However, low-velocity flow may suggest distal obstruction or high pulmonary vascular resistance.

Norwood Operation

In patients who have the Sano modification of the Norwood operation (right ventricle to pulmonary artery conduit), the proximal end and length of the conduit can be visualized from subcostal and parasternal views angled toward the right chest (Fig. 49.13). Suprasternal imaging will show the distal portion of the conduit as it enters the branch pulmonary arteries. The normal Doppler flow pattern shows predominant antegrade flow during systole and a small amount of holodiastolic flow reversal that can be seen in the branch pulmonary arteries as well. Cardis et al. reported typical early postoperative peak gradients of 9–58 mmHg, though gradients did not correlate to oxygen saturations in this review [71]. Dynamic obstruction can occur at the site of the ventriculotomy, which can be seen as color turbulence and a dynamic flow pattern. Branch pulmonary arteries may become distorted over time as the conduit contracts leading to stenosis.

When concerns for neo-aortic arch obstruction exist, suprasternal or subcostal sagittal imaging will provide the best views of the proximal and distal arch. In the setting of significant obstruction, a typical "coarctation pattern" with diastolic flow continuation is often not present because of the abnormal distensible properties of the homograft material used for the reconstruction. Lemler et al. reported a "coarctation index" in which the ratio between the widest portion and narrowest portion of the descending aorta less than 0.7 in conjunction with a peak Doppler-derived gradient of greater than 30 mmHg correlates to a peak to peak gradient of >20 mmHg in the cardiac catheterization lab [72]. A change in ventricular shortening or an increase in the severity of tricuspid regurgitation also suggests the development of distal arch obstruction in these patients. The arch gradient can also be estimated by measuring the TR jet velocity and comparing it to the systemic blood pressure. In the setting of significant tricuspid valve regurgitation or impaired ventricular function, Doppler gradients may be underestimated. Significant neo-aortic regurgitation is unusual early after the Norwood requiring assessment and follow-up by echocardiography if present. In patients with mitral atresia,

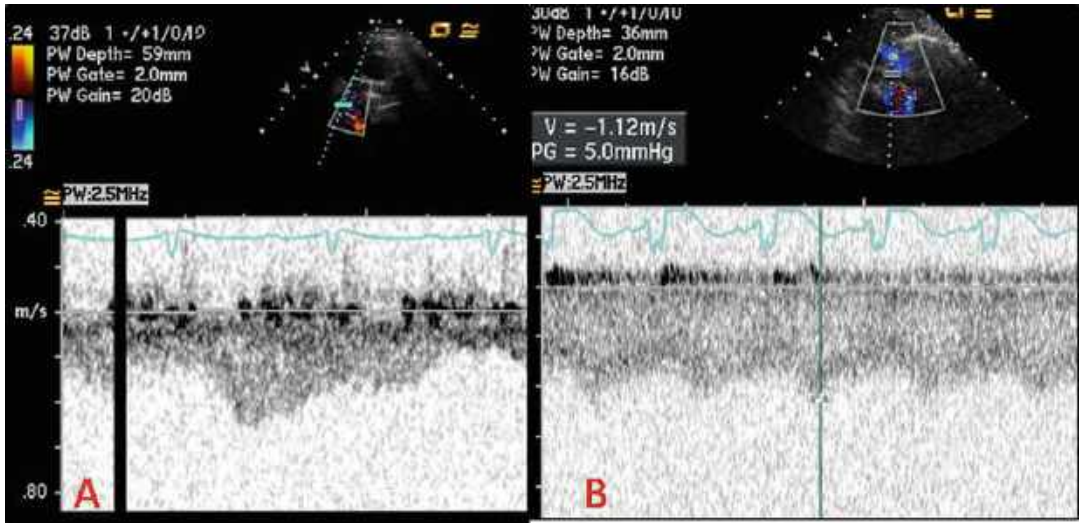

Fig. 49.14 (**a**) Normal Doppler flow pattern bidirectional Glenn shunt demonstrating low-velocity, phasic flow with respiratory. (**b**) Abnormal Doppler flow pattern in a bidirectional Glenn shunt at the right pulmonary anastomotic site demonstrating high-velocity continuous flow without respiratory variation

assessment of the atrial communication is also required to assure unobstructed flow from the pulmonary veins to the right atrium.

Cavopulmonary Shunts (Glenn, Hemi-Fontan, Fontan)

Bidirectional Glenn shunts and hemi-Fontan connections are best visualized from suprasternal views, while the inferior portions of the Fontan connections are best seen from subcostal views. Low-velocity flow with respiratory variation generally indicates normal cavopulmonary flow patterns, while continuous high-velocity flow patterns indicate obstruction (Fig. 49.14). Two-dimensional views can be impaired by poor acoustic windows, but color Doppler can highlight regions of narrowing and flow turbulence. Flow through the Fontan connection can be evaluated to look for obstruction and measure the gradient across the fenestration if present. The trans-fenestration gradient estimates the difference between the pulmonary venous chamber pressure and the Fontan baffle pressure but does not identify the actual measurement. If Fontan baffle obstruction is suspected, TEE may be of value to assess for thrombus formation.

Summary

Echocardiography in the pediatric cardiac intensive care unit is an important modality to diagnose congenital and acquired heart disease, as well as to provide valuable information regarding cardiovascular physiology. Communication between the echocardiographer and the intensive care unit team allows for targeted examinations that address specific physiologic questions as described in the previous sections and impact management to improve overall care.

Developing Techniques: The Future of Monitoring

50

Kyle Lieppman, Alejandro A. Floh, and Steven M. Schwartz

Abstract

The fundamental goal of critical care medicine is to optimize cardiac output to maintain adequate organ perfusion and meet the body's metabolic demands. Historically, monitoring cardiac output was limited to indirect measures of the physical exam and biochemistry. The pulmonary artery catheter was the first widely adapted instrument to quantify cardiac output at the bedside, but its use has been curtailed, especially in pediatrics, due to its invasiveness and associated complications. Newer cardiac output monitoring technologies have recently emerged and are being slowly integrated into routine clinical practice.

Cardiac output devices have evolved to become less invasive in hopes of minimizing side-effect profiles. In general, these devices fall into three broad categories: intermittent measurements based on transpulmonary dilution, continuous monitoring based on analysis and integration of the invasive arterial waveform, and continuous measurements based on changes to electrical impulses across the thoracic cavity. Lastly, commercial devices that determine the adequacy of distal perfusion through tissue-based assessment have also been recently introduced. Volume assessment of physiologic compartments (e.g., intravascular, intrapulmonary) is also possible by several companies. Adult data showing acceptable accuracy and precision exists for many of the newer devices, but validation in pediatric patients, particularly infants and neonates, is scant.

This chapter will provide readers a detailed review of the underlying physiology for the emerging cardiac output devices and present their validation studies in the field of pediatrics. It will also provide a framework for assessing their utility in a pediatric intensive care unit.

Introduction

Hemodynamic surveillance forms the hallmark of critical care patient monitoring. Historically, adequacy of cardiac output has relied on assessment of clinical indices including patient vital signs, capillary refill, peripheral body temperature, urine output, and biochemistry. However, with increasing evidence of poor physical exam reliability, direct measurement of absolute cardiac output has been sought to direct patient care [1, 2]. Pulmonary artery catheterization with measurement of cardiac output by thermodilution has been used extensively in various adult settings [3]. Unfortunately, due to a significant complication burden and limited utility for children with congenital heart disease who often have residual intracardiac shunts, the use of this technique has always been limited in pediatrics and, over the past decade, has declined even further. Measurement of cardiac output has instead focused on development of newer methods that might offer both accuracy and minimal invasiveness and with the capability of repeated or continuous measurements for pediatric patient monitoring. Furthermore, newer technology has also attempted to address the ability of determining the adequacy of the cardiac output in meeting the hemodynamic and perfusion demands of the body.

This chapter will review emerging technologies for monitoring cardiac output and tissue perfusion that are now slowly transitioning from research tools into clinical applications for monitoring postoperative cardiac patients in the critical care unit. For a summary of the principles, advantages, and disadvantages of the different systems discussed in this chapter, please see Table 50.1.

Transpulmonary Dilution Techniques

Clinically accurate and reliable measurement of cardiac output was first introduced in adults over 40 years ago using the pulmonary artery catheter, which became the clinical standard [3]. However, lack of demonstrable clinical benefit in several studies have led to questions about its utility in goal-directed patient care, particularly in light of the incidence of complications including hemorrhage, thrombosis, infection, and vessel injury. Comparable studies in pediatrics have not been undertaken; however, the side-effect profile has propelled the study of less invasive technologies [4]. These newer techniques largely employ the concept of transpulmonary dilution of an indicator as the core method by which cardiac output is calculated.

Most cardiac output monitoring devices incorporate an indicator dilution method of measurement [5]. Similar to pulmonary artery catheters, cardiac output is based on an indirect Fick calculation using the integral change of the indicator concentration over time. Following injection of an indicator, it is diluted by the blood flow, and the indicator will both appear at the downstream sensor sooner and be cleared faster with a higher cardiac output. The monitoring device generates a curve of the indicator concentration over time (Fig. 50.1); a lower area under the indicator time curve signals a shorter circulation time and thus a higher cardiac output. Test injections are usually conducted in triplicate, with the average forming the final reported cardiac output value. Unlike the traditional pulmonary artery catheter, these devices examine transpulmonary dilution, during which the tracer is injected in a large systemic vein and the downstream measurement occurs in a systemic artery. One important effect of this approach is that the dilution time is

Table 50.1 Summary of cardiac output monitoring devices

Name	Physiologic principles	Age group	Advantages	Disadvantages
PiCCO	TPTD + Arterial pressure-based CCO	Well validated in children	Multiple hemodynamic parameters	Requires central arterial catheter
		CCO less well validated in children	Continuous	
COstatus (Transonic, NY, USA) – transpulmonary	Transpulmonary ultrasound dilution	Validated in animal studies and adults	Standard AC and CVC	Intermittent measurement
		Only one study validation in children	Nontoxic indicator	Circuit needs replacement 24–36 h
			Minimal blood loss	Potential for fluid overload
			Can measure other volume status parameters	
LiDCO (LiDCO Systems, London, UK)	Transpulmonary lithium dilution + arterial pressure-based CCO	One validation in children	Continuous	Potential significant blood loss
		Not approved for use <40 kg		
Dye densitogram analyzer (Nihon Kohden, Tokyo, Japan)	Pulsed dye densitometry	No validation studies in pediatrics	Noninvasive	Appropriate signal detection mandatory
			Use of peripheral venous catheter	
FloTrac/Vigileo system (Edwards Lifesciences, CA, USA)	Arterial pulse contour analysis	Not validated in pediatrics	Continuous	Arterial wave artifacts, irregular pulse influence measurements
			No calibration	
MostCare (PRAM) (Vytech, Padova, Italy)	Arterial pulse contour analysis	One validation study in children	Continuous	Calibration not possible
Nexfin (BMEYE, Amsterdam, The Netherlands)	Arterial pulse contour analysis (finger cuff)	Adults only	Noninvasive	Not feasible for small children
			Continuous	
USCOM (Uscom, Sydney, Australia)	Transcutaneous Doppler	Adults	Noninvasive	Intermittent
		More validation in pediatrics needed		Operator and flow dependent
				Nomogram based estimates
Bioimpedance	Electrical impedance (surface electrodes)	Adults/pediatrics	Noninvasive	Inaccurate in intensive care settings
			Continuous	Not well validated in pediatrics
NICOM (Cheetah Medical, Tel Aviv, Israel)	Bioreactance (surface electrodes)	Validated in adults	Noninvasive	–
		No validation studies in pediatrics	Continuous	
OPS and SDF	Direct, bedside in vivo observation of the microcirculation	Observation studies in pediatric sepsis	Provide assessment of adequacy of oxygen delivery	–
		Adults		

AC arterial catheter, *CCO* continuous cardiac output, *CVC* central venous catheter, *TPTD* transpulmonary thermodilution

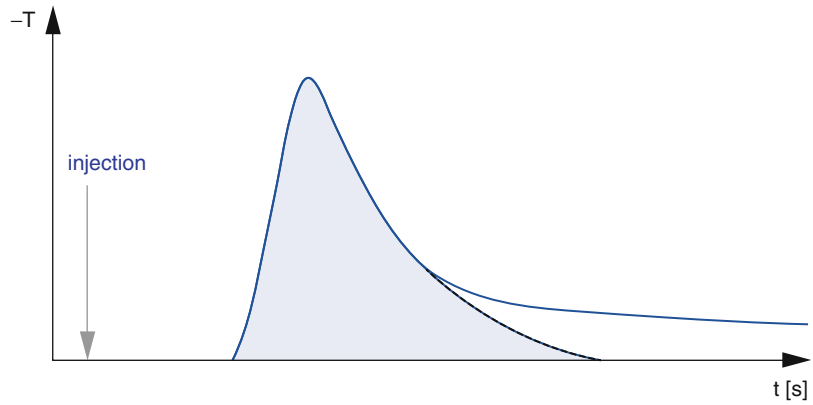

Fig. 50.1 A thermodilution curve from a transpulmonary cardiac output monitoring device: the period from indicator injection to measurement of curve represents the transit time. The dilution curve indicates the measured change in temperature over time (an equivalent curve would be formed using other indicator techniques). Cardiac output is calculated by a modification of the Stewart-Hamilton equation and is inversely related to the area subtended by the dilution curve

lengthened over a period of several cardiac cycles, decreasing the impact of beat-to-beat and respiratory variability on the final value [6].

The accuracy of the transpulmonary dilution method is based on several technical and physiological assumptions that must be met in order for this technique to be accurate. These include adequate mixing of blood and indicator, minimization of indicator loss, and need for constant blood flow through the circulation. Abnormal circulation resulting from valvular regurgitation, intracardiac shunts, or extremely impaired cardiac output result in erroneous results [7]. These devices are therefore limited to children with biventricular anatomy and physiology and thus cannot be used in a large number of children with congenital heart disease.

Nevertheless, when used appropriately, these devices can provide information that may be useful for patient evaluation and management.

Transpulmonary Thermodilution

The Transpulmonary thermodilution (TPTD) technique uses thermal energy as an indicator. Ice-cold saline is injected in a central venous catheter, and a thermistor-tipped catheter positioned in a large systemic artery, usually femoral or axillary, measures downstream temperature. The volume of injectate is weight based and ranges between 2 and 20 mL [8]. In contrast to the traditional pulmonary artery catheter, this method is considered less invasive as both venous and arterial catheters are usually used as part of standard care; thus, placement of additional catheters is not required.

The commercially available PiCCO system (Pulsion®, Munich, Germany) has been widely used in adult and pediatric ICU settings (Fig. 50.2). Thermistor-tipped arterial catheters ranging in size from 3F to 5F are available, allowing for measurement in any patient above 3.5 kg. It has been validated in several juvenile animal and pediatric human studies against perivascular flow probes, pulmonary artery catheters, and direct cardiac output calculation by Fick method [9–11].

With the data acquired by transpulmonary thermodilution, volume for several physiologic compartments can be calculated. The total volume of distribution is determined based on mathematical and experimental models where an indicator is injected into several mixing chambers arranged in series. Specifically, the Stewart-Hamilton principle, in which cardiac output is measured from the total indicator used and the integral of indicator concentration over time, is used to describe the relationship where

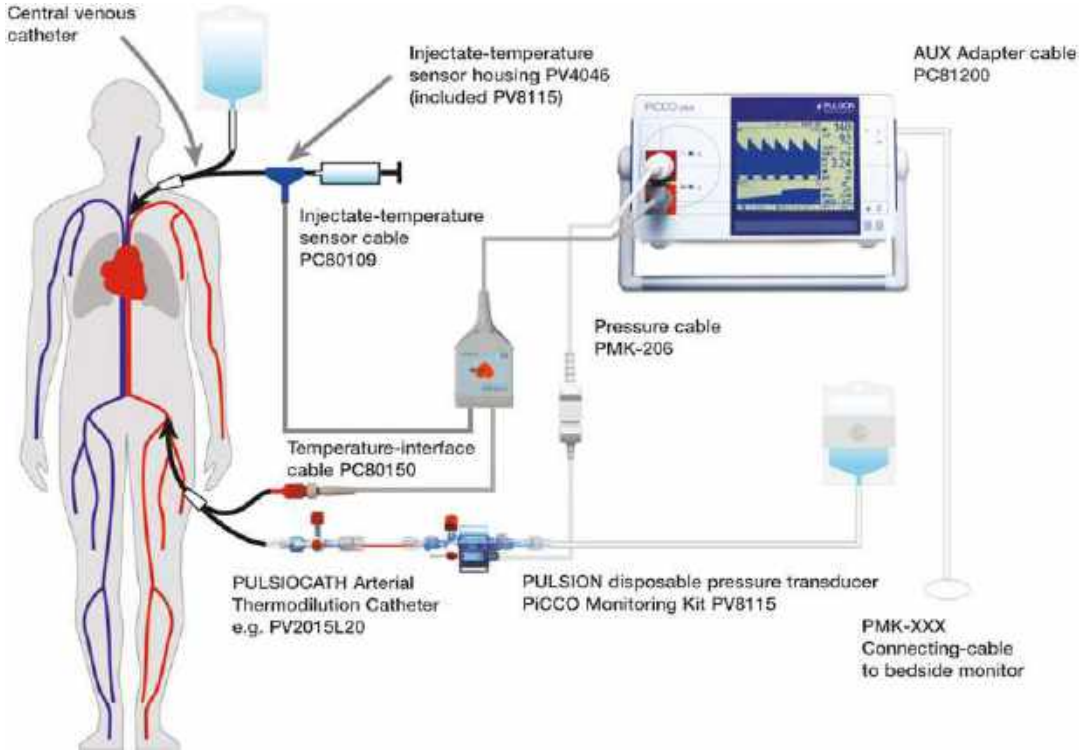

Fig. 50.2 A schematic representation of the PiCCO system by Pulsion®: ice-cold saline is injected into a central venous catheter. A thermistor-tipped arterial catheter measures the change in temperature in a central artery, usually the femoral or axillary. All data are presented in real time on the display screen. Both access catheters can also participate in ongoing hemodynamic monitoring. The arterial pressure curve is also used for continuous cardiac output monitoring by pulse contour analysis

volume equals the product of flow and mean transit time. This calculated volume of distribution is called the intrathoracic thermal volume (ITTV) and is the product of cardiac output and mean transit time (time at which 50 % of indicator detected); ITTV represents the total blood volume in the cardiopulmonary circulation at end of diastole. The total amount of volume in the pulmonary space (pulmonary thermal volume) can also be calculated from the thermodilution curve; when subtracted from the ITTV, the global end-diastolic volume (GEDV) is determined, representing the total volume of blood in all cardiac chambers at the end of diastole. In experimental animal models and neonatal observational trials, GEDV outperformed clinical markers of preload in correlating with stroke volume and cardiac output. Finally, degree of pulmonary edema measured as extravascular lung volume can also be calculated from the above data set. Pediatric studies, compared to adults, are sparse and additional validation is required. The above static volume indices have the potential to form an integral component in a patient's clinical assessment and a valuable tool in guiding therapeutic interventions [12].

Ultrasound Dilution

The COstatus device (Transonic Systems Inc., Ithaca, NY, USA) is based on the changes to ultrasound velocity of circulating blood following dilution by a saline injection. Ultrasound velocity is dependent on protein and ion concentrations and generally measures between 1,560 and 1,585 m/s. Saline dilution decreases the ultrasound velocity, which can be measured over time

and converted to a measure of blood concentration, which is then used to calculate cardiac output [13]. The saline dilution is accomplished via an extracorporeal arterial–venous connection, which is established between a central venous catheter and a central or peripheral arterial line. These connections are primed with approximately 5 mL of heparinized saline, and a roller pump maintains constant blood flow through the circuit at a rate of 8–12 mL/min. Normal isotonic saline, heated to body temperature (37 °C), is injected at a volume of 0.5 mL/kg (maximum 30 mL) into the venous limb of the circuit, and ultrasound velocity of circulating blood is then continuously monitored at the arterial limb. Cardiac output is calculated as the product of the volume of isotonic saline injection and decrease in ultrasound velocity over the integral of ultrasound velocity over time. Consistent with other dilution devices, the injections occur in triplicate with a final mean value ultimately reported.

Ultrasound dilution has been validated in numerous animal and adult models [13–16]. In the only published pediatric series, ultrasound dilution correlated well with cardiac output measured by pulmonary artery catheterization in children undergoing cardiac catheterization following cardiac transplants. This study was limited to children above 1 year of age and 10 kg and showed means bias of 4.1 mL/min with a precision of 0.8 L/min [17].

The major advantage of the COstatus technique is its ability to use peripheral arterial catheters that are part of routine postoperative care of children. Other benefits include the use of nontoxic indicator and minimization of blood loss. Nevertheless, COstatus affords only intermittent measurement of cardiac output using a circuit that must be replaced every 24–36 h. A potential for fluid overload exists with repeated saline injections for each measurement. Ultrasound dilution technology also allows for assessment of total end-diastolic volume (TEDV), central blood volume (CBV), and active circulating volume (ACV). ACVI is defined as the volume of blood in which the indicator mixes in 1 min from the time of injection and represents the total amount of blood in the circulatory system, actively participating in cardiac output. The ACV may have clinical value in assessing a patient's volume status [18]. CBV is the product of cardiac output and the mean indicator transit time from the injection site (central vein) to the recording site (peripheral artery) and represents the volume of blood in the heart, lungs, and great vessels [19]. Finally, TEDV is analogous to the GEDV as determined by the PiCCO system and is considered to be equivalent to the preload volume of the heart. This is based on the underlying assumption that the majority of time of the arterial curve versus the venous curve is due to indicator traversing the heart chambers; TEDV is then calculated using the width of the arterial and venous curves at one-half the maximum height [20]. Although several small adult cohort data show a correlation between TEDV and CBV and cardiac preload, no pediatric studies are currently available.

Lithium Dilution

Transpulmonary lithium dilution uses an isotonic solution of lithium chloride as the indicator and requires standard venous and arterial catheters and a lithium sensor [21]. The commercially available device is marketed under the name LiDCO (LiDCO Systems, London, UK). Similar to COstatus, LiDCO makes use of usual arterial access such as the radial artery. Following injection of lithium chloride (0.002–0.004 mmol/L) into a standard central venous or peripheral venous catheter, the resulting arterial lithium concentration-time curve is recorded by a lithium sensor attached to the patient's existing arterial line and is interpreted by the LiDCO device. A constant flow of 3–4 mL/min is established by a roller pump directing arterial blood through a three-way connector to pass by the lithium sensor that detects the voltage across a lithium selectively permeable membrane. The voltage is related to the concentration of lithium (corrected for sodium). Each measurement requires approximately 3 ml of blood. Cardiac output is the product of the injected lithium dose, the area subtended by the lithium dilution curve and

1 − packed cell volume. The packed cell volume is calculated by dividing hemoglobin concentration (g/dl) by 34, the correction factor accounting for the distribution of lithium in the plasma. Cardiac output measurements are an average of 2–3 injections.

LiDCO has been validated in pediatric patients using transpulmonary thermodilution as the reference technique. Seventeen patients in a pediatric intensive care unit were studied and the results demonstrated safety, feasibility, and reasonable correlation with transpulmonary thermodilution measurements [22].

With three injections required for every cardiac output measurement, and 3–4 mL blood loss per reading, recurrent measurements can lead to significant blood loss for small infants. Furthermore, the maximum recommended total cumulative dose of lithium chloride is 3 mmol, corresponding to approximately 20 individual injections of 0.15 mmol for adults. The dose used in children for a single CO measurement is 0.002–0.009 mmol/kg, which has no known pharmacological effect [23]; however, repeat cardiac output measurements should be limited to avoid overaccumulation of lithium. The LiDCO device has not received FDA approval for children weighing less than 40 kg.

Pulsed Dye Densitometry

With pulsed dye densitometry, intermittent cardiac output measurements can be obtained at the bedside using a finger or nose clip device and a dye densitogram analyzer based on the same principles that are applied to pulse oximetry [24]. However, for substances in the blood other than hemoglobin, the alteration due to arterial pulsation is used to estimate its concentration in the blood. In this dye dilution technique, indocyanine green, a nontoxic substance, is employed as the indicator. Indocyanine green is cleared exclusively by the liver, with a half-life of approximately 4 min, and it takes >20 min to be metabolized completely in the blood. It is injected into a central vein with a measured arterial concentration change based on transcutaneous signal detection adapted from pulse oximetry. In contrast to the conventional dye dilution method, this technique does not require blood sampling. Cardiac output and circulating blood volume can be calculated by analyzing the pulsatile change in dye concentration in the arterial blood. Appropriate signal detection is mandatory and high heart rate, poor peripheral circulation, interstitial edema, and movement artifacts negatively influence this.

Studies in adults are limited and this technique has not been validated in pediatrics, but an animal study comparing it with ultrasound flow probe showed good correlation [25]. Its applicability in clinical practice is unknown.

Arterial Waveform Analysis

Continuous analysis of pulse contour allows for beat-to-beat assessment of cardiac output, in contrast to the repeated intermittent measures inherent in transpulmonary dilution techniques. Pulse contour analysis is a based on the principle that the area subtended by the arterial pulse wave reflects stroke volume and arterial compliance. Proprietary computer algorithms analyze the arterial pressure waveform and calculate cardiac output as the product of the determined stroke volume and the instantaneous heart rate [26]. Some devices providing pulse contour analysis require calibration against an indicator dilution technique, whereas others do not. Those that require calibration have generally been incorporated into devices that already use transpulmonary dilution techniques.

Pulse contour cardiac output algorithms have been designed for the adult population and have not been extensively studied in pediatrics. Several patient characteristics in children may affect the reliability of these monitors. Firstly, the developing vascular system is structurally and functionally different in children than adults. Since vascular capacitance plays an integral role in pulse contour analysis, such changes may make measurement in children less accurate. Secondly, an optimal pressure transducing system requires low compliance tubing and careful calibration. Dampened waveforms,

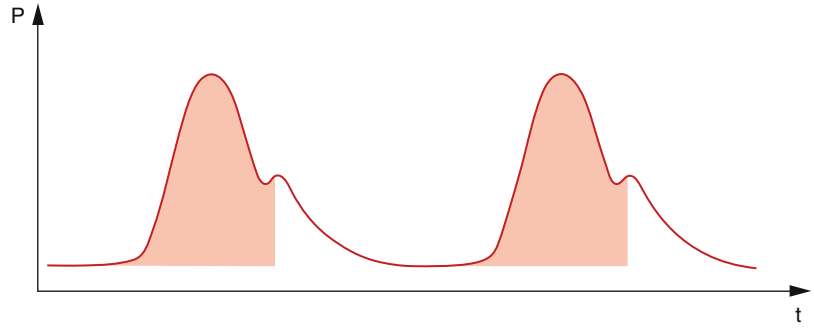

Fig. 50.3 Pulse contour analysis: cardiac output is continuously calculated by an algorithm that incorporates the area subtended by systolic portion of the arterial waveform (*shaded area* flanked by the systolic upstroke until the dicrotic notch), aortic compliance, and a patient-specific factor derived from calibration with thermodilution. Repeat calibration with thermodilution is required every 8 h and when significant hemodynamic shifts occur

movement artifacts, and catheter kinking are common in infants and small children and may adversely affect the derived cardiac output from the arterial waveform.

Pulse Contour Analysis

The PiCCO2 system (Pulsion®, Munich, Germany) integrates pulse contour analysis to the PiCCO system described above. To determine continuous pulse contour cardiac output, an algorithm incorporating the area under the systolic portion of the arterial waveform, aortic compliance, and a patient-specific calibration factor determined by the bolus thermodilution measurement of cardiac output is used (Fig. 50.3). It requires an initial calibration using transpulmonary thermodilution, with regular recalibration at a maximum interval of 8 h necessary to ensure measurement accuracy. More frequent calibration is required when patient-related factors, such as profound alterations in hemodynamic status, change [27].

To date, the use of the PiCCO2 pulse contour system in pediatric patients has not been adequately validated. A comparative cardiac output study in children prior to and following cardiac surgery showed poor agreement (percentage error $\pm$ 52 %) between pulse contour analysis measurements and TPTD [28]. The weak agreement persisted despite surgical correction of all intracardiac shunts. Smaller patient size, lower absolute cardiac output values, higher heart rates, and greater aortic compliance compared with adults may affect or limit the accuracy and precision of PiCCO2 analysis in children necessitating its cautious use. Its clinical strength and utility may be in its ability to detect changes in the hemodynamic profile. The absolute cardiac output may be considered a rough estimate, but changes in measured cardiac output could alert the clinician, which would make it a useful tool.

Another potential physiologic parameter evaluated by the PiCCO2 system is fluid responsiveness. Variations in the pulse pressure analysis are detected across the respiratory cycle and calculated as the difference of max stroke volume and mean stroke volume divided by the mean stroke volume [29]. Since pulse pressure reflects stroke volume, variations to measured pulse pressure through the respiratory cycle are thought to correspond to the effects of positive pressure ventilation on stroke volume in intubated children. Several adult studies have shown that elevation to stroke volume variation was associated with an increased fluid responsiveness. Although data in adults is sparse, there is an absence of pediatric data.

LiDCO/PulseCo

The PulseCo method (LiDCO Systems, London, UK), incorporated in the LiDCO device, converts

the arterial waveform to a nominal stroke volume using a pressure–volume transformation [23]. Unlike the PiCCO2 algorithm that uses only the systolic portion of the pulse pressure wave, the entire arterial pressure curve is incorporated into the PulseCo Pulse Power Analysis. In doing so, this device theoretically incorporates the influence of peripheral resistance. The proprietary algorithm used by PulseCo analyzes the pressure waveform against a table derived from the curvilinear relationship of pressure and volume which seems to be similar in different subjects. In this way, a standardized volume waveform is constructed from the original arterial pressure input, which reflects the power generated by each heart beat and becomes the source of cardiac output assessment. The area subtended by standardized volume waveform when calibrated against transpulmonary lithium dilution is used as the basis for calculating stroke volume and, therefore, cardiac output. Periodic calibration against the transpulmonary dilution technique is required to maintain accuracy. Theoretically, this analysis is less vulnerable to inaccuracy due to damping of pulse pressure waveform and can be used in any artery.

This measurement technique has been validated in a pediatric study against pulmonary artery thermodilution. Twenty children with structurally normal hearts undergoing routine catheterization hemodynamic assessment for transplantation surveillance or investigation of primary pulmonary hypertension were studied. Patients with known intracardiac or extracardiac shunting were excluded [30]. PulseCo was determined to be very precise and accurate, with a percentage error of 8.8 % and relative bias of 6 % between measurements.

The method seems promising, but further studies are warranted and the use of lithium should be considered, although the integration of continuous CO analysis from arterial pulse pressure by the LiDCO device may limit the frequency of lithium use. As with PiCCO2, the accuracy and precision are dependent on the frequency of recalibration, which place limitations to its long-term use. Unfortunately, for those caring for large numbers of patients with residual shunts, the need to validate the measurement against a transpulmonary dilution technique may also be problematic.

FloTrac/Vigileo

The FloTrac/Vigileo system (Edwards Lifesciences, Irvine, CA) is another cardiac output monitoring system based on analysis of the systemic arterial pressure wave. An important distinction for this device is that it does not require calibration. The stroke volume is derived by a proprietary algorithm, using the patient's vascular resistance and arterial compliance based on sex, height, weight and age, and the pulse pressure waveform characteristics [31].

The FloTrac algorithm does not calculate the area under the pressure waveform. Instead, stroke volume is calculated by waveform analysis. Together with patient demographic information, the waveform is analyzed to calculate the standard deviation of the arterial pressure, which is proportional to pulse pressure. The standard deviation of the arterial pressure is multiplied by a conversion factor, which incorporates the effects of resistance and compliance and also converts the standard deviation of the arterial pressure into ml/beat. This relationship can vary widely between patients and also in a single individual as hemodynamics change. Its calibration constant is recalculated every 60 s.

There is a growing body of adult-based evidence characterizing its utility in critical illness for which it is FDA approved [32, 33]. Only one validation study has been done in the pediatric population. Teng et al. compared this device with pulmonary artery catheter derived intermittent cardiac output measurements in pediatric patients with cardiomyopathy, pulmonary hypertension, or post-cardiac transplant who presented for heart catheterization [34]. An unacceptably high percentage error (80 %) was found between the two methods. Since the algorithm used by the device is based on the vascular properties of elderly patients, it should be used cautiously in other populations with different vascular compliance, which most certainly includes children.

PRAM

The Pressure Recording Analytical Method (PRAM) (Vytech, Padova, Italy) also analyzes the systemic arterial pressure waveform morphology to calculate cardiac output [35]. The results of this beat-to-beat analysis allow for determination of the stroke volume, which is then used to calculate cardiac output multiplying stroke volume by heart rate. This method, studied in children by Calamandrei et al. [36], has been compared with transthoracic Doppler echocardiographic measurements. The study showed that the mean difference between the two methods was 0.12 ± 0.27 L·min^{-1} (95 % CI -0.54 to 0.77 L·min^{-1}) with a percent error of 21 %. The major problem with this comparison is that echocardiographic determination of cardiac output in children is a poor gold standard and has shown to be generally unreliable due to high interoperator variability in being a reliably precise measure of cardiac output [37]. Nevertheless, PRAM might still be useful in pediatric patients, but clearly, additional clinical validation studies are warranted.

Noninvasive Continuous Finger Arterial Pressure and Cardiac Output Monitoring

Blood pressure and cardiac output can be obtained using a continuous, noninvasive, finger arterial pressure measurement technique. This method requires an inflatable finger cuff that incorporates a photoplethysmographic sensor, a rapid-reacting pneumatic servo system and a device that can interpret the signal. The plethysmographic signal drives the servo system in such a way that the finger arterial wall is constantly kept unloaded. The cuff pressure then is a reflection of the finger arterial pressure. After application of a software algorithm, a brachial pressure curve is generated [38]. The Nexfin HD device (BMEYE, Amsterdam, the Netherlands) incorporates an arterial pressure-based pulse contour continuous cardiac output monitoring method that can be applied to the arterial waveform from the finger artery.

Thus far, it has been limited to adult studies, which have shown acceptable results in healthy volunteers. However, acceptable reliability reflected by a relative error of 29 % was found in a single study comparing Nexfin with pulmonary artery catheter data in ICU patients [39]. Due to physical characteristics of infants and small children, it is unlikely that this device would ever have clinical relevance in this population. Further validation studies are needed.

Other Methods

Continuous Wave Doppler Ultrasound

The Ultrasonic Cardiac Output Monitor (USCOM) (Uscom, Sydney, Australia) is a portable apparatus for measuring cardiac output through transcutaneous analysis of aortic or pulmonary artery flow using continuous wave Doppler ultrasound. The Doppler flow is measured using a handheld probe positioned on the thorax. The subject's height and a nomogram incorporated into the software estimates the valve cross-sectional area so that cardiac output can be calculated from the measured flow across the aortic or pulmonary valve [40, 41]. In one animal study, USCOM compared favorably with data obtained from an ultrasound flow probe around the ascending aorta [42]. Nevertheless, a validation study in children comparing USCOM with pulmonary artery thermodilution found measurements unreliable in representing the absolute cardiac output in children undergoing cardiac catheterization [40].

The USCOM technology has inherent weaknesses that may lead to poor reliability. First, cardiac output measurements are operator and flow signal dependent. Second, its usage of nomogram based estimates of the cross-sectional area of the aorta and pulmonary valves could introduce error into the results. The validity of this technique requires further studies.

Thoracic Bioreactance/Impedance

Thoracic bioreactance is a noninvasive method that analyzes intrabeat variations of transthoracic voltage in response to an injected high-frequency current [43]. Bioreactance uses a high-frequency sine wave generator and four dual electrodes. The variation in the frequency spectra of a delivered oscillating current that occurs when the current traverses the thoracic cavity is analyzed. The signal-to-noise ratio in bioreactance is approximately 100-fold greater than in traditional bioimpedance, which reduces the amount of error due to artifact. Thoracic bioimpedance provides continuous hemodynamic data [44]. In this system, a high-frequency electrical current of known amplitude and frequency is applied at source electrodes, and the change in voltage across the thorax is measured at the receiving electrodes. A ratio is obtained between the voltage and current amplitudes corresponding to a measure of transthoracic current resistance (impedance). Cardiac output is determined by converting variations to impedance to the proportion of fluid in the thorax. The amount of intrathoracic fluid is, in turn, related to blood flow in the aorta, which is systemic cardiac output.

Studies determining accuracy of cardiac output measured by bioimpedance in adults have shown discrepant results. Although, there is adequate correlation with pulmonary artery catheter thermodilution in some clinical settings [45], cardiac output determined by bioimpedance has been shown to be inaccurate in intensive care units and other settings where significant signal noise exists [46]. In one pediatric study comparing bioimpedance with the direct Fick method in children with repaired and palliated congenital heart disease, only 55 % of measurements were within 30 % of each other, making it an unreliable tool in this population [47].

With regard to bioreactance instead of bioimpedance, studies in adults have validated the basic principles of this technique and have found a good correlation and concordance between bioreactance and other methods for the measurement of cardiac output [48, 49]. Only one study has attempted to use this technique to measure cardiac output in children, and no validation studies have been done [50].

Microcirculatory Changes

Utility of cardiac output guided therapy has been questioned in large adult trials that demonstrated no benefit in pulmonary artery catheter use in several disease states. One potential explanation is that this device measures absolute cardiac output and not effective cardiac output and adequacy of distal organ perfusion. Efforts to better quantify perfusion to the microcirculation have been undertaken to provide bedside assessment of the adequacy of tissue oxygen delivery, which in many ways is the Holy Grail of intensive care therapy. Research has demonstrated that in various disease states, including cardiogenic or hemorrhagic shock, discernable changes occur in the microcirculation that could serve as an indicator of tissue hypoperfusion and could be of prognostic value [51, 52].

Several modalities have been designed to quantify these microcirculatory changes but have been generally confined to the laboratory setting. Nevertheless, selective devices including Orthogonal Polarization Spectroscopy (OPS) and Sidestream DarkField imaging (SDF) have been translated to bedside tests. These technologies are video-based devices that have recently been implemented in handheld form.

OPS and SDF are based on properties of light rays passing through tissue. As a light source is applied against tissue, light rays are reflected by the deeper tissue layers providing transillumination of the superficial tissue [53]. These techniques employ different light sources; however, both the wavelengths selected emit light rays that are absorbed by the hemoglobin contained in the red blood cells. As such, blood vessels are seen as black or gray bodies, making the microvascular vessels clearly visible and easily analyzed [54, 55]. Different variables including vascular density and heterogeneity of perfusion can then be measured; with the estimate of capillary density and

assessment of the proportion vessels perfused being the most relevant for tissue perfusion [56].

Adult studies have shown that patients admitted to the ICU for severe heart failure or cardiogenic shock had microvascular circulatory alterations, consisting of a decrease in vessel density and in the proportion of perfused capillaries [57]. Most of the literature, including studies of pediatric populations, has looked at the microcirculatory changes that occur secondary to sepsis and modeled with endotoxin. In pediatric patients with septic shock, Top et al. used OPS to examine the microcirculatory changes that occurred in the buccal mucosa and found that compared with non-survivors, survivors had an increase in the density of the functional capillaries [58].

While most of the adult literature has focused on the microcirculatory changes that occur in sepsis, it is rational to think that these devices could also play a role in assessing the microcirculation of other low flow states. This may form the foundation of future investigation.

Conclusion

Improving cardiac output monitoring in the pediatric cardiac intensive care unit forms the foundation of numerous new technologies that are being introduced to bedside care. Each technology strives to improve accuracy, precision, and versatility, allowing reliable measurements across several disease states and cardiac physiologies while minimizing their invasiveness. Bedside tests are now available to analyze cardiac output intermittently or on a continuous basis. Furthermore, additional physiologic data may be available depending on the manufacturer.

At this time, the majority of validation studies have been completed in adult settings. Although the results may be extrapolated to the pediatric patients, differences in size, vascular compliance, and other tissue characteristics mandate that pediatric specific studies be completed. Additionally, the challenges posed by the unusual physiologic situations frequently encountered in pediatric cardiac patients such as residual shunts, valvular dysfunction, and non-pulsatile pulmonary circulations may limit applicability of some of these techniques and require careful study. Nevertheless, there is optimism that new methods of hemodynamic surveillance will be available at a reduced side-effect burden.

Intracardiac Interactions

51

Andrew Redington and Michael Mendelson

Abstract

The function of the left and right ventricles is inextricably linked. Shared muscle fibers, a common septum, and the surrounding pericardium and thoracic chamber inevitably impose series, parallel, geometric, and electrical interaction of the ventricles. The hemodynamic effects are immediate, independent of neural influences or circulating factors, and prominently contribute to the cardiovascular response in various disease states. A fundamental understanding of these interactions in the structurally normal and congenitally malformed heart is crucial for informed clinical decision-making. This chapter explores the anatomic basis and physiologic responses of intracardiac interactions in the normal heart and in congenital and acquired heart disease, highlighting the consequent clinical implications.

Introduction

Optimal cardiac function is dependent upon supportive interactions between the left and right ventricle [1, 2]. Shared muscle fibers, a common septum, and the surrounding pericardium and thoracic chamber link the ventricles in a way that makes the more traditional approach to assessment of function as two isolated pumps working in series, outdated. Indeed, not only is the capacity to generate cardiac output augmented by ventricular interactions in the normal heart, but disruptions of this balance through alterations in ventricular geometry (in response to variations in pressure or volume) or structure (in congenital defects) impairs the filling and function of the other ventricle. Consequently, due to their contiguous anatomic relationship, dysfunction of one ventricle directly influences the function of the other ventricle.

Our understanding of these interactions has advanced over the last 50 years through evidence from isolated cardiac muscle experiments, intact animal studies, and more recent clinical observations in children and adults. These studies reveal that ventricular-ventricular interactions are more than interesting observations in a laboratory setting but are physiologically important effects with significant clinical implications. The hemodynamic effects are immediate, independent of neural influences or circulating factors, and prominently contribute to the cardiovascular response in various disease states. A fundamental understanding of these interactions in the structurally normal and congenitally malformed heart is crucial for informed clinical decision-making.

This chapter explores the anatomic basis and physiologic responses of intracardiac interactions in the normal heart and in congenital and acquired heart disease, highlighting the consequent clinical implications. Invasive, noninvasive, and bedside methods of assessing ventricular interactions are presented. The terms ventricular interactions, ventricular-ventricular interactions, and ventricular interdependence and ventricular coupling will be used interchangeably. Cardiopulmonary interactions are described elsewhere.

Anatomic Basis of Ventricular Coupling

The anatomic positions of the two ventricles form the basis of ventricular interactions [3]. The apical and inferior inlet components of the ventricles sit in direct opposition to their counterparts through a shared myocardial septal wall. The outlet components are arranged differently. The left ventricle is bullet-shaped with an inlet and outlet in approximately the same plane, which allows for high-pressure output into the systemic circulation. The mitral and aortic valves sit adjacent to each other with fibrous continuity between their leaflets and fit into the circular profile of the left ventricle. In contrast, the right ventricle is shaped similar to a "bellows," which allows for efficient output into a low resistance pulmonary circulation. The inlet and outlet of the right ventricle are in very different planes. A muscular supraventricular crest separates the tricuspid and pulmonary valves, with the pulmonary valve positioned superiorly within a freestanding muscular infundibulum. Conversely, the aortic valve is wedged between the two atrioventricular valves. Under usual physiologic conditions, the right ventricle is indented by the left ventricle and wraps around the anterior portion of the left ventricle, setting the scene for the ventricles to interact directly (Fig. 51.1).

In addition, shared myocardial fibers at the superficial epicardial layer and deeper muscular layers encircle both ventricular chambers and contribute to contraction and shortening [4]. Recent studies have suggested that the entire myocardium can be unraveled in a single muscular band [5]; however, this remains controversial, disputed, and attributed to an artifact of specimen preparation [6]. However, no matter which school one aligns with, the concept that the right and left ventricles are formed by common components is indisputable. Histological studies of the left ventricle show that mid-wall fibers run circumferentially and parallel to the

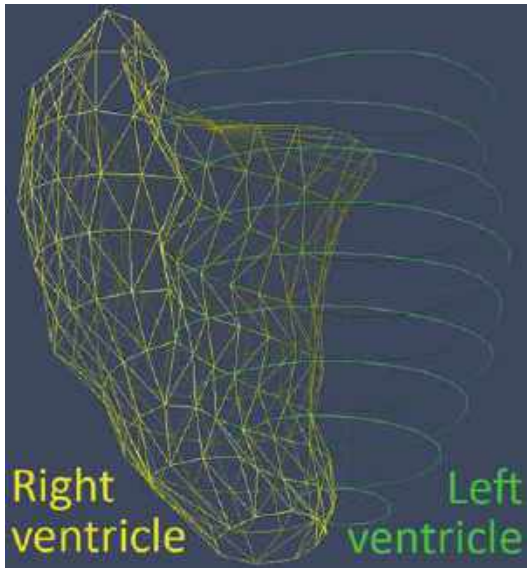

Fig. 51.1 Wireframe outline derived from magnetic resonance imaging demonstrating the normal configuration of the indented right ventricle as it partially wraps around the left ventricle. Although displayed separately, their close spatial relationship is clear. Their *integrated* anatomic relationship is demonstrated in Fig. 51.2

atrioventricular groove [7]. The twisting motion of left ventricular contraction is created by subendocardial and subepicardial fibers running at crossed angles to each other and the circumferential mid-wall fibers [8]. At the base of the right ventricle, there are longitudinally oriented fibers forming the septoparietal trabeculations and the septomarginal trabeculation. Septal wall fibers have been attributed mainly to the left ventricular myocardium. A demarcation within the interventricular septum can be seen in high-resolution ultrasound imaging delineating the larger left and smaller right ventricular components [9]. Recent studies using specialized magnetic resonance imaging (MRI) techniques are giving new insight into the shared myocardial structure. Using MRI diffusion tensor imaging, Schmid et al. [10] have analyzed fiber orientation in almost microscopic detail. They showed the shared nature of myofibers traversing between left and right ventricles, underscoring their inseparable anatomic relationship (Fig. 51.2).

Physiologic Mechanisms

Various mechanisms are implicated in ventricular interactions. There are direct mechanical forces related to the pressure gradient across the interventricular septum and transmission of forces along the connections of the ventricular free walls and interventricular septal margins. The elastance (and conversely, the compliance) of one ventricle varies in response to changes in pressure and volume in the opposite ventricle. Additionally, severe distortion of one ventricle has consequences for coronary perfusion of the other. The relative contributions of these dynamic effects in addition to differences in the geometry, architecture, muscle mass, and electrical activation between the left and right ventricle are all components of ventricular interactions and will be discussed in more detail below.

Ventricular-ventricular interactions are most clearly seen during rapid changes in ventricular volume or pressure. In the structurally normal heart, direct ventricular interactions help buffer changes in response to hemodynamic alterations associated with inspiration or moving from supine to standing. When moving from supine to standing, right ventricular volume decreases due to diminished venous return. As a result of ventricular interactions, the left ventricular compliance increases and allows for easier filling. The pulmonary bed serves as a reservoir allowing the left ventricle initially to maintain stroke volume. The effect of normal respiration, while clearly a component of the cardiopulmonary interactions discussed elsewhere, also induces dynamic changes in right ventricular volume, stroke volume, and in turn left ventricular output, via a similar mechanism.

However, these and other indirect ventricular interactions will not be discussed further in this chapter. They are related to the intuitive circulatory series effect where the output of one ventricle provides the input of the other. While important, such interactions form the basis of much of the traditional concepts of circulatory support, discussed elsewhere in this text. In contrast, direct ventricular interdependence is less

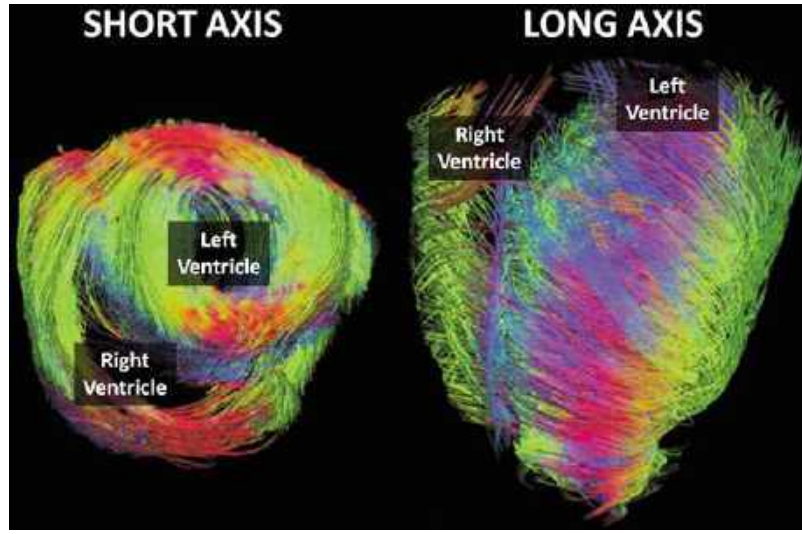

Fig. 51.2 Magnetic resonance diffusion tensor imaging demonstrating the shared myocardial fibers of the left and right ventricles from above the base of the heart (*short axis*) and from the anterior surface *(long axis*) (Adapted from Schmid P et al. [10])

well understood; the effects are immediate and may even be dynamic throughout the cardiac cycle and perhaps represent an "untapped" area of potential cardiovascular therapy. Direct interactions are estimated to contribute approximately half as much as series interactions and are further reduced with an open pericardium [11]. The physiologic effects of ventricular-ventricular interactions in systole and diastole will be explored separately.

Left Ventricular Contributions to Right Ventricular Systolic Function

The normal right ventricular ejection profile is very different to that of the left ventricle, but is dependent on the left for a substantial portion of its basal output. The normal right ventricle begins to eject early, without a well-defined isovolumic systolic contraction phase, and in late systole, the right ventricle continues to eject blood into the pulmonary arteries despite muscle relaxation and a declining ventricular pressure. Consequently, the right ventricular pressure-volume loop is triangular or trapezoidal shaped as compared to the square or rectangular left ventricular profile with ill-defined isovolumic contraction and relaxation phases [12]. While right ventricle muscle fibers have been shown to exhibit faster twitch velocities and altered excitation-contraction coupling in isolated muscles bundle experiments compared to left [13, 14] and respond differently to inotropes in vitro [15], muscle fibers of the right and left ventricle are not significantly different in terms of overall contractile function when tested in isolation, with a similar time course of pressure development regardless of ventricular origin [16]. This implies that the unusual contractile pattern of the right ventricle, and the ability of the left ventricle to contribute to it, is dependent on its low afterload.

That the left ventricle is a major contributor to right ventricular systolic pressure generation and outflow is now well established. In an important and often cited study from 1943, Starr [17] demonstrated that the central venous pressure of dogs did not rise after cautery of the right ventricular free wall. The right ventricle continued to generate flow (and maintain a low venous pressure) despite obliteration of most of the free wall muscular pumping capacity, providing early evidence that the left ventricle played a significant role in right ventricular function.

During normal sinus rhythm, the left and right ventricles exhibit a single concurrent peak in

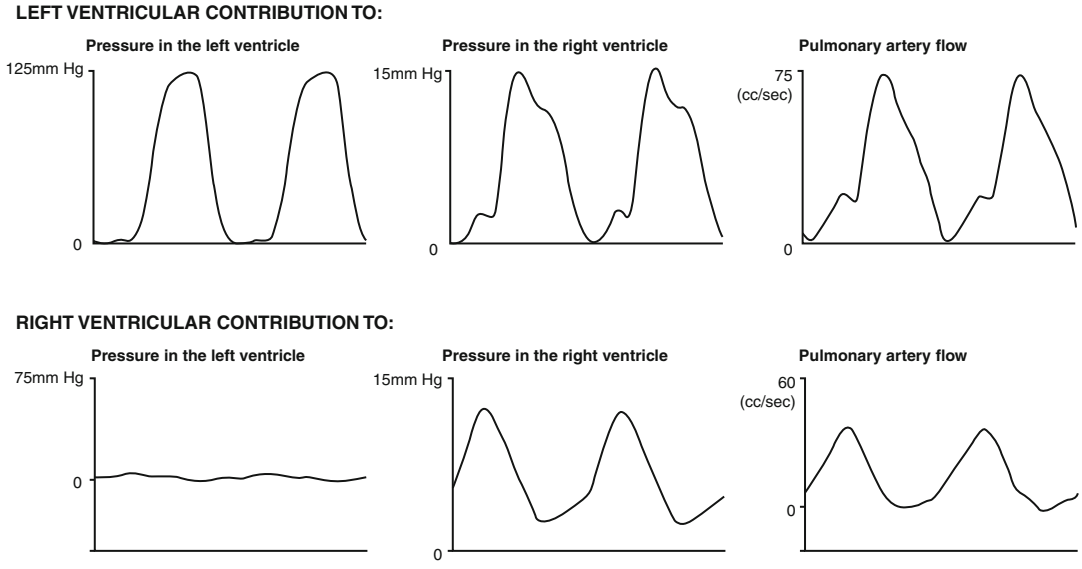

Fig. 51.3 Data from electrically isolated but functionally contiguous heart studies. By extending the interval between ventricular pacing, the influence of one ventricle can be seen on the other (see text for details) (Adapted from Damiano RJ, Jr. et al. [19])

pressure generation [16]. However, when the timing of ventricular contractions is shifted (i.e., pacing or a bundle branch block), it becomes apparent that the left ventricular contraction can be "seen" in the right ventricle independent of the force generated by the right ventricle. With asynchronous ventricular contraction, two distinct peaks in right ventricular pressure generation are evident, while the left ventricle remains single peaked. The phenomenon was observed in animal models with asynchronous pacing [18] and where the right ventricle was electrically isolated from the rest of the heart with a complete ventriculotomy and cryoablation [19]. In electrically isolated right ventricles, increasing the time interval between right and left ventricular pacing allowed a measurement of left ventricular contribution. Up to 60–70 % of the right ventricular force and pulmonary artery flow generated were attributed to the left ventricle in that artificial model (Fig. 51.3). Among adults with right bundle branch block and delayed right ventricular electrical depolarization, a similar double-peaked pattern was observed with the first peak in right ventricular pressure corresponding to the peak of pressure generation (dP/dt_{max}) in the left ventricle [20].

As a result, it is estimated that 20–40 % of basal right ventricular power output is attributable to the left ventricle in a structurally normal heart [1]. This clearly may have important implications for the perioperative management of children with congenital heart disease.

Right Ventricular Contributions to Left Ventricular Systolic Function

The right ventricle makes a similar absolute contribution to the left ventricle, but because the pressure in the left ventricle is higher, the relative impact is much less [21]. Left ventricular systolic pressure was shown to drop by 5–10 % when right ventricular contraction is impaired during selective right coronary artery occlusion in animal models [22]. In the same animal model of an electrically isolated right ventricle as previously discussed, Damiano et al. [19] demonstrated a similar right ventricular contribution of ~5 % to left ventricular pressure.

Ventricular interactions must be taken into context of the complex relationship between preload, end-diastolic volume, and myocardial function. In an animal model where preload and afterload conditions were varied, the contribution of the right ventricle to left ventricular performance was increased when the left ventricle was heavily loaded [23]. In a model of right ventricular pressure overload induced by pulmonary artery banding, the sudden release of the pulmonary artery bands in late diastole results in a drop in left ventricular systolic pressure during the next beat despite no change to left ventricular preload, volume, or afterload [24]. The decrease in left ventricular systolic pressure suggests that ventricular interactions are augmented with increased afterload. This was also demonstrated in reverse on left-to-right interactions, with rapid aortic constriction resulting in an increase in right ventricular systolic pressure and contractility [25]. Some of these concepts will be explored later when potential therapeutic implications of intracardiac interactions are discussed.

Diastolic Ventricular Interactions

Diastolic interactions may be manifested as changes during early rapid filling (altered relaxation) or as changes in late diastolic chamber compliance. Evidence for the latter was provided as early as 1910 by Bernheim [26], who noted that venous congestion could be a result of right ventricular compression due to a severely dilated or hypertrophied left ventricle. Such diastolic interaction can occur in both directions and in 1956, Dexter [27] described a "reverse Bernheim effect" where severe right ventricular dilation due to the prolonged left-to-right shunt of an atrial septal defect resulted in bulging of the septum into the left ventricle and poor left ventricular filling. The magnitude of this ventricular interaction is greater with right ventricular dilation affecting left ventricular pressures than the reverse [28].

It is now well established that acute dilation of one ventricle inversely alters the diastolic chamber compliance of the other ventricle [29]. In effect, distention of one ventricle impairs the filling of the other. It is important, however, to distinguish these effects on chamber compliance from altered myocardial stiffness. Chamber compliance is the change in ventricular pressure relative to a change in volume, and when constrained by a common pericardium, an acute change in volume of one chamber will lead to a reduced ratio in the other. This should be distinguished from myocardial stiffness, a function of intrinsic muscle stress–strain relationship. Myocardial stiffness is reflective of the inherent properties (i.e., fibrosis, ischemia, edema), physiologic remodeling (i.e., normal growth), or pathological remodeling (i.e., hypertrophy) [30]. Chronic changes in myocardial stiffness ultimately may have the same effect as acute changes in chamber compliance. As a result of progressive ventricular dilation, the pressure-volume curve of the opposite ventricle becomes steeper and is shifted to the left. This is likely due to alterations in end-systolic septal shape and position due to loading conditions of the opposite ventricle [31].

The diastolic pressure-volume relationship is nonlinear, which has been attributed to different types of structural myofibers and interstitial components being stretched at different pressure-volume ranges [32]. In the low pressure-volume range, there is only a small increase in pressure for an increase in volume, but as the volume increases, the ventricular pressure acutely rises as the stretch is more strongly opposed by rigid fibers and the interstitium. Diastolic dysfunction has largely focused on late diastolic compliance (or restrictive physiology), as reflected in antegrade flow in the pulmonary arteries during end diastole, and is likely driven by impaired myocardial properties and stiffness [33]. Early diastolic dysfunction is becoming increasingly recognized as an important issue in congenital heart disease. Although less well understood, ventricular dyssynchrony is likely a major factor. An extended duration of systole in one ventricle

can reduce time in diastole and adversely affect ventricular filling in the other. The effects of right ventricular pressure loading on left ventricular relaxation will be explored in further detail below.

Structure as a Link to Function and Clinical Correlation

The close ventricular anatomic relationship provides the substrate for ventricular interactions. There have been attempts to relate the structural correlates of function in complex mathematical models, but the interactions can be considered relatively simply in terms of the following: (1) the interventricular septum, (2) the ventricular free walls, and (3) the pericardium.

Septum

The septum is an effective area of force communication between the ventricles. The interventricular septum alters in shape in relation to the transseptal gradient. End-systolic septal shape and position is driven by changes in systolic loading conditions. For example, right ventricular hypertension causes a progressive leftward septal shift in systole and is dependent on the end-systolic transseptal gradient. In diastole, septal shape and position largely reflects relative ventricular volume. Right ventricular volume loading causes leftward shift of the septum in end diastole. The end-diastolic position of the septum has been shown to determine the magnitude and direction of septal motion in systole.

Transseptal interactions are mediated by the wall thickness and subsequently changes in septal wall compliance. Increasing septal wall thickness and decreasing compliance reduces transseptal ventricular interactions. For example, septal hypertrophy, created by chronic right ventricular pressure overload, reduced the effect of right ventricular pressure on the left ventricular pressure-volume relationship. By inducing ventricular hypertrophy (with pulmonary artery banding or renal artery hypertension in instrumented dogs), Little et al. [34] and Slinker et al. [35] demonstrated a significant reduction on ventricular pressure and volume interactions.

Free Walls

The right ventricle wraps around the elliptical left ventricle, which results in shortening of the right ventricular chamber during contraction of the left ventricle. The left ventricle base and apex rotate in opposite directions as the ventricular muscle mass shortens, thickens, and twists along the long axis, which draws the intertwining muscle bundles that bind both ventricles together. As the left ventricle twists, it pulls the right ventricular free wall towards the septum, essentially independent of active right ventricular free wall contraction. Donald and Essex in 1954 [36] destroyed the right ventricular free wall (directly and by coronary ischemia) in dogs and showed no change in exercise capacity. The preservation of right ventricular contraction despite a noncontractile free wall has been further demonstrated in multiple animal model experiments where the right ventricular free wall is severely damaged by induced coronary ischemia [36], cauterization [37], or complete replacement with noncontractile artificial material [38] with little impact on venous pressure and right ventricular output. The movement of the interventricular septum and the noncontractile free wall can displace a significant amount of blood as a result of work generated by the left ventricle.

Hoffman and colleagues in 1994 [39] replaced the entire free wall of the right ventricle of eight dogs with a noncontractile glutaraldehyde-treated bovine pericardial patch and studied the effects of increasing right ventricular volume and pressure overload. The reasonable right ventricular pressure generated at baseline diminished as the right ventricular size was increased (Fig. 51.3). In addition the right ventricular pressure and cardiac output decreased with partial pulmonary artery occlusion. This implies that the left ventricular contribution to right

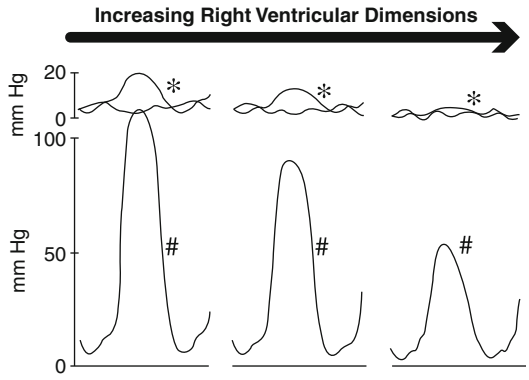

Fig. 51.4 Data from a surgical preparation in which the right ventricular free wall was removed and replaced with a noncontractile pericardial bag, the size of which could be varied (see text for details). Note that the ability of the left ventricle to augment right ventricular pressure (*) is diminished as the "'right ventricle" is increased in size. Interestingly, the left ventricular pressure (#) development also falls as "right ventricular" size increases (Adapted from Hoffman D et al. [39])

ventricular free wall shortening is attenuated with right ventricular dilation or pressure overload (Fig. 51.4).

Pericardium/Thoracic Chamber

As discussed above, the pericardial and extracardiac pressures influence ventricular interactions. Ventricular chamber compliance is directly affected by pericardial pressure.

The pericardium accentuates diastolic ventricular interdependence but may not be as important as an element in systolic ventricular interdependence. Nonetheless, the effects on the circulation as a whole may be profound, as evidenced by the cardiovascular collapse associated with pericardial tamponade and "pseudotamponade" (due to constrictive forces of tissue edema, lung hyperinflation, and chest wall restriction) seen in patients after cardiac surgery.

Atrium and Atrioventricular Synchrony

Intact atrioventricular synchrony contributes to biventricular filling and is an important determinant of systemic output. Synchronized atrioventricular pacing has been shown to increase cardiac output by 15–20 % as compared to isolated ventricular pacing [40]. The value of atrioventricular synchrony has been well established and is a fundamental consideration for optimizing cardiac output.

As previously discussed, atrial volume also plays a role in ventricular interdependence, primarily via acute effects on total cardiac volume, when constrained by the pericardium. It has been shown that changes in atrial volume can alter the amount of ventricular interaction [41]. It is likely therefore, that in the presence of ventricular disease, or when direct ventricular-ventricular interactions are adverse, that changes in atrial volume will exaggerate these acute effects on overall cardiovascular performance. A good example of this is in the immediate post-cardiac transplant period, where right ventricular contractile performance is often undermined. Under these circumstances, cardiac output can be critically dependent on right atrial size, with small increases in preload leading to a rapid reduction in cardiac output. In effect, the transplanted right heart has fallen over the peak of its Starling curve, and sometimes the only effective treatment is venesection, thereby restoring right atrial volume, abrogating the adverse effects on ventricular interactions, and paradoxically increasing cardiac output.

Lesion-Specific Considerations

Right Ventricular Pressure Overload

In response to a distal obstruction, there is an increase in ventricular systolic duration, pressure, and volume and ultimately an increase in end-diastolic volume and a fall in ejection fraction. The right ventricle is especially intolerant of acute changes in afterload. In addition to the effects on the ventricle proximal to the obstruction, there is an effect on the opposing ventricle. Right ventricular dilation due to pressure overload results in distortion to left ventricular geometry, and this has predictable effects on

systolic performance, as discussed above. For example, albeit in a normotensive right ventricular model, Brookes et al. [42] showed that acute right ventricular dilation leads to reduced left ventricular contractility, which was amplified in the setting of an intact pericardium. However in chronic pulmonary hypertension, it is likely diastolic interactions that predominate. Under these circumstances, right ventricular systolic duration lengthens to a point whereby it modifies early diastolic left ventricular relaxation. Indeed, under extreme circumstances, the right ventricle (and hence the septum) remains in systole throughout the period of left ventricular relaxation. As a result, the duration of left (and right) ventricular filling is markedly abbreviated, may occur exclusively with atrial contraction, and in turn limits cardiac output [43]. This is manifested as a reverse A-E ratio in the transmitral Doppler filling pattern. A more direct illustration of this interaction comes from elegant MRI studies performed by Gan [44], Marcus [45], and coworkers in patients with pulmonary hypertension. They showed that cardiac output has only had a weak inverse correlation with the degree of right ventricular dilation and that there was a much stronger correlation with left ventricular end-diastolic dimension. As left ventricular filling was compromised, regardless of the size of the right ventricle, cardiac output fell. Furthermore, they also showed that left ventricular size (and by inference cardiac output) was dependent, as expected form the physiology described above, on R-R interval. As heart rate increased, left ventricular volume fell.

These observations have potential implications for clinical management. In the context of an isolated poorly functioning right ventricle, augmenting left ventricular function may help the right ventricle through ventricular-ventricular interactions. Independent of increased coronary perfusion, increasing left ventricular afterload increases left ventricular systolic pressure, which, through the mechanisms already described, has been shown to improve right ventricular function. Increasing left ventricular afterload by aortic banding, in the context of a well-functioning left ventricle, can improve right ventricular stroke volume in experimental pulmonary hypertension [46]. More recently this phenomenon has been confirmed and expanded upon in experimental models. Apitz and coworkers [47] showed an increase not only in stroke volume but also in right ventricular contractility with aortic banding in the setting of acute right ventricular hypertension. Interestingly, in their model there was a reflex reduction in heart rate associated with aortic banding, obviating the beneficial effects of an increased right ventricular stroke volume on cardiac output. However, they went on to show similar effects on right ventricular contractile performance of systemic vasoconstriction using vasopressin, but this was not associated with a change in heart rate and consequently cardiac output increased.

While these experimental observations are interesting and may represent a therapeutic option under some circumstances, the use of vasoconstrictor therapy in these tenuous circulations cannot be recommended without further clinical validation. Clearly, augmenting left ventricular afterload, in the presence of even occult left ventricular dysfunction, may in itself worsen the cardiac output.

Right Ventricular Volume Overload

Ventricular interdependence is apparent with acute changes in ventricular volume. As discussed, rapid changes in ventricular volume result in immediate changes in opposing ventricular pressure. As opposed to pressure loading, right ventricular volume loading has the opposite effect on left ventricular ejection fraction [48]. There is also ample clinical evidence of left ventricular dysfunction with chronic right ventricular volume overload. Right ventricular volume overload (due to a large atrial septal defect, severe tricuspid regurgitation or pulmonary insufficiency, etc.) will result in an increased right ventricular end-systolic and end-diastolic volume with a normal ejection fraction and a concomitant decrease in left ventricular end-diastolic volume and decrease in left ventricular ejection fraction in children. This is due to septal

shift and altered diastolic configuration contributing to decreased left ventricular distensibility and reduced left ventricular end-diastolic and stroke volume. Compared with age-matched controls, the left ventricular ejection fraction was lower in patients with right ventricular volume overload, even at similar end-diastolic volumes [49]. Clinical validation of this interrelationship has been demonstrated in studies after transcatheter closure of atrial septal defects, where the left ventricular function improves acutely after removal of the right ventricular volume overload [50].

Dilated Cardiomyopathy

We have already discussed the potential for beneficial interactions on acute right ventricular dilation and failure by modifying left ventricular loading conditions, but there may also be ways in which function in the dilated and failing left ventricle may be modified. Changes in cardiac shape, as in a dilated cardiomyopathy, result in abnormalities in orientation of myocardial fibers. A spherical (as opposed to elliptical) ventricle has been shown to have excessive rotation but decrease in linear "twist" and subsequent decreased ejection fraction. The dilated ventricle in a dilated cardiomyopathy generates adverse ventricular interactions, likely as a result of decreased contribution from septal mechanisms and altered muscle fiber orientation. It is unsurprising then that coexisting right ventricular dysfunction in the setting of left ventricular cardiomyopathy markedly worsens survival [51]. Restoring positive ventricular interactions can improve cardiac output. In an animal model of isolated right ventricular dysfunction and dilation as a result of induced coronary artery ischemia, Danton et al. [52] showed the unloading of the dilated right ventricle with a bidirectional cavopulmonary connection (superior vena cava to pulmonary artery connection) resulted in improved left heart performance. Unloading the left or right ventricle in the context of heart failure with a ventricular-assist device also has important implications for improving ventricular interactions and has been shown to result in improved remodeling of the opposing ventricle [53].

Schranz et al. [54] have taken this concept still further. Speculating that increased right ventricular afterload will augment right ventricular contributions to left ventricular ejection, his group has treated children with dilated left ventricular cardiomyopathy by pulmonary artery banding. Although small numbers of patients have been treated and it is difficult to separate an effect of decreased overall ventricular preload, they have showed increased left ventricular ejection fraction and clinical improvement in some patients.

Tetralogy of Fallot

Tetralogy of Fallot is often considered to be a model of chronic right ventricular failure secondary to pulmonary regurgitation and obstruction. However, it is now well described that late after repair of tetralogy of Fallot, there is a progressive decline in left ventricular ejection fraction that has a linear correlation with right ventricular ejection fraction [55]. Overall, up to 20 % of adults after repair have important left ventricular dysfunction [56], and abnormal left ventricular function in the presence of chronic pulmonary insufficiency and right ventricular dilation predicts a worse outcome [57]. Right-left ventricular electromechanical dyssynchrony and residual right ventricular diastolic dysfunction in combination with direct mechanical interactions has been suggested as a cause of the left ventricular dysfunction [58, 59]. The linear relationship between indexed right ventricular end-diastolic volume (by MRI) and left ventricular end-diastolic pressure (measured by catheterization within 6 months of the MRI) supports that right ventricular dilation impairs left ventricular diastolic function [60]. Abnormal left ventricular strain patterns on speckle-tracking echocardiography have been identified [61] suggesting possible subclinical myocardial damage, a known feature of cardiopulmonary bypass post-tetralogy

repair [62]. Specifically, left ventricular radial and circumferential strain were more affected than longitudinal strain, suggesting that ventricular-ventricular interactions with shared subepicardial fibers and circumferential midwall fibers may be more prominent than subendocardial longitudinal fibers [63]. Ventricular dyssynchrony and biventricular dysfunction is amplified with exercise [64].

Going along with these observations, pulmonary valve replacement resulted in improvement in left heart function as demonstrated on magnetic resonance imaging 2–3 years after replacement, especially among those most severely affected [65]. There may also be a subgroup of patients where electrical dyssynchrony between the right and left ventricle drives functional decline. Calabro's group has shown that excessive time delay between the onset of contraction predicts worse exercise performance and a higher likelihood of ventricular arrhythmia late after repair [66]. Resynchronization therapy is being explored for a limited number of patients with decreased function and a wide QRS complex (often in conjunction with an implantable cardiac defibrillator). The acute hemodynamic effects can be positive, and some long-term outcomes in scattered case reports [67] suggest this may be a promising therapy for some of those that do not respond to pulmonary valve replacement. However, the number of patients reported is extremely limited, which prevents drawing more widespread assumptions of benefit at this point [68].

Ebstein's Anomaly

Left ventricular dysfunction is a feature seen in Ebstein's anomaly that has been attributed to abnormal ventricular interactions and geometric deformation. The "atrialized" component of the right ventricle among patients with Ebstein's anomaly is thin walled. After studying seven patients with Ebstein's anomaly with exercise testing, echocardiography, and radionuclide angiography, Benson et al. [69] suggested that the "atrialized" septal wall was displaced leftward during diastole, which reduced left ventricular end-diastolic volume and decreased resting ejection fraction. Preserved exercise capacity is a result of compensation by the left ventricular free wall and paradoxical motion of the septum to augment right ventricular function. Among 539 patients with Ebstein's anomaly operated on at the Mayo Clinic, Rochester, Minnesota, there were 50 patients (9.3 %) with moderate-to-severe left ventricular dysfunction [70]. Although overall left ventricular dysfunction improved after repair or replacement of the tricuspid valve, however, persistent left ventricular dysfunction was a predictor of late mortality [71]. While this might be related to loss of the beneficial effect of left ventricular contraction on right ventricular performance (and vice versa), this is speculative. Furthermore, left ventricular dysfunction may be a result of other factors than ventricular interactions as Ebstein's anomaly has been associated with other left-sided lesions included left ventricular non-compaction, mitral valve prolapse, mitral valve dysplasia, and bicuspid aortic valve [72], and all of these factors may play a role in the overall hemodynamic milieu.

The Systemic Right Ventricle

While much of the discussion has concentrated on the physiologic effects of altered ventricular geometry on myocardial performance and chamber properties of the other ventricle, patients with congenitally corrected (cc-) transposition of the great arteries (TGA) and simple TGA after atrial repair have a unique interaction, whereby changes in geometry may directly affect systemic atrioventricular valve function. That is not to say that myocardial interactions would not be anticipated. It has been shown that among these patients with a systemic morphologic right ventricle, the pressure-volume relationship of the right ventricle resembles the rectangular shape of a morphologic left ventricle with a defined isovolumic contraction and relaxation [73]. This suggests that the pressure-volume relationship

depends on pressure loading conditions rather than on intrinsic properties of the myocardium, and also implies that similar (albeit with differing morphologic substrates) ventricular-ventricular interactions may be at play in these patients (albeit virtually unexplored).

Whereas normal left ventricles twist uniformly clockwise when viewed from apex to base, systemic morphologic right ventricles had disparate regions of alternating twist and regions with no twist between them [74]. Shortening and strain rates differed in a systemic single morphologic right ventricle post-Fontan compared to a systemic biventricular morphologic right ventricle (i.e., post-atrial baffle for TGA). Regional strain, twist, and radial motion differ in the systemic right ventricle with and without a corresponding left ventricle and are different from a normal systemic left ventricle.

It is beyond the scope of this chapter to discuss systemic (morphologically tricuspid) atrioventricular valve dysfunction in detail, but suffice it to say that the natural history of the systemic morphologic right ventricle is related to progressive tricuspid valve failure, usually beyond the third decade of life. Under the physiologic conditions imposed by uncomplicated atrial repair of TGA or repaired cc-TGA, the interventricular septum bows into the subpulmonic left ventricle. This alters the usual ventricular geometry and deforms the subvalvar apparatus of the tricuspid valve resulting in regurgitation. Staged pulmonary artery banding and a double switch procedure (atrial and arterial switch operations) have been suggested to improve long-term outcomes [75], but the results have been disappointing, particularly in terms of left ventricular performance [76]. In addition to "training" the subpulmonary morphologic left ventricle to higher pressures, pulmonary artery banding has the advantage of partially restoring septal position, ventricular geometry, and potentially improving atrioventricular valve regurgitation and may be a destination therapy itself, without progressing to an arterial switch. There remains debate as to the wider utility of such approaches, although for some patients it can be remarkably effective.

Single Ventricle

It seems unusual to review children with "single-ventricle" physiology during a discussion of ventricular-ventricular interactions. A successful Fontan operation in a patient with tricuspid atresia was once used as evidence of an unnecessary right ventricle. Perspectives have changed and strong evidence continues to emerge about the importance of the interactions with the rudimentary chamber and absence of beneficial interventricular interactions for the management and outcomes of these children.

Among children with hypoplastic left heart syndrome, the interventricular septum was recently identified as playing an important role in altering adjoining ventricular morphology and function. Survival of staged palliation among children with hypoplastic left heart syndrome was severely reduced among those with a thick interventricular septum, which may be a result of impaired right ventricular diastolic filling, abnormal coronary blood flow to the hypertrophied hypoplastic left ventricle, or contributed to abnormal ventricular torsion and right ventricular dysfunction [77].

Ventricular mechanics are also altered in the longer term, as demonstrated by Fogel et al. [78] in elegant MRI studies. They showed that the single systemic left ventricle does not "twist" as much as the normal left ventricle. Absence of a right ventricle results in abnormalities of the left ventricular twist. Systolic twist is important for distributing stress, strain, and storage of potential energy for diastolic recoil. This may be a result of altered cardiac muscle fiber orientation. The major influence of the right ventricle on systemic left ventricles is on strain and radial motion of the septal wall. There was lower circumferential shortening strain in the septal wall and a significantly higher measure of stretch. This occurs either as direct effect of right ventricular pressure or a passive effect without a right ventricle to anchor the left ventricle.

Finally, Tanoue et al. [79] showed that patients with a hypoplastic but hypertensive right ventricle and a systemic left ventricle (i.e., patients with pulmonary atresia and intact

ventricular septum) have reduced left ventricular performance compared to those with rudimentary right ventricular chambers in tricuspid atresia. Interestingly, the same group also demonstrated improved left ventricular performance after right ventricular decompression during the Fontan procedure [80].

Conclusions

The ventricles do not function in isolation of each other, and the ventricular interactions are a consequence of the close anatomic relationship between them. Ventricular-ventricular interactions provide insight into cardiovascular responses to disease states in normal and congenitally malformed hearts. It is important to consider abnormalities in ventricular function in relation to the opposite ventricle. Ventricular-ventricular interactions have a major impact on perioperative management and progress in patients with complex congenital heart disease and must be weighed carefully during clinical decision-making. For the future, a better understanding of these sometimes complex interactions may lead to improved risk stratification and directed therapies.

Cardiopulmonary Interactions

52

Ronald A. Bronicki and Daniel J. Penny

Abstract

An understanding of the interactions between the respiratory and circulatory systems is essential for the optimal care of the critically ill patient. In this chapter, the physiological underpinnings of these interactions will be discussed, demonstrating that not only does the respiratory system profoundly impact circulatory performance but also that reciprocal influences exist whereby the circulation powerfully influences respiratory function. It will be shown how these reciprocal interactions are mediated not only through local mechanical influences originating with the thorax but also through centrally mediated neural mechanisms, and some of their important clinical implications will be described.

Introduction

There has long been interest in the interrelationships between the cardiovascular and respiratory systems. Indeed, the Emperor Huang-Ti wrote in "The Yellow Emperor's Classic of Internal Medicine," some 4,000 years before William Harvey described the circulation, that "the lungs are connected to the skin and rule over the heart" [1]. In the very first studies to measure arterial pressure in the early eighteenth century, Stephen Hales observed that the height of the column of blood in the tube used to cannulate the artery varied with respiration. By 1853 Donders had postulated that changes in pleural pressure would have implications for left ventricular filling [2].

However it was not until the 1940s that the systematic study of cardiopulmonary interactions began in earnest. Interestingly it was military rather than medical imperatives that stimulated these studies as it was observed that to maintain adequate oxygenation during high altitude combat flying during World War II, it was necessary for the pilot to breathe 100 % O_2 administered under positive pressure using a tightly fitting mask [3]. The hemodynamic effects of this technique were examined by Fenn, Rahn, and Otis who demonstrated reductions in cardiac output during positive pressure mask respiration [4]. These studies were continued in the post-war era with the Nobel Prize-winning work of Cournand who examined the implications of different modes of positive pressure ventilation on cardiac output and on ventricular transmural pressure [5, 6]. These landmark studies heralded the modern era of investigation beginning with the work of Guyton and others [7, 8].

In this review, the current concepts of the interrelationships between respiratory and circulatory function will be discussed, exploring not only how the lungs impact cardiovascular performance but also how the circulation can have profound effects on respiratory function. These interactions occur both as a consequence of the mechanical relationships between the heart and lungs within the thorax and also through centrally mediated neural mechanisms.

Basic Mechanisms

Pressure–Volume Relationships

The fundamental property of an elastic structure is its ability to offer resistance to a distending or collapsing force and to return to its resting volume after the force has been removed. The extent to which a structure undergoes a change in volume depends on the compliance of the structure and the magnitude and direction of the pressure exerted across the wall (the transmural pressure, Ptm). Compliance is the ratio of change in volume to change in pressure and is inversely related to elastance. The Ptm is equal to the difference between intra- and extracavitary pressures, where a positive Ptm distends the cavity and a negative Ptm causes the structure to reduce in size.

Pressure–Flow Relationships

The physical principles that govern the flow of fluids (liquid or air) through conducting passages, such as vessels and airways, whether rigid or collapsible, are derived from the general laws of hydrodynamics. The behavior of flow (Q) through a collapsible tube depends on the inflow pressure (Pi), the outflow pressure (Po), the pressure surrounding the tube (Ps), the Ptm, and the compliance of the structure (Fig. 52.1). When the tube has a positive Ptm throughout, the tube is widely patent and Q is proportional to the pressure gradient Pi–Po (corresponding to zone III conditions). With a constant Pi and Po, as the Ps increases, the Ptm decreases. As a result, the volume of the tube decreases, its pressure increases, and volume is translocated from this compartment to the next compartment. Resistance to flow increases and flow is proportional to the pressure gradient Pi–Ps (zone II conditions). As Ps increases further, the Ptm becomes negative, the tube collapses, and resistance to flow increases further (zone I conditions).

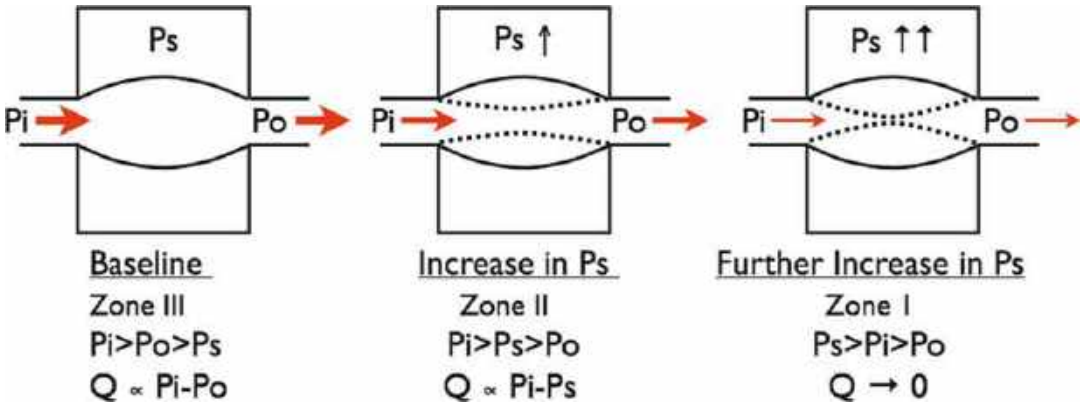

Fig. 52.1 *The principles which govern the flow of fluid through a collapsible tube*. *Pi*, *Po*, and *Ps* represent inlet, outlet, and surrounding pressure respectively. As low levels of Ps, the magnitude of flow through the tube is principally governed by the difference between Pi and Po (zone III conditions). If Ps is increased above Po, flow is governed by the difference between Pi and Ps (zone II conditions). Further increases in Ps to levels greater than Pi result in cessation of flow

The Effects of Respiration on Cardiovascular Function

There has been considerable interest over the past 50 years in the mechanisms whereby respiratory function can influence circulatory performance. It is now appreciated that this powerful influence is of considerable clinical significance, particularly in the mechanically ventilated. It is also recognized that it is mediated through multiple interrelated physiological mechanisms.

The Effects of Respiration on Right Ventricular Preload

Venous return is dependent upon the pressure gradient between the extrathoracic venous system and right atrium (RA) and is inversely related to the resistance to venous return. Resistance to venous return is affected by extremes in blood viscosity and increases slightly with adrenergic stimulation [9–11]. Otherwise, this pressure gradient is the determinant of venous return and, under most conditions, cardiac output (CO). The pressure within the systemic venous bed is the upstream driving pressure for venous return and is thought to be equal to the mean systemic pressure (Pms) [12]. The Pms is derived by stopping the circulation and allowing blood to redistribute and the pressures throughout the circulation to equilibrate. The Pms is a function of blood volume and capacitance of the systemic circulation. The systemic venous circulation is 18 times more compliant than the systemic arterial circulation and has much greater capacitance, so that the majority of intravascular volume resides with the venous circulation, specifically within the splanchnic, splenic, and hepatic venous reservoirs [13].

When Pra rises, a compensatory increase in Pms must occur if venous return is to be maintained. As Pra increases by 1 mmHg, venous return decreases by 14 % in the absence of circulatory reflexes, and as Pra increases further and approaches Pms, venous return ceases unless compensatory circulatory reflexes restore an adequate upstream driving pressure for venous return (Fig. 52.2). Compensatory increases in Pms result from increases in intravascular volume and decreases in venous capacitance. Based on studies in dogs, the relationship between intravascular volume and Pms has been found to be linear while the relationship between venomotor tone and the Pms is curvilinear [14, 15]. With removal of all vasomotor tone, the Pms falls from 7 to 5 mmHg; stimulating a Cushing reflex and

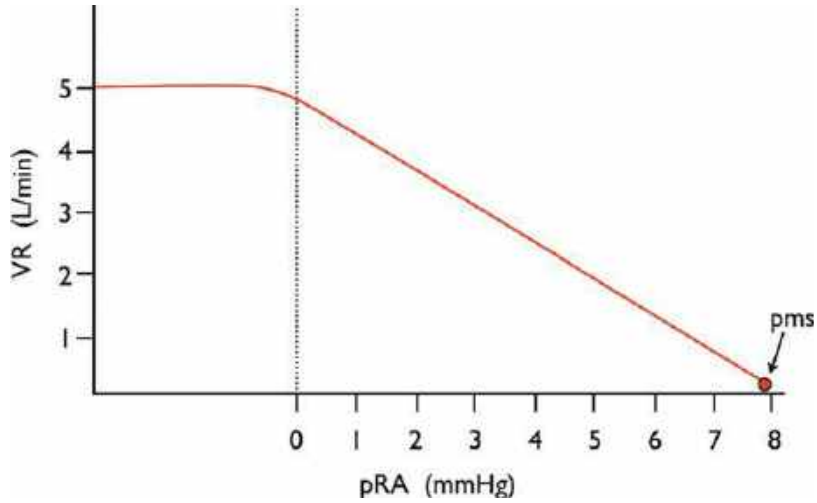

Fig. 52.2 *The theoretical relationship between right atrial pressure (Pra) and venous return (VR)*. VR achieves a plateau as Pra falls below zero. This is because the vena cava collapses as it enters the thorax and zone I conditions occur. *Pms* represents mean systemic pressure

norepinephrine and epinephrine infusions raise the Pms, plateauing between 15 and 19 mmHg.

Acutely, as Pra increases vasoconstriction of venous capacitance vessels (primarily mediated by catecholamines, angiotensin, endothelin-1, and vasopressin) reduces their compliance and increases the Pms, while mobilizing blood from the peripheral circulation to the thorax [12, 13, 16]. Thus, the function of venous capacitance vessels is essential to acutely maintaining an adequate Pms. This response is complemented over time by the antidiuretic effects of vasopressin and by stimulation of the renin–angiotensin–aldosterone system [17]. As the Pms decreases, venous return invariably decreases. For example, furosemide exerts a direct and immediate vasodilatory effect on venous capacitance vessels, causing venous return to diminish [18]. Similarly, the inflammatory response characteristic of sepsis causes vasomotor paresis, as well as an increase in vascular permeability, both of which lower the Pms.

Changes in intrathoracic pressure (ITP) affect Pra by altering the RA Ptm. During spontaneous inspiration, the decrease in intrapleural pressure causes the RA Ptm to increase. As a result, the right atrium distends, its pressure decreases, and venous return is augmented. As the diaphragm descends, intra-abdominal pressure increases and the Ptm for the intra-abdominal venous capacitance vessels decreases. This effectively decreases the compliance of these vessels and their pressure raises, thereby increasing the longitudinal pressure gradient for venous return from the inferior vena cava [19, 20]. Thus, during inspiration, venous return from the inferior vena cava is increased due to a decrease in Pra and an elevated inferior vena cava pressure. This is in contrast to venous return from the head and neck vessels, which are exposed to atmospheric pressure.

Venous return increases as Pra decreases and then plateaus. The negative ITP generated during inspiration is transmitted to the RA and to the veins as they enter the thorax. And when the vascular Ptm becomes negative at the thoracic inlet, as may occur with maximal inspiration or during a Mueller maneuver, the veins collapse limiting venous return (zone I, II conditions, Fig. 52.1) [21]. Further decreases in Pra have no effect on venous return because flow is now a function of the difference between Pms and atmospheric pressure or abdominal pressure. When the outflow or downstream pressure is elevated, as in heart failure and pericardial tamponade, the Ptm of the veins at the thoracic inlet remains positive even with marked decreases in ITP. In this instance, venous return is limited by the outflow pressure (zone III conditions).

Positive pressure ventilation (PPV) decreases the RA Ptm and Pra increases. As a result,

the pressure gradient for venous return decreases. It is important to recognize that the increase in Pra results from an increase in ITP and a reduction in RA volume. It may seem counterintuitive that an increase in Pra causes venous return to decrease because Pra is considered a surrogate for RV volume. However, as ITP changes, it is the change in the RA Ptm that governs venous return. The same holds true for volume expansion. For venous return to increase, Pms must increase to a greater extent than does Pra. In this instance, the increase in venous return causes the Pra and therefore the RA Ptm to increase. Whether it is due to a change in ITP or intravascular volume, it is the effect of these interventions on the RA Ptm and the pressure gradient Pms–Pra that determines venous return [22].

During PPV, the increase in ITP causes the diaphragm to descend, and the resulting increase in intra-abdominal pressure decreases the compliance of abdominal venous capacitance vessels. This contributes to a compensatory increase in Pms. The extent to which venous return is affected by PPV depends on where the ventricle resides on its pressure–volume curve, the adequacy of the circulatory reflexes to maintain Pms, and on the degree to which alveolar pressure is transmitted to the cardiac fossa. While PPV increases lung volume by increasing airway pressure, the degree to which lung volume and ITP increase is a function of respiratory mechanics [23].

Ultimately, right ventricular filling is a function of ventricular diastolic Ptm, ventricular compliance, and venous return [24]. A noncompliant ventricle or one surrounded by increased ITP requires a higher than normal intracavitary pressure to achieve a normal end-diastolic volume (Fig. 52.3).

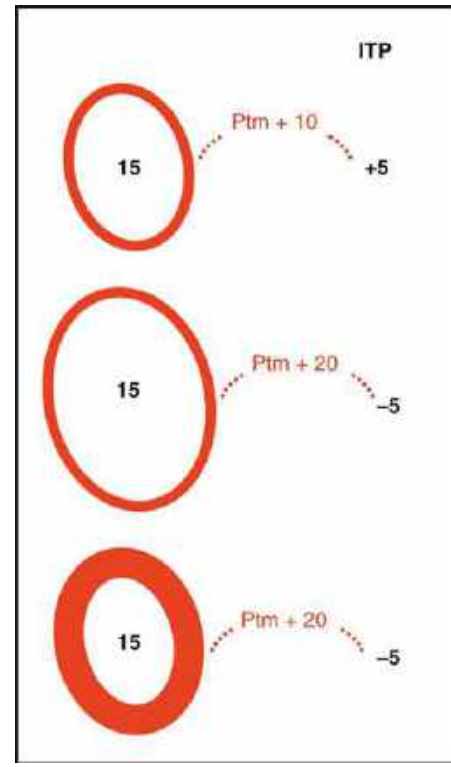

Fig. 52.3 *The effect of alterations in intrathoracic pressure (ITP) and ventricular compliance on ventricular filling*. Ventricular filling pressure is constant (15). During positive pressure ventilation (*upper panel*), intrathoracic pressure is +5 and the transmural distending pressure (Ptm) is +10. During negative pressure ventilation, the ventricle is more distended because Ptm is +20 (*middle panel*). In the *bottom panel*, the Ptm is also 20, but the ventricle fills to a lesser extent because it is less compliant

The Effects of Respiration on Right Ventricular Afterload

Respiration affects pulmonary vascular resistance (PVR) by altering carbon dioxide levels and blood pH, alveolar oxygen tension, and lung volumes. Respiratory and metabolic alkalosis cause pulmonary vasodilation, while acidosis causes vasoconstriction. Alveolar hypoxia constricts pulmonary arterioles, diverting blood flow from poorly ventilated to well-ventilated alveoli. This improves the matching of ventilation to perfusion, thereby improving oxygenation.

By applying the laws of hydrodynamics, one can appreciate the effects of changes in lung volume on PVR (Fig. 52.4). It is not the absolute change in ITP that affects PVR but rather the transpulmonary pressure gradient (alveolar pressure–intrapleural pressure) and the resulting change in alveolar volume. Functional residual capacity (FRC) is the lung volume from which normal tidal volume breathing occurs. PVR is lowest near FRC and increases at both high and

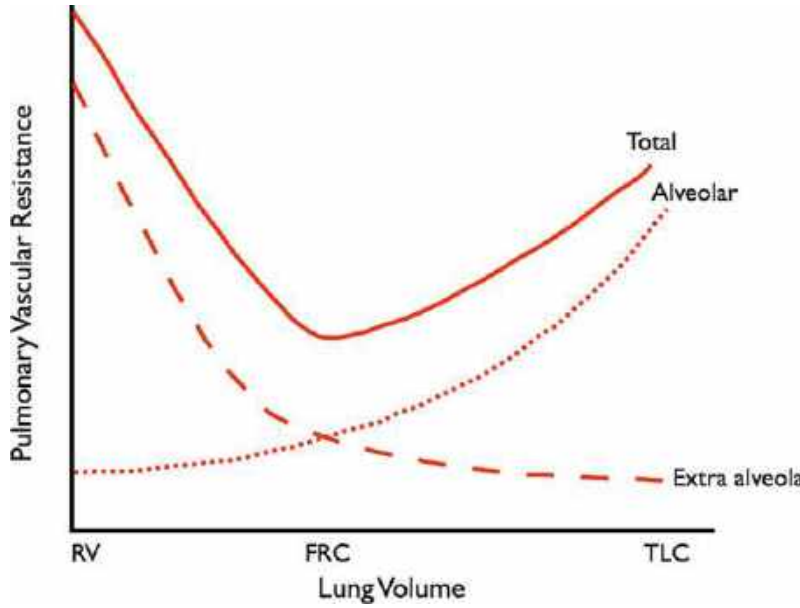

Fig. 52.4 *Changes in pulmonary vascular resistance as lung volume is altered*. Resistance is lowest at lung volumes around functional residual volume (*FRC*). At higher levels of distension pulmonary vascular resistance is increased because of compression of alveolar vessels, while resistance is increased at low volumes due to compressions of extra-alveolar vessels

low lung volumes. The pulmonary vascular bed consists of alveolar and extra-alveolar vessels. Alveolar vessels lie within the septa, which separate adjacent alveoli. Alveolar pressure is the surrounding pressure for these arterioles, capillaries, and venules. Extra-alveolar vessels are located in the interstitium and are exposed to intrapleural pressure.

As lung volume decreases below FRC, the radial traction provided by the pulmonary interstitium diminishes, leading to a decrease in the cross-sectional area of the extra-alveolar vessel. In addition, at low lung volumes, alveolar collapse leads to HPV and further increases in the resistance of extra-alveolar vessels. Despite a decrease in the resistance of alveolar vessels (the Ptm for the alveolar vessel increases as alveolar pressure falls), the net effect is a marked increase in PVR at low lung volumes. As lung volume rises above FRC, PVR increases. Large tidal volumes or tidal volumes superimposed on an elevated FRC significantly increase PVR, as the alveolar Ptm increases, distending alveoli and compressing alveolar vessels. While either positive or negative pressure ventilation provides radial traction, thereby increasing interstitial volume and decreasing interstitial pressure, the net effect is a marked increase in PVR as lung volumes approach total lung capacity.

By applying the laws of hydrodynamics for a collapsible tube to the pulmonary circulation, one can further appreciate the effects that changes in lung volume have on PVR, as well as how these changes affect the regional distribution of pulmonary blood flow. The Pi is pulmonary arterial pressure (Ppa), the Ps is alveolar pressure (Palv), and the Po is pulmonary venous pressure (Ppv). In the pulmonary circulation, there is a vertical hydrostatic pressure gradient from most dependent to most superior portions of the lung. Because the weight of air is negligible, there is no measurable vertical gradient for Palv.

In the more gravity-dependent regions of the lung, Ppa and Ppv are greater than Palv and the Ptm for the alveolar vessel is positive throughout. In this instance, flow is proportional to the pressure gradient between Ppa and Ppv (i.e., zone III conditions). In regions of the lung where Palv exceeds Pv and Ppa $>$ Palv, the alveolar vessel is compressed as its Ptm decreases. In this region, resistance to blood flow increases, and blood flow is governed by the difference in pressure between Ppa and Palv (i.e., zone II conditions). And when Palv exceeds Ppa, the vascular Ptm is negative

and the alveolar vessel collapses and blood flow ceases (i.e., zone I conditions).

In the absence of cardiopulmonary disease, zone I conditions do not exist; however, they may be present in a variety of clinical scenarios. In addition to increases in Palv, zone I conditions may be created when CO and Ppa are low. Conversely, an increase in Palv may not create alveolar dead space if, for example, pulmonary venous hypertension is present as in congestive heart failure. Further, in the congested state, zone III conditions predominate and alveolar distension leads to the propulsion of pulmonary blood and an increase in pulmonary venous return [25, 26].

The Effects of Respiration on Left Ventricular Preload

Respiration affects left ventricular preload by altering right ventricular preload, afterload, and the effective compliance of each ventricle. As discussed, during spontaneous respiration, the fall in ITP increases the gradient for venous return and RV filling. As a result, RV diastolic volume and pressure increase. The intraventricular septum (IVS), which normally bows into the RV because LV pressures are greater than RV, occupies a more neutral position between the two ventricles during diastole (Fig. 52.5). The LV is restrained not only by the deviated septum and RV pressure but also its free wall is constrained by the pericardium and distended alveoli. This effectively decreases its compliance. Even though LV filling pressures are elevated, the intrapericardial pressure has risen to a greater extent, and the net effect is a reduction in LV diastolic Ptm, cavitary volume, filling, and stroke volume [27]. The mechanism by which the filling of one ventricle affects the filling of the other is known as diastolic ventricular interdependence and is in part responsible for pulsus paradoxus, the fall in systemic pressure during inspiration [28].

The effect of PPV on LV preload depends on the extent to which the gradient for venous return is compromised and where the ventricle resides on its pressure stroke volume curve and on the extent to which RV afterload is increased.

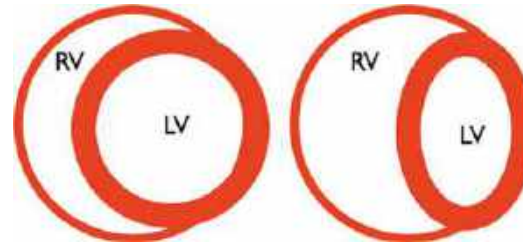

Fig. 52.5 *Ventricular interdependence*. Under normal conditions the ventricular septum is oriented such that the left ventricle (*LV*) in its *short axis is circular*. Under conditions when the pressure in the right ventricle (*RV*) is elevated, the septum is displaced to the left, LV volume falls and its filling is impaired

The RV has less contractile reserve than the LV, rendering it sensitive to PPV-induced increases in PVR. The combined effect of reduced RV output and diastolic ventricular interdependence lead to reduced LV filling and stroke volume. Further, as LV filling decreases, its pressure-generating capabilities are diminished. This adversely affects RV output, as LV contraction contributes to RV pressure generation and ejection [29]. This decrease in LV assistance to RV function leads to greater increases in RV volumes, further compromising LV filling. This phenomenon is referred to systolic ventricular interdependence. Ultimately, the extent to which the LV fills is a function of pulmonary venous return, ventricular diastolic Ptm, and its compliance (Fig. 52.3).

The Effects of Respiration on Left Ventricular Afterload

Respiration has a profound effect on left ventricular afterload. As ITP varies, so too does the Ptm for the intrathoracic vascular structures. On the arterial side, changes in the Ptm for the intrathoracic arterial system alter the driving pressure for propelling blood from the thorax. While the right atrium and vena cava are much more compliant than the arterial vessels, it is the compliance and Ptm for the arterial vessels that determine the extent to which changes in ITP affect LV afterload [30, 31].

According to Laplace's law, the systolic Ptm is an important determinant of left ventricular

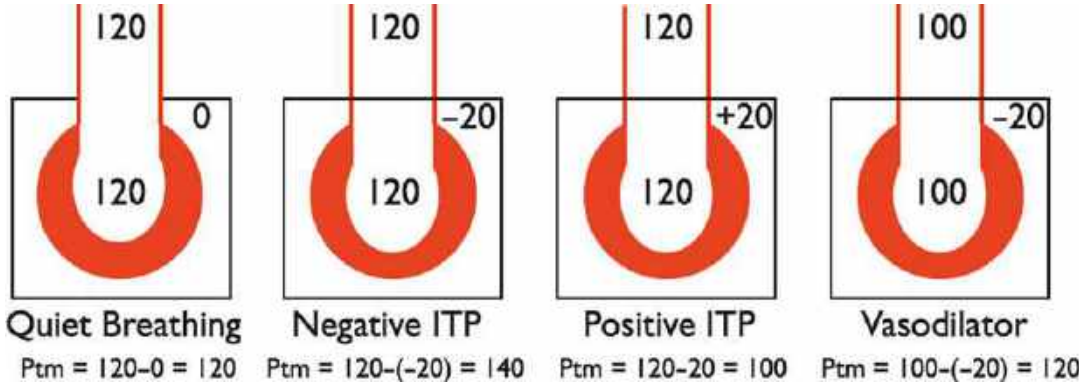

Fig. 52.6 *Theoretical relationship between intrathoracic pressure and left ventricular afterload*. During periods of quiet breathing in which intrathoracic pressure (*ITP*) is 0, the transmural pressure is equal to left ventricular pressure (120) (*left-hand panel*). When ITP is negative the distending pressure is increased and wall stress within the ventricle is elevated. The opposite occurs when ITP is positive. The increase in distending pressure imparted by a negative ITP can be reversed by vasodilator treatment, which restores distending pressure to baseline levels (*Right-Hand Panel*)

afterload and may be calculated by taking the difference between peak left ventricular cavitary or aortic systolic pressure and ITP. Thus, as ITP falls during spontaneous inspiration, or aortic systolic pressure rises, LV afterload increases (Fig. 52.6). Positive ITP, which occurs with grunting, and with the application of PPV, produces a reduction in LV afterload [32].

During spontaneous inspiration, the fall in ITP during ventricular diastole causes the Ptm for the intrathoracic arterial vessels to increase. As a result, their volumes increase and their pressures decrease, causing a decrease in antegrade flow runoff and an increase in intrathoracic aortic blood volume for the subsequent LV ejection. A fall in ITP during ventricular systole decreases the egress of blood from the thorax as well as decreasing LV ejection, contributing to the fall in aortic systolic pressure. This represents the systolic component of pulsus paradoxus [33].

With PPV, the decrease in Ptm for the intrathoracic arterial vessels decreases their effective compliance. As a result, their volumes decrease and their pressures increase relative to extrathoracic arterial vessels, creating a waterfall-like effect and driving blood into the extrathoracic compartment [34]. An increase in ITP therefore unloads the LV while increasing aortic pressure ("reverse pulsus paradoxus"). Even though aortic pressure increases, the LV Ptm has decreased, as intrapleural pressure has risen to a greater extent than aortic pressure. If the increase in ITP is confined to diastole, the LV ejects into a relatively depleted thoracic arterial system, while a selective increase in ITP during ventricular systole augments left ventricular ejection. Both the magnitude of the rise in ITP and its duration, as well as its timing, affect aortic flow. An increase in ITP timed to ventricular systole has a greater affect on CO than one timed to diastole, as the pressure gradient for venous return is unaffected by changes in ITP limited to ventricular systole [35, 36].

Clinical Implications of the Respiratory Influences on Cardiovascular Performance

Understanding the physiologic principles that govern the effects of respiration on cardiovascular function is essential to optimizing the care of critically ill patients. Particular consideration must be given to the interaction between

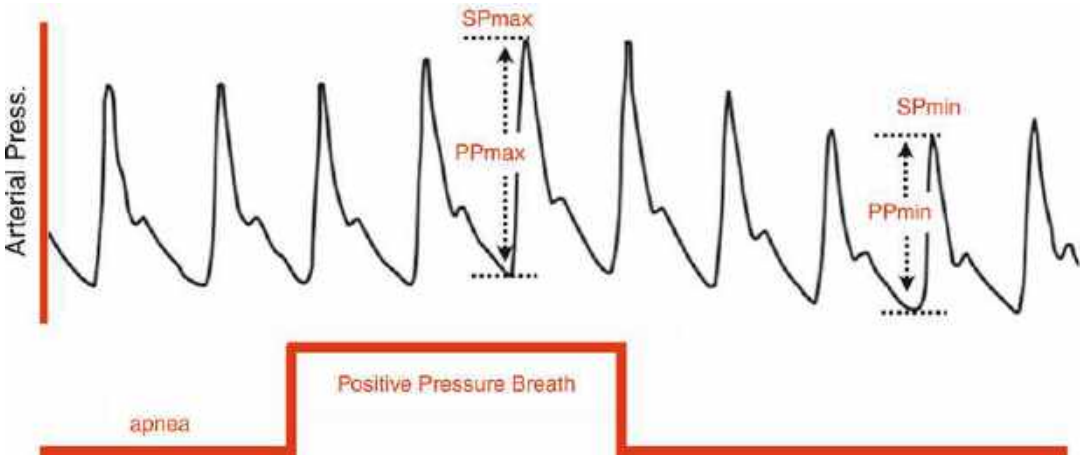

Fig. 52.7 *Variation in arterial pressure during a positive pressure breath. SPmax* and *SPmin* denote maximal and minimal systolic arterial pressure, while *PPmax* and *PPmin* represent maximal and minimal pulse pressures

respiration and right and left ventricular loading conditions; diastolic and systolic ventricular interdependence is a factor to right and left ventricular diastolic and systolic function.

Systolic Pressure Variation and Pulse Pressure Variation as an Indicator of Volume Status

Optimizing intravascular volume is key to the maintenance of ventricular preload and in turn CO in the critically ill patient. Examination of the variation in arterial pressure that occurs during PPV has been shown to be highly predictive of fluid responsiveness [37].

From an apneic baseline, during PPV, the systolic arterial pressure rises due to the effects of an increase in ITP on the thoracic arterial vessels. The rise in systolic pressure is referred to as the "maximum systolic pressure." After a cardiac cycle or two, the systolic pressure decreases, falling below the apneic baseline (Fig. 52.7). This is due to the effect of an increase in ITP on the right heart [38]. The fall in systolic pressure is referred to as the "minimum systolic pressure." The pressure gradient between the maximum and minimum systolic pressure is the systolic pressure variation.

Studies have demonstrated that the greater the systolic pressure variation, the more likely the patient is to be fluid-responsive [37]. If the circulation responds favorably to volume, the initial PPV-induced increase in systemic pressures increases further and the subsequent decrement in systemic pressures lessens or is abolished. Because the right atrium is much more compliant than the intrathoracic arterial system, the effects of changes in ITP have a much greater effect on venous return than LV afterload. Thus, the primary mechanism responsible for a PPV-induced systolic pressure variation is a decrease in venous return and corresponding changes in the minimum systolic pressure rather than changes in the maximum systolic pressure.

The Patient with Left Ventricular Systolic Dysfunction

Systolic heart failure is characterized by small stroke volume and low CO despite elevated ventricular volumes and pressures. Cardiogenic pulmonary edema reduces lung compliance and leads to exaggerated negative ITP and increase in LV afterload in spontaneously breathing patients, further impairing cardiovascular function. Cardiopulmonary distress stimulates

neurohormonal systems, further increasing LV afterload. Rasanen and colleagues found that extubation from PPV to spontaneous respiration adversely affected myocardial oxygen transport and function in patients with acute myocardial infarction complicated by respiratory failure, resulting in ischemia and elevation of LV filling pressure [39]. Scharf and colleagues demonstrated acute LV regional akinesis during a Mueller maneuver in patients with preexisting LV dysfunction [40].

In patients with LV systolic dysfunction, the beneficial effects of a positive ITP on LV afterload predominate over the effects on venous return, so long as an adequate albeit elevated ventricular filling pressure is maintained [41–43].

Thus, PPV has a favorable impact not only on CO but also on myocardial energetics, as it reduces LV end-diastolic volume and systolic Ptm by eliminating exaggerated negative pressure breathing. Further, by unloading the respiratory pump, CO is redistributed from the respiratory apparatus to other vital organs, while decreasing circulatory demand.

An additional consideration is the use of noninvasive PPV in patients with heart failure and LV dysfunction, as studies in adults with acute cardiogenic pulmonary edema have shown a significant reduction in the need for intubation and early mortality with the institution of this supportive modality [44, 45]. Haruki and colleagues demonstrated that the prolonged use of noninvasive ventilation for at least 4 h per day for 6 months led to ventricular remodeling and improved ventricular diastolic and systolic function in patients with chronic heart failure [46].

Left Ventricular Diastolic Dysfunction

Diastolic heart failure is characterized by small stroke volumes and low CO, which results from inadequate ventricular filling. Thus, the function of venous capacitance vessels and the affects of changes in ITP on circulatory function are of great importance, as has been demonstrated in patients with diastolic dysfunction resulting from a number of causes. Hypertrophic cardiomyopathy is characterized by diastolic dysfunction and the development of diastolic heart failure. In these patients, PPV-induced decreases in venous return are poorly tolerated. Further, by decreasing LV preload and afterload, PPV may, if the substrate for an obstruction to LV outflow is present, create or exacerbate an intracavitary obstruction by reducing LV operating volumes [47].

Right Ventricular Diastolic Dysfunction

The effects of ventricular loading conditions in the setting of diastolic disease are exemplified in the postoperative management of patients following repair of tetralogy of Fallot. In these patients, biventricular systolic function is normal; however, RV diastolic dysfunction is common, and in approximately one third of these patients, restrictive RV physiology has been demonstrated in the immediate postoperative period [48]. Restrictive physiology is characterized by antegrade pulmonary blood flow resulting from atrial systole. Shekerdemian and colleagues demonstrated a significant increase in cardiac output when patients were converted from PPV to negative pressure ventilation (NPV) [49]. This favorable response is the result of an increase in venous return and the effective compliance of the RV, the generation of diastolic forward pulmonary arterial flow, and potentially the result of a shortening of the time available for pulmonary regurgitation. Although converting from PPV to NPV improves CO in these patients, it is unclear if global and regional oxygen transport balance improves when CO is limited and the respiratory pump is loaded. In support of the proposed benefit of establishing spontaneous respiration, early after tetralogy of Fallot repair was our observation of a significant improvement in cerebral oxygenation immediately after extubation [50]. In a subsequent study, it was demonstrated that although extubation led to a significant increase in CO and cerebral oxygenation, the metabolic cost of loading the respiratory musculature came at some expense in terms of mesenteric perfusion [51].

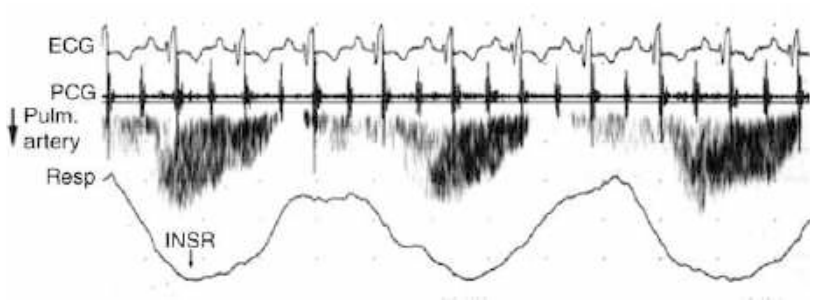

Fig. 52.8 *Doppler examination of flow into the pulmonary artery in a patient with a cavopulmonary shunt*. Inspiration (a downward deflection on the respirometer (*resp*)) is associated with a surge in blood flow into the pulmonary artery. *ECG* electrocardiogram, *PCG* phonocardiogram (Used with permission from Redington et al. Br Heart J 1991; 65: 213–217)

Although NPV is rarely used in the postoperative care of patients with RV diastolic dysfunction, the aforementioned data highlighted the impact of changes in ITP on RV performance in this setting. Consistent with these observations, a more recent study demonstrated that airway pressure release ventilation, which minimizes the increase in ITP by permitting spontaneous respiration without pressure support throughout the ventilator cycle, significantly increased CO in patients following repair of TOF when compared to conventional PPV [52].

The Patient After Cavopulmonary Anastomosis or Fontan Operation

Following Fontan-like operations, the transpulmonary pressure gradient is the difference between the central venous pressure (which is equal to the pulmonary artery pressure) and the pressure in the pulmonary venous atrium. As there is no subpulmonic pumping chamber to overcome the resistance of the pulmonary circulation, pulmonary blood flow is a passive phenomenon which is acutely influenced by small changes in ITP and transpulmonary gradient. Systolic function is generally normal while there is invariably some degree of ventricular diastolic dysfunction, with incoordinate wall motion further compromising ventricular filling [53, 54]. For these reasons, the function of venous capacitance vessels is of great importance, and the effects of changes in ITP on venous return predominate over its effects on afterload of the systemic ventricle.

In spontaneously breathing Fontan patients, Redington and colleagues previously demonstrated using pulsed wave Doppler flow analysis a marked increase in pulmonary blood flow during normal inspiration and further increases with the Mueller maneuver (Fig. 52.8) [55]. Shekerdemian and colleagues demonstrated a marked increase in pulmonary blood flow when patients were changed from PPV to NPV using a cuirass immediately following the Fontan procedure [56]. Conversely, the Valsalva maneuver-generated retrograde flow (away from the lungs) and cavitary size were significantly reduced. These maneuvers demonstrate the effects of changes in ITP without an attendant change in lung volume and PVR. Williams and colleagues demonstrated a stepwise reduction of cardiac output with increasing levels of PEEP in children after the Fontan operation [57].

In the immediate postoperative period, stimulation of neurohormonal pathways leads to a compensatory increase in venous pressures. Several studies have also demonstrated adaptive changes taking place over time in the peripheral circulation that serve to maintain venous return. Krishnan and colleagues studied patients remote from surgery and found significantly reduced venous capacitance compared with age-matched controls, as well as significantly

elevated microvascular filtration pressures and filtration thresholds [58]. A further example of the vulnerability of the Fontan circulation to factors that compromise venous return is the hemodynamic consequence of hemi-diaphragmatic paralysis. Inspiration and diaphragmatic descent increase intra-abdominal pressure, decreasing the Ptm of intra-abdominal venous capacitance vessels and contributing to the longitudinal pressure gradient for systemic venous return. Phrenic nerve injury following the Fontan procedure and resulting hemi-diaphragmatic paresis would be expected to compromise venous return from the largest venous reservoir. Indeed, several studies have demonstrated reduced hepatic venous flow during inspiration, and portal venous flow loses its normal expiratory augmentation in patients with hemi-diaphragmatic paralysis [59]. In these patients, hemi-diaphragmatic plication only partially restores sub-diaphragmatic venous return, as this does not compensate for the loss of diaphragmatic descent during spontaneous breathing.

The Interaction Between Respiration and Cardiopulmonary Resuscitation

Effective CPR depends on adequate venous return to the heart after each compression cycle, and the advent of mechanical devices that enhance venous return has been an area of investigation for the last several years [60]. One such device is the inspiratory impedance threshold valve (ITV). During the decompression phase of CPR, a negative ITP is created as the chest wall recoils back to its resting position. This creates a pressure gradient for systemic venous return. The ITV prevents the inflow of gas during the decompression phase, generating a greater negative ITP in a manner akin to the Mueller maneuver. Several studies in animals have demonstrated a significant increase in stroke volume and CO, including a significant increase in myocardial and cerebral perfusion, with the use of the device [61].

The Effects of Circulatory Performance on Respiratory Function

In the examination of cardiopulmonary interactions, it is entirely appropriate that the greatest emphasis has been on the impact of respiratory mechanics on cardiovascular function. It must also be noted that such interactions exist in the reverse direction; in other words, cardiovascular function may significantly influence respiratory function. There has been an increasing interest in the physiological and pathological implications of these influences.

The Effects of Pulmonary Capillary Pressure on the Movement of Fluid Within the Lung

The maintenance of an optimal balance between forces that drive water from the pulmonary capillaries into the airspace and the mechanisms for its removal is essential for the avoidance of pulmonary edema. Under normal circumstances, fluid escaping from the pulmonary capillaries into the interstitium does not enter the alveolar airspace because of the tight alveolar epithelial barrier. Furthermore, fluid is transported across the alveolar epithelium from the airspace through energy-consuming sodium and chloride transport processes [62].

One of the dominant forces that regulate pulmonary fluid balance is microvascular pressure, such that the movement of fluid between the vascular bed and the interstitium is determined by the Starling equation, represented by the following equation:

$$J_V = K[(Pc\text{-}Pi) - \sigma(\pi c - \pi i)]$$

where J_v is net transvascular fluid flux; K is the permeability constant of the membrane; Pc and Pi are the capillary and interstitial hydrostatic pressures, respectively; $\boldsymbol{\sigma}$ is the reflection coefficient; and πc and πi are the plasma protein osmotic

pressure in the capillaries and the interstitium, respectively.

The healthy lung is protected from the effects of elevations in microvascular pressure by a number of factors, including a reduction in interstitial osmotic pressure because of entry of dilute fluid into the interstitial space, the considerable capacitance of the interstitial space, and the reserve flow capacity of the pulmonary lymphatic system. These factors protect the normal lung against the development of edema for microvascular pressures up to approximately 21 mmHg. However, in conditions associated with increased capillary permeability, alveolar fluid accumulation will occur at lower pressures.

The Effect of Pulmonary Microvascular Perfusion on Lung Mechanics

Acute changes in pulmonary microvascular perfusion may have profound effects on respiratory system mechanics. In an isolated lung model, the elastance of the lung was significantly higher when perfusion to the lung was arrested [63]. Furthermore, in a study of the effects of an abrupt cessation of pulmonary flow (during pulmonary balloon valvuloplasty) on respiratory function in children, inflation of the balloon resulted in an immediate increase in respiratory system resistance and a reduction in compliance [64]. The underlying mechanism for this phenomenon remains to be defined. It is of interest that more than a century ago it was suggested that the perfused pulmonary capillary bed may have some of the features of erectile tissue, which would splint the alveoli open [65]. This hypothesis is consistent with the observation of alterations in the orientation of elastin fibers in the alveolar septa of unperfused lungs, which may adversely influence lung compliance.

Oxygen Delivery to the Respiratory Muscles

Under normal conditions, the diaphragm consumes less than 3 % of global oxygen delivery (DO_2) and receives less than 5 % of CO. However, with an increase respiratory load, diaphragmatic oxygen demand may increase to over 50 % of the global oxygen consumption (VO_2) [66]. In order to meet these increased demands, diaphragmatic blood flow must increase. When diaphragmatic oxygen transport balance is inadequate, either because of excessive oxygen requirements or limited DO_2, respiratory pump failure may ensue.

Clinical Implications of the Effects of Circulatory Performance on Respiratory Function

The Effect of Heart Failure on Respiratory Pump Function

Respiratory pump failure occurs when neuromuscular competency of the ventilatory pump is impaired, when the load imposed on the respiratory system is excessive, or when respiratory muscle oxygen transport balance is impaired. The benefits of mechanical ventilation under these circumstances are well documented. In the presence of heart failure, respiratory function is often impaired through the effects of increased left atrial pressure and lung water on lung compliance and further exacerbated by the cardiopulmonary interactions already described, resulting in an increase in load on the circulatory and pulmonary systems. This can result in derangement of respiratory muscle oxygen balance, where the increased oxygen demands may not be adequately met by a failing circulation. Aubier and colleagues demonstrated in a dog model of cardiogenic shock that the ability of the diaphragm to generate force was similar to that for ordinary quiet breathing [67]. Mechanical ventilation plays a vital role in the management of heart failure not only by improving CO, myocardial energetics, and respiratory pump function but also through improving global oxygen transport balance [68]. Viires and colleagues demonstrated that in a low-CO state, animals receiving mechanical ventilation had significantly greater

organ perfusion, including the brain, compared to spontaneously breathing animals [68].

The importance of maintaining respiratory muscle oxygen transport balance has also been demonstrated in patients receiving mechanical ventilation for acute respiratory failure with underlying ventricular dysfunction, in whom an inability to wean from ventilation is related to a worsening of left ventricular function and respiratory muscle oxygen transport balance [69]. These studies demonstrate not only the importance of diaphragmatic blood flow in preserving respiratory pump function but also the phenomenon that diaphragmatic blood flow is protected to an equal or even greater extent than is cerebral and myocardial blood flow when CO is limited. With mechanical ventilation, substantial quantities of oxygen are released for other organs; meanwhile, respiratory muscle and cardiac oxygen consumption are decreased significantly.

The Effects of Congenital Heart Disease with Left-to-Right Shunting on Pulmonary Function

Large, nonrestrictive ventricular septal defects and aorta–pulmonary artery communications allow for the complete equilibration of pressures between the pulmonary and systemic circulations during ventricular systole. This coupled with the obligatory increase in pulmonary flow, which increases over the first several weeks of life, leads to pulmonary venous hypertension. Interstitial and alveolar edema develops as extravascular lung water formation exceeds pulmonary clearance, decreasing lung compliance. Small airway resistance increases as fluid accumulates in the bronchovascular sheath, leading to external compression of bronchioles. In addition, lower airway disease leads to incomplete alveolar emptying, hyperinflation, and flattened diaphragms, resulting in a decrease in diaphragmatic preload and ventilatory capacity. Impaired respiratory mechanics and exaggerated negative pressure breathing increase ventricular afterload while increasing caloric expenditure. Infants also have less respiratory reserve primarily due to a highly compliant chest, which results in a decrease in the outward elastic recoil of the chest wall and a decrease in FRC. Further, the diaphragm of an infant possesses relatively less fatigue-resistant fibers, and the force generated by the inspiratory muscles is partially wasted with the distortion of the highly compliant chest wall. All of these factors contribute to the onset of cardiopulmonary failure in this patient group.

Changes in Lung Mechanics During Acute Pulmonary Hypertension

Infants after surgical correction of congenital heart disease, particularly those with preoperative left-to-right shunts, are at risk of acute and severe pulmonary hypertension in the postoperative period. In its most severe form, this may become manifest as a so-called pulmonary hypertensive crisis in which there is an abrupt and severe increase in pulmonary vascular resistance, resulting in a critical reduction in CO. A characteristic observation during these episodes is that the patient has “stiff lungs” making mechanical ventilation difficult. Ventilatory difficulties during acute pulmonary hypertensive events are at least in part due to an acute reduction in respiratory compliance, which may respond to inhaled nitric oxide and may also be further exacerbated by increased resistance (Fig. 52.9) [70, 71].

Centrally Mediated Cardiopulmonary Interactions

In addition to the cardiopulmonary interactions mediated through direct mechanical influences within the thorax, there is accumulating evidence of important additional interactions coordinated through neuronal networks within the brainstem. These networks, which control both respiratory and cardiovascular function, reside in overlapping adjacent columns in the rostral medulla. Respiratory activity occurs through the phasic oscillators located within these columns, and while automatic activity of the heart is

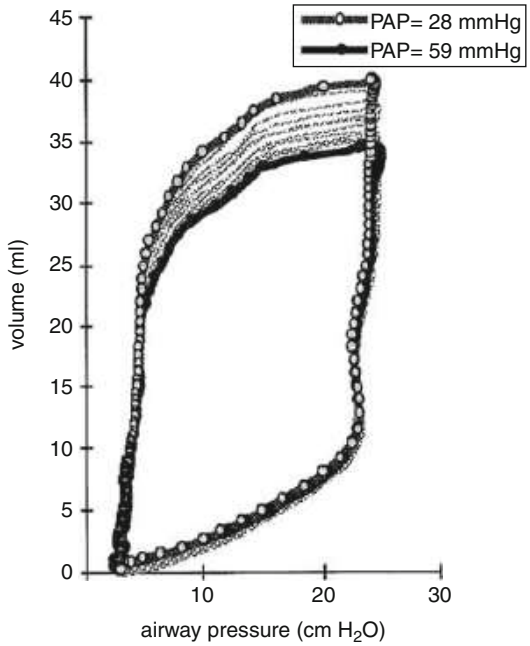

Fig. 52.9 *Changes in airway pressure and lung volume during mechanical ventilation in a patient experiencing an acute increase in pulmonary arterial pressure (PAP).* As PAP increased from 28 to 59 mmHg, the changes in lung volume during inspiration were reduced, reflecting an acute reduction in respiratory system compliance (Used with permission from Schulze-Neick et al. Intensive Care Med 1999; 25: 76–80)

primarily mediated by cardiac pacemaker cells, centrally regulated vagal and sympathetic autonomic tone powerfully modulate heart rate, vascular resistance, and arterial pressure. There is increasing evidence of reciprocal interactions between these two activities such that not only is there respiratory modulation of the brainstem mechanisms mediating cardiovascular control; there is, in addition, evidence that the cardiac cycle contributes to the modulation of medullary respiratory outputs.

These centrally mediated cardiopulmonary interactions appear to occur through a number of mechanisms including (1) direct reciprocal interactions between the respiratory and circulatory oscillators within the brainstem itself, (2) the effect of afferent impulses transmitted from pulmonary stretch receptors and chemoreceptors through the vagus, which modulate the efferent outputs to the sinus node and the vascular bed, and (3) modulation of the brainstem respiratory oscillators by afferents from the vascular baroreceptors.

Centrally Mediated Modulation of Cardiovascular Function by Respiration

The influences of the respiratory oscillation on cardiovascular function have long been recognized. Variations in heart rate during the respiratory cycle (so-called sinus arrhythmia) is one of the most obvious of these influences and is likely to represent the direct and indirect respiratory modulation of cardiac vagal efferents. In addition, alterations in arterial blood pressure during the respiratory cycle (so-called Traube–Hering waves) may, at least in part, reflect respiratory influences on sympathetic nervous activity.

The apparently irregular discharges of the sympathetic efferents appear to be related to cumulative inputs from multiple sources. One important input is the respiratory oscillator. Respiration may further modulate central cardiovascular control through the powerful modulation of sympathetic output by changes in arterial pH and CO_2 and to a lesser extent the arterial O_2 concentration. It is likely that these influences are mediated through effects of the peripheral chemoreceptors on sympathetic premotor neurons, given that blockade of central respiratory rhythm does not alter the sympathetic response to hypoxia.

Centrally Mediated Modulation of Respiration by the Cardiovascular System

Although less widely accepted, a number of experimental approaches indicate that the central respiratory generator is modulated by inputs from the cardiovascular system. Acute reductions in arterial blood pressure, as occurs during hemorrhage, may rapidly increase ventilation, which is thought to reflect the influences of baroreceptor

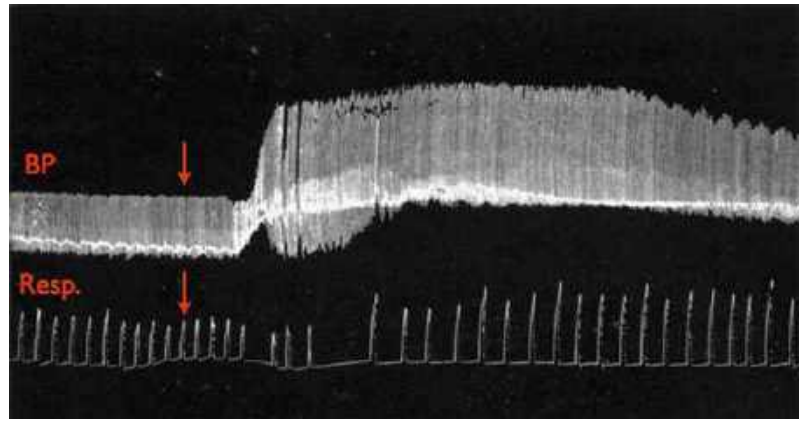

Fig. 52.10 *Suppression of respiration (resp) evoked by an increase in blood pressure (BP) after intravenous injection of epinephrine (arrow) in an anesthetized dog* (Reproduced with permission from Heymans et al. J Physiol 1930; 69: 254–266)

inputs on central respiratory drive [72]. While it has been suggested that these observations may also indicate reduced perfusion of the carotid body, the observation that an acute *increase* in arterial pressure results in bradypnea (Fig. 52.10), the observation that selective increases in carotid sinus pressure reduces ventilation even when the carotid body is destroyed, and the observation that electrical stimulation of barosensitive nerves alter respiratory effort all point to a significant role of the vascular baroreceptors in the modulation of central respiratory control [73, 74].

Phase Locking Between Respiration and Heart Rate

A further intriguing observation from recent signal analysis studies is of a considerable phase locking between cardiovascular and respiratory rhythms. Simultaneous recordings of cardiac and respiratory signals demonstrate that under some conditions either inspiration or expiration occur at a constant interval after a heartbeat [75]. It is likely that this cardiorespiratory coupling which has been demonstrated in adults during rest, sleep, and while under general anesthesia reflects coordinating influences between the cardiac and respiratory oscillators. This coupling appears to be less well developed in infants [76]. The physiological advantages conferred by this coupling are poorly understood, although it may be that by optimizing the coordination between the cardiac and respiratory cycles, arterial oxygenation may be improved and ventilation–perfusion mismatch reduced [77].

Clinical Implications of Centrally Mediated Cardiopulmonary Interactions

Cheyne–Stokes Respiration (CSR) or Periodic Breathing (PB)

In patients with chronic heart failure, these abnormal phenomena represent clinically important, centrally mediated cardiopulmonary interactions. The mechanisms which underpin them appear to be multiple, including an increased sensitivity of chemoreceptors to arterial O_2 and CO_2 changes, reduced chemoreceptor system damping by decreased total body stores of O_2, or a delay in information transfer between the lungs and brain, resulting from the reduced systemic flow. Patients with CSR or PB demonstrate depressed baroreceptor sensitivity and increased chemoreceptor sensitivity. When chemoreceptor sensitivity is blunted in patients with CSR or PB by either hyperoxia or administration of dihydrocodeine, a normal respiratory pattern is restored. Irrespective of the underlying mechanism, CSR or PB in patients with chronic heart failure may be independently associated with increased sympathetic activity and ventricular arrhythmia and is known to be a marker of poor prognosis [78, 79].

Obstructive Sleep-Disordered Breathing

Another clinically relevant cardiopulmonary interaction occurs through the cessation of airflow, which occurs during sleep-disordered breathing. This is known to increase sympathetic activity and alter baroreceptor gain and thereby contribute to systemic hypertension and predispose to arrhythmia. Application of positive pressure ventilation may be beneficial.

The importance of discussing disorders of the respiratory system in the context of cardiopulmonary interaction is that they may be a cause of or contribute to cardiovascular disease. This is exemplified in the syndrome of obstructive sleep-disordered breathing (OSDB). OSDB is a relatively common respiratory disorder occurring in approximately 3 % of all children, and it is associated with other conditions commonly found in the intensive care setting, such as Down syndrome, neuromuscular disease, craniofacial abnormalities, and heart failure. OSDB, like other disease of the respiratory system, primarily affects cardiovascular function by altering ITP and gas exchange.

OSDB is characterized by repetitive episodes of inspiratory flow limitation or cessation of inspiratory flow and results primarily from impaired upper airway function during sleep. This leads to the generation of exaggerated negative ITP with increased LV afterload and impaired gas exchange. Hypoxemia and hypercapnia stimulate baro- and chemoreceptors, leading to activation of the sympathetic nervous system and renin–angiotensin–aldosterone system. As a result, biventricular afterload increases further and stroke volume and CO fall. Exaggerated negative pressure breathing also leads to an increase in venous return, leftward deviation of the ventricular septum, and reduced LV filling, contributing to a decrease in CO. The impact of exaggerated negative pressure breathing on cardiovascular function is even greater in the patient with underlying LV systolic dysfunction. These factors adversely affect myocardial oxygen transport balance and may precipitate myocardial ischemia. Kuniyoshi and colleagues prospectively evaluated the relationship between the day and night variation of presentation for acute myocardial infarction [80]. The odds of having OSDB in those patients whose AMI occurred between 12 a.m. and 6 a.m. was six-fold higher than in those having an AMI during the remaining 18 h of the day, and of all the patients having an AMI between 12 a.m. and 6 a.m., 91 % had OSDB.

Recurrent hypoxia leads to ischemia–reperfusion injury and the generation of an inflammatory response. Inflammatory mediators such as oxygen free radicals further injure the myocardium and impair endothelial function, contributing to increases in ventricular afterload. Over time, these cumulative effects lead to ventricular remodeling and the development of RV and/or LV diastolic and systolic heart disease [81]. Noninvasive continuous positive airway pressure (CPAP) or bi-level positive airway pressure (BIPAP) support markedly reduce the incidence and severity of OSDB and in doing so improve gas exchange and eliminates wide swings in ITP. Over time, the use of noninvasive positive airway pressure support improves cardiovascular function with several studies having demonstrated significant improvements in RV and LV diastolic and systolic function and reductions in biventricular afterload [82–84].

Respiratory-Sympathetic Coupling in Systemic Hypertension

There has been recent interest in the relationship between respiratory-sympathetic coupling and essential hypertension. While an understanding of the multiple pathophysiological interactions which result in essential hypertension remains incomplete, both animal models and the human condition are known to be associated with increases in sympathetic nervous activity. Animal models indicate that enhanced respiratory-sympathetic coupling may contribute to these increases [85]. Even before the onset of hypertension, spontaneously hypertensive rats had significantly greater respiratory-related bursts of sympathetic nervous activity compared to

normotensive controls. It has been suggested that that this enhanced coupling will produce larger Traube–Hering waves that may summate to contribute to the elevated arterial pressure in the hypertensive animals.

Conclusion

Powerful reciprocal interactions occur between lungs and the circulation. These interactions are mediated not only through local mechanical influences originating within the thorax but also through centrally mediated neural mechanisms. Most emphasis has been placed on the mechanisms through which the respiratory system influences circulatory performance. These influences are multifaceted, mediated through alterations in venous return, RV and LV afterload, and ventricular interdependence. They can be used as powerful tools in the optimization of systemic DO_2 in the critically ill patient and in patients with congenital heart disease and may maintain optimal ventricular performance in the setting of chronic heart failure. Although there has been less emphasis on the reciprocal mechanisms whereby the circulation alters lung mechanics, this phenomenon is of increasing clinical interest, particularly in the treatment of the patient with congenital heart disease associated with excessive pulmonary flow or acute pulmonary hypertension.

Airway Management in Congenital Heart Disease

53

Dean B. Andropoulos

Abstract

Airway management in patients with congenital heart disease is an important therapeutic modality to support these patients through critical illness, surgery, and other procedures. Airway management in these patients is complicated by lesser cardiopulmonary reserve due to cardiac pathophysiology, and the significant incidence of craniofacial syndromes and anatomic airway anomalies in this population. This chapter will present the developmental anatomy of the normal airway and then review major syndromes in congenital heart disease patients associated with abnormal airway anatomy. Indications for tracheal intubation and the airway examination will then be presented. Techniques for endotracheal intubation will be reviewed, followed by management of the difficult airway. Approach to extubation of the trachea will then be presented. Finally, techniques for noninvasive ventilation and tracheostomy in the patient with congenital heart disease will be reviewed.

Introduction

Patients with congenital and acquired heart disease frequently require assisted ventilation during management of cardiac or respiratory failure, or procedures including surgery or interventional catheterization. Airway management in these patients is complicated by lesser cardiopulmonary reserve due to cardiac pathophysiology, and the significant incidence of craniofacial syndromes and anatomic airway anomalies in this population. This chapter will present the developmental anatomy of the normal airway and then review major syndromes in congenital heart disease patients associated with abnormal airway anatomy. Indications for tracheal intubation and the airway examination will then be presented. Techniques for endotracheal intubation will be reviewed, followed by management of the difficult airway. Approach to extubation of the trachea will then be presented. Finally, techniques for noninvasive ventilation and tracheostomy in the patient with congenital heart disease will be reviewed.

Developmental Anatomy of the Normal Pediatric Airway

There are many changes to airway anatomy in the growth and development from neonate to infant, child, and adolescent and adult that affect the approach to airway management and tracheal intubation [1]. The first is the size of the skull, especially the occipital cranium, which is relatively larger in the neonate and small infant, compared to the child and adolescent. This is important because of the need to achieve the "sniffing" position during direct laryngoscopy, with flexion of the base of the cervical spine to align the axes of the pharynx, larynx, and trachea. The infant's occiput is often large enough so that placing a small towel beneath it is not necessary to achieve neck flexion, as it is in older children and adults. Naso- and oropharyngeal anatomy is often different from age 3 to 8 years with the presence of adenoidal and tonsillar hypertrophy which may obstruct the airway or make tracheal intubation more difficult. The notion that neonates are obligate nasal breathers has largely been disproven. The relative volume of the tongue is larger in neonates and infants compared to the adult, predisposing to earlier airway obstruction during face mask ventilation.

The epiglottis of the infant is relatively narrow and short and angled posteriorly into the lumen of the airway. The epiglottis and laryngeal opening of the small infant is often described as "omega-shaped," and the soft pliable epiglottis makes the airway prone to obstruction at this level. As the child grows, the epiglottis becomes more cartilaginous, U-shaped, stiffer, and less prone to obstruction. The position of the larynx is relatively higher in early infancy, starting at the C2 level, descending to the C4–C5 level by age 3 years, and C6 by adulthood. These airway features of the young infant mean that the glottic opening is usually easily visualized using a straight laryngoscope blade placed on the undersurface of the epiglottis. Although largely preference of the laryngoscopist, older children and adults' glottic openings are often more easily visualized with a curved laryngoscope blade placed in the vallecula anterior to the base of the epiglottis, with the stiff epiglottis easily lifted out of the line of visualization.

The narrowest portion of the airway in infants and young children is at the cricoid ring and in older children and adults is at the level of the vocal cords. Recent imaging studies have demonstrated that the relative difference in airway diameter in infants between cricoid and vocal cords is minimal, and so the classical teaching that uncuffed endotracheal tubes are indicated in the first 6–8 years of life has been challenged [1–3] (see below). The length of the trachea (distance from vocal cords to carina) changes significantly with age; in the 3 kg neonate, it is only 3–4 cm, increasing to 5–6 cm by 1 year of age [4]. Therefore, especially in the small infant, precise placement of the tip of the endotracheal tube is crucial [5].

Syndromes Associated with Abnormal Airway Anatomy

Congenital heart disease patients often have associated genetic or dysmorphic syndromes that involve the airway. Anatomic features of these syndromes that complicate airway management include macroglossia, micrognathia, limited neck extension, limited mouth opening, and nasopharyngeal airway obstruction [6]. All of these features may interfere with mask ventilation, direct laryngoscopy, and tracheal intubation. One of the most common cardiogenetic syndromes is trisomy 21, with a large tongue, smaller subglottic and tracheal diameters, and atlanto-occipital instability being the problems that may affect airway management [7]. Attention to upper airway patency during mask ventilation, displacement of the large tongue during direct laryngoscopy, holding the cervical spine in neutral position without excessive flexion or extension, and potentially selecting a tracheal tube 0.5 mm smaller diameter are often necessary.

Velocardiofacial syndrome, associated with microdeletions of chromosome 22q11.2, may be seen with conotruncal anomalies including truncus arteriosus, interrupted aortic arch, and tetralogy of Fallot. The phenotypes in this syndrome are highly variable, but some patients have high arched palate, cleft palate, and varying degrees of micrognathia, which may complicate airway management. The CHARGE association (*C*oloboma, *H*eart defect, *A*tresia choanae, *R*etarded growth, Genital abnormalities, *E*ar anomalies) often has choanal atresia as a prominent feature; complete nasopharyngeal obstruction necessitates treatment as a neonate and may complicate management of the associated cardiac defects. Noonan syndrome patients may have a webbed neck and very limited neck movement that complicates direct laryngoscopy.

Micrognathia syndromes are the most common cause of difficult tracheal intubation in pediatric patients, and this can be present in patients with syndromic and non-syndromic congenital heart disease. The Pierre Robin sequence (cleft palate with micrognathia), Goldenhar syndrome (hemifacial microsomia), and Treacher Collins syndrome are three of the most common. The small mandible limits the hypopharyngeal space, into which the tongue is normally displaced during direct laryngoscopy to expose the larynx. Direct laryngoscopy is often impossible in these conditions, necessitating alternate methods for tracheal intubation (see below). Presence of any of these genetic syndromes affecting the airway mandates very careful airway assessment and consultation from experts in the management of the difficult airway.

Indications for Tracheal Intubation

Airway management during procedures is the most common indication for tracheal intubation in congenital heart disease. Tracheal intubation is mandatory for all forms of cardiac surgery, whether intracardiac using cardiopulmonary bypass or extracardiac surgery on the heart or great vessels. For interventional cardiac catheterization, tracheal intubation is often indicated especially for small infants, where provision of a patent airway for optimal oxygenation and ventilation and immobility provided by muscle relaxants facilitate the performance of the procedure. Diagnostic procedures such as cardiac MRI where breath holding is planned are also indications for tracheal intubation, depending on the age of the child and their ability to cooperate. Tracheal intubation is often indicated for other procedures, such as noncardiac surgery, or diagnostic catheterization or electrophysiologic study with ablation, depending on the preference of the practitioner or institution, or the patient's comorbidities.

In the setting of the acutely ill patient with congenital or acquired heart disease, the decision to intubate the trachea and institute mechanical ventilation is made when respiratory distress, diagnosed by observing for one or more of significant tachypnea, retractions, cyanosis with pulse oximeter saturation (SpO_2) often 10 % or more lower than baseline, and significant hypercarbia, heralds risk for respiratory arrest as well as cardiovascular decompensation.

In addition, low cardiac output in the absence of intrinsic pulmonary disease is often an indication for tracheal intubation with positive pressure ventilation to minimize oxygen consumption from work of breathing and optimize oxygen delivery by improving gas exchange and reducing left ventricular afterload [8]. Chest radiographs of symptomatic patients with congenital heart disease who require intubation often reveal significant pulmonary edema, lobar or whole-lung infiltration or collapse, or significant cardiomegaly causing airway compression. Short of intubation, noninvasive ventilation methods as outlined below are sometimes useful, while other medical therapy is given time to be effective. Arterial blood gases are the standard for assessing gas exchange, and often an arterial catheter is present in the intensive care patient when deciding to intubate. If not, chest radiography, pulse oximetry, venous or capillary blood gases, and clinical assessment can generally provide sufficient information for making this decision. Early intervention before severe cardiopulmonary compromise is preferable to waiting for the patient to experience respiratory or cardiac arrest. However, intubating the trachea and instituting positive pressure ventilation has potential for severe hemodynamic compromise in the patient with marginal cardiopulmonary status. Emergency tracheal intubation in cardiac patients, as opposed to proactive intubation before the patient is in extremis, is associated with higher complication rates, including mortality and need for mechanical support [9]. In addition, common problems during the assisted mask ventilation and intubation process, such as laryngospasm or upper airway obstruction, more commonly lead to cardiac arrest from hypoxemia or pulmonary hypertension in patients with congenital heart disease [10].

The Airway Examination

The airway must be assessed before tracheal intubation, even in the emergency situation. A history of difficult tracheal intubation or mask ventilation must be noted in the medical record and communicated to the parents and to all providers caring for the patient. In the adult patient, the Mallampati score is a validated predictor of difficult airway management, both mask ventilation and tracheal intubation [11]. The patient is asked to open the mouth and protrude the tongue as much as possible, and the degree of visibility of the oropharyngeal structures correlates with difficult mask ventilation, laryngoscopy, and tracheal intubation (Table 53.1).

Table 53.1 Mallampati scoring system for airway assessment

Mallampati score	Oropharyngeal structures visible
I	Full visibility of tonsils, uvula, soft palate
II	Hard and soft palate, upper half of tonsils and uvula
III	Only soft and hard palate and base of uvula visible
IV	Only hard palate visible

Despite widespread use of this score, it has not been fully validated in pediatric patients, and the infant and young child will not cooperate for the examination. A similar assessment can be done quickly with the patient crying. Despite these limitations, the principles of the Mallampati score seem valid when approaching pediatric patients. The other important predictors consistently associated with difficult airway management in pediatric patients are micrognathia, limited mouth opening, limited neck mobility, and conditions limiting the submandibular space.

Endotracheal Intubation and Airway Management

Basic equipment and preparations for intubation include laryngoscopes and endotracheal tubes (ETT) in appropriate sizes, oral airways, working suction immediately at hand, and high-flow oxygen source and manual ventilation bag that is easily operated, either of self-inflating type or of anesthesia-type configuration such as a modified Jackson-Rees bag (Fig. 53.1). Methods to detect

Fig. 53.1 Pediatric airway equipment: In the foreground are assorted sizes of oral airways (*1*), Miller 0 and 1 straight laryngoscope blades and pediatric laryngoscope handle (*2*), McGill forceps for nasotracheal intubation (*3*), and Macintosh 1 and 2 curved laryngoscope blades (*4*). A pediatric stylet and face masks are in the middle of the photo (*5*) and an assortment of cuffed and uncuffed small endotracheal tubes at the back of the photo (*6*)

exhaled CO_2, either colorimetric or continuous monitors, are mandatory to ensure the tube is in the trachea [12].

In general, FiO_2 of 1.0 is always recommended for preoxygenation and initial management immediately after ETT placement. Evaluation of the airway for possible difficult mask ventilation and intubation is mandatory before administering drugs that will render the patient apneic. If difficulty is anticipated, requesting assistance from an anesthesiologist or otolaryngology surgeon is very important to avoid a disastrous "cannot ventilate, cannot intubate" situation (see below). Also, a full stomach mandates suction of gastric contents before intubation when possible and cricoid pressure during mask ventilation before intubation. The head is positioned neutral in the case of an infant, or with a small towel under the occiput in an older child, to achieve the "sniffing position" during laryngoscopy to align the axes of the pharynx, larynx, and trachea. First, the patient is preoxygenated with a tight-fitting face mask for 3–5 min if possible, then induction drugs are given, and positive pressure ventilation is instituted early and gently. Jaw thrust or oral airway is used if there is inadequate chest rise with bag and mask ventilation. Cricoid pressure is applied by an assistant in the case of a full stomach. With loss of consciousness and adequate muscle relaxation, the laryngoscope is inserted into the right side of the mouth, the tongue swept to the left out of the midline, and the blade advanced until the epiglottis is visualized. The blade is advanced further, into the vallecula with a curved blade, or under the epiglottis with a straight blade; the handle lifted with a gentle upward motion at a 45° angle to the surface of the bed; and the position adjusted until the arytenoid cartilages and vocal cords are in view. The "BURP" maneuver (*B*ackward, *U*pward, *R*ightward *P*ressure) on the cricoid cartilage by an assistant often is very effective to improve visualization. The ETT with a stylet bent at a 45° angle ("hockey stick" configuration) is inserted by direct visualization, taking care to insert the tube to the correct depth using markings on the tube and guidelines for the tube size. In modern practice, a cuffed ETT is recommended for virtually all patients, with the exception of some small neonates where an uncuffed 3.0 or 3.5 mm ETT is used. A common guide to ETT size selection is

$$(16 + \text{patient age in years})/4$$

For example, a 4-year-old patient will then require a 5.0 mm ETT. Since this formula was

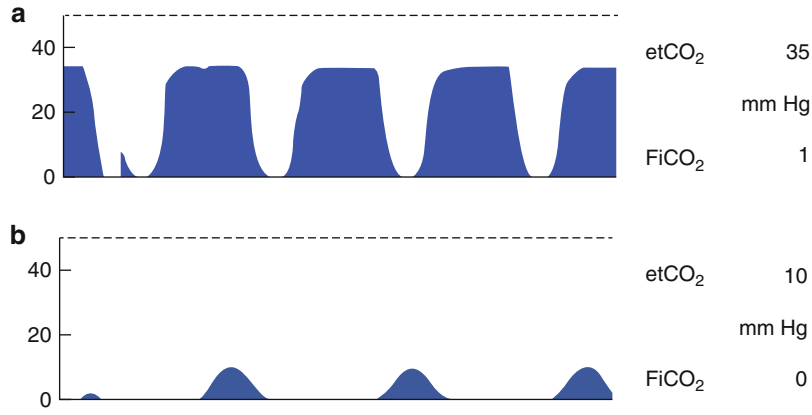

Fig. 53.2 (**a**) Normal end-tidal CO_2 waveforms after successful tracheal intubation, with adequate ventilation and cardiac output. Note full waveform, long plateau phase, value of 35 mm Hg, and persistence of CO_2 over multiple breaths. (**b**) Abnormal CO_2 waveform: note small waveform, no plateau, value of only 10 mm Hg. Causes include low cardiac output with low pulmonary blood flow, severe cyanosis, or large ETT leak

developed for uncuffed ETT, many practitioners will use the cuffed ETT 0.5 mm smaller, i.e., a 4.5 mm cuffed ETT for a 4-year-old patient.

Ventilation should be initiated gently; excessive positive pressure in combination with the cardiovascular depression often seen with induction drugs can result in cardiovascular collapse. Breath sounds are auscultated; the stomach is also auscultated to help rule out esophageal intubation; detection of adequate end-tidal CO_2 that is persistent for six or more breaths is a critical confirmatory step (Fig. 53.2a). Low levels of end-tidal CO_2 often indicate low cardiac output, severe cyanosis with large end-tidal to arterial CO_2 difference, or large leak around the ETT (Fig. 53.2b). If there is no end-tidal CO_2, causes include esophageal intubation, or poor pulmonary blood flow or cardiac arrest, or severe bronchospasm preventing gas exchange. If this occurs, the first reaction is often to remove the ETT and reinsert; however, strong consideration should be given to having the most experienced airway manager rapidly perform a direct laryngoscopy; often the ETT will indeed be correctly positioned. This avoids the unnecessary situation of an arrested patient in whom the ETT has just been inappropriately removed. Blood pressure, heart rate, and SpO_2 must be monitored continuously after tracheal intubation; patients will sometimes require intravascular volume bolus, or pressors such as a small dose of epinephrine, to restore desirable hemodynamics. In the case of a very tenuous patient, anticipation of full cardiac arrest should be made.

Depth of insertion of the ETT is crucial, especially in small infants where total length of the trachea may be only 3–5 cm. Using the depth markings on the tube, the ETT is advanced until the desired mark at the level of the vocal cords. The chest is auscultated for equal breath sounds; a chest radiograph is obtained as soon as possible after securing the tube. Other methods of estimating proper orotracheal depth of insertion include deliberately placing the tube in the right main stem bronchus and then auscultating the left chest during rapid hand ventilation while the tube is being withdrawn. When breath sounds appear, the ETT is at the carina; the tube is then withdrawn another 1–1.5 cm for final positioning. Also, with an orotracheal tube, an estimate of proper distance from the lip to the ETT tip in the trachea is (ETT size $\times$ 3). However, this calculation only provides an estimate and is based on the assumption that the ETT size is appropriate for the child's age. Therefore, the estimate will not apply to a child with an abnormally narrow airway requiring a smaller diameter ETT than would be predicted for their age. A nasotracheal tube will in general require to be placed with the tip 2 cm deeper than an oral tube

Table 53.2 Endotracheal tube and laryngoscope blade sizes

Age	Weight (kg)	ETT size (mm)	Laryngoscope blade
Premature neonate	<2.5	3.0 uncuffed	Miller 0
Full-term neonate	2.5–4	3.5 uncuffed or cuffed	Miller 1
1–6 months	4–6	3.5 cuffed	Miller 1
6–12 months	6–8	3.5–4.0 cuffed	Miller 1, Wis-Hipple 1.5
1–2 years	8–10	4.0–4.5 cuffed	Wis-Hipple 1.5
2–3 years	10–12	4.5 cuffed	Wis-Hipple 1.5, Macintosh 2
4–5 years	12–18	4.5–5.0 cuffed	Macintosh 2, Miller 2
5–7 years	18–24	5.0–5.5 cuffed	Macintosh 2, Miller 2
8–10 years	24–35	5.5–6.0 cuffed	Macintosh 3, Miller 2
11–13 years	35–40	6.0–6.5 cuffed	Macintosh 3, Miller 2
14–16 years	40–50	6.5 cuffed	Macintosh 3, Miller 2
16 years and above	50 and over	7.0–7.5 cuffed	Macintosh 3, Miller 2

in newborns and infants and 3 cm deeper in older children. ETT position should always be confirmed on a chest radiograph.

The tip of the ETT may migrate significantly with changes in head and neck position, especially in small infants and with orotracheal tubes. The tip position will follow the movement of the patient's chin, i.e., neck extended and rotated will withdraw the tip of the ETT, and flexion of the neck with chin midline will advance the tip. Table 53.2 lists recommended ET tubes and laryngoscope blades by patient age and weight.

Cuffed Versus Uncuffed Endotracheal Tubes

As noted above, the differences in airway diameter at the cricoid ring and vocal cords and the change in these relative diameters with age are now known to be less than formerly believed, and thus, the practice of using only uncuffed ETT until age 6–8 years has been challenged. Many practitioners will now use only cuffed ETT, with the exception of very small neonates. The advantages of a cuffed ETT include ability to seal the leak around the tube for effective ventilation and prevention of aspiration of orogastric contents. Disadvantages include the outer diameter of the cuffed ETT being approximately 0.5 mm larger and the potential for high inflating pressures in the cuff to cause mucosal edema, ischemia, and necrosis, leading to subglottic stenosis. A tube size 0.5 mm inner diameter smaller is often chosen with cuffed ETT. In addition, limiting intracuff pressure to 20–25 mm Hg or less with a pressure-limiting device is prudent for longer term intubations. Finally, newer cuff designs, including a shorter length cuff and higher compliance material resulting in lower intracuff pressures, are desirable (Fig. 53.3). It is prudent to evaluate for the presence of a leak around the ETT with the cuff deflated immediately after placement and before tracheal extubation.

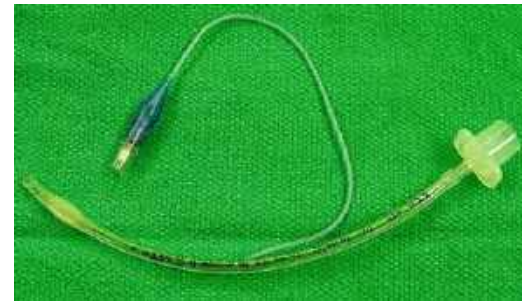

Fig. 53.3 3.5 mm cuffed endotracheal tube with high-volume, low-pressure cuff. This tube is recommended for large neonates and infants in the first 6–12 months of life

Outcome studies of cuffed vs. uncuffed ETT both for pediatric intensive care and for operating room anesthesia have revealed no differences in rates of postextubation stridor and need for racemic epinephrine, subglottic stenosis, or tracheostomy [13–15].

Oral Versus Nasotracheal Intubation

In the emergency intubation situation, oral tracheal intubation is mandatory to establish an

effective airway as quickly as possible. Both preparation time and time to insert the ETT are shorter with the oral route. The oral ETT must be securely attached and stabilized; there are many techniques, but all should stabilize the ETT position with minimal movement allowed while protecting the underlying skin integrity. Disadvantages of orotracheal tube placement for longer term airway management include movement or dislodgement by the tongue, obstruction by teeth with biting, and limited access for oral care.

Nasotracheal intubation is chosen in many programs for cardiac surgery in small infants and for perceived better stability of fixation of the ETT, especially if transesophageal echocardiography is utilized. Also, for longer term intubations, the possible better airway stability and patient comfort and better access to the oral cavity for mouth hygiene are cited advantages of the nasotracheal route. Disadvantages include epistaxis, possibility to shear off adenoid tissue, sinusitis in older patients, and damage to the skin or cartilage of the nose if the ETT is tight fitting at the nare [1].

Nasotracheal intubation can be performed electively or in the urgent situation by an experienced practitioner after the orotracheal airway has been established and the patient stabilized. Contraindications to nasal intubation include epistaxis, severe coagulopathy, choanal atresia or stenosis, repaired cleft palate, or skull base fractures. The nares should be suctioned gently and prepared with a vasoconstrictor such as oxymetazoline 0.05 % drops, taking care to limit the total dose to avoid systemic absorption. The larger nare is selected, and the lubricated ETT is gently advanced through the choanae with a rotating motion, along the floor of the nasopharynx, with the bevel of the ETT oriented vertically. Direct laryngoscopy is performed, and the tip of the ETT is grasped with a Magill forceps and directed through the glottic opening. Directing the ETT posteriorly and rotating the tip so the bevel is oriented vertically so that the narrowest diameter passes through the vocal cords is often necessary. Before final passage, the end of the tube is visualized to ensure that it is not occluded by blood, clots, or adenoidal tissue. The tube is never forced into the glottis; if it will not pass, it is removed, the patient mask is ventilated to improve oxygenation and ventilation, and an ETT 0.5 mm smaller is passed.

Sedation, Analgesia, and Muscle Relaxation for Tracheal Intubation

Tracheal intubation is painful, anxiety provoking, and stimulating to the sympathetic nervous system which may cause undesirable effects such as severe pulmonary and systemic hypertension. Adequate sedation and analgesia must be provided for all conscious patients, including neonates. Only in extremis, i.e., during CPR, is it appropriate to intubate the trachea without these agents. Muscle relaxation is usually necessary to relax the vocal cords to prevent laryngospasm and prevent coughing with insertion of the ETT and other movement, as well as effective ventilation immediately after ETT placement. This need for sedation, analgesia, and muscle relaxation must be balanced against the risk of hemodynamic compromise from positive pressure ventilation and the cardiovascular effects of the drugs.

Before selecting a drug regimen for tracheal intubation, consideration of circulatory physiology and current hemodynamic status is crucially important. Then, the hemodynamic goals for the induction of sedation and analgesia should be considered. Only then can the most appropriate selection of drugs and dosages, with a thorough knowledge of their anticipated hemodynamic effects, be made. Table 53.3 lists drugs, drug classes, and doses [16].

For many cardiac patients requiring tracheal intubation, a regimen of small doses of midazolam and fentanyl, with repeated doses titrated according to hemodynamic responses, is very appropriate, providing sedation and analgesia with little or no change in hemodynamic status. Larger doses of fentanyl are needed to prevent pulmonary hypertension, and lower doses of these drugs are required for the very tenuous patient where a reduction in sympathetic tone with large doses of opioids can result in hemodynamic collapse. Thus, instead of one single preplanned dose, repeated titration of smaller

Table 53.3 Medications for sedation, analgesia, and muscle relaxation for endotracheal intubation

Medication	Drug class	Dose	Comments
Fentanyl	Opioid analgesic	1–5 mcg/kg	Titrate to effect; chest wall rigidity
Midazolam	Benzodiazepine sedative/anxiolytic; $GABA_A$ binding	0.025–0.1 mg/kg	Best amnestic agent
Ketamine	Arylcyclohexylamine sedative and analgesic; NMDA blocking	1–2 mg/kg	Use antisialogogue; possible direct myocardial depression
Etomidate	Imidazole derivative sedative/hypnotic; $GABA_A$ binding	0.2–0.4 mg/kg	Best for hemodynamic stability; temporary adrenal suppression
Propofol	Alkylphenol sedative/hypnotic; $GABA_A$ binding	1–2.5 mg/kg	Veno- and vasodilator
Vecuronium	Non-depolarizing neuromuscular blocking agent	0.1–0.2 mg/kg	No hemodynamic effects; muscle relaxation in 2–3 min
Rocuronium	Non-depolarizing neuromuscular blocking agent	0.6–1.2 mg/kg	Minimal hemodynamic effect; muscle relaxation 1.5–2 min
Cisatracurium	Non-depolarizing neuromuscular blocking agent	0.15–0.3 mg/kg	Minimal hemodynamic effect; muscle relaxation 1.5–2 min
Pancuronium	Non-depolarizing neuromuscular blocking agent	0.1–0.15 mg/kg	Vagolytic; requires 3–5 min for full muscle relaxation

Abbreviations: *$GABA_A$* alpha subunit of the γ-aminobutyric acid receptor, *NMDA* N-methyl-D-aspartate receptor

doses, based on individual patient response, is often very effective. Addition of a non-depolarizing muscle relaxant ensures excellent intubating conditions.

Ketamine is an extremely useful drug for tracheal intubation in many patients, given as a single agent or together with opioids and benzodiazepines. Ketamine provides both sedation and analgesia, and its vagolytic effects resulting from the inhibition of reuptake of norepinephrine into presynaptic sympathetic nerve junctions provide an increase in heart rate and blood pressure that is desirable in many patients with limited cardiovascular reserve. If tachycardia is to be avoided, it is often not the best choice. It is important to note that in the stressed and dysfunctional myocardium, ketamine may be a direct myocardial depressant. Hemodynamic collapse may occur with ketamine in patients with depressed myocardial function in the face of maximal endogenous sympathetic stimulation and exogenous catecholamine administration.

Propofol is a ubiquitous drug in pediatric anesthesia; however, it causes significant venous and arterial vasodilation when given in standard induction doses as used for general anesthesia. This reduction in preload, and afterload, is very undesirable in many patients with cardiac disease, including those with dilated cardiomyopathy and very poor myocardial contractility, those with left-sided obstructive lesions, and those patients in whom preservation of systemic vascular tone is essential (e.g., patients with tetralogy of Fallot and severe desaturation due to cyanotic spells). Propofol may be used carefully in small titrated doses in some patients; only in those with adequate myocardial reserve can a full induction dose of propofol be used for tracheal intubation. In general, propofol would not be recommended as an induction agent for intubation in the intensive care unit.

Etomidate is a hypnotic agent that will produce excellent sedation before tracheal intubation. Of all available agents, it has no direct myocardial depressant effects at induction doses. When used with a small dose of fentanyl and a non-depolarizing muscle relaxant, this agent provides excellent hemodynamic stability, even in those patients with significantly depressed myocardial function, usually resulting in induction of anesthesia with no change in heart rate, blood pressure, preload, afterload, or cardiac output. Even a single dose may cause a short-lived adrenal suppression, however, so this agent is used infrequently and only when clearly indicated.

Management of the Difficult Airway

Difficult mask ventilation and/or tracheal intubation is a major cause of morbidity, cardiac arrest, and mortality when anesthetizing pediatric patients. The risk for adverse outcome is greatly increased in patients with congenital heart disease because of limited cardiopulmonary reserve [10]. A history of difficult intubation, or an abnormal airway examination predicting higher risk for difficult intubation, necessitates consultation and assistance from an airway expert, i.e., anesthesiologist and/or otolaryngologist. The Cormack-Lehane laryngoscopic grade describes the direct laryngoscopic view of the glottic opening and is important to record after each tracheal intubation [17] (Table 53.4). In the case of unanticipated difficult mask ventilation or tracheal intubation, emergent assistance from an expert must be sought. The general principles of managing the difficult airway include having backup plans if direct laryngoscopy is unsuccessful, including the presence of an experienced anesthesiologist, and, in the case of anticipated severe difficulty, having a surgeon present who can provide a surgical airway by tracheostomy or cricothyrotomy. Backup equipment and personnel are assembled, and the procedure is planned with all participants understanding their roles. If time allows and significant difficulty is anticipated, moving the patient to an operating room with full access to surgical equipment and personnel is often prudent.

Table 53.4 Cormack-Lehane direct laryngoscopic view grading system

Grade	Laryngoscopic view
I	Vocal cords fully visible, including anterior commissure
II	Only posterior half of vocal cords visible
III	Only arytenoids visible, no vocal cords visible
IV	Only epiglottis visible; no arytenoids or vocal cords

The general principles for managing the difficult airway include effective preoxygenation with FiO_2 1.0 and tight-fitting face mask and maintaining spontaneous ventilation for as long as possible during the procedure. In the infant and young child, who cannot cooperate with light levels of sedation accompanied by topical anesthesia to the airway, this is difficult, but intravenous sedative agents such as ketamine are often extremely useful to provide sedation and analgesia while maintaining respiratory drive. If ketamine is used, glycopyrrolate administration is recommended to mitigate the increase in secretions with ketamine. Maintaining spontaneous ventilation allows at least some gas exchange, whereas if ventilation is abolished with deep sedation or muscle relaxation and mask ventilation cannot be accomplished, an emergent situation results. Topical anesthesia with local anesthetic nebulization, spray, or gel can be provided, and a direct laryngoscopy can be quickly performed. At times the ETT can be placed directly using this technique. If the glottis cannot be visualized, an alternate technique is used. This can involve one of several methods depending on the experience and preference of the practitioner. Before rendering the patient apneic with sedatives or muscle relaxants, demonstration of adequate assisted face mask ventilation must first be accomplished.

The laryngeal mask airway (LMA) can be used for management of the difficult airway (Fig. 53.4). After sedation, it can be placed and with proper positioning can both improve ventilation by opening the airway and allowing assisted ventilation and act as a conduit either for direct passage of an endotracheal tube blindly down the lumen of the LMA or, more commonly, for fiber-optic intubation, where a small ETT is placed over the FOB, the scope is passed through the lumen of the LMA into the trachea, and the ETT is advanced into the trachea. Correct position is confirmed by direct visualization of the ETT in the trachea with identification of cartilaginous tracheal rings and the carina and by detection of exhaled CO_2 and effective ventilation.

Pediatric video laryngoscopes are now available that allow visualization of the larynx even in neonates, in many cases where conventional direct laryngoscopy is impossible (Fig. 53.5). These devices have a fiber-optic light source in

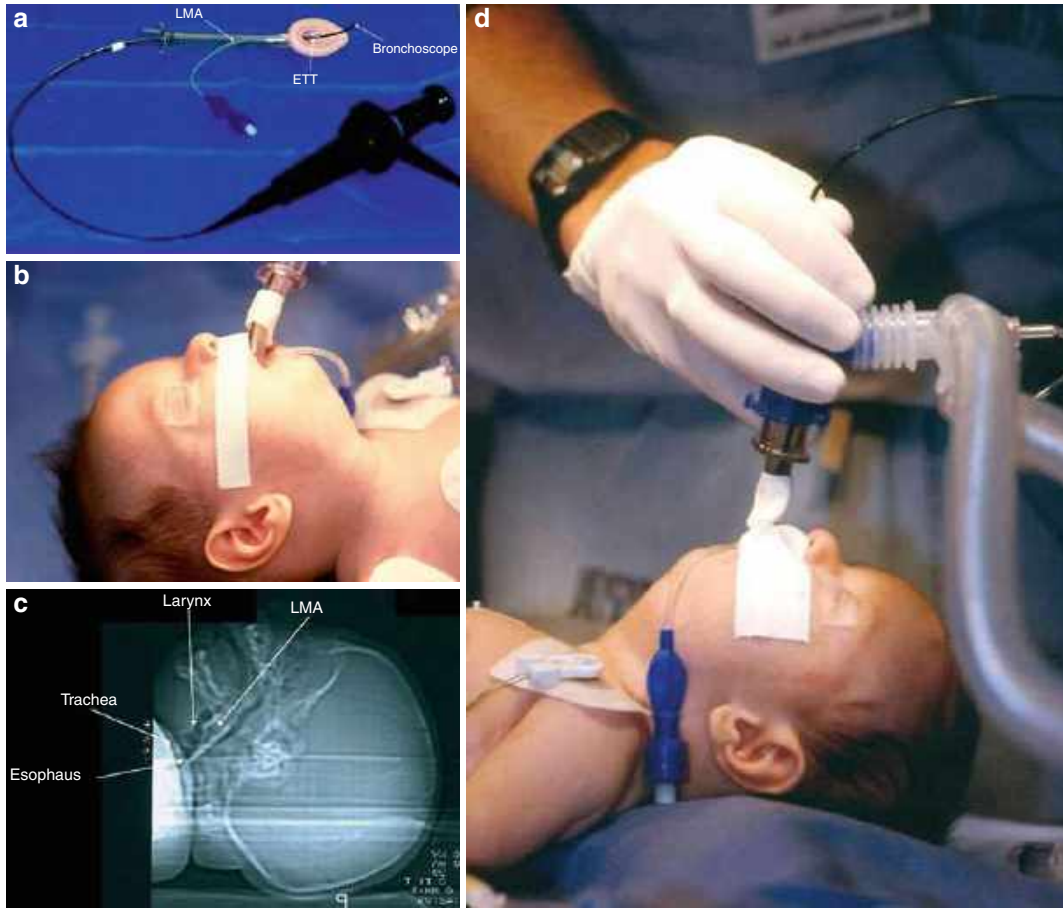

Fig. 53.4 (**a**) Size 1 laryngeal mask airway (*LMA*) with pediatric fiber-optic bronchoscope and endotracheal tube loaded on the scope. (**b**) LMA placement in a 2-month old with micrognathia. (**c**) Lateral view CT scan of the LMA in situ. (**d**) Fiber-optic bronchoscopy (*FOB*) through the LMA. When the FOB is successfully passed into the trachea, the ETT is advanced over the bronchoscope, through the LMA, and into the trachea

the blade, with a miniaturized camera at the tip, with images transmitted to a video screen. This design allows indirect viewing of the larynx around the acute angle created by micrognathia or other anatomic abnormalities, preventing a direct view of the larynx. The ETT is then inserted, manipulated, and advanced into the trachea by viewing the image on the video screen.

Failure to intubate the trachea via direct laryngoscopy, fiber-optic laryngoscopy, or video laryngoscopy often necessitates a surgical airway. Needle cricothyrotomy is impossible in small children due to the small dimensions of the anatomy and the small catheters limiting any gas exchange. This technique is only possible in older children; the jet ventilation under high pressures and flows with this method is fraught with risk of complications from pneumothorax, pneumomediastinum, and tracheal injury. Needle cricothyrotomy should be viewed as a last resort while preparations are made for a surgical airway. Surgical cricothyrotomy may be lifesaving; it can be accomplished by direct incision and insertion of a small ETT, or with a prepackaged kit, using the Seldinger technique where a needle and a guidewire are first inserted, followed by a dilator with a cricothyrotomy tube. Emergency tracheostomy is technically difficult but should proceed in an emergent situation where previous methods have failed. It is important to attempt to

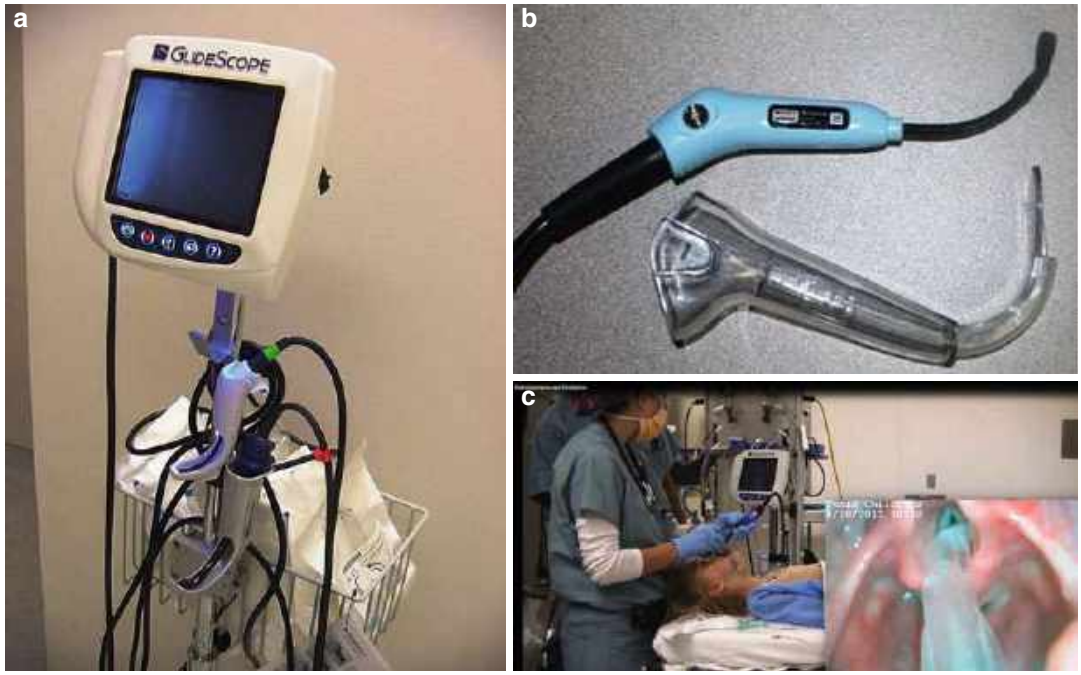

Fig. 53.5 Video laryngoscopic intubation (**a**) GlideScope® screen and several sizes of laryngoscopes, including neonate and child. (**b**) GlideScope (*top*) with disposable plastic pediatric blade. (**c**) The anesthesiologist views the airway on the video screen, while directing the endotracheal tube through the glottis opening (*inset*)

ventilate and oxygenate the patient during surgical airway placement. Cardiopulmonary resuscitation efforts, including ECMO cannulation, may be necessary in some situations.

The incidence of difficult intubation in the pediatric cardiac population has not been well described; there are few studies documenting this incidence even in the general pediatric anesthesia population. Akpek et al. retrospectively studied 1278 pediatric patients undergoing congenital heart surgery and observed an incidence of difficult intubation of 1.25 % [18]. The 16 cases were all 2-ventricle patients, and 8 had a known genetic or dysmorphic syndrome. Micrognathia, macroglossia, restricted neck movement, and tracheal deviation were the recorded causes of difficult intubation. Fiberoptic or video laryngoscopic intubation was not used in this series; there were no cardiac arrests or permanent injuries. In a recent retrospective review of over 11,000 tracheal intubations in pediatric anesthetic patients, cardiac surgery patients (944 of the total) had an incidence of difficult laryngoscopy and intubation of 3.6 %, which was significantly higher than the general population of 1.35 % and the highest incidence of any surgical specialty, including oral-maxillofacial surgery [19]. These data suggest a relatively high risk of difficult intubation in the congenital heart disease population and support the practice of thorough airway assessment and consultation with airway management experts if a difficult airway is suspected. For a detailed description of management techniques for the difficult airway, the reader is referred to several excellent sources [1, 20].

Tracheal Extubation

Early Tracheal Extubation

Many centers have adopted "fast-tracking" programs for early tracheal extubation after simple or even moderately complex cardiac surgery. The drivers for this practice include the desirable

hemodynamic advantages of negative pressure ventilation in the bidirectional cavopulmonary shunt and in the Fontan circulation, less need for sedation, more comfort for the patient and faster progress through the ICU, and avoidance of barotrauma and lower risk of nosocomial pneumonia. Extubation can be accomplished in the operating room or early in the ICU course in the first 1–4 h. Institutional practices vary widely, from no early extubation in any patients, to focusing upon specific patient groups, to aggressively extubating all patients possible, including even small infants undergoing moderately complex surgery [21, 22]. Criteria for early extubation include hemodynamic stability on minimal or no inotropes, normal sinus rhythm, minimal bleeding, minimal pulmonary disease, low doses of fixed anesthetic agents and reversal of muscle relaxants allowing appropriate neuromuscular status, and ability of the ICU nursing staff, anesthesiologists, or intensivists to monitor and support the patient airway after extubation, including reintubation in a timely fashion. A careful and cautious approach is recommended, to avoid having to emergently reintubate an unstable patient. Most important of all is an institutional commitment to provide multidisciplinary collaboration to support this practice, specifically to include a period of observation (at least 30 min, but generally longer) by a skilled individual such as an experienced cardiovascular anesthesiologist or intensivist, whose only role during this time is to observe the patient. Moreover, the practice of early extubation requires the presence on the ICU at all times of a physician with the necessary skills for urgent reintubation.

Extubation After Difficult Tracheal Intubation

It is also important to note that in the patient with difficult tracheal intubation, the extubation of the trachea is also fraught with potential for airway compromise, and the same team of experts who participated in the intubation procedure should be consulted and the extubation planned carefully [1]. This may require the presence of an anesthesiologist in the ICU or on occasions may be most appropriately performed in the operating room with immediate availability of an otolaryngologist who can directly visualize the airway or even proceed urgently to provide a surgical airway if necessary.

Alternate Ventilation Strategies: Noninvasive Ventilation

With the recognition that mechanical ventilation is a source of barotrauma, volutrauma, and infection, recent years have witnessed resurgence in popularity of noninvasive ventilation techniques, either to prevent intubation or as an immediate postextubation therapy to prevent reintubation. Moreover, noninvasive positive pressure ventilation can provide useful cardiovascular support in patients with borderline or depressed systolic ventricular function. In neonates and small infants, nasal CPAP is often very effective and surprisingly well tolerated, and routine use of this modality after extubation in small infants is used in many PCICUs. CPAP of 5–10 cm H_2O for periods of 24–72 h is often utilized [23]. High-flow nasal cannula oxygen provides lower levels of positive pressure support, with humidified gas routed through a heated humidified circuit at flows of 5–25 L/min, and is an effective therapy for patients of all ages. In older patients unable to tolerate nasal CPAP or where it is not effective, CPAP or bi-level positive airway pressure (BiPAP), using a tight-fitting nasal mask, a mask covering the nose and mouth, or a full-face device, can provide very effective noninvasive positive pressure respiratory support [24].

Tracheostomy in Patients with Congenital Heart Disease

The decision to establish a long-term airway by tracheostomy in patients with congenital heart disease is a complex one. The usual indication is need for prolonged respiratory support from ongoing cardiopulmonary failure, often in combination with poor nutritional status, or in some

cases for recurrent upper airway or lower airway obstruction due to anatomic abnormalities such as severe micrognathia or compression of trachea or bronchi from enlarged cardiac chambers or aberrant great vessels [25]. Tracheostomy allows a secure, patent airway with little or no need for sedation, with a lower risk of lower respiratory tract infection, allowing long-term ventilation while the patient can be more active, feed, grow, and optimize neurodevelopment. However, there is often a concern that tracheostomy may complicate future cardiac surgery, with the proximity of the tracheostomy to the sternotomy, and bacterial colonization from bypassing the normal upper airway defense mechanisms, leading to a perceived higher risk of perioperative infection, including mediastinitis, although this impression is not supported by the limited literature available [25]. In patients with tracheostomy who require cardiac surgery, the tracheostomy is replaced with an endotracheal tube, either in the tracheostomy stoma, or placed translaryngeally, to allow the anesthesiologist better airway access. The length of time for endotracheal intubation before a tracheostomy is placed depends on the patient's exact situation, their age, and institutional preferences, but many practitioners would consider 30 days endotracheal intubation without prospect of imminent extubation an indication for tracheostomy for infants, and potentially a shorter period of intubation for older children and adolescents.

The tracheostomy procedure itself is carefully planned, with constant communication between surgeon and anesthesiologist, and the ETT is not withdrawn until the surgeon has incised the trachea, prepared the tracheostomy site and tube, and placed stay sutures in the edges of the tracheostomy to allow for rapid reestablishment of the airway [1]. The ETT is withdrawn slowly to just above the tracheostomy, but the tip is maintained below the vocal cords. After the tracheostomy tube position is confirmed by presence of end-tidal CO_2, effective ventilation, and equal breath sounds, it is secured with sutures to the skin and tracheostomy ties, and only then should the ETT be removed. Postoperative care usually requires deep sedation for several days to prevent excessive movement that would dislodge the tracheostomy. Patients with critical airways may need prolonged sedation. When the tracheostomy tract starts to mature, after 4–7 days, the tracheostomy tube is exchanged, and if there is no difficulty, the sedation and ventilatory support can be reduced significantly.

Conclusion

Airway management in pediatric patients with congenital or acquired heart disease requires special care and vigilance, combining the technical difficulties of managing patients with small airways, with the added risk of limited cardiopulmonary reserve. Careful planning is essential, taking into account the patient's hemodynamic status and the anticipated responses to the sedative and analgesic drugs, as well as the institution of positive pressure ventilation. Plans for resuscitation must be made for patients with marginal hemodynamic status. For the patient with the known or anticipated difficult tracheal intubation, thorough planning with consultation and assistance from skilled specialists in airway management is essential to optimize outcomes.

Pharmacokinetics and Application to Pediatric Practice

54

Denise L. Howrie and Carol G. Vetterly

Abstract

Infants, children, and teens present unique challenges in the appropriate, effective, and safe use of medications and are exposed to strikingly large numbers of medications, regardless of age. It is important to base drug selection on a foundational knowledge of pharmacokinetics and pharmacodynamics. Additionally, the progress of pharmacogenomics and the promise of personalized medicine can best be understood and utilized for pediatric patients when built upon pharmacokinetics and pharmacodynamics principles, especially when incorporated with knowledge of the influence of organ maturation upon drug handling. This chapter highlights important principles of pharmacokinetics, with applications and examples to enable pediatric practitioners to enhance drug use across the continuum of pediatric ages.

Introduction

The phrase "children are not little adults" reminds us that infants, children, and teens present unique challenges in the appropriate, effective, and safe use of medications. Pediatric patients, particularly in the hospital setting, are exposed to strikingly large numbers of medications, regardless of age, as described by Feudtner et al. who also documented greater numbers and types of drugs in children's hospitals as compared to general hospitals and in children with less common pediatric conditions [1]. It is therefore important to base drug selection on a foundational knowledge of pharmacokinetics [2] and pharmacodynamics. Additionally, the progress of pharmacogenomics and the promise of personalized medicine can best be understood and utilized for pediatric patients when built upon pharmacokinetics and pharmacodynamics principles, especially when incorporated with knowledge of the influence of organ maturation upon drug handling. Many excellent reviews of pediatric pharmacokinetics have been published [3–13]. This chapter highlights important principles of pharmacokinetics, with applications and examples to enable pediatric practitioners to enhance drug use across the continuum of pediatric ages.

Definitions and Principles

Pharmacokinetics is the study of the movement of drugs through the body, reflecting drug absorption, distribution, metabolism, and excretion/elimination [2–13]. This science describes the relationship between dose administered and drug exposure over time and, in pediatrics, must encompass age-related maturation. *Pharmacodynamics* is the study of the biochemical and physiological action or effects of drugs at the site of action, relating to the mechanisms of action of drugs [7, 9].

In establishing the relationship of drug concentrations to pharmacologic effect, animal models are initially used to determine the *median "effective" dose* (50 % experience therapeutic effects), *median "toxic" dose* (50 % experience adverse effects), and *therapeutic index* (the ratio of toxic dose to therapeutic dose). This establishes the *therapeutic window* of the agent [7]. For a drug with a narrow therapeutic index, a small change in serum concentration may dramatically change risk of toxicity [2] and may suggest a value for routine serum concentration monitoring (often called *therapeutic drug monitoring*; TDM) to guide drug use. Commonly evaluated drugs using TDM strategies in children include anti-infectives including vancomycin, aminoglycosides, and voriconazole; anti-epileptic drugs including phenytoin, carbamazepine, valproate, and phenobarbital; immunosuppressants including tacrolimus and cyclosporine; and chemotherapeutic agents such as methotrexate.

Sequential drug concentrations may be measured, usually using plasma sampling, and used to profile pharmacokinetic data and generate a *model* to quantify drug movement throughout the body. Because of the complexity of drug distribution, it may be necessary to profile the drug as it moves through one or more tissue *compartments* [2]. A *compartment* is a hypothetical space describing the relationship between drug dosage and amount of drug in the body at a given time. For many drugs for which TDM monitoring is used, a simplistic "one-compartment" approach is used, assuming the drug concentration in plasma immediately equilibrates instantaneously postinjection and treating all fluids and tissue as "one space" [6, 9]. In fact, this behavior is not seen for most drugs but can be used to describe when distribution is rapid when compared to absorption or distribution [9]. The ability to perform pharmacokinetic calculations using a one-compartment model facilitates accurate dose calculations in the patient care setting, as for aminoglycosides and vancomycin. For most drugs, however, *multi-compartment* models more accurately portray drug movement over time, as a two-compartment model [9]. In this model, initial concentrations achieved post-dose fall rapidly due to distribution followed by a slower decline due to drug elimination [9].

The half-life of a drug is defined as the time required for plasma concentrations to be reduced by 50 %, varying by drug clearance rates and drug

distribution [7]. It is important to analyze, through plasma concentration decline, the pattern of elimination for each individual drug. The elimination of most drugs may be described by *first-order pharmacokinetics* profile when the *fraction* of drug is eliminated at a constant rate per unit time and the *rate* of drug elimination is dependent upon the concentration of drug remaining in the body [2, 7]. This is in contrast to drugs such as phenytoin, alcohol, and aspirin that demonstrate *zero-order pharmacokinetics* when the *rate* of elimination is constant and the *fraction* of drug eliminated is dependent upon drug concentration. Elimination follows zero-order kinetics, for example, when CYP enzymes binding is saturated by drug molecules and further elimination cannot occur until binding sites become available [2, 7].

The term *steady state* refers to an equilibrium in which rate of drug administration equals rate of drug elimination, which is estimated to occur at approximately five times the drug half-life when 97 % of steady-state serum concentration fluctuation occurs [2, 6]. The term *clearance* refers to the volume of blood from which a drug is cleared per unit time [6, 9]. At steady state, the following relationship can be expressed: $dose = CL \times Cp$, *where* $CL = clearance$ *and* $Cp = average$ *steady-state concentrations*.

Drug Absorption and Pediatric-Specific Application

Drug absorption can be defined as the process of drug entry into the systemic circulation from the site(s) of administration [2–13]. Absorption efficiency is determined by mechanical factors such as dosage formulation (as in liquid or tablet form) as well as physiochemical factors such as molecular weight and ionization [2]. It is also helpful to consider both rate and extent of absorption [6]. The bioavailability of a drug is defined as the fraction of a given drug dose that is available at the site of action to exert its pharmacologic effect [2, 7], determined by extent of absorption and "first-pass" metabolism as may occur in the liver and gastrointestinal tract [2, 6, 7] often through effects of local CYP450 enzymes. The absolute drug bioavailability is determined as the ratio of drug amounts reaching systemic circulation following oral administration versus drug concentrations reaching systemic circulation following intravenous administration [9].

Oral/Enteral

The majority of commercially available medications are administered via the oral route. Orally administered medications require drug absorption in the gastrointestinal tract, determined by variables including surface area of the gastrointestinal tract, rates of stomach emptying and intestinal transit, pH of the stomach and small intestines, as well as blood flow to the absorption site.

The rate of oral/enteral drug absorption is generally slowed in infancy when compared to older children and adults [3]. Efficiency of absorption of drugs following oral administration may be variable, especially during infancy in the presence of prolonged gastrointestinal emptying time (6–8 h), unpredictable gastric peristalsis, and delayed time to peak concentrations [3, 5]. Gastric emptying times approach adult values by 6–8 months [5, 6, 8]. Prolonged gut motility of 8–96 h in premature infants contrasts with adult values of 4–12 h [11].

Effects upon absorption may result from the observed dramatic changes in gastric pH in infancy, as pH values of 1–3 are achieved within 24 h after birth, become acid neutral by 1 week of age, and slowly decline over 2–3 years to adult values [4, 6, 12]. Resulting changes in ionization may include greater absorption of beta-lactam antibiotics or reduced absorption of weakly acidic drugs, as demonstrated for phenytoin and phenobarbital in the higher pH environment of the newborn stomach [6, 8, 12].

Additional variables such as reduced glutathione-*S*-transferase activity, altered gut microflora, changes in splanchnic blood flow, diseases affecting gastrointestinal integrity, and diarrheal illness may contribute to altered efficiency of drug absorption and bioavailability when compared to older children and adults [3]. Reduced bile salt concentrations in young infants [6, 8] may reduce absorption of lipophilic drugs such as fat-soluble vitamins. However, although

rate of absorption, time of peak concentration, and actual concentration achieved may be affected, overall bioavailability may be unchanged, despite the many variables cited [8].

Other Routes

Absorption of medications through the skin may be dramatically increased, especially in infants, due to greater relative body surface area, enhanced hydration of epidermis and decreased thickness of the epidermis and stratum corneum [3–6, 8]. The ratio of total body surface area to body mass is greater in infants and children when compared to adults [3–5, 8].

Absorption from intramuscular injection sites may be less predictable in neonates due to variation in peripheral perfusion and limited muscle mass [3–6, 8, 11]. However, increased capillary density (25–50 %) [8] may result in efficient drug absorption for many drugs from intramuscular injection sites [11].

Drugs administered via *the rectal route* pass directly into the systemic circulation via the hemorrhoidal veins, bypassing any "first-pass" effects [2, 11]. Involuntary dose evacuation and incomplete absorption may limit this route of use. However, rectal administration of benzodiazepines such as diazepam [11] solution achieves effective concentrations for termination of seizures.

Drug Distribution and Pediatric-Specific Application

Drug distribution, the movement of drug through the body, occurs from transit via blood and diffusion through cell membranes into various body tissues via concentration gradients [2–13]. Drug usually undergoes rapid distribution to highly perfused organs (liver, kidneys) with variable patterns of distribution to other tissue compartments. Efficiency of distribution is determined by drug characteristics (lipid solubility, protein and tissue binding, pH and ionization, cellular membrane permeability) as well as patient characteristics (blood flow, body composition, total body water, disease states) [2, 7].

The apparent volume of distribution (Vd) of a drug indicates the extent of drug distribution into body fluids/tissues by relating the amount of drug in the body to measured plasma concentration (Css). Factors that cause shifts in drug from one compartment to another will cause changes in drug Vd. The Vd may also guide assumptions of drug distribution, as Vd less than 0.1 L/kg reflects intravascular space, Vd 0.1–0.3 L/kg reflects extravascular space, and Vd 0.6–0.7 L/kg reflects total body water space [6]. Calculated Vd values greater than 1 L/Kg reflect drugs with primarily extravascular distribution [2, 9].

The following equation demonstrates the relationship of total amount of drug in the body to plasma drug concentration and can be used to calculate drug "loading doses" to rapidly achieve target blood concentrations [7, 9]:

$$\text{Vd (L/Kg)} = \frac{\text{Amount of drug (mg)}}{\text{Css (mg/L)}}$$

For example, phenytoin dose requirements for a 20 Kg patient can be rapidly calculated by assumption of drug-specific Vd = 1 L/kg (or 20 L) and a target serum concentration of 20 mg/L:

$$\text{Drug dose (mg)} = 20\ \text{L}(1\ \text{L/Kg} \times 20\ \text{Kg}) \times 20\ \text{mg/L} = 400\ \text{mg}$$

There is significant age-related variability in volume of distribution for hydrophilic drugs such as penicillins, cephalosporins, and aminoglycosides due to changes in total body water. When compared to older children and adults, newborns and infants demonstrate higher percentage of body weight as total body water (and therefore larger Vd per body weight) [9]: 80 % total body weight in premature infants and 75–80 % in full-term newborns as compared to 50–60 % in adults [4–6, 8, 11]. Neonates and young infants also have a greater extracellular fluid compartment relative to body weight when compared to adults [3–6, 9]. When this pharmacokinetic parameter is considered, higher drug loading doses and daily maintenance doses per body weight may be required for hydrophilic

drugs in infants and young children [8]. However, not all medications show this pattern of Vd change over time

Preterm infants have significantly lower body fat (1 %) when compared to full-term infants (15 %) and adults (20 %) [5, 9]. Drugs that are lipid soluble would demonstrate lower volume of distributions in premature infants [9] which could lead to potentiated pharmacologic effects and toxicity. However, these effects are not generally observed, perhaps because of distribution to non-adipose tissues or other unique factors [8]. As the infant ages, the percentage of body weight contributed by fat doubles by 4–5 months [11] and increases up to approximately 10 years of age [6].

Plasma protein binding is another important determinant of drug distribution [7] with clinically relevant variations in infants and children, especially for drugs which demonstrate extensive binding to plasma proteins such as albumin and alpha-1-acid-glycoprotein (α-1-AG) [9]. Drug binding to albumin, the major plasma protein, is usually reversible, with multiple binding sites for acidic drugs [2]. Drug response in infants for phenytoin or valproate may be accentuated due to higher "free" or "unbound" drug concentrations due to lower albumin concentrations in the first year of life (75–80 % of adult values) and reduced affinity of fetal albumin [3–6, 8, 13]. Also, the potential competition of drugs with serum bilirubin that is also albumin bound requires caution with use of anionic drugs such as ceftriaxone and sulfonamides [4, 6].

As α-1-AG binds basic drugs, changes in α-1-AG occurring as an acute phase reaction may result in lower free concentrations of drugs such as lidocaine. In infants, α-1-AG concentrations are only 50 % that of adult levels, increasing slowly over the first year of life [4].

Drug Metabolism and Pediatric-Specific Application

Efficiency of drug removal by the liver (hepatic extraction ratio) is affected by hepatic blood flow, protein binding, and intrinsic metabolic activity [2–13]. Hepatic clearance of a drug (CLh) is defined as the volume of blood from which the drug is completely removed per unit time, which is a function of hepatic blood flow and extraction ratio of drug as follows:

$$\mathrm{CLh} = \mathrm{Q} \times \frac{\mathrm{Ci} - \mathrm{Co}}{\mathrm{Ci}}$$

where Q = hepatic blood flow, Ci is concentration of drug entering the liver, and Co is concentration of drug leaving the liver. For drugs such as metoprolol, propranolol, lidocaine, and nitroglycerin, clearance is greatly dependent upon hepatic blood flow and dosage adjustments should be considered.

Metabolism is the process by which a substance is biochemically transformed through a variety of chemical reactions. Metabolites may be either pharmacologically active (with greater, equal, or less activity relative to parent drug) or pharmacologically inactive forms [7]. Biotransformation occurs primarily in the liver [9], although metabolism may also proceed in the skin, lungs, intestine, and kidney [7, 8]. Drug metabolism generally proceeds through Phase I reactions (oxidation, reduction, sulfoxidation, hydrolysis) and Phase II reactions (conjugation, acetylation, glutathione conjugation, sulfation, and methylation) [2, 7, 8]. Phase I reactions generally result in more polar metabolites through biotransformation via mixed-function oxidase systems including cytochrome P450 reductase enzymes. In Phase II reactions, conjugation occurs with glucuronic acid, sulfuric acid, acetic acid, or an amino acid to increase polarity.

Drug metabolism in the liver proceeds via cytochrome P450 enzymes, which may also be found in the small intestine, kidney, lung, and brain. CYP isoenzymes are classified in families and subfamilies based on amino acid sequences. Over 90 % of common medications are metabolized by seven isoenzymes: CYP3A4, CYP3A5, CYP1A2, CYP2C9, CYP2C19, CYP2D6, and CYP2E1 [6, 12]. Multiple factors affect individual CYP activity including genetics and ethnicity, environmental factors (such as nicotine and ethanol), diseases, and concurrent medications which may act as competitive substrates, inhibitors, or inducers.

The CYP3A4 isoenzyme pathway is responsible for metabolism of over 75 % of all medications used in clinical practice. Forty percent of CYP3A4 activity is found in the small intestine, producing the "first-pass" phenomenon of drug metabolism prior to systemic exposure [6] and determining bioavailability of drugs including opioids, calcium channel blockers, and β-blockers. Examples of drug substrates for the CYP3A4 enzyme pathway include acetaminophen, lidocaine, prednisone, tacrolimus, amiodarone, calcium channel blockers, many benzodiazepines, lovastatin, and warfarin. Potent inhibitors of 3A4 activity include macrolide antibiotics such as erythromycin, azole antifungals such as fluconazole and voriconazole, and antidepressants such as sertraline, fluoxetine, and nefazodone. CYP3A4 inhibition due to constituents of grapefruit juice is a relatively new observation, requiring patient and caregiver counseling to avoid dietary sources of this fruit when prescribed medications such as cyclosporine, tacrolimus, warfarin and other medications. Enzyme activity is also affected by potent inducers including phenytoin, phenobarbital, carbamazepine, and rifampin. Additionally, interindividual CYP3A4 activity is widely variable, with 4–13-fold differences in drug clearance rates.

The CYP2D6 isoenzyme pathway affects approximately 25 % of drugs. This enzyme pathway demonstrates important variability based upon genetic polymorphisms, as discussed in later chapters. As many as 3–10 % of the Caucasian and 0–2 % of Asian and African-American populations may demonstrate slowed rates of drug metabolism and referred to as "poor metabolizers" for substrates including opioids.

The CYP2C19 isoenzyme pathway also demonstrates significant genetic variability caused by polymorphisms, potentially affecting approximately 15 % of medications. Approximately 3–5 % of Caucasians, 18–23 % of Asians, and 5 % of African-Americans demonstrate reduced CYP2C19 activity, increasing the risk of delayed drug metabolism and toxicity. Substrates for this isoenzyme system include *S*-warfarin, propranolol, and diazepam. Examples of drugs that may inhibit this system include fluconazole and potentially other azole antifungals, such as voriconazole, as well as omeprazole, sertraline, fluoxetine, and isoniazid. Inducing substances include phenytoin, phenobarbital, and carbamazepine as well as rifampin.

Another isoenzyme pathway responsible for metabolism of approximately 5 % of drugs is the CYP1A2 system, with important substrates including theophylline, R-warfarin, and caffeine, and inhibitors including azole antifungals, macrolides, fluvoxamine, paroxetine, and isoniazid.

Liver size relative to body weight changes during childhood, with maximum relative weight at 1–2 years of age when capacity for drug metabolism is generally at its greatest [11]. In infants and young children, Phase I reactions generally mature by age 1 year, while Phase II reactions may mature at a slower rate over years as exemplified by slowed development of acetyltransferase that limits accurate assessment of acetylation status until after several years of age. Slowed glucuronidation activity may have contributed to the observed toxicity of chloramphenicol and defects in bilirubin metabolism in young infants. Development of glucuronidation activity to adult values has been reported to occur over widely variable time periods from 3 months to >3 years of age. Sulfate conjugation can be an alternative pathway of metabolism for morphine and acetaminophen during infancy, while caffeine is formed to a greater extent from theophylline in full-term infants when compared to children and adults [13].

CYP activity is present at 30–60 % of adult values in infancy [4], and each CYP enzyme undergoes a unique rate of maturation. For example, CYP3A7 demonstrates greater expression in fetal liver [8] and regression to 10 % after age 3 months and undetectable levels in adults [3, 4]. CYP3A4 is reported to express at 50 % adult values between ages 6 and 12 months, with low activity in utero but rapid development within a week of life [3, 4] and throughout the first year of life [8]. Lower levels of CYP3A4 in infancy may have led to inability to clear cisapride and sildenafil and therefore increase drug toxicity risk [4, 8].

CYP2C, involved in metabolism of warfarin, phenytoin, and diazepam, demonstrates 33 % of eventual activity in the first month of life [4]. Interestingly, elevated CYP2C content has been reported in SIDS with a possible role of pulmonary smooth relaxation by endogenous substances metabolized through this system [4].

CYP1A2, involved in metabolism of acetaminophen, warfarin, caffeine, and theophylline, has low activity in neonates, develops in 1–3 months [3], and achieves 50 % adult activity by ages 1–9 years [4, 8]. CYP2E1 isoenzymes develop to 40 % values by age 1 year, with eventual adult values at 1–10 years [4]. CYP2D6 activity rapidly reaches adult levels by 2 weeks of age [8].

Phase II metabolism pathways also show significant maturation over time in newborns and young infants. Uridine 5′-diphosphoglucuronyltransferases (UGT) pathways similarly show diverse activity and development over age groups. UGT1A1 which is involved in acetaminophen and ibuprofen metabolism achieves adult levels by 3–6 months of life, with demonstrated activity soon after birth [8]. UGT1A9, however, matures to 64 % of adult levels over 2 years of age [8, 12]. Also, compensatory pathways may be prominent as exemplified by greater sulfation activity for acetaminophen [6] and N3-demethylation of caffeine more prominent in infants as compared to adults [4, 8].

Overall, infants show decreased ability to eliminate drugs, while young children are able to metabolize drugs via hepatic pathways more efficiently than adults and will require higher daily doses per body mass [7], with gradual conversion to adult patterns and rates during puberty [12].

Drug Excretion/Elimination and Pediatric-Specific Application

Drugs undergo excretion as active or inactive polar compounds through urine, bile, sweat, and other body fluids or via lung, with renal and biliary excretion generally most significant. Renal excretion of drug occurs through glomerular filtration, tubular secretion, and tubular reabsorption. Factors affecting glomerular filtration include protein binding (as only "free fractions" are filtered), molecular size, and quality and quantity of nephrons. Tubular secretion of weak organic acids or bases occurs via active transport subject to competition with other substances as well as two other nonspecific systems for anions and cations [2]. Tubular reabsorption of drugs occurs via active or passive transport in the distal tubule and is dependent upon urine pH, urine flow rates, and drug properties including ionization.

Kidney size relative to body weight changes during childhood, with maximum relative weight at 1–2 years of age when capacity for drug excretion is generally at its greatest [11]. Glomerular filtration function is dramatically reduced in newborns. Increases in glomerular filtration rate (GFR) occur in the 1st weeks of life [5] to achieve 50–60 % of adult function by the 3rd week of life [3] and adult values by 5–12 months of age [3, 6, 12, 13]. By ages 3–6 years, GFR values exceed adult values and higher daily doses per body mass are required in comparison to adult doses due to this increased GFR [6, 8].

Premature infants show slower improvement of GFR when compared to full-term infants, with continued reduced drug clearance despite chronologic age [8]. Drugs dependent upon glomerular filtration will show a decreased drug clearance through early infancy, more apparent in premature infants, and likely require dosage reduction.

Tubular secretion rates are also reduced in neonates [3, 5] and mature during the first year of life, reaching adult values by age 1 year [11, 12]. Tubular secretion, therefore, matures much later than glomerular filtration functionality. The development of renal excretion pathways must be considered for appropriate prescribing of many drugs in infancy, especially when drugs with narrow therapeutic indices are administered such as vancomycin and aminoglycosides [11].

Overall, children clear drugs via renal pathways more efficiently than adults [8] and will

require higher daily doses per body mass [7], with gradual conversion to adult patterns and rates during maturation.

Conclusions

The challenge of pediatric pharmacotherapy is providing safe and effective drug therapy across the continuum of pediatric patient ages, from newborns through adolescence. In order to achieve this, one must understand principles of pharmacokinetics and anticipate age-related changes that will affect drug selection and dosing. The ever-growing scientific evidence of drug handling, especially in vulnerable newborn and premature infants, provides a sound foundation for therapy, upon which newer knowledge of pharmacodynamics and pharmacogenomics can be built.

Pharmacogenomics: A Pathway to Individualized Medicine

55

Denise L. Howrie and Raman Venkataramanan

Abstract

Since the 1950s, the field of pharmacogenomics has rapidly expanded, yielding valuable evidence of the link of genetics and drug response whether due to alterations in drug metabolism, transport, target proteins, or genetically determined disease severity. The patient genome is postulated to account for 20–95 % of the variability of drug response. The impact of pharmacogenomics transcends the individual, with major repercussions upon drug discovery and development in pharmaceutical industry as well as the economics of health care. This chapter summarizes important principles and relevant examples.

Keywords

Pharmacogenomics • Pharmacogenetics • DNA • RNA • Drugs • Metabolism • Genome

Introduction

The history of pharmacogenetics dates from the 1950s with the observation of primaquine-induced hemolysis in the presence of glucose-6-phosphate dehydrogenase deficiency, establishing that drug-related toxicity may occur in genetically predisposed individuals. Since then, the field of pharmacogenomics has rapidly expanded, yielding valuable evidence of the link of genetics and drug response whether due to alterations in drug metabolism, transport, target proteins, or genetically determined disease severity. The patient genome is postulated to account for 20–95 % of the variability of drug response. The analysis of DNA sequencing and variation in single-nucleotide polymorphisms (SNPs) brings the hope of personalizing drug therapy for an individual. However, the impact of pharmacogenomics transcends the individual, with major repercussions upon drug discovery and development in pharmaceutical industry as

well as the economics of health care [1–3]. The following summarizes important principles and relevant examples [1–21].

Definitions and Overview

Pharmacogenomics, which is inclusive of the field of pharmacogenetics, may be defined as the study of variations in DNA and RNA characteristics in relationship to drug response reflecting the variation in the entire genome, describing often a more population-based focus [1–8]. *Pharmacogenetics* is the study of the role of genetic variations affecting an individual patient and the drug-specific response, often focused on a single or on a few gene analyses. The concept of "personalized medicine" is the extension of these studies intended to optimize drug therapy while limiting toxicity based upon genetic patterns or to choose therapy that is most likely to be effective and safe [1, 2].

The "genotype" refers to the genetic pattern of an individual, while the "phenotype" refers to the outcome of the interaction of genes with environmental factors (such as diet, drugs, and other exposures). Single-nucleotide polymorphisms (SNPs) constitute 90 % of all human genome variation with over four million mapped in the human genome [4]. These differences in one base pair in DNA may affect biotransformation pathways as demonstrated for many key hepatic isoenzyme families. Genetic copy-number variations (CNVs) also account for genomic variation. SNPs occurring within the same DNA region may be inherited in concert as haplotypes.

The term *genetic polymorphism* refers to naturally occurring differences in DNA sequence in individuals, usually present in a frequency of at least 1 % [4, 6]. These polymorphisms may affect enzymes, drug transporters, and/or receptors, with changes resulting in increased, decreased, or unchanged drug activity [5]. Polymorphisms may affect individuals or reflect pattern within ethnic groups. A given genetic polymorphism may significantly determine drug pharmacokinetics or pharmacodynamics and/or disease activity and severity.

Pharmacogenetics and Biotransformation

Although pharmacogenetics is perceived as a relatively recent area of study, there is extensive retrospective history of the impact of genetics upon biotransformation and toxicity. Examples include isoniazid-related peripheral neuropathy in patients with *N*-acetyltransferase deficiency ("slow acetylators" in 50 % African-Americans and Caucasians) and glucose-6-phosphate dehydrogenase deficiency with subsequent risk of hemolysis with multiple drugs [2].

In the 1970s, variability of drug metabolism was first documented through evidence of reduced metabolism in up to 10 % of Europeans for debrisoquine [6]. Subsequent research into cytochrome P450 isoenzyme families resulted in identification of this pathway as CYP2D6. Extended knowledge of drug-metabolizing enzymes provided the early foundations of pharmacogenetics. Variation in individual genotypes may correspond to observed phenotypic presentations, with characterization of drug metabolism varying from "poor" to "ultrafast" [8].

Of the over 57 different CYP isoenzymes and 42 involved in metabolism [4], polymorphisms leading to absence of enzyme activity exist in four major families: CYP2D6, CYP2C19, CYP2A6, and CYP3A5 [4, 6]. Limited relevance of CYP3A4 variants has been proposed, despite extensive variation in CYP3A4 activity and the large number of drugs undergoing biotransformation through this system. However, polymorphisms of CYP3A5 may be present in 60 % of African-American and 33 % of Caucasians [4].

As over 25 % of all drugs undergo metabolism via CYP2D6, genetic influences may exert more dramatic effects upon these drugs. Over

80 unique allelic variants in CYP2D6 have been determined, with patterns of "poor metabolism," "intermediate metabolism," and "ultrafast metabolism." [7] Alleles associated with impaired metabolism include CYP2D6*10 (East Asia), CYP2D6*17 (Africa), and CYP2D6*9 and CYP2D6*41 (Europe). However, ultrarapid metabolism has also been detected in subjects with CYP2D6*1 or CYP2D6*2 alleles. For example, lack of effective codeine conversion to the active component morphine in CYP2D6*4 homozygous individuals (so-called "slow metabolizers") results in little or no analgesia. However, "rapid metabolizers" may risk excessive opioid toxicity due to higher than usual morphine generation [1, 2, 4]. Conversion of tramadol to *O*-desmethyltramadol may also be affected by CYP2D6 polymorphism in a similar manner [4]. The conversion of tamoxifen via CYP2D6 to endoxifen is required for biologic activity in breast cancer so that patients showing reduced metabolism may show increased tendency to relapse [4, 6].

There are over 16 variations in CYP2C19 activity, ranging from deficient, reduced, normal, to increased [7]. CYP2C19*17 is associated with ultrarapid metabolism, while CYP2C19*2 and CYP2C19*3 identify poor metabolism [7]. Polymorphisms in CYP2C19 SNPs, for example, have been correlated with altered activity of proton pump inhibitors such as omeprazole, with higher blood levels and acid suppression in poor metabolizers and lower blood concentrations and resulting drug effects in the ultrarapid metabolizers [6, 7]. Other substrates for CYP2C19 include citalopram and select benzodiazepines including diazepam [6]. There are at least 27 variant alleles for CYP2C19, with frequency reflecting ethnicity: 15 % Caucasians, 30 % Asians, and 17 % African-Americans.

Over 33 variant alleles for CYP2C9 have been noted, mostly related to decreased activity. Either or both of two common alleles, CYP2C9*2 or CYP2C9*3, are found in 30 % of Northern Europeans and associated with reduced enzyme activity [7]. These polymorphisms may be of greatest importance with drugs such as warfarin, explaining 10–20 % variability in dose requirements [6] with increased risk of anticoagulation and lower daily dose needs [7].

Other CYP isoenzymes of potential importance in discussion of pharmacogenetics include CYP2B6 which may predispose to efavirenz-associated central nervous system toxicity and CYP2A6 which may be of clinical significance in nicotine dependency [4].

Pharmacogenetics of Other Reactions

Polymorphisms of conjugation reactions with reduced or absent activity have been documented for methylation reactions such as thiopurine *S*-methyltransferase (TPMT; 1 in 300 Europeans) and glucuronidation as for UDP-glucuronosyl transferase (uridine diphosphoglucuronosyl transferase). Assessment of genotype is recommended for TPMT when mercaptopurine or thioguanine may be prescribed, screening for TPMP homozygous or individuals at increased risk of severe hematologic toxicity who may benefit from dosage adjustment or who should not be treated with these agents [8]. UGT1A1*28 allele determination is also recommended when irinotecan use is proposed [6].

Transporter gene pharmacogenomic studies for ABCB1 gene and *p*-glycoprotein response have yielded conflicting data. As discussed by Cavallari and Yam, drugs that are substrates for *p*-glycoprotein-facilitated transport may also be subject to CYP450 biotransformation, leading to more complex impacts of genetic variations [4].

Pharmacogenetics and Drug Targets Including Receptors and Enzymes

Pharmacogenetics of drug target molecules may also determine drug responses independent of or in addition to biotransformation [2, 4–8]. Polymorphisms of drug receptors including beta-adrenergic receptors have been the source

of extensive research, given importance in diseases including hypertension, heart failure, and asthma. Beta-adrenoreceptor genes ADRB1 and ADRB2 provide targets for catecholamines and other medications, with SNPs associated with altered responsiveness of the receptor [8]. Reduced responsiveness to beta-agonist therapy and loss of asthma control has been observed in patients with beta-2 receptor arginine genotype as compared to glycine genotype, with 15–20 % of African-Americans and Caucasians possessing the arginine genotype.

Genetic polymorphisms for other drug receptor genes are also relevant to cardiovascular pharmacotherapy including angiotensin-converting enzymes, angiotensinogen, apolipoprotein E, and cholesteryl ester transfer protein [7]. Polymorphisms in the ACE gene may be linked to plasma concentration of ACE but results of study of ACE inhibitor response are conflicting. However, it is possible that multiple genetic variants determine ACE inhibitor responsive, rather than a single gene [4].

Genetic variation in target enzymes is also of importance for warfarin and statins. Variability in the gene encoding vitamin K epoxide reductase (VKORC1) has been demonstrated, with four haplotypes that contribute to variation in warfarin dose requirements. HMG-CoA reductase is the target enzyme for the statins; two polymorphisms of the gene coding this enzyme are documented.

Pharmacogenetics of Toxicity

Drug toxicity may occur as an extension of deficiency of drug detoxification or transport. However, idiosyncratic toxicities have been reported which also are examples of pharmacogenetics. Drug-induced liver disease has been associated with occurrence of HPA-B*5701 allele. This allele has also been incriminated in abacavir-induced hypersensitivity reactions; genetic testing is recommended prior to initiation of abacavir as an antiviral agent [6]. Severe cutaneous reactions with carbamazepine including Stevens-Johnson syndrome have been associated with HLA-B*1502 allele in Asians, with variation in incidence depending upon place of ancestry from Asia. As a result, in 2007 the FDA recommended all patients of Asian descent be screened for this allele prior to initiation of therapy [5].

Increased risk of thromboembolic disease during oral contraception use is well documented, particularly when variation in genes for factor V Leiden or prothrombin gene variations are present. Genetic predisposition may also be incriminated in risk of QT-interval prolongation and risk of torsades de pointes due to genetic mutations in channel proteins affecting potassium and sodium transport [4].

Specific Cardiovascular Agents of Interest

The following are brief summaries of documented relationships of cardiovascular pharmacogenomics for target drugs, with more extensive published reviews available [9–16].

Warfarin

Wide interindividual variations in drug dosing and response for warfarin exemplify the potential impact of pharmacogenetics in clinical practice [4, 9, 12, 15, 16]. Multiple genetic variations in warfarin biotransformation pathways have been documented.

This anticoagulant undergoes complex biotransformation, as it is a racemic mixture of the S isomer (metabolized through CYP2C9) and less active R isomer (metabolized through CYP3A4, CYP1A1, CYP1A2, CYP2C8, CYP2C9, CYP2C18, and CYP2C19). As the S isomer accounts for the majority of anticoagulant activity with highest inhibition of the VKORC1 enzyme in vitamin K-dependent clotting, variants in CYP2C9 increase risk of bleeding or delayed onset of drug effects. Although variants are rare in Asians and African-Americans, Caucasians may demonstrate alterations in CYP2C9*2 (8–20 %) or CYP2C9*3 (6–10 %) activity, with

altered drug pharmacokinetics and increased risk of elevated INR and bleeding. Importantly, there may be delay in time to optimal INR due to delayed clearance [15].

Additionally, multiple polymorphisms in the target VKORC1 gene coding vitamin K epoxide reductase activity have been documented, altering pharmacodynamic responses for warfarin independent of CYP2C9 activity. Depending upon the individual's genotype pattern, warfarin doses may be widely variable. VKORC1 polymorphism vary by race and may explain why, for example, Asian patients require lower daily drug doses when compared to doses for those of European or African ancestry [15].

The changes in VKORC1 and CYP2C9 activity account for approximately 40 % of variation. Polymorphisms in CYP4F2 (vitamin K_1 oxidase, responsible for epoxide form metabolism) may also affect dose requirements. Genotyping of VKORC1 and CYP2C9 may assist in drug dosing and has been the basis for over 40 pharmacogenetically based dosing algorithms. Warfarin labeling includes a table of starting doses based upon patient VKORC1 and CYP2C9 genotyping. Warfarin pharmacogenomic testing is available, although expensive and with limitations in profile of polymorphisms detected. At this time, there is no consensus as to who should be tested, when it should occur, and the predictive nature of dosing tables. Clinical utility of testing remains to be validated, with extensive studies currently underway.

Clopidogrel

Clopidogrel, as an antiplatelet agent, demonstrates reduced drug responsiveness in up to 30 % of patients [4, 9–13, 15]. It is a prodrug requiring a two-step activation by multiple CYP450 isoenzymes including CYP2C19 pathways to generate the active metabolite, with reduced rates of metabolism, decreased platelet activation, and higher risk of cardiovascular event compared to those with normal CYP2C19 activity [10]. Carriers of CYP2C19*2 and CYP2C19*3 are "poor metabolizers," with nonfunctional enzymes, while carriers of CYP2C19*17 demonstrate increased activity ("ultrarapid metabolizers"). CYP2C19*2 polymorphism is found in approximately 15 % Caucasians and Africans and 30 % Asians [12].

In 2010, a black box label was added for clopidogrel (Plavix) to highlight the role of *CYP2C19* gene variants in drug response, specifically "slow metabolizers." However, as reviewed by Goswami et al., studies of CYP2C19 polymorphism and drug efficacy have yielded variable results, suggesting that this polymorphism may account for only 12 % of response variability [11].

CYP2C19 genotyping is available for diagnostic testing. Complete genotyping profiles are not available and the testing is expensive. The Clinical Pharmacogenetics Implementation Consortium has provided an algorithm for antiplatelet agents using genetic testing [13]. However, routine genetic testing is not yet supported and the clinical utility of such testing has not been demonstrated [15].

Beta-Blockers

Response to beta-blockers may also be influenced by genetic polymorphism [4, 12, 14]. Polymorphisms in CYP2D6 may determine pharmacokinetic variation for selected beta-blockers such as metoprolol and carvedilol, as highlighted in drug labeling. Other SNP variations in beta-1 and beta-2 receptor genes as well as polymorphisms in alpha-receptors may also influence drug response, although data has been inconsistent.

Statins

HMGCR inhibitors also provide examples of pharmacogenetic linkage to observations of drug dosing, efficacy, and toxicity [4, 12]. Pharmacokinetic variations with altered dose requirements may result from polymorphisms of CYP3A4 enzymes. The presence of H7 haplotypes of HMGCR and L5 haplotype of LDLR

may reduce state responsiveness. Genotyping may also be helpful in prediction of risk of myalgias and other muscle toxicity. The SLC01B1*5 allele mediating hepatic uptake has been associated with higher statin concentrations and may dramatically increase risk of myopathy or myalgias [4, 12].

Pharmacogenomic Testing and Utilization

In 2011, over 70 medications contained pharmacogenomic information in FDA-approved drug labeling. FDA-required labeling revisions have been made for dozens of drugs including warfarin, carbamazepine, imatinib, warfarin, irinotecan, and mercaptopurine [17–21]. Pharmacogenetic testing is available for many commonly used medications ranging from anti-infective agents, chemotherapeutic agents, immunosuppressants, antiepileptic agents, cardiovascular agents, to warfarin, although there are relatively few FDA-approved pharmacogenetic test methods available [11]. Stanek et al. reported only 10.3 % of surveyed physicians had ordered such testing in the preceding 6-month interval, while 26.4 % anticipated ordering testing in the next 6-month period. Although 97.6 % of physicians agreed that pharmacogenetics may affect drug response, less than 30 % had received relevant education in the area [18]. In a random telephone survey, most US adults favored testing to evaluate side effect risk and to improve dosing or drug selection. However, those surveyed were unlikely to authorize testing if there was a chance of DNA sharing and loss of confidentiality [19].

Pharmacogenetic testing generally occurs for an individual patient for a target drug. However, a more prospective use of pharmacogenetics has been proposed using data embedded in electronic medical records so as to prospectively aid drug prescribing. Initial work by Schildcrout et al. has demonstrated that approximately 65 % of over 50,000 patients were exposed to at least one pharmacogenetic target drug and that 383 toxicity events could have been prevented with preemptive genotyping programs [17]. Johnson et al. described a customized system for generating patient-specific genotyping for a wide array of SNPs with relatively low cost and rapid turnaround, with capability of placement in a patient medical record [20]. O'Donnell et al. also reported a medical model for implementing preemptive genotyping which could be the basis for further study of genetic utility [21].

The universal use of pharmacogenetic testing remains controversial, even for drugs with known genetic variations that may significantly affect toxicity risks or efficacy. Variable reimbursement practices, especially for private insurers, high test cost, and significant lag time to results provide logistical impediments. The greater question is the utility of testing and impact on outcomes of therapy, which remain active areas of research for major drugs at this time.

Conclusion

Drug response is the result of the complex interplay of environmental and genetic factors. Drug biotransformation and interaction with target receptors or enzymes is determined by genotype and is significantly a product of patient heredity. "Personalized medicine" using preemptive pharmacogenetic information linked to medical records for use at time of initial prescribing may reduce patient risk and enhance outcomes. As rapid scientific and technologic advances are enabling these advancements, the next critical research questions must examine the utility of pharmacogenetic testing in patient care.

Ionotropic, Lusitropics, Vasodilators and Vasoconstrictors

56

Ryan Flanagan, Carol G. Vetterly, and Ricardo Muñoz

Abstract

This chapter is intended to review the vasoactive medications that are described as inotropes, lusitropes, vasoconstrictors, and vasodilators. The inotropes include dobutamine, dopamine, epinephrine, norepinephrine, isoproterenol, dopexamine, and digoxin. The lusitropes include milrinone and inamrinone. The vasoconstrictors include phenylephrine and vasopressin, and the vasodilators include enalapril, esmolol, hydralazine, labetalol, nitroglycerin, nitroprusside, sildenafil, and verapamil. The chapter will provide an overview of the medications and primarily focus on the drug's mechanism of action, therapeutic uses, pediatric drug dosing, and adverse effects associated with their use.

Keywords

Digoxin • Dobutamine • Dopamine • Enalapril • Epinephrine • Esmolol • Hydralazine • Inamrinone • Inotropes • Isoproterenol • Labetalol • Lusitropes • Milrinone • Nitroprusside • Nitroglycerin • Norepinephrine • Phenylephrine • Sildenafil • Vasoconstrictors • Vasodilators • Vasopressin • Verapamil

Introduction

Vasoactive drugs are the primary group of medications used to maintain the cardiocirculatory system in patients requiring cardiovascular support and when treating cardiovascular failure. These cardiovascular medications target specific receptors. The primary receptor sites are in the myocardium as well as in the pulmonary and systemic vasculature. It is imperative to appropriately differentiate between these sites, as medications bind to specific receptors to exert their effects. This chapter will provide an overview of vasoactive medications, including those belonging to the categories of inotropes, lusitropes, vasodilators, and vasoconstrictors.

Inotropes

Dobutamine

Dobutamine stimulates beta-1-adrenergic receptors in the heart, which results in increased cardiac contractility and heart rate. It possesses mild beta-2 and vascular alpha-1 activity. This results in strong ionotropic effect without producing vasoconstriction [1]. Dobutamine is used for the management of patients with heart failure and shock. Its onset of action via the intravenous route is 1–10 min with its maximal effect seen within 10–20 min. Metabolism occurs in the liver to inactive metabolites by catechol-orthomethyltransferase followed by glucuronidation. Its half-life is approximately 2 min and it is eliminated by the kidneys and in the bile. Dobutamine increases cardiac contractility, cardiac output, stroke volume, and blood pressure by its potent inotropic and mild systemic and pulmonary vasodilator effects [1]. Dobutamine increases urine output when administered following volume replacement. Adverse effects that may be associated with the use of dobutamine include hypertension, arrhythmias, headache, vomiting, nausea, cramps, paresthesias, phlebitis, or dyspnea. Dobutamine is administered as a continuous infusion and the dose is titrated based on the patient's clinical response. The usual dose range is 2–15 mcg/kg/min. Higher doses may be warranted in certain clinical situations.

Dopamine

Dopamine stimulates both dopaminergic and adrenergic receptors in a dose-dependent manner. Lower doses stimulate dopaminergic receptors which results in renal and mesenteric vasodilation and increased perfusion. Intermediate doses produce effects on both dopaminergic and beta-1-adrenergic receptors which result in an increased heart rate and cardiac index as well as increased renal blood flow. High doses of dopamine stimulate alpha-adrenergic receptors, producing vasoconstriction and increased blood pressure and heart rate [2]. High doses of dopamine may also be used as adjunctive therapy for the treatment of unresolved shock following volume resuscitation. Its onset of action is approximately 5 min, and it must be administered by a continuous infusion due to its short duration of action which is approximately 10 min. Seventy-five percent of the dose is metabolized in the plasma, kidneys, and liver to inactive metabolites by monoamine oxidase and catechol-o-methyltransferase, and 25 % is metabolized to the active metabolite of norepinephrine. Its half-life is 2 min. Its clearance is prolonged in patients that have both hepatic and renal dysfunction. Dopamine has exhibited nonlinear kinetics in children, and steady state may not be achieved for approximately 1 h, as compared to 20 min in adults [3, 4]. Dopamine increases cardiac contractility and output and improves blood pressure. It also increases urine output in patients who have been adequately hydrated. Adverse reactions associated with dopamine include tachycardia, vasoconstriction, ectopic beats, widened QRS complexes, AV conduction disturbances, hypertension, ventricular arrhythmias, gangrene of the extremities, angina, dyspnea, headache, nausea, vomiting, azotemia, and decreased urine output with high doses. As described above, the hemodynamic effects of dopamine are dose dependent.

Doses of 1–5 mcg/kg/min (low doses) produce an increase in renal and mesenteric blood flow and urine output. Doses in the range of 5–15 mcg/kg/min (intermediate doses) result in increased renal blood flow, heart rate, cardiac contractility, cardiac output, and blood pressure. High dose dopamine of greater than 15 mcg/kg/min produces predominately alpha-adrenergic effects including vasoconstriction and increased blood pressure. In children, the doses range from 1 to 20 mcg/kg/min and are titrated to the desired response. In some exceptional clinical situations, doses may be increased to 50 mcg/kg/min. Doses may exhibit individual variation depending upon the density of dopaminergic receptors.

Epinephrine (Adrenaline)

Epinephrine is a sympathomimetic agent that possesses a diverse range of effects. It stimulates alpha-, beta-1-, and beta-2-adrenergic receptors resulting in relaxation of smooth muscle of the bronchioles, cardiac stimulation, and dilation of skeletal muscle vasculature. Lower doses ($<$0.3 mcg/kg/min) can cause vasodilation through stimulation of beta-2-vascular receptors. At high doses ($\geq$0.3 mcg/kg/min), alpha-adrenergic effects predominate and produce constriction of skeletal and vascular smooth muscle resulting in an increase in systemic vascular resistance and mean arterial pressure [5]. Continuous infusions of epinephrine are used in the management of patients with compromised cardiac contractility and chronotropy, such as low cardiac output syndrome, post-cardiopulmonary bypass, or myocardial dysfunction with other etiologies. It is also used in treatment of refractory, fluid-resistant hypotension and shock. The onset of action is rapid and it is extensively metabolized in the liver by the enzymes catechol-*o*-methyltransferase and monoamine oxidase. Adverse effects associated with epinephrine include arrhythmias, angina, tachycardia, anxiety, headache, nausea, vomiting, urinary retention, and decreased renal and splanchnic blood flow. The dose for continuous infusion for inotropic and chronotropic support ranges from 0.01 to 0.2 mcg/kg/min, with the aim of achieving desired effects at the lowest dose. Treatment of refractory hypotension and shock utilizes a higher continuous infusion dose in the 0.1–1 mcg/kg/min range.

Norepinephrine (Noradrenaline)

Norepinephrine stimulates alpha-adrenergic receptors and beta-1-adrenergic receptors causing peripheral vasoconstriction as well as increased contractility, heart rate, and coronary artery vasodilation. This results in increased systemic blood pressure and coronary blood flow. The vasoconstrictive (alpha) effects are clinically greater than the inotropic and chronotropic effects (beta). This vasoactive medication is utilized in the management of severe hypotension and shock that is refractory to volume replacement [6]. Norepinephrine has a rapid onset of action and a short duration (1–2 min) of vasopressor effects; therefore, it must be administered by a continuous infusion. It is metabolized by catechol-o-methyltransferase and monoamine oxidase enzymes and is excreted extensively in the urine (85–95 %) as inactive metabolites. Norepinephrine increases arterial blood pressure through vasoconstriction and causes minimal change in heart rate or cardiac output. Adverse effects of norepinephrine infusions may include arrhythmias, bradycardia, dyspnea, and skin necrosis if extravasation occurs. It is administered as a continuous infusion at a dose range of 0.05–2 mcg/kg/min [7].

Isoproterenol

Isoproterenol stimulates beta-1 and beta-2 receptors which results in increases in heart rate and cardiac contractility, and produces vasodilation of the peripheral vasculature. It also causes relaxation of bronchial, gastrointestinal, and uterine smooth muscle. Isoproterenol is used to treat

bradyarrhythmias, refractory torsades de pointes, and AV nodal block in both adults and children. Intravenous isoproterenol has an immediate onset of action and a duration of action of approximately 10 min. It has a half-life of two and a half to 5 min. It is metabolized through conjugation reaction in many tissues including liver and lung tissue, and it is excreted in the urine as sulfate conjugates [8]. Patients may exhibit dose-dependent vasodilation due to unopposed beta-2 agonism elicited by isoproterenol. Isoproterenol may cause adverse reactions which include angina, flushing, hypertension, hypotension, premature ventricular beats, ventricular arrhythmia, hypokalemia, hyperglycemia, nausea, vomiting, dyspnea, and Adams-Stokes attacks. Isoproterenol is administered as a continuous infusion with pediatric dosing ranging from 0.05 to 2 mcg/kg/min and should be titrated to the desired response. The adult dose ranges from 2 to 20 mcg/min and the infusion rate is titrated to the desired clinical response.

Dopexamine

Dopexamine is a beta-2-adrenoreceptor agonist with less activity on the beta-1 receptors and DA1 and DA2 receptors [9]. Its onset of action is 10–15 min and it is metabolized in the liver to a great extent by monoamine oxidase and catechol-ortho-methyltransferase. Its half-life is approximately 7–11 min and it is eliminated in the urine and the bile. Dopexamine decreases afterload through its effects on arterial vasodilation. It is also produces mild cardiac stimulation through its positive ionotropic effects. It does not cause vasoconstriction because it has no alpha-adrenergic effects. Dopexamine's adverse effect profile includes sinus tachycardia, angina, chest pain, arrhythmias, tremors, hypokalemia, hyperglycemia, and phlebitis [9]. It is administered as a continuous infusion and the dose range in children, including infants and neonates, and adults is 0.5–6 mcg/kg/min. The dose should be titrated to achieve the desired clinical response with the minimum effective dose necessary to produce the effect.

Digoxin

Digoxin is classified as a cardiac glycoside which is derived from the foxglove plant *(Digitalis purpurea)*. It produces its positive inotropic effect by increasing the inward movement of calcium ions by inhibiting the sodium and potassium ion movement across the membrane in the myocardium. This ion transport system moves sodium ions out of the cell and transports potassium ions into the cell. By inhibiting Na^+/K^+-ATPase, cardiac glycosides cause intracellular sodium concentration to increase. This leads to an accumulation of intracellular calcium through the Na^+-Ca^{++} exchange system. In the heart, increased intracellular calcium causes more calcium to be released by the sarcoplasmic reticulum, making more calcium available to bind to troponin C, which increases contractility of the myocardial muscle. Inhibition of Na^+/K^+-ATPase in vascular smooth muscle causes depolarization, which produces smooth muscle contraction and vasoconstriction [10].

The onset of action of an intravenous dose ranges from 5 min to 1 h. An oral dose can take as long as 2 h to demonstrate an effect. The maximum effect of heart rate control of an intravenous dose may range from 1 to 6 h, and an oral dose from 2 to 8 h. It is absorbed in the upper small intestines by passive non-saturable diffusion [11]. The distribution phase of digoxin ranges from 6 to 8 h. It is extensively distributed to peripheral tissues with concentrations in the heart, liver, kidney, skeletal muscle, and intestines. During this phase, the pharmacologic effects do not correlate well with serum concentrations. It is 25 % bound to plasma proteins and is metabolized by sequential sugar hydrolysis in the stomach. Digoxin has a very long half-life. In the infant population, the half-life ranges from 18 to 25 h. The half-life in children and adults are 35 h and 36–48 h, respectively [11]. As a result of its prolonged half-life, loading doses are required to rapidly achieve the desired plasma concentrations. This is referred to as digitalization. Digoxin has a narrow therapeutic window; therefore, it is imperative to maintain plasma concentrations between 1 and 2 ng/ml. Drug

Table 56.1 Digoxin dosing table

	Total digitalizing dose (mcg/kg)		Daily maintenance dose (mcg/kg)	
Age	Oral	IV	Oral	IV
Preterm infant	20–30	15–25	5–7.5	4–6
Full-term infant	25–35	20–30	6–10	5–8
1 month– 2 years	35–60	30–50	10–15	7.5–12
2–5 years	30–40	25–35	7.5–10	6–9
5–10 years	20–35	15–30	5–10	4–8
Greater than 10 years	10–15	8–12	2.5–5	2–3

levels above 2 ng/ml can produce digoxin toxicity which can produce fatal arrhythmias [10].

The dosing for digoxin based on lean body weight in patients with normal renal function is reflected in the following Table 56.1.

Half of the total digitalizing dose should be administered as the initial dose. This should be followed by one quarter of the dose administered 8 h later, followed by the remainder of the loading dose, 8 h after that. In patients less than or equal to 10 years of age, the daily maintenance dose is divided into a twice daily dose. For patients greater than 10 years old, the daily maintenance dose is given as a single daily dose. In end-stage renal disease, the loading dose should be modified by a 50 % decrease. In patients with renal dysfunction, the maintenance dose should be adapted based on creatinine clearance. If the creatinine clearance is in the range of 10– 50 ml/min, 25–75 % of the normal daily dose should be administered. If the creatinine clearance is less than 10 ml/min, 10–25 % of the normal daily dose should be given.

The most common adverse reactions that can result from digoxin in children are cardiac conduction disturbances and tachyarrythmias [12]. Infants may demonstrate sinus bradycardia as an indication of digoxin toxicity. Cardiovascular adverse reactions include asystole, atrial nodal ectopic beats, atrial tachycardia with or without AV block, bigeminy, PR prolongation, SA block, sinus bradycardia, ST segment depression [12], ventricular arrhythmias, ventricular tachycardia, ventricular fibrillation, and first-, second-, or third-degree heart block. Central nervous system side effects include dizziness, headache, and delirium. Other adverse reactions associated with digoxin toxicity include hyperkalemia, abdominal pain, vomiting, diarrhea, feeding intolerance, and blurred vision or diplopia.

Lusitropes

In addition to the drugs belonging to the class named intropes, there are drugs that possess lusitropic properties and also have an important role in the management of patients with heart failure.

Cardiac muscle contraction is regulated by intracellular concentrations of cAMP as a second messenger. The activation of sympathetic adrenergic receptors to the cardiac muscle releases norepinephrine as well as increases the amounts of epinephrine and norepinephrine circulating in the body. They bind to beta-1 receptors in the heart and are coupled to Gs proteins. This then activates adenyl cyclase to form cyclic AMP (cAMP) from ATP. Increased amounts of cAMP result in increased contractility (also referred to as inotropy) as well as heart rate (chronotropy) [13]. The enzyme cAMP-dependant phosphodiesterase breaks down cAMP. If this enzyme is inhibited, the amount of cAMP is increased, resulting in increased cardiac output. Systemic vascular resistance is also reduced because of the effect of cAMP on vascular smooth muscle. Increased cAMP in smooth muscle causes relaxation due to the mechanism of cAMP inhibiting myosin light chain kinase, an enzyme which assists in muscle contraction [13]. Drugs that have lusitropic properties produce ventricular

relaxation. Cardiac-selective phosphodiesterase inhibitors (PDE-3) such as milrinone and inamrinone have positive lusitropic effects.

Milrinone

Milrinone selectively inhibits phosphodiesterase type 3 in cardiac and vascular tissues. This results in inotropic effects and vasodilation with minimal chronotropic effects. It has an onset of action of 5–15 min and is approximately 70 % bound to plasma proteins. Milrinone is partially metabolized in the liver and has a half-life of approximately 2.5 h in patients with normal renal function. Eighty-five percent is excreted in the urine via active tubular secretion in its unchanged form within 24 h [12, 14]. Milrinone is used for short-term management of acutely decompensated heart failure and for short-term improvement in hemodynamics; it may also be used for longer-term management of patients with persistent cardiac failure (i.e., while awaiting orthotopic heart transplant). The major adverse reactions associated with the use of milrinone that occur with a frequency of 1 % to greater than 10 % include ventricular arrhythmias, supraventricular arrhythmia, hypotension, angina, and headache. Milrinone dosing may include an optional loading dose of 50 mcg/kg infused over 10 min, followed by a maintenance infusion dose of 0.25–0.75 mcg/kg/min. In some cases where hypotension is present, the maintenance infusion may be started without administering a loading dose. This could delay the hemodynamic effect by several hours [15]. In patients with renal impairment, the continuous infusion dose should be reduced based on creatinine clearance and clinical effects.

Inamrinone

Inamrinone is a type III phosphodiesterase inhibitor that is used for short-term therapy in patients with unresponsive heart failure. Inamrinone inhibits myocardial cAMP phosphodiesterase activity and increases intracellular levels of cAMP which produces positive inotropic effects and increases cardiac output. Its pulmonary and systemic vasodilator properties reduce preload and afterload. Inamrinone has a very rapid onset of action of 2–5 min with peak effects seen in 10 min. It has a dose-dependent duration of effect, with lower doses reaching 30 min and higher doses as long as 3 days. Inamrinone has a half-life of approximately three and a half hours but increases to 6 h in adult patients with heart failure. Ten to forty percent of a dose is excreted unchanged in the urine [16]. Adverse reactions with an incidence reported in the range of 1–10 % include arrhythmias, hypotension, nausea, vomiting, and dose-related thrombocytopenia. The dose utilized in heart failure includes a 0.75 mg/kg loading dose over 2–3 min followed by a maintenance infusion of 5–10 mcg/kg/min. The bolus dose may be repeated after 30 min. The daily dose should not exceed 10 mg/kg per 24-h period. In renal dysfunction, the dose for infants and children requires an adjustment to 50 % of dose if the creatinine clearance is between 10 and 29 ml/min and 25 % of the dose be administered if the creatinine clearance is below 10 ml/min [12].

At this time, inotropic medications have not demonstrated consistent hemodynamic improvement other than in short-term use in patients with heart failure. There are new drugs in development with unique mechanisms such as istaroxime which has been developed as a non-glycoside inhibitor of the sodium-potassium-ATPase with stimulatory effects on the sarcoplasmic reticulum calcium pump (SERCA) also with lusitropic and inotropic properties [17].

Vasoconstrictors

Phenylephrine

Phenylephrine is a vasoconstrictive sympathomimetic agent. It acts primarily upon alpha-adrenergic receptors to invoke a potent vasoconstrictive effect. It has only minimal effects upon beta receptors and is most commonly used to treat hypotension in states of low systemic vascular resistance such as in distributive shock. Another common use of phenylephrine within the

realm of pediatric cardiology is in the treatment of refractory hypoxemia in tetralogy of Fallot in order to promote increased pulmonary blood flow by elevating the systemic vascular resistance. Its almost pure alpha-adrenergic effects lead to abrupt increases in both systolic and diastolic blood pressures with little to no direct effect on cardiac output or heart rate. Although phenylephrine does not directly alter heart rate or cardiac output, there is a baroreceptor-mediated, reflex bradycardia that is evoked with the abrupt increase in systemic blood pressure which can affect cardiac output.

Phenylephrine has a rapid onset of action with almost immediate effects when administered by way of the intravenous route with a duration lasting 15–20 min. Alternative routes of administration include intramuscular and subcutaneous injection which both have an onset of action within 10–15 min and a duration that can last 1–2 h [18]. It is metabolized in the gastrointestinal tract (intestinal wall and liver) with a half-life of approximately 2.5 h eventually being excreted mainly via the kidneys [19].

The typical dosing range for phenylephrine as an agent to treat hypotension is 5–20 mcg/kg/dose IV every 15–20 min as required, and it may also be given as an IV continuous infusion at rates ranging from 0.1 to 0.5 mcg/kg/min titrated to effect. If IV access is unavailable, it can be given either IM or subcutaneously at 0.1 mg/kg/dose (maximum dose 5 mg) every 1–2 h as required [18].

Vasopressin

Vasopressin is a vasoconstrictive agent that has widespread effects throughout the body. At low doses, vasopressin acts in the renal collecting ducts, causing a concentration of urine and decreased volume of urine via resorption of water without any negative effects on GFR [20]. At higher doses, vasopressin acts directly upon vascular smooth muscle activating phospholipase C and increasing intracellular calcium concentrations which both result in vasoconstriction [20].

Although pediatric data supporting the use of vasopressin is limited, multiple randomized studies have examined the use of vasopressin in the adult population. Studies evaluating the efficacy of vasopressin versus epinephrine in the setting of cardiac arrest have shown improved outcomes when treating asystole [21] or out of hospital ventricular fibrillation [22]. The asystole comparison study showed no difference among patients presenting in ventricular fibrillation or pulseless electrical activity treated with either vasopressin or epinephrine [21].

The onset of action for vasopressin administered IM or subcutaneously is typically 1 h with an antidiuretic duration of effect lasting 6–8 h and a vasoconstrictive duration of effect lasting 30–60 min when administered as a single intravenous bolus dose [22]. When used in the setting of vaso-plegic hypotension, vasopressin is most often administered via a continuous infusion. Vasopressin is metabolized rapidly in the liver and kidneys with a half-life of 10–20 min [23]

Vasopressin dosing in the pediatric population has not been well established but has been commonly used in the range of 0.0002–0.003 units/kg/min as an IV continuous infusion. Resuscitative doses as a single 40 unit IV bolus have been used in the adult population when treating both shock and cardiac arrest unresponsive to initial defibrillation [18]. For pediatric patients, a dose of 0.4 units/kg has been used for this indication [12].

Vasodilators

Enalapril is an angiotensin-converting enzyme inhibitor (ACE-I) acting through competitive inhibition. Enalapril when administered orally is converted to its active form in the liver, enalaprilat, resulting in potent inhibition of angiotensin-converting enzyme (ACE) preventing the conversion of angiotensin I to angiotensin II. Angiotensin II is a potent vasoconstrictor, so by reducing the circulating levels of angiotensin II, there is less vasoconstriction, leading to decreases in blood pressure, preload, and afterload by reducing systemic vascular resistance [20, 24].

Enalapril can be administered orally for chronic therapy in multiple applications (congestive heart failure, hypertension, atrioventricular valve regurgitation), and it can also be administered IV (enalaprilat) to treat systemic hypertension.

Reduction of ACE activity by enalapril ultimately attenuates the plasma aldosterone levels which can lead to an increased plasma potassium concentration as a side effect. For this reason plasma electrolytes should be monitored. Another common side effect is hypotension, requiring initiation of ACE-I therapy at a very low (test) dose and then titrated up to the desired effect. Special caution must be taken when ACE-I therapy is started in patients with compromised cardiac output such as those with decompensated heart failure. Although ACE-I therapy dilates both the afferent and efferent arterioles, it can cause decreases in renal function and GFR if used in patients with compromised cardiac output [24].

Oral enalapril has an onset of action within 1 h, whereas the IV formulation, enalaprilat, has an onset of action in approximately 15 min. Enalapril is metabolized mainly in the liver to its active form, enalaprilat. It is mainly excreted in the kidneys but also partially in the feces. The half-life of enalapril varies by age with a typical half-life of 10 h in neonates and premature infants, 2–4 h in infants and children, and 4–5 h in adults with heart failure. Enalaprilat, the active metabolite, has a longer half-life of 12 h in neonates, 6–10 h in infants, and 35–38 h in adults.

The dosing of enalapril is typically titrated to effect in the setting of heart failure. Initiation of oral enalapril therapy should be with small "test" doses of 0.05–0.1 mg/kg (max 2.5–5 mg) in infants and children. In premature infants suggested dosing ranges start at 0.01 mg/kg/day. After establishing each patient's individual response to ACE-I therapy, the dose is escalated up to the range of 0.1–0.5 mg/kg/day in once or twice divided daily doses over a period of 10–14 days [25–27]. IV enalaprilat is also titrated to effect with doses of 5–10 mcg/kg/dose every 8–24 h to achieve the desired effect. The adult dose of IV enalaprilat is 0.625–1.25 mg/dose (max 5 mg/dose) every 6 h. When administered IV, enalaprilat should be infused over 5 min. Enalapril should be renally dosed in individuals with renal impairment, and although it has been suggested that higher doses may be required in individuals with liver disease, no hepatic dosing adjustments have been established.

Esmolol

Esmolol is class II antiarrhythmic exerting its effects on the sympathetic nervous system through beta blockade. Esmolol is an intravenous selective beta blocker with selective action on β1 receptors. The beta blockade of β1-selective agents acts primarily at the SA and AV nodes with a net result of prolonging the sinus cycle length, thereby slowing the heart rate. At significantly higher doses (100 times) esmolol has effects on the vascular beds with some β2 effect. In pediatric cardiology, esmolol is most often used for acute control of hypertension with indications for treating hypertension secondary to beta blocker withdrawal, patients recovering from aortic dissection, and patients in the postoperative period following cardiac surgery, especially those with high pressure anastomoses [29]. Esmolol is also used for its effects on the rate of conduction through the AV node in the setting of supraventricular tachycardia, namely, atrial fibrillation and atrial flutter [30].

Esmolol has a rapid onset of action with a peak effect within 5 min. The duration of effect after discontinuation of infusion is 10–30 min with the heart rate and blood pressure effects waning before the effects on shortening fraction and cardiac index [31]. Esmolol is metabolized rapidly inside red blood cells with a half-life ranging from 3 to 10 min. It is primarily excreted in the urine as an acid metabolite which has very little to no pharmacologic effects within the circulatory system.

In the adult population, loading doses of 500 mcg/kg over 1 min, followed by a continuous infusion of 50 mcg/kg/min escalated up in 50 mcg/kg/min increments every 4 min to a maximum of 300–350 mcg/kg/min – titrating to effect – have been established in the treatment

of both postoperative hypertension and rate control of supraventricular tachycardia. Loading doses may be used but have not shown equal efficacy in the pediatric population [32, 33]. Postoperative tachyarrhythmias and hypertension in the pediatric population are typically treated with a continuous infusion starting at 50 mcg/kg/min with dose escalations of 50 mcg/kg/min every 4–6 min to a typical max dose of 300–350 mcg/kg/min, but doses as high as 1,000 mcg/kg/min have been reported in the literature [33].

Hydralazine

Hydralazine is a peripheral vasodilator that acts mainly upon the systemic arterioles to relieve hypertension by decreasing systemic vascular resistance. In pediatric cardiology, its main indication is for the treatment of essential hypertension administered either via the oral or parenteral routes (IM or IV).

Hydralazine has an onset of action of 5–15 min IV and 1 h when administered orally. When administered orally, the duration of effect is 3–8 h. The peak response is seen within 1–1.5 h when administered IV [34]. Hydralazine is metabolized by acetylation in the liver. Patients deemed "fast metabolizers" often require an increased dose [35] of up to 60 % more drug. The half-life ranges from just over 3 h for fast acetylators and to nearly 5 h for slow acetylators [36]. Hydralazine is excreted by the kidneys and also in the feces. Because it is renally excreted, hydralazine should be renally dosed in patients with renal impairment.

In infants and children, oral hydralazine is initially dosed at 0.75–1 mg/kg/day in two to four divided doses (maximum 25 mg/dose). The dose is then titrated up to effect to a maximum of 5 mg/kg/day in infants and 7.5 mg/kg/day in children in two to four divided doses (maximum 200 mg/day). The parenteral routes (IM, IV) are initially dosed at 0.1–0.2 mg/kg/dose (maximum 20 mg/dose) every 4–6 h as needed up to a maximum of 1.7–3.5 mg/kg/day in four to six divided doses [18].

Labetalol

Labetalol is an antihypertensive agent with both alpha and beta blocking effects. Although it is not FDA approved for use in the pediatric population, it is often used for the treatment of hypertension. Labetalol exerts adrenergic blockade of both beta-1 and beat-2 receptors as well as alpha receptors. Labetalol has been shown to be efficacious in adult studies for treatment of hypertension in the outpatient setting [37, 38].

In adult studies, labetalol has been shown to have an initial response of 5 min and 2–4 h for the IV and oral formulations, respectively. The peak effect of the oral formulation is observed at 2–4 h which is also when the highest rate of orthostatic hypotension has been observed. Following an oral dose, the duration of effect is typically 8–12 h. The elimination half-life is 5.5 h when administered IV and 6–8 h when administered orally [39]. Labetalol is metabolized in the liver and excreted renally.

Dosing guidelines in pediatrics for the use of labetalol are not well established as the safety and efficacy have not been proven in large studies. Recommended oral dosing based upon a case series is 1–3 mg/kg/day orally in 2 divided doses up to 10–12 mg/kg/day (maximum 1,200 mg/day) [40]. A different case series recommended intravenous dosing starting with a bolus dose of 0.55 mg/kg followed by a continuous infusion of 0.78 mg/kg/h (range 0.25–1.5 mg/kg/h) for treating hypertension in patients unable to take oral medications [41, 42].

Nitroglycerin

Nitroglycerin is an organic nitrate that acts through vasodilation of the vascular smooth muscle, but in particular, nitroglycerin has been used to induce coronary arterial vasodilation. Nitroglycerin exerts its effects by acting as a source of nitric oxide for the body, ultimately activating guanylate cyclase and increasing the intracellular cGMP levels. Adult studies have established the efficacy and superiority of nitroglycerin in the treatment of angina [43, 44]. For this reason,

nitroglycerin is used both in the acute treatment and prophylaxis of acute angina in adult populations [45]. In the pediatric population, nitroglycerin is used both for the acute treatment of hypertensive urgency and also following cardiac surgery and catheterization procedures to improve coronary blood flow and myocardial perfusion.

In the pediatric population, IV nitroglycerin is typically administered as a continuous infusion. The onset of action is within 1–2 min with a half-life of 1–4 min. Nitroglycerin is extensively metabolized in the peripheral vasculature as well as the liver. One important point is that after 24–48 h of use via continuous infusion, diminished efficacy, or tolerance, can be observed [46].

Typical IV continuous infusion dosing is initiated at 0.25–0.5 mcg/kg/min titrated up for desired effect by increasing the infusion in 0.5–1 mcg/kg/min increments every 3–5 min up to the usual maximum dose of 5 mcg/kg/min. As the dose of nitroglycerin increases, the most common cardiac side effects are hypotension and reflex tachycardia [18].

Sodium Nitroprusside

Sodium nitroprusside is a powerful systemic arterial and venous dilator. Its mechanism of action is similar to that of nitroglycerin as it acts to donate nitric oxide causing vascular smooth muscle relaxation. By relaxing vascular smooth muscle, nitroprusside decreases systemic vascular resistance. In adult patients, nitroprusside is used in the treatment of hypertensive crisis as well as in treatment of congestive heart failure. When employed in the pediatric population, nitroprusside is typically used to treat hypertension in the inpatient setting as a continuous IV infusion. Nitroprusside's pharmacokinetics makes it quite useful as an agent to carefully titrate systemic blood pressure on a minute-to-minute basis. Due to its short half-life, nitroprusside is not commonly used in bolus dosing as its effect rapidly disappears with discontinuation of the drug.

Nitroprusside has a quick onset of action within less than 1 min. The peak response is seen within 1–2 min and its half-life is only 3–4 min. Nitroprusside is rapidly metabolized by red blood cells ultimately releasing cyanide. The metabolite cyanide is then metabolized by the liver and kidney to thiocyanate. Although renal/hepatic dosing adjustments of nitroprusside are not recommended, caution has been advised to avoid accumulation of the harmful metabolite cyanide. Monitoring of serum cyanide and thiocyanate levels is recommended especially in individuals with hepatic impairment and requiring an infusion beyond a 48-h period [47].

The typical initial rate for a continuous infusion of nitroprusside is 0.5–1 mcg/kg/min, and it is titrated up in 0.5–1 mcg/kg/min increments to a maximum dose of 10 mcg/kg/min. The average dose is 3 mcg/kg/min.

Sildenafil

Sildenafil is a pulmonary and, to a lesser extent, systemic vasodilator. Sildenafil acts by inhibition of phosphodiesterase type 5 (PDE-5). PDE-5 acts by degrading intracellular cGMP within smooth muscle cells. This action leads to increased levels of cGMP within the smooth muscle cells causing vasodilation. Although large clinical trials establishing the efficacy of sildenafil in the pediatric population have not been undertaken, it has become an extremely commonly used drug in the treatment of pulmonary arterial hypertension in the pediatric population, even in patients with structural heart disease [48]. Sildenafil has also been used as an adjunctive short-term therapy while weaning patients from inhaled nitric oxide [49–51].

The pediatric-specific pharmacokinetics of sildenafil employed as a pulmonary vasodilator is not well established. Sildenafil is metabolized mainly in the liver by CYP450 3A4. One study in neonatal patients found a lower clearance of sildenafil in patients 1 day of age when compared to infants at 7 days of age. This effect was

presumably due to maturation of the specific enzymes responsible for the metabolism of sildenafil [52].

Typically dosing of sildenafil is initiated at low "test" doses while monitoring for adverse effects, the most common being hypotension. The oral test dosing is typically in the range of 0.25 mg/kg/dose given every 6–8 h. After safe dosing is observed for 1–2 days, the oral dose is titrated up to provide the desired effect to a maximum daily dose of 4–8 mg/kg/day divided every 6–8 h [51]. In August 2012, the FDA released a warning against the use of sildenafil for pediatric patients (ages 1 through 17) with PAH based on their interpretation of the STARTS-2 study data. The FDA warning stated that this recommendation against sildenafil use is based on a recent long-term clinical pediatric trial showing that children taking a high dose of sildenafil had a higher risk of death than children taking a low dose, and that the low doses of sildenafil are not effective in improving exercise ability. However, many treating pulmonary hypertension clinicians disagree with the warning as the extension study had no placebo arm; the 3-year survival in low, medium, or high dose groups is similar to that found in several recent registries; and sildenafil is approved in Europe by the European Medicines Agency after evaluating the same data.

Although no significant pediatric data for the IV dosing of sildenafil exists, IV dosing of sildenafil has been reported in a small neonatal case series using a 0.4 mg/kg loading dose followed by a continuous infusion of 1.6 mg/kg/day for the treatment of PPHN. Intravenous doses of 10 mg every 8 h have been reported in older teens and adults when employing IV sildenafil for the treatment of pulmonary hypertension.

Verapamil

Verapamil is a calcium channel blocker that has both class IV antiarrhythmic properties and vasodilatory properties. As a calcium channel blocker, verapamil blocks the intracellular flux of calcium ions in both vascular smooth muscle and myocardial cells. Although verapamil is mainly used to influence the ventricular response of supraventricular tachyarrhythmias, it also acts to decrease systemic blood pressure by preventing peripheral vasoconstriction. Calcium channel blockers can have a negative inotropic effect on myocardial cells which has been shown to be pronounced in neonates and young infants. Due to the risk of cardiovascular collapse in young infants, IV verapamil should be avoided in this population [54].

Verapamil has a quick onset of action when administered IV with a peak effect within 1–5 min. When administered orally, its peak effect is observed at 1–2 h. Orally, the duration of action is 6–8 h with a half-life of 4–7 h in infants and 4–12 h in adults. When administered IV, the half-life is much shorter, with a duration of effect lasting only 10–20 min. Verapamil is metabolized in the liver and excreted renally. Dosing should be adjusted in patients with renal impairment [18]. Whenever verapamil is administered IV, patients should be monitored and IV calcium should be readily available.

In the pediatric population, typical IV dosing is 0.1–0.3 mg/kg/dose (maximum 5 mg/dose). The dose may be repeated once in 30 min if adequate response is not achieved. Oral dosing is typically 4–8 mg/kg/day divided every 8 h [18].

Diuretics

57

Donald Berry

Abstract

Diuretics are drugs that increase the rate of urine flow to reduce fluid overload in both acute and chronic disease states. By producing natriuresis and by decreasing total body sodium (Na^+) content, extracellular fluid volume is reduced. There are several different classes of diuretics, with the loop diuretics and thiazide diuretics being the ones most often used. Loop diuretics include furosemide, bumetanide, torsemide, and ethacrynic acid. Loop diuretics block the Na^+-K^+-$2Cl^-$ symporter in the thick ascending limb of the loop of Henle. Since the loop of Henle is where a large proportion of Na^+ and water is normally reabsorbed, this makes loop diuretics the most effective diuretics for removing fluid from the body. Adverse effects of loop diuretics include fluid and electrolyte imbalances and ototoxicity. Thiazide diuretics inhibit Na^+-Cl^- symport beyond the loop of Henle in the distal convoluted tubule, where a smaller proportion of the filtered sodium and water is available for reabsorption. Thiazides can be effective when a more moderate diuresis is desired or when combined with a loop diuretic to enhance urine output by its action at an additional site in the nephron. This class includes chlorothiazide and hydrochlorothiazide and the thiazide-like diuretic metolazone. Adverse effects of thiazide diuretics include fluid and electrolyte imbalances, impaired glucose tolerance, and lipid abnormalities. The aldosterone antagonist spironolactone is a weak diuretic and is primarily used for its potassium-sparing effect.

To effectively prescribe diuretics, caregivers must find the threshold quantity of drug that must be reached at the drug site of action in order to produce diuresis. Once the effective dose is identified, it can be given as often as needed to maintain the response according to the duration of effect of the drug. Diuretic braking and diuretic resistance can both create challenges in reaching urine output goals.

Introduction

Diuretics are drugs that increase the rate of urine flow [1] to reduce fluid overload in both acute and chronic disease states [2]. By producing natriuresis and decreasing total body sodium (Na^+) content, extracellular fluid volume is reduced [3]. Diuresis is indicated to remove excess fluid in patients who are in the immediate postoperative period after cardiothoracic surgery. During cardiothoracic surgery with cardiopulmonary bypass (CPB), patients receive large volumes of fluid that distribute throughout the body as a result of capillary leak syndrome [4], accompanied by intravascular hypovolemia and renal hypoperfusion [2]. After a brief initial period of adequate urine production, urine output decreases, and diuretic therapy is required to aid in removal of the excess fluid administered during CPB. Diuretics can also be useful to reduce the pulmonary venous congestion seen in hypertrophic cardiomyopathy and congestive heart failure caused by myocarditis [4], congenital heart defects, cardiomyopathies, inherited metabolic disorders, and infectious diseases [5, 6]. Patients with pleural effusions also benefit from treatment with diuretics.

There are several different classes of diuretics, with the loop diuretics and thiazide diuretics being the ones most often used. Understanding the function of the nephron will aid in understanding how the different classes of diuretics work and the rationale for using alone or in combination. Approximately 99 % of the initial glomerular filtrate is reabsorbed by the nephron before it exits the collecting duct, producing only 1 ml of urine for every 100 ml of plasma filtered. The proximal tubule is the site for 65 % of the reabsorption of filtered solutes (primarily sodium). No clinically useful diuretics act primarily on the proximal tubule [4]. The loop of Henle reabsorbs about 25 % and is the site of action of the loop diuretics. The final 10 % is reabsorbed in the distal convoluted tubule, where the thiazide diuretics have their effect [1].

Loop Diuretics: Pharmacology

Loop diuretics include furosemide, bumetanide, torsemide, and ethacrynic acid. Loop diuretics block the Na^+-K^+-$2Cl^-$ symporter in the thick ascending limb of the loop of Henle, causing reduced reabsorption of sodium and water resulting in an isoosmotic diuresis. Since the loop of Henle is where 25 % of Na^+ and water is normally reabsorbed, this makes loop diuretics the most effective diuretics for removing fluid from the body [3]. Loop diuretics also inhibit Ca^{++} and Mg^{++} reabsorption in the ascending limb. The net effect is a profound increase in urinary excretion of Na^+ and Cl^- as well as marked increases in excretion of K^+, Ca^{++}, and Mg^{++}. Loop diuretics, particularly furosemide, also have direct venodilating effects that increase systemic venous capacitance and reduce left ventricular filling pressure [1]. Renal blood flow is also increased and is thought to be caused by a prostaglandin-mediated renal vasodilation [7].

To reach their site of action, loop diuretics must be actively secreted into the proximal convoluted tubule by the organic acid transport system [3]. Oral bioavailability is good at 80–100 % for all the loop diuretics except furosemide, which has a reported bioavailability of 45–65 % [8]. When switching from IV to oral dosing, furosemide will most likely need

a dosing adjustment to maintain similar effectiveness, whereas the other loop diuretics will not. The loop diuretics are primarily eliminated by the kidneys, except for torsemide, whose primary route of elimination is hepatic metabolism. Equivalent IV doses are 40 mg furosemide, 30 mg ethacrynic acid, 10 mg torsemide, and 1 mg bumetanide [3]. The onset of action after an IV dose of a loop diuretic is 5–10 min with a duration of 2–3 h for all except torsemide, which has a reported duration of 6 h [9]. After an oral dose, diuresis begins in 30–60 min with a duration of 6–8 h and up to 12 h with ethacrynic acid.

Pediatric dosing for furosemide ranges from 0.5–2 mg/kg IV to 1–4 mg/kg orally every 6–24 h. Preterm and term infants have prolonged half-lives compared to older patients, so less frequent dosing (once or twice daily) should be used to decrease the risk of adverse effects [7]. Adolescent and adult patients may use doses of 20–40 mg IV or 20–80 mg orally. A continuous infusion may be used at doses of 0.05–0.4 mg/kg/h to help prevent hemodynamic instability with intermittent doses or in patients who have poor responses to intermittent doses. To prevent a delay in the onset of diuresis, a loading dose of furosemide should be administered prior to starting the continuous infusion. In studies in pediatric post-cardiac surgery patients, the total daily furosemide dose was 20 % lower with continuous infusion than with intermittent injections while at the same time maintaining adequate urine output [7].

Bumetanide, which has good oral bioavailability, is given in doses of 0.015–0.1 mg/kg/dose orally or IV every 6–24 h, with adult doses in the 0.5–2 mg range. It may also be administered by continuous infusion. Torsemide, primarily used in adult populations, is used in doses of 10–20 mg IV or orally once daily. Finally, ethacrynic acid is usually given IV in doses of 0.5–1 mg/kg (up to 100 mg) given every 8–24 h or oral doses of 1–3 mg/kg (up to 200 mg/day) given once or twice daily.

Since there is a threshold drug concentration that must reach the site of action in order for diuresis to occur with loop diuretics, the dose must be titrated in each patient to determine the dose that will cause diuresis [10]. This effective dose can then be given at a frequency to provide the desired daily urine output.

Loop Diuretics: Adverse Effects

Most adverse effects of loop diuretics are due to iatrogenic abnormalities in fluid and electrolyte balance. Hyponatremia can occur due to significant depletion of total body sodium, and hypovolemia can result in hypotension and circulatory collapse. Large losses of potassium and/or magnesium put patients at risk for cardiac arrhythmias, and a hypochloremic alkalosis can result from increased urinary excretion of chloride and hydrogen ions. Acetazolamide, a carbonic anhydrase inhibitor, can be used to correct this, as it significantly increases bicarbonate excretion by action in the proximal tubule. Hypocalcemia may also result from overuse of loop diuretics. Infants receiving loop diuretic therapy may be predisposed to development of renal calcifications, especially if premature, due to high urinary calcium excretion rates [7].

Ototoxicity, ranging from tinnitus to reversible or permanent hearing loss, is a concerning adverse effect of loop diuretics. It is thought to be a result of high peak concentrations of the drugs reaching the Na^+-K^+-$2Cl^-$ cotransport system in the inner ear [3, 11] and is most often associated with rapid administration of IV doses. Administering the dose at a rate not exceeding 0.5 mg/kg/min (4 mg/min in an adult) is thought to decrease the risk of ototoxicity, as well as administration by continuous infusion. Other methods to minimize the risk of ototoxicity include avoidance of other ototoxic drugs (i.e., aminoglycosides), use of the minimum dose that will elicit the desired response, and avoid use in severe renal failure. Ethacrynic acid induces ototoxicity more often than other loop diuretics. For that reason, its use should be reserved for patients who have allergic reactions to the other loop diuretics.

Drug interactions may occur when some drugs are given concomitantly with loop

diuretics. Aminoglycosides and platinum-based antineoplastics have ototoxic potential that is additive when given with loop diuretics. NSAIDs decrease the effect of loop diuretics. Loop diuretics can also increase the concentration of propranolol [3].

Thiazide Diuretics: Pharmacology

Thiazide diuretics inhibit Na^+-Cl^- symport beyond the loop of Henle in the distal convoluted tubule, where only 10 % of the filtered sodium and water is available for reabsorption [3]. Thiazides can be effective when a more moderate diuresis is desired or when combined with a loop diuretic to enhance urine output by its action at an additional site in the nephron. This class includes chlorothiazide and hydrochlorothiazide and the thiazide-like diuretic metolazone. Thiazides increase Ca^{++} reabsorption when administered chronically and can be a good choice in patients with calciuria [3].

Thiazides, like loop diuretics, must be actively secreted into the proximal tubule by the organic acid transporter. Oral bioavailability is poor for chlorothiazide (10–20 %), but much better for hydrochlorothiazide (60–80 %) and metolazone (40–65 %) [9]. With an IV dose of chlorothiazide (the only injectable thiazide), onset of diuresis occurs in 15 min and lasts for 2 h, while an oral dose of either chlorothiazide or hydrochlorothiazide will produce a diuresis in 2 h that will last 6–12 h. Metolazone is only available in oral form. It has an onset of action of 1 h that persists for up to 24 h, making dosing very convenient.

Chlorothiazide, when given IV, is usually dosed 1–4 mg/kg given twice daily to pediatric patients, but doses up to 10 mg/kg have been used. Adult IV dosing is 100–500 mg/day given as 1 or 2 divided doses. Because of the poor oral bioavailability, the oral dosing is much higher, at 10–20 mg/kg given twice daily, with adult doses ranging from 125 to 500 mg given once or twice daily. Hydrochlorothiazide is only available in oral dosage forms and is dosed 2–3 mg/kg/day given as 1 or 2 doses, with the adult dose of 25–200 mg per day. The thiazide-like diuretic metolazone is also available only as an oral dosage form. Children's dosing is 0.2–0.4 mg/kg/day divided every 12–24 h, and adults receive 2.5–20 mg as a single daily dose [8].

Thiazide Diuretics: Adverse Effects

Like the loop diuretics, the most serious adverse effects are related to fluid and electrolyte abnormalities [1]. These include volume depletion with hypotension, hypokalemia, hyponatremia, hypomagnesemia, hypochloremia, and hypercalcemia. Thiazide diuretics can decrease glucose tolerance causing hyperglycemia. This effect appears to be due to reduced insulin secretion [1] or decreased sensitivity to insulin [3]. Elevations in total cholesterol and triglycerides, along with decreased HDL cholesterol levels, have occurred in patients taking thiazide diuretics.

Patients taking thiazide diuretics are at risk for arrhythmias, especially if they are also taking digoxin, due to the hypokalemia and hypomagnesemia they cause. NSAIDs can reduce the effectiveness of thiazide diuretics, and this combination should be avoided. Patients who are taking bile acid sequestrants should take them at least 2 h before their diuretics so as to not reduce their effectiveness [1].

Potassium-Sparing Diuretics: Pharmacology

The aldosterone antagonist spironolactone is a weak diuretic and is primarily used for its potassium-sparing effect. Aldosterone binds to mineralocorticoid receptors in the late distal tubule and collecting duct, causing retention of sodium and water and increasing the excretion of potassium (K^+) and hydrogen (H^+) [1]. Spironolactone inhibits the binding of aldosterone to the mineralocorticoid receptor, resulting in an increased excretion of Na^+ and decreased secretion of K^+ and H^+. Because of this mechanism, the clinical efficacy of spironolactone is proportional to endogenous levels of aldosterone.

Spironolactone does not require secretion into the renal tubule to be effective. It has good bioavailability and is metabolized to both active and inactive metabolites. The active metabolite canrenone has a much longer half-life than its parent drug, prolonging the antagonism of aldosterone to 2–3 days [8]. Dosing for infants and children is 1–3.5 mg/kg/day, up to 100 mg/day, in divided doses every 6–12 h. The adult dose for edema/hypokalemia is 25–200 mg/day in 1 or 2 doses.

Potassium-Sparing Diuretics: Adverse Effects

The major adverse effect of spironolactone is life-threatening hyperkalemia. Potassium levels should be monitored carefully, especially if other medications that can cause hyperkalemia (ACE inhibitors, NSAIDs) are being used, and spironolactone should not be used in patients with renal failure. Due to its steroid structure, it can also cause gynecomastia, hirsutism, and menstrual irregularities.

Prescribing

There are several key points that should be remembered when prescribing diuretics. The first is that there is a threshold quantity of drug that must be reached at the drug site of action in order to produce diuresis. Diuretics must be titrated in each patient to find the dose that will produce a desired response without being excessive. Exceeding the maximally effective diuretic dose increases the risk of toxicity without providing additional benefit [7]. Once the effective dose is identified, it can be given as often as need to maintain the response according to the duration of effect of the drug [10]. Secondly, since loop diuretics are pharmacologically similar, only one should be used in a diuretic regimen. If the response to a loop diuretic is inadequate, the addition of another diuretic with a different mechanism of action should be tried.

Diuretic effect can be reduced by the body's compensatory mechanisms. The first is diuretic braking, where there is a decreased response to a diuretic after the first dose is administered. Renal compensatory mechanisms that attempt to retain sodium to restore sodium balance include activation of the sympathetic nervous system, activation of the renin-angiotensin-aldosterone axis, and decreased arterial blood pressure [1]. A continuous infusion of the loop diuretic may be tried, as constantly maintaining an effective amount of diuretic at the site of action may result in an increased response [10]. Diuretic resistance to loop diuretics can occur with long-term administration. Higher solute loads formed in the loop of Henle are presented to the more distal regions of the nephron, which then become hypertrophied and increase the reabsorption of sodium reducing overall diuresis. Thiazide diuretics block sodium reabsorption in the distal tubule where the hypertrophy occurs, achieving a sequential nephron blockade that may help overcome the resistance to the loop diuretic [12]. In the hospital setting, administering an IV dose of chlorothiazide 30 min before or at the same time as an IV dose of furosemide can enhance urine output.

Beta-Blockers

58

Emily Polischuk and Donald Berry

Abstract

While β-blockers have become a cornerstone for treatment of hypertension and heart failure in adults, recommendations from the literature regarding the use of these medications in infant, children, and adolescent patients are still largely variable. Additionally, differences in the etiology of heart failure between adult and pediatric patients make it difficult to extrapolate adult data and recommendations to the pediatric population. Despite these differences, there is evidence that pediatric and adult patients experience similar alterations to the neuroendocrine axis during heart failure, indicating a place in therapy for β-blockers [1]. β-Blockers have shown some benefit in pediatric patients with hypertension, but should not be used as first-line therapy [2, 3]. Attention must be paid to the individual properties (cardioselectivity, intrinsic sympathomimetic activity, alpha-adrenergic antagonism, lipophilicity) when choosing an agent [4]. Therapy should be initiated with low doses and titrated slowly to avoid adverse effects [5].

Introduction

β-Adrenergic antagonists exhibit their actions by inhibition of the β-receptors. Originally designed to block both β1- and β2-receptors ("nonselective"), later agents were formulated to selectively inhibit β1 receptors only. β-Blockers can be categorized as first generation (nonselective), second generation (β1-selective) or third generation (selective or nonselective, with additional cardiovascular actions) [4]. β-Receptors can be found throughout the body, with the majority located on the smooth muscle of the heart (β1) and lungs (β2). Activation of the β1-receptors by catecholamines has positive chronotropic (increased rate) and inotropic (increased contractility) effects on the heart. Therefore, inhibition of these receptors slows heart rate and decreases contractility. Activation of the β2 receptors by catecholamines causes bronchial smooth muscle relaxation; therefore, blockade of the receptors has the capability of causing bronchoconstriction. While the effect is usually not seen in healthy individuals, those with underlying pulmonary disease such as asthma or chronic obstructive pulmonary disease (COPD) may experience life-threatening bronchospasm. For this reason, use of nonselective β-blockers is contraindicated in this patient population [4].

Use in Heart Failure

Inhibition of the sympathetic nervous system with β-blocker therapy is a standard approach used for heart failure in adults. While the idea of decreasing the rate and contractility of the already failing heart may seem counterintuitive, many large-scale clinical trials of β-blockers have demonstrated improvements in left ventricular function, a decrease in symptoms, and prolonged survival in adult heart failure patients [1]. When cardiac output fails to meet the demands of the body, activation of the renin-aldosterone-angiotensin system, activation of the sympathetic nervous system, and cytokine-induced inflammation occur. Resultant release of metabolites causes fluid-retaining mechanisms in the kidney as well as increases in systemic vascular resistance. Activation of the sympathetic nervous system causes a release of catecholamines and subsequent increases in heart rate and contractility [2]. While these responses all work to increase cardiac output and blood pressure, over time, the sustained effects of the β activation can lead to progressive myocardial damage. Dilation, hypertrophy, and fibrosis of the heart, known as cardiac remodeling, can occur and lead to a progressive stage of heart failure with even further decreases in cardiac function [1, 6].

Heart failure therapy via β-blockade has several proposed mechanisms. Inhibition of β1-receptors during endogenous catecholamine release can prevent cardiac remodeling and preserve function of the myocardium [1]. A slowed heart rate can cause decreases in myocardial oxygen demand [7]. Increases in sympathetic tone lead to a decrease in density of β1-receptors (downregulation), but administration of β-blockers can cause upregulation of beta receptors [1]. The antiarrhythmic properties of the drugs can have membrane-stabilizing effects and suppress ventricular ectopic activity [7]. There is also data that shows when added to therapy with angiotensin-converting enzyme (ACE) inhibitors; metoprolol may decrease circulating concentrations of rennin and angiotensin II [7, 8].

Adult heart failure is most often due to left ventricular dysfunction and usually acquired over time due to ischemic heart disease, hypertension, or myocarditis. Heart failure in pediatric patients can be acquired, but is most often secondary to congenital structural defects [6]. Despite these physiologic differences, the neurohormonal mechanisms of heart failure in children seem to mirror those in adults. It has been shown that plasma norepinephrine levels are increased in children with worsening heart failure [9]. Additionally, norepinephrine levels decrease to normal with surgical correction or medical therapy [10]. Downregulation of β-receptors on the myocardium has also been observed in children, similar to findings in adults [1].

Evidence regarding the use of β-blocking agents in pediatric patients is somewhat

conflicting [11]. A number of case reports and smaller studies have demonstrated benefits of β-blockers in children with heart failure, including symptom improvement and increased left ventricular ejection fraction [8, 12–16]. However, the only large, multicenter, randomized, double-blind, placebo-controlled study to date failed to show significant improvements in clinical heart failure outcomes in children and adolescents [17]. This study compared carvedilol to placebo and was the first to find no benefit of beta-blocker use in children with heart failure. These findings may be partially attributed to study design [11]. A prespecified subgroup analysis noted significant interaction between treatment and ventricular morphology ($P = 0.02$), indicating a possible differential effect of treatment between patients with a systemic left ventricle (beneficial trend) and those whose systemic ventricle was not a left ventricle (non-beneficial trend). The study was underpowered to determine subgroup effects [11]. Despite these results, β-blockers continue to be used for pediatric heart failure patients. Therapy should be initiated on a case-by-case basis, beginning with lower doses and slowly titrating to effect [1]. Monitor for adverse effects, and do not start β-blockers in patients who are hemodynamically unstable [5]. β-Blockers should not be used as monotherapy, but can be combined with diuretics and ACE inhibitors [1]. Carvedilol and metoprolol have been studied most extensively in heart failure and are the β-blocking agents of choice for this indication [12–15, 17].

Use in Hypertension

The use of β-blocker therapy in children with hypertension has not been extensively studied, with most data being extrapolated from adult dosage recommendations [3]. These medications can be considered for use in pediatric hypertensive patients, but are usually considered to be second- or third-line therapy due to lack of data to support their use. No direct comparisons of β-blockers and first-line therapies (ACE inhibitors, calcium channel blockers, or diuretics) have been conducted [3]. While benefit of β-blockers in hypertension has been demonstrated in some smaller studies and case reports, therapy should be individualized, slowly titrated, and closely monitored for adverse effects [18].

Propranolol

Propranolol is the most extensively used and studied nonselective beta-blocking agent. It has equal affinity for the β1- and β2-receptors, has no intrinsic sympathomimetic activity, and has no alpha-blocking properties [4]. β-Receptor blockade causes a decrease in heart rate, decreased contractility, and a subsequent decrease in cardiac output [5]. Propranolol has been shown to cause a decrease in mean heart rates, decreased renin and aldosterone levels, and improved Ross heart failure scores in infants with congenital heart disease and severe congestive heart failure caused by left-to-right shunts [16].

Propranolol is almost completely orally absorbed and undergoes extensive first-pass metabolism by the liver. Bioavailability is 26 $\pm$ 10 % and may be increased as much as 50 % by concomitant administration with a high-protein meal. Half-life elimination is 4–6.5 h in children and 4–6 h in adults and is prolonged in patients with liver dysfunction. Onset of action with immediate-release products is 1–2 h, with duration of effect lasting approximately 6 h [5, 19]. Recommended initial oral dosing varies based on age and reason for use. Oral dosing in children is usually 0.5–1 mg/kg/day in divided doses every 6–12 h with gradual increases every 5–7 days based on effect. Maximum daily dose is 8 mg/kg/day, not to exceed adult dosing. Adult hypertension dosing with immediate-release oral products is initiated at 40 mg twice a day, titrated to a maximum of 160 mg twice daily [5, 19]. Dosage adjustments are not necessary for patients with renal dysfunction but may be required in patients with hepatic dysfunction [5, 19].

Propranolol has the ability to precipitate or worsen heart failure, especially for patients in the compensatory phase. Hypoglycemia may occur, especially after prolonged physical exertion or in patients with renal failure. Propranolol may mask

signs of hyperthyroidism. Abrupt discontinuation of the medication can cause withdrawal and may cause myocardial infarction in patients with angina pectoris. Propranolol has been shown to cause adverse events in animal reproduction studies and is therefore classified as pregnancy category C. It is excreted into breast milk, but this risk is thought to be minimal [5, 19].

While propranolol is generally well tolerated, it should be closely monitored in patients with heart failure due to its propensity to worsen this disease state. Cardiovascular effects include bradycardia, hypotension, impaired contractility, and Raynaud's syndrome. Adverse effects of the central nervous system include dizziness, insomnia, lightheadedness, and cognitive dysfunction. Other adverse effects include hyperglycemia, hyperkalemia, impotence, bronchospasm, respiratory distress, wheezing, increased liver enzymes, paresthesias, weakness, nausea, vomiting, and diarrhea [5, 19].

Propranolol is frequently used to treat or prevent hypercyanotic episodes in tetralogy of Fallot. Currently, many centers advocate for surgical repair rather than delaying surgery as surgical outcomes have improved and palliation of tetralogy of Fallot with propranolol is difficult and not always reliable. Initial oral dosing is 1 mg/kg/day every 6 h; if ineffective, may increase dose by 1 mg/kg/day to a maximum of 5 mg/kg/day. Some centers have used 0.5–1 mg/kg/dose every 4 h while awake, but usually, these patients require surgical intervention rather than continued palliation. Intravenous dosing is 0.01–0.2 mg/kg/dose infused over 10 min with a maximum dose of 1 mg for infants and 3 mg for children.

Metoprolol

Metoprolol is a β-blocker that is selective for the β1-receptors at therapeutic doses. At very high doses (>100 mg/day), it can also inhibit β2-receptors. It has no intrinsic sympathomimetic activity and does not exhibit any alpha blockade [4]. Blockade at β1-receptors decreases heart rate and contractility, therefore decreasing cardiac output, and also decreases blood pressure [5]. Studies of metoprolol in pediatric heart failure patients have demonstrated improvement in ventricular function as well and decreased levels of natriuretic peptide and norepinephrine [12]. Metoprolol has also been shown to be a safe and effective treatment option for hypertension in pediatric patients [18].

Pharmacokinetic data for metoprolol in children has been shown to be similar to that in adults. Oral absorption is rapid and complete, with extensive first-pass metabolism in the liver by cytochrome p450 enzymes (specifically CYP2D6). This can lead to a large variation in half-life based on pharmacogenomics and an individual's capacity for this pathway. Half-life in CYP2D6 poor metabolizers is 7.5 h, while half-life is only 2.8 h in CYP2D6 extensive metabolizers. The antihypertensive effects of oral immediate-release metoprolol take place within 15 min, while full effect of beta blockade may not be seen for an hour. Antihypertensive effects last 6 h, while beta blockade may last longer, dependent on dose [5]. Initial oral dose for hypertension in children is typically 1–2 mg/kg/day administered in two divided doses, with dosage increases based on response. Initial oral dose for heart failure in children is 0.1-0.2 mg/kg/dose given twice daily, then increased slowly as needed to a maximum of 1.1 mg/kg/day (range 0.5-2.3 mg/kg/day). Dosages above 200 mg have not been evaluated. Adult oral dosing for heart failure is initiated at 12.5-25 mg daily using extended release tablets, titrated slowly to a maximum dose of 200 mg. Dosage adjustments are not necessary for patients with renal dysfunction, but may be required in patients with hepatic dysfunction [5, 19].

Like propranolol, metoprolol also has the propensity to worsen or precipitate heart failure [5]. Although metoprolol is β1 selective at therapeutic doses, it still should be used with caution in patients with bronchospastic disease. Abrupt discontinuation of metoprolol can precipitate heart failure; therefore, discontinuation of the medication should be done as a slow taper over 1–2 weeks. Use with caution in combination with potent inhibitors of the CYP2D6 isoenzyme. Metoprolol is pregnancy category C and is excreted into the breast milk [5, 19].

Common adverse effects with metoprolol include bradycardia, hypotension, dizziness, tiredness, and GI upset. Other possible adverse effects include second- and third-degree heart block, bronchospasm, and hepatic dysfunction evidenced by increases in transaminases, alkaline phosphatase, and LDH. Agranulocytosis or thrombocytopenia, pruritus or worsening of psoriasis, and reduction in peripheral circulation can also occur [5, 19].

Carvedilol

Carvedilol is a nonselective β-blocker with additional α1-blocking properties. Blockade at the α1 receptor causes a decrease in peripheral vascular resistance. Carvedilol also has antioxidant properties. It has membrane-stabilizing effects but no intrinsic sympathomimetic activity [4]. Carvedilol decreases pulmonary capillary wedge pressure, heart rate, systemic and renal vascular resistance, and decreases plasma rennin activity [7]. It is the most commonly studied β-blocker in pediatric heart failure trials and is the only β-blocker that has been compared to placebo in a large, multicenter, randomized, controlled, double-blinded study [17]. Several small trials have linked carvedilol to improved symptoms and heart function in pediatric heart failure patients [13–15].

Carvedilol is almost completely orally absorbed and undergoes extensive first-pass metabolism by the liver, primary by cytochrome p450 isoenzymes CYP2D6 and CYP2C9. Bioavailability is increased in patients with CHF [5]. One study found that half-life of the medication increases with age; 2.2 h in infants and children 6 weeks to 3.5 years, 3.6 h in patients 5.5–19 years, and 5.2 h in adults 24–37 years [20]. Dosing of carvedilol is not well established in children. One study of carvedilol in pediatric heart failure patients reported an initial mean dosing range of 0.075-0.08 mg/kg/dose twice daily using immediate release tablets. Dose can be increased by 50 % every 2 weeks. The usual reported maintenance dose range is 0.3-0.75 mg/kg/dose twice daily with a maximum daily dose of 50 mg [15]. A wide range of dosages have been used in clinical trials [13–15, 17]. Initial adult dosing of immediate-release oral formulation in heart failure patients is 3.125 mg twice daily with slow titration after 2 weeks. Initial adult dosing of immediate-release formulation for treatment of hypertension is 6.25 mg twice daily with slow titration after 1–2 weeks. Carvedilol does not require dose adjustment in renal failure and should not be used in patients with severe liver dysfunction [5].

Similar to other medications in its class, carvedilol can cause a worsening of heart failure or precipitate heart failure [5]. Carvedilol should be used with caution in patients with bronchospastic disease. Taking the medication with food can slow absorption and should lessen side effects of bradycardia and hypotension. Like all beta-blockers, the carvedilol should not be abruptly stopped but should be tapered slowly. Carvedilol is pregnancy category C. It is unknown if it is excreted into the breast milk [5].

Adverse effects with carvedilol are similar to other beta-blockers. Bradycardia, hypotension, dizziness, tiredness, and GI upset are common. Other adverse effects are AV block, bronchospasm, increased BUN and decreased renal function, and hepatic dysfunction. Thrombocytopenia, pruritus or worsening of psoriasis, blurred vision, hypertriglyceridemia, hypercholesterolemia, and weight gain can also occur [5, 19].

Kelli L. Crowley and Ricardo Muñoz

Abstract

Fenoldopam, levosimendan, and nesiritide are drugs with novel mechanisms of action that are used in the treatment of cardiovascular disorders. Fenoldopam is a potent vasodilator due to its action as a selective postsynaptic dopamine agonist. It is indicated for rapid blood pressure reduction. Fenoldopam is administered intravenously by continuous infusion and titrated until the target blood pressure is achieved. There are pediatric dosing recommendations available for this agent. Levosimendan, which is a calcium sensitizer, has a combination of both vasodilatory and inotropic activities and may be used in cases where either action is desired. The indication for levosimendan is short-term treatment of acutely decompensated severe chronic heart failure when conventional therapies have not provided adequate effects. This drug is administered intravenously as an initial bolus followed by a continuous infusion that is titrated to effect. There is currently no dosing information available for patients less than 18 years of age. Nesiritide is a natriuretic peptide that binds to the guanylate cyclase receptor on vascular smooth muscle and endothelial cells leading to smooth muscle relaxation. Dosing recommendations available for adult patients suggest an optional intravenous bolus followed by a continuous infusion. There is currently no dosing recommendation available for the pediatric population.

Introduction

Drugs with novel mechanisms of action that are used in cardiovascular therapies include fenoldopam, levosimendan, and nesiritide. Fenoldopam is a potent vasodilator used for rapid blood pressure reduction in adult and pediatric patients. Levosimendan and nesiritide are used in the treatment of acutely decompensated heart failure. The mechanism of action, pharmacokinetics and pharmacodynamics, associated adverse effects, indication, and available dosing recommendations in addition to general information for each of these agents are discussed in this chapter.

Fenoldopam

Fenoldopam is a dopamine agonist used for emergent blood pressure reduction in adult and pediatric patients with severe hypertension through its rapid vasodilatory action [1]. Fenoldopam exerts limited adrenergic effects [2]. Clinical studies have been performed in pediatric patients ranging in age from full-term neonate to 12 years of age [3, 4]. Corlopam® is the marketed brand name in the United States and Canada.

The mechanism of action of fenoldopam is as a selective postsynaptic dopamine agonist (D_1-receptors) [4]. It has six times the potency of dopamine with regard to renal vasodilation [5]. This vasodilation causes decreased peripheral vascular resistance with increased renal blood flow, diuresis, and natriuresis. All of these actions result in hypotensive effects [4].

Fenoldopam has been shown to produce dose-related decreases in blood pressure [1, 3]. A greater initial dose results in a more rapid and larger effect on blood pressure, while a lower dose will have only a modest effect. The onset of action for fenoldopam is 15 min and the duration of effect is 1 h. Upon discontinuation, blood pressure will return to its original measurements without evidence of rebound effect [3]. Half-life elimination is approximately 5 min in adult patients and 3–5 min in pediatrics [2]. Steady-state concentrations are reached after 4 half-lives or about 20 min [3]. Fenoldopam undergoes hepatic metabolism via methylation, glucuronidation, and sulfation. It appears that the 8-sulfate metabolite may be active. Excretion is primarily urinary (90 %) with 10 % in feces [2]. Renal blood flow and urine output is significantly increased during therapy [5, 6]. The effects of hemodialysis on fenoldopam clearance have not been studied, although clearance is unchanged in patients receiving continuous ambulatory peritoneal dialysis (CAPD) due to end-stage renal failure. Severe hepatic failure does not affect clearance [3].

Fenoldopam is indicated for the inpatient management of severe hypertension in adults with or without renal dysfunction. It is approved for use for up to 48 h. Fenoldopam has a pediatric indication for short-term therapy, duration up to 4 h, for blood pressure reduction [2].

Cardiovascular adverse effects that have been observed with a frequency of ≥ 5 % include cutaneous flushing and hypotension [1, 4]. Other documented cardiovascular effects are angina pectoris, bradycardia or tachycardia, chest pain, extrasystoles, heart failure, ischemic heart disease, myocardial infarction, palpitations, and electrocardiogram abnormalities [1, 3]. Neurological effects may include headache in greater than 5 % of patients receiving fenoldopam. Less than 5 % of recipients demonstrate anxiety, dizziness, and pyrexia. Nausea will be experienced by greater than 5 % of all patients, while abdominal pain, constipation, diarrhea, and vomiting may occur < 5 % of the time. Various other adverse effects that have been observed in patients include hyperglycemia, hypokalemia, elevation in lactate dehydrogenase (LDH), bleeding, leukocytosis, increased hepatic transaminases, back pain, increased intraocular pressure, blood urea nitrogen (BUN)/creatinine escalation, oliguria, dyspnea, and diaphoresis [1, 2].

Fenoldopam should be administered intravenously by continuous infusion via a mechanical infusion pump at an initial dose of 0.03–0.1 micrograms (mcg)/kg/min for adult patients. Bolus dosing is not recommended and should

not be administered. The rate may be titrated upward every 15 min in increments of 0.05–0.1 mcg/kg/min until the target blood pressure is achieved [2]. It is advantageous to avoid rapid decreases in blood pressure. The maximum dosage administered in clinical trials is 1.6 mcg/kg/min [2]. Frequent blood pressure and heart rate monitoring should be performed while patients are receiving this drug. When transitioning patients to oral antihypertensive therapy, fenoldopam may be either immediately discontinued or tapered gradually. The duration of therapy in trials did not exceed 48 h [3].

A continuous infusion rate of 0.2 mcg/kg/min administered intravenously via mechanical infusion pump is the initial dosing regimen for pediatric patients ages < 1 month through 12 years [7, 8]. This may be increased by 0.3–0.5 mcg/kg/min every 20–30 min if titration is required [2, 3]. A maximal dose of 0.8 mcg/kg/min is recommended [1, 7, 8]. Continuous blood pressure and heart rate monitoring is also recommended in the pediatric population. Trials did not include subjects with ages 12–16 years: dosing is to be based on clinical condition and concomitant drug therapy [3]. Usage in pediatric patients is FDA approved for up to 4 h in duration [2]. Within 30 min of discontinuation, blood pressure and heart rate will return to baseline values [3].

No dosing adjustments are required in patients with either renal or hepatic impairment. There has been no evaluation of fenoldopam dosing during hemodialysis, and as such no dosing recommendation adjustments can be made [2].

Levosimendan

Levosimendan, a calcium sensitizer, has a combination of both vasodilatory and inotropic activities and may be used in cases where either is indicated [9]. Cardiac muscle contraction force is enhanced, while ventricular relaxation is not affected. The vasodilation is a result of opening ATP-sensitive potassium channels in vascular smooth muscle. There is a reduction in preload and afterload, an increase in contractility and preservation of diastolic function [10]. Levosimendan is marketed internationally under the trade name of Simdax®. It is not available in the United States but is used in Europe, South America, and Asia [11].

Levosimendan is classified as a calcium sensitizer. It displays two mechanisms of action, the first being calcium sensitization making the heart contraction stronger by binding to troponin C. The force of the cardiac contraction is increased without accumulation of calcium. The second mechanism is an opening of vascular smooth muscle potassium channels which widens both coronary and peripheral blood vessels thereby increasing vasodilation [11].

The pharmacodynamic effects of levosimendan are dose dependent and are linear within the dosing range of 0.05–0.2 mcg/kg/min [10, 12]. Improved hemodynamic effects include increased cardiac output, stroke volume, ejection fraction, and heart rate. The hemodynamic effects that are decreased include systolic and diastolic blood pressures, pulmonary capillary wedge pressure (PCWP), right atrial pressure, and peripheral vascular resistance [10]. Myocardial perfusion is improved without a significant increase in oxygen consumption [11]. When administered at recommended doses, plasma catecholamine levels are not increased [13].

Levosimendan is highly protein bound to albumin and plasma proteins (97–98 %) in the serum. Metabolism is complete and occurs in the liver via conjugation and in the intestine via reduction (5 % of the total dose) [11]. There are two metabolites, OR-1855 and OR-1896, which are not considered to affect the degree of hemodynamic effect of levosimendan but are responsible for its prolonged effects after discontinuation. Prolonged effects may be experienced for up to 9 days in select patients [11]. Neither the parent drug nor the metabolites inhibits the CYP450 enzymes [10]. Levosimendan is not dialyzable [10].

Levosimendan is indicated for the short-term treatment of acutely decompensated severe chronic heart failure when conventional therapies have not provided adequate effects. It may also be

used when inotropes are required [9, 10]. There is literature describing investigation of the use of levosimendan for the support of patients with ischemic heart disease [14–16], post-cardiac surgery [17], and cardiogenic or septic shock [18, 19]. Levosimendan is not recommended for administration to children and adolescent patients less than 18 years of age [10]. There is currently an ongoing clinical trial assessing the efficacy and safety of levosimendan in critically ill children. It is a comparison of levosimendan versus intensified conventional inotrope therapy in critically ill pediatric patients with persistent severe acute heart failure after receiving conventional inotropic treatment [20]. In addition, there is published data regarding the safety and efficacy of levosimendan usage pre- and post-surgery in pediatric populations with congenital heart disease [21–23].

Common adverse effects associated with levosimendan in clinical trials include ventricular tachycardia, atrial fibrillation, hypotension, ventricular extrasystoles, and headache [24]. Other adverse reactions that have been observed in patients are dizziness, tachycardia, cardiac failure, myocardial ischemia, nausea, vomiting, constipation, diarrhea, insomnia, decreased hemoglobin, and hypokalemia [9].

Levosimendan therapy is initiated with an intravenous loading dose of 6–12 mcg/kg administered over 10 min. For patients receiving concomitant vasodilators or inotropes at the start of levosimendan therapy, the 6 mcg/kg dosing strategy should be utilized. Higher loading doses are associated with a greater hemodynamic response. The loading dose is followed with a continuous infusion administered at 0.1 mcg/kg/min [24]. After a period of 30–60 min, the patient's clinical response should be evaluated. If the patient becomes hypotensive and/or tachycardic, the dose may be decreased by 50 % to 0.05 mcg/kg/min or the medication discontinued. Conversely, if the initial dosing is tolerated and a greater hemodynamic effect is desired, the infusion rate may be increased to 0.2 mcg/kg/min [10]. The recommended duration of administration of levosimendan is 24 h. Upon discontinuation of this drug, the hemodynamic effects will continue for at least 24 h and possibly up to 9 days in select patients [10].

There are currently no manufacturer dosing recommendations for pediatric patients less than 18 years of age [10]. If levosimendan is used in the treatment of neonates, infants, or children, a loading dose of 12 mcg/kg infused over 1 h followed by a continuous infusion of 0.1 to 0.2 mcg/kg/min for 24 h may be considered [25].

Levosimendan can be administered to patients with mild to moderate hepatic or renal dysfunction. Caution should be exercised, but no dosing adjustment is required. Patients should not receive levosimendan if severe renal impairment (creatinine clearance $<$ 30 ml/min) or severe hepatic impairment is present [10].

Nesiritide

Nesiritide is a recombinant human B-type natriuretic peptide (BNP) prescribed in patient populations diagnosed with acutely decompensated heart failure experiencing dyspnea while at rest or with minimal activity. BNP is a neurohormone that causes natriuresis and vasodilation [26, 27]. It is manufactured under the brand names of Natrecor ® and Noratak® internationally.

Nesiritide is a natriuretic peptide that binds to the guanylate cyclase receptor on the vascular smooth muscle and endothelial cells. Smooth muscle relaxation occurs as a result of increased intracellular concentrations of cyclic guanosine monophosphate (cGMP) [28]. This smooth muscle relaxation leads to a reduction (dose dependent) in pulmonary capillary wedge pressure (PCWP) and systemic arterial pressure with the end result being an improvement of dyspnea [27, 29].

Onset of action of nesiritide occurs in 15 min at which time 60 % of the full effect on PCWP (observed at 3 h) is achieved [28]. Duration of the effect on systolic blood pressure is greater than 60 min and can extend to several hours in some patients. It has been demonstrated that hemodynamic effects last longer than what would be

expected when considering half-life data [30]. Catecholamines are suppressed and sympathetic activation does not occur [27, 29, 31]. Nesiritide also increases glomerular filtration rate and promotes natriuresis [26, 29]. Mean clearance (CL) is 9.2 ml/kg/min. Once steady state is achieved at the recommended dose, BNP will be elevated 3–6 times greater than the baseline endogenous level [28].

Metabolism of nesiritide occurs through proteolytic cleavage by endopeptidases, cellular internalization, and proteolysis after receptor binding [28]. Nesiritide displays biphasic characteristics with initial half-life elimination of 2 min and terminal half-life elimination occurring at 18 min [29]. Although nesiritide is mainly eliminated by metabolism as described, it is also excreted in the urine via renal filtration [28]. Elimination in patients with chronic renal insufficiency is not considered to be significantly different than in those with normal kidney function.

The clinical use of nesiritide is for the treatment of acutely decompensated heart failure in patients with dyspnea at rest or with minimal activity [26, 27]. Nesiritide improves dyspnea by reducing PCWP [27]. This agent should not be administered to patients who should not receive vasodilators or with low cardiac filling pressures [28].

Hypotension is one of the most frequent adverse effects experienced with nesiritide [26]. It was observed in 11 % of patients with 4 % being symptomatic at the recommended dosing regimen. This percentage will increase to 17 % when higher than recommended dosing is administered [27]. Prescribers should also be aware that hypotension may be prolonged [29]. Other cardiovascular effects observed include ventricular tachycardia and extrasystoles, angina, bradycardia, tachycardia, atrial fibrillation, and AV node conduction abnormalities [26, 27]. It is important to note that ventricular tachycardia, ventricular extrasystoles, and angina occurred with less or equal frequency to placebo or other standard therapies [29].

Renal function may be affected with serum creatinine increases $>$ 0.5 mg/dl over baseline occurring in 11–28 % of patients receiving nesiritide [26, 29]. If there is reliance on the renin-angiotensin-aldosterone system for renal perfusion, patients may experience azotemia [30]. There has been an association suggested between nesiritide and renal impairment, so comprehensive monitoring is required [32].

Other notable adverse events include headache, nausea, back pain, dizziness, and anxiety [29]. Rare reports of hypersensitivity reactions have been documented [33]. It may be possible that there is an increased risk of mortality with the use of nesiritide [34].

There are manufacturer dosing recommendations available for adult patients. An optional 2 mcg/kg intravenous bolus of nesiritide may be used followed by a continuous infusion administered at 0.01 mcg/kg/min [28, 29]. It is recommended to not exceed this dosing for initiation of therapy. Although a typical dosing range of 0.01–0.03 mcg/kg/min can be found in published literature, there is very limited data regarding dose escalation above 0.01 mcg/kg/min, so this should be limited to select patients and monitored closely [27, 29, 30]. Also, experience is limited regarding the extension of therapy beyond 48 h [28]. In the event that patients become hypotensive while receiving nesiritide, the infusion rate should be decreased or administration discontinued. Blood pressure support measures such as I.V. fluids or Trendelenburg positioning should be used [28]. If desirable, therapy can be reinstituted at a 30 % reduction of the previous dose without further bolusing [28].

Although there is no maximum dosing weight recommended by the manufacturer, the PRECEDENT trial used a maximum weight of 160 kg and the VMAC trial used a maximum weight of 175 kg [26, 29]. Clinical judgment should be used with patients with morbid obesity.

No dosing adjustment is required for patients having renal or hepatic impairment [28]. However, caution should be used for patients with renal dysfunction or alteration of the renin-angiotensin-aldosterone system. In these patients, renal function should be monitored rigorously [33].

There is currently no dosing recommendation available from the manufacturer for the pediatric population. However, several case reports and small retrospective studies that used dosing similar to adults have been published. Feingold and Law reported their experience in 3 children ages 7, 17, and 19 years old [35]. They used an IV loading dose of 1 mcg/kg followed by a continuous infusion of 0.005–0.02 mcg/kg/min, with 2 patients responding to treatment. Mahle and colleagues treated 30 children between the ages of 5 days and 16 years with diagnoses of congenital heart defects, dilated cardiomyopathy, or cardiac transplant with nesiritide [36]. Dosing included a 1 mcg/kg IV bolus dose in 80 % of the patients and a continuous infusion range of 0.005–0.02 mcg/kg/min. The authors found that the improved natriuresis and diuresis resulted in improvement in hemodynamics, not well controlled by standard therapies, and was well tolerated in infants and children. Jeffries and colleagues published a prospective evaluation of nesiritide use in 32 children ages 1 month to 20 years with heart failure of various etiologies [37]. No bolus dose was used, and the continuous infusion rate was initially 0.01 mcg/kg/min, with titration up to 0.03 mcg/kg/min if needed. There was no hypotension or arrhythmias, and urine output increase and CVP decrease were statistically significant.

Antiarrhythmic Drugs

60

Alejandro J. López-Magallón, Nils Welchering, Juliana Torres Pacheco, Donald Berry, and Ricardo Muñoz

Abstract

Antiarrhythmic drugs are a daily necessity in the Cardiac Critical Care setting. Nonetheless, they are not exempt of potentially serious side effects. This chapter gives a brief description of basic electrophysiology concepts, a practical classification of antiarrhythmic agents, and a list of the most important drugs available in the Critical Care armamentarium. Information relevant to their clinical use, including indications, mechanism, pharmacodynamics/pharmacokinetics, adverse effects, and dosing, is included. A solid knowledge of these concepts will be most helpful to

Introduction

Rhythm disorders and the need to consider antiarrhythmic drugs are daily staples in the Cardiac Intensive Care Unit. Nevertheless, caregivers should always be wary about their relatively limited efficacy and inherent propensity for side effects [1]. Overall enthusiasm for a chronic medical treatment-only approach for serious cardiac arrhythmias has waned worldwide since the publication of the CAST report, documenting an increase in mortality with the use of type I agents in patients after myocardial infarction. Other studies investigating different types of antiarrhythmics have resulted in similarly worrisome findings [2]. Hence, drug treatment should be reserved for potentially serious arrhythmias, using the single most effective agent with the widest therapeutic range at the lowest effective dose whenever possible. An informed approach based on practical electrophysiology concepts and knowledge of individual drug pharmacology will render best results [3, 4].

Basic Electrophysiology

The Action Potential

The electrical impulse of the heart is the summation of minute electrical currents generated by thousands of individual cardiac cells. It is described as the cardiac action potential and is classically divided into five phases. Phase 0 corresponds to depolarization, phases 1–3 correspond to repolarization, and phase 4 corresponds to the resting phase [1] (Fig. 60.1).

At resting potential, cardiac myocytes maintain a negative electrical gradient relative to the extracellular environment (phase 4). Then, rapid channels in the cell membrane open, allowing positively charged sodium ions to rush into the cell, changing the transmembrane potential (phase 0). The depolarization of one cell transmits to adjacent cells, and the electrical impulse spreads across the heart. Once a cell is depolarized, it cannot be depolarized again until reversal of the ionic fluxes that occur during depolarization. This process of getting the ions back is called repolarization and corresponds to phases 1–3, and the time from the end of phase 0 to late in phase 3 is called refractory period since the cell is refractory to depolarization until after it is repolarized [1, 3].

Repolarization begins rapidly (phase 1), mostly due to the inactivation of the fast sodium channels, and is immediately delayed by a plateau phase (phase 2), which is unique to cardiac cells. Phase 2 is mediated by slow calcium channels, allowing for positively charged calcium ions to enter the cell slowly, interrupting repolarization and prolonging the action potential. This plateau phase of the cardiac action potential is sustained by a balance between inward movement of calcium and outward movement of potassium. The continued positive outward flow of potassium ions after inactivation of calcium channels initiates

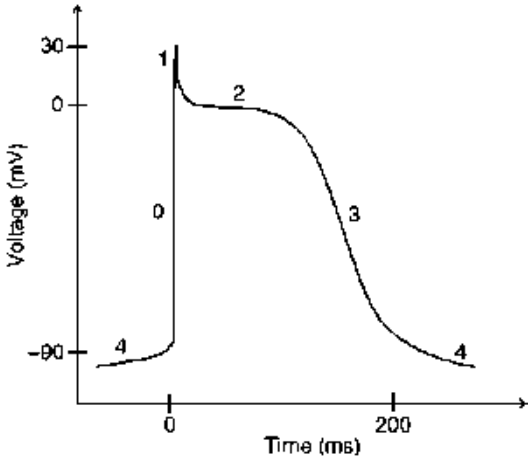

Fig. 60.1 Action potential of a Purkinje fiber. Phase 4 is the resting before stimulation, phase 0 is the rapid depolarization, phase 1 is the initial stage of repolarization, phase 2 is the plateau phase, and phase 3 is the rapid repolarization

Table 60.1 The Vaughan-Williams classification

Class	General mechanism	Drugs
I	Na^+ channel blockade	
Ia	Moderately conduction slowing	Quinidine
	Moderately action potential prolongation	Procainamide
		Disopyramide
Ib	Minimally conduction slowing	Lidocaine
	Action potential duration shortening	Mexiletine
		Phenytoin
Ic	Marked conduction slowing	Flecainide
	Minimal prolongation of action potential	Propafenone
		Encainide
II	β-blockade	Propranolol
		Metoprolol
		Atenolol
III	Prolong action potential duration	Amiodarone
		Sotalol
		Ibutilide
IV	Ca^+ channel blockade	Verapamil
		Diltiazem

repolarization once again (phase 3) and has the effect of returning the action potential toward its negatively polarized state. The intrinsic ability of cardiac cells to spontaneously initiate propagation of an action potential is called automaticity [3].

The sinus node is the normal site of impulse formation in the heart. Impulse propagation then occurs through the atrial myocardium and then to the atrioventricular (AV) node. Because the refractoriness of AV nodal cells is both voltage and time dependent, there is a decrease in conduction velocity between atria and ventricles, and rapid or closely coupled beats can be filtered. The cardiac impulse then continues through the His bundle, then divides into the right and left bundle branches and then into the Purkinje fibers. Cardiac action potential shape differs within the different specialized cells, as sinus and AV nodes present a slow depolarization phase. Purkinje fibers, on the other hand, are characterized by a rapid conduction velocity permitting the electrical impulse to be rapidly distributed throughout the ventricles.

While the cardiac action potential represents the electrical activity of a single cardiac cell, a surface ECG reflects the electrical activity of the entire heart. The P wave represents the atrial depolarization, the QRS complex represents the ventricular depolarization, and the ST segment and the T wave reflect ventricular repolarization. The action potential duration of ventricular muscle is thus represented by the QT interval [1].

Antiarrhythmic drugs change the shape of the cardiac action potential by altering the channels that control ionic flow across the cardiac cell membrane [5].

Two general classification schemes have been set forth for antiarrhythmic drugs, the *Vaughan-Williams* scheme, initially proposed in 1971, and the *Sicilian Gambit*, proposed around 20 years later.

The Vaughan-Williams classification is the most practical one from the clinical point of view, perhaps more importantly due to its prognostic value as to the proarrhythmic effects of a given drug based on its effect on myocardial action potential [5] (Table 60.1).

The Vaughan-Williams system groups drugs according to their major mechanism of action, that is, according to which channels they bind and block on the cardiac cell membrane.

Class I drugs act by reducing the atrial, ventricular muscle and Purkinje cell depolarization

by fast inward sodium current, impeding the access of sodium to the ion pathway. Drugs in the IA group slow conduction moderately, widen QRS, and also increase the effective refractory period (ERP). They share the additional property of delaying repolarization by an independent effect on outward potassium currents unrelated to sodium channel block [3]. Quinidine is one of the oldest antiarrhythmic drugs and shares some anticholinergic properties with disopyramide [6]. Although quinidine is efficient in reducing the occurrence of ventricular ectopic depolarizations [7], it has a higher arrhythmogenic risk (prolonged QT interval may be observed at therapeutic concentrations) than the other class IA agents [8] and it is rarely used nowadays. Procainamide elicits similar electrophysiological changes, but QT interval prolongation is less pronounced at therapeutic concentrations than quinidine and disopyramide [9], so it became a safer option for the treatment of junctional ectopic tachycardia [10, 11]. Notwithstanding this, it has also been relegated as a second-line drug for acute treatment of serious rhythm disorders in the Critical Care environment.

Class Ib compounds do not slow conduction and actually decrease the duration of action potential. They are useful only for the management of ventricular tachyarrhythmias [3]. As mexiletine is only available for oral administration [12], lidocaine is considered the second-line therapy for ventricular arrhythmias in acute situations such as pulseless ventricular tachycardia and ventricular fibrillation [1, 13]. Mexiletine is also a more profound negative inotropic agent than lidocaine [14].

Class Ic agents are effective at much lower concentrations than Ib drugs and produce a pronounced slowing of conduction velocity, widening QRS with little effect on ERP [4]. They are used to treat ventricular and supraventricular tachyarrhythmias and are contraindicated in patients with structural heart disease due to the risk of precipitating life-threatening ventricular arrhythmias [2] and depressing systolic function. Propafenone is a relatively safe drug, as its proarrhythmic effects appear to be less frequent than those reported for encainide or flecainide [15, 16].

Class II antiarrhythmic agents act by competitive antagonism at adrenergic receptors, thus blocking sympathetic stimulation. Beta-blockers can be considered the safest class of antiarrhythmics due to their predictable side effects. They are used to treat atrial and ventricular tachyarrhythmias and also hypertension and congestive heart failure [3]. Metoprolol and atenolol are commonly used cardioselective beta-blockers and present a potential advantage in asthmatic and diabetic patients, as they preferentially inhibit β1 receptors. Non-cardioselective beta-blockers (that bind to both β1 and β2 receptor types) include propranolol and nadolol. Propranolol has a short half-life (3–5 h) and has been used most extensively in the pediatric population. Carvedilol and labetalol have additional α-adrenergic blocking properties, thus reducing peripheral vascular resistance more than other beta-blockers [17].

Class III drugs block potassium channels and delay repolarization but usually have mixed effects. Amiodarone can be considered the workhorse of the antiarrhythmic armamentarium in the Critical Care setting, given its superiority in reducing recurrence of ventricular arrhythmias and atrial fibrillation. It has been incorporated as the first-line medical choice for serious atrial and ventricular arrhythmias in ACLS and PALS algorithms [13]. The wide spectrum of electrophysiologic effects of Amiodarone are a reflection of its sodium channel blocking (class I), beta-blocking (class II), potassium channel blocking (class III), and calcium channel blocking (class IV) properties. It is also a systemic vasodilator. On the other hand, its complex pharmacokinetics, significant and serious side effects, and extremely prolonged half-life mandate careful consideration before its use. Sotalol is a nonspecific beta-adrenergic receptor blocker and potassium channel-blocking agent that is used in managing ventricular arrhythmias and atrial fibrillation. It has a much shorter half-life than amiodarone, allowing for therapeutic levels to be attained sooner. However, it can increase the risk of bronchospasm in sensitive patients [18]. Ibutilide is a short-acting intravenous potassium channel blocker used only for the acute termination of atrial fibrillation or flutter in adults [3].

Class IV action drugs reduce inward calcium currents and are used to treat atrial tachyarrhythmias [19]. These agents are differentiated according to their relative effects on vascular smooth muscle (vasodilation), myocardium (contractility), or conduction and pacemaker tissues (automaticity). Diltiazem is a calcium channel blocker that exhibits intermediate vasoselectivity, and verapamil demonstrates increased negative chronotropic, dromotropic, and inotropic cardiac effects. This is especially worrisome in infants, which are highly dependent on calcium-mediated inotropy. Clinically, diltiazem and verapamil exert a similar suppressive effect on the AV node and are useful for treating and preventing AV nodal reentrant tachycardia [20, 21].

Not inserted in this classification are adenosine, atropine, and digoxin, having effects by different mechanisms. Adenosine causes sinus and AV nodal depression and shortens atrial refractoriness. Because of its extremely short half-life of 7–10 s, adenosine is the drug of choice for termination of paroxysmal SVT [22]. Atropine is an anticholinergic and antispasmodic agent indicated for bradycardia and asystole [23]. Digoxin has as primary mechanism of action the ability to inhibit membrane-bound alpha subunits of sodium-potassium ATPase (sodium pump). It does not restore sinus rhythm but decreases the ventricular rate in supraventricular tachycardia, reducing the frequency of symptomatic atrial fibrillation [24].

IA Agents

Procainamide

1. *General Aspects/Comments, Classifications, Definitions, and General Uses*

Procainamide is a class IA antiarrhythmic with some anticholinergic effects.

2. *Mechanism of Action*

Procainamide is a potent sodium channel blocker with less marked potassium channel-blocker properties. It decreases myocardial excitability and conduction velocity, resulting in a prolongation of the effective refractory period. Furthermore, myocardial contractility is depressed by procainamide. It is more effective at faster heart rates, with proarrhythmic properties being exacerbated at slower heart rates. N-acetyl procainamide (*NAPA*), its active metabolite, has a predominant class III effect, prolonging the action potential duration in ventricular muscle and Purkinje fibers in a dose-dependent manner.

3. *Pharmacokinetics/Pharmacodynamics*

The onset of action occurs 10–30 min after I.M. administration, and its peak concentration is reached between 15 min and 1 h after administration. Procainamide is well absorbed orally, and it is acetylated in the liver to NAPA. The half-life of procainamide/NAPA in children is 1.7 h/6 h and in adults 2.5–4.7/6–8 h depending upon hepatic and renal function. Blood levels should be closely monitored in patients with renal failure. Procainamide is partially dialyzable, whereas NAPA is not dialyzable.

4. *Clinical Indication/Uses*

Procainamide has been used for treatment of acute supraventricular tachycardia due to accessory pathway, ventricular tachycardia, premature ventricular contractions, and atrial fibrillation or flutter. Currently, it is most commonly used for the treatment of junctional ectopic tachycardia [10, 11].

5. *Contraindications/Side Effects*

Contraindications include any degree of atrioventricular heart block without a readily available pacemaker, torsades de pointes tachycardia, and systemic lupus erythematosus. Use procainamide only with extreme caution in patients with myasthenia gravis or who are intoxicated with cardiac glycosides. High levels of NAPA can produce early afterdepolarizations [4], especially in renal and hepatic dysfunction. Exacerbation of congestive heart failure may occur due to negative inotropic effect, and electrolyte imbalances, especially hypokalemia, should be corrected prior to and during therapy.

The most common side effects include hypotension, gastrointestinal disturbances (nausea, vomiting, diarrhea), drug-induced fever, conduction disturbances, and ventricular

tachyarrhythmia. Serious but less common side effects are agranulocytosis with chronic use and lupus-like symptoms [25].

Fatal poisoning by procainamide can easily occur due to its narrow therapeutic range. Symptoms include sinus bradycardia and arrest; PR, QRS, and QT prolongation; torsades de pointes; depressed myocardial contractility; hypotension; pulmonary edema; seizures; coma; and respiratory arrest. Treatment of poisoning is symptomatic. Sodium bicarbonate may treat QRS prolongation and hypotension.

6. *Doses*

For infants and children, an I.V. loading dose of 3–6 mg/kg/dose over 5 min is given, with an upper limit of 100 mg/dose. This dose may be repeated every 5–10 min to a maximum total dose of 15 mg/kg, not exceeding 500 mg in 30 min.

Maintenance procainamide is given by continuous I.V. infusion of 20–80 mcg/kg/min with a maximum dose of 2 g/day [26].

For adult patients, an I.V. loading dose of 50–100 mg/dose, repeated every 5–10 min, is administered until the patient is controlled or alternately loaded with 15–18 mg/kg infused over 30 min. The maximum loading dose should not exceed 1 g.

The maintenance continuous I.V. infusion required is usually 3–4 mg/min with a range of 1–6 mg/min. Oral maintenance dosing of 50 mg/kg/day divided every 6 h is usually used for long-term therapy where oral dosage forms are available.

Procainamide requires dosing adjustment in renal dysfunction. For oral therapy, patients with a ClCr of 10–50 mL/min should be administered with a dose every 6–12 h and, for a ClCr less than 10 mL/min, doses every 8–24 h. With I.V. therapy, a loading dose reduction to 12 mg/kg is recommended in patients with severe renal dysfunction. For maintenance infusions, a reduction of the dose by 30 % is recommended for moderate renal dysfunction, and a 60–70 % reduction for severe renal dysfunction.

Therapeutic serum levels are as follows: procainamide, 4–10 mcg/mL; NAPA levels, 6–20 mcg/mL; and sum of procainamide and NAPA, 10–30 mcg/mL. *ECG monitoring* (*QTc*) *is mandatory during procainamide therapy*.

Disopyramide

1. *General Aspects/Comments, Classifications, Definitions, and General Uses*

Disopyramide is a class 1A antiarrhythmic used in the conversion and prevention of atrial fibrillation, atrial flutter, and SVT. It is also used to treat life-threatening ventricular arrhythmias such as sustained ventricular tachycardia.

2. *Mechanism of Action*

Disopyramide is a potent sodium and potassium channel blocker. It prolongs the action potential duration in Purkinje tissue more than the effective refractory period. It shows anticholinergic as well as potent negative inotropic effects.

3. *Pharmacokinetics/Pharmacodynamics*

Disopyramide is well absorbed orally, with an onset of action of 0.5–3.5 h. The peak serum concentration of the immediate-release form is reached in 2 h. It is highly protein bound. Clearance is greater and half-life shorter in children vs. adults. It has a half-life of 3–5 h in children [27] and 4–10 h in adults. Disopyramide is metabolized in the liver, and its major metabolite has anticholinergic and antiarrhythmic effect. It is ultimately eliminated in the urine as both unchanged drug and metabolites.

4. *Clinical Indication/Uses*

Disopyramide helps to prevent recurrence of atrial fibrillation after successful cardioversion and may terminate or decrease the atrial cycle-length in atrial flutter. In this clinical setting, the ventricular rate must be controlled before administration to prevent the paradoxical presentation of 1:1 AV conduction with faster ventricular rates during atrial flutter. It has been used for symptomatic relief in patients with obstructive hypertrophic cardiomyopathy [28].

5. *Contraindications/Side Effects/Interactions*

Contraindications to disopyramide use include preexisting ventricular dysfunction or second- or third-degree AV block (unless a functioning pacemaker is present) and congenital long QT

syndrome. Use with extreme caution in patients with myasthenia gravis or glaucoma due to anticholinergic effects. As with procainamide, exacerbation of congestive heart failure may occur due to negative inotropic effect, and electrolyte imbalances, especially hypokalemia, should be corrected prior to and during therapy.

The most common adverse effects are related to parasympatholytic actions and include urinary retention, constipation, blurred vision, closed-angle glaucoma, and dry mouth.

The most serious adverse effects of disopyramide are myocardial depression and ventricular arrhythmias and rarely agranulocytosis, thrombocytopenia, hepatic toxicity, and hypoglycemia.

There are several drug-drug interactions that can interfere with disopyramide therapy. Hepatic microsomal-inducing agents like phenytoin, phenobarbital, and rifampin may lower disopyramide serum concentrations. Clarithromycin and erythromycin may increase disopyramide concentrations and should not be used simultaneously. Drugs that prolong the QT or other antiarrhythmic drugs may potentiate disopyramide proarrhythmic properties. Avoid concomitant administration with verapamil.

6. Doses

Recommended oral dosing for children younger than 1 year is 10–30 mg/kg/day in four divided doses; for children 1–4 years, 10–20 mg/kg/day in four divided doses; for children 4–12 years, 10–15 mg/kg/day in four divided doses [29]; and children 12–18 years, 6–15 mg/kg/day in four divided doses. For adults <50 kg, administer 100 mg every 6 h or 200 mg every 12 h if using the controlled-release dosage form. In patients >50 kg, administer 150 mg every 6 h or 300 mg every 12 h if using the controlled-release dosage form.

Disopyramide requires a dose adjustment in renal dysfunction. Recommendations for adults (using non-sustained-release capsules) are to give 100 mg every 8 h if the ClCr is 30–40 mL/min, 100 mg every 12 h if the ClCr is 15–30 mL/min, and 100 mg every 24 h for a ClCr less than 15 mL/min.

IB Agents

Lidocaine

1. *General Aspects/Comments, Classifications, Definitions, and General Uses*

Lidocaine is used for ventricular arrhythmias, including ventricular tachycardia and ventricular fibrillation, especially after acute MI or cardiac surgery. It is also used as a local anesthetic [4].

2. *Mechanism of Action*

Lidocaine is a rapid sodium channel blocker with effects on the His-Purkinje system and ventricles. It suppresses the automaticity of the conduction tissue by increasing the electrical stimulation threshold in those areas and decreasing spontaneous depolarization during diastole [30].

3. *Pharmacokinetics/Pharmacodynamics*

The onset of action of a single I.V. bolus dose is between 45 and 90 s with duration of 10–20 min. Lidocaine is extensively metabolized in the liver to less active metabolites, and its half-life is 2–3 h. An increased half-life can be found in liver diseases, congestive heart failure, as well as shock and renal failure. Most of lidocaine is cleared by the liver [1], and the metabolites are then excreted in the urine.

4. *Clinical Indication/Uses*

Lidocaine is indicated for treatment of ventricular arrhythmia, tachycardia, and fibrillation. It is considered a second choice alternative for ventricular arrhythmias in many acute situations, including pulseless ventricular tachycardia and ventricular fibrillation [1, 13]. Nonetheless, it has not proven to improve rates of return of spontaneous circulation compared with amiodarone.

5. *Contraindications/Side Effects*

Contraindications to lidocaine use include sinus/AV block without the assistance of a pacemaker and WPW syndrome. Lidocaine should be used with caution in heart failure, hypotension, shock, and hepatic disease. Increased serum levels may occur with concurrent use with cimetidine or beta-blockers. Additive effects with other class

I antiarrhythmics and amiodarone can result in cardiotoxicity.

The most common adverse effects occur in the central nervous system and are characterized by slurred speech, perioral numbness, dizziness, seizures, and paresthesias. Respiratory arrest can be a serious complication of lidocaine therapy.

Cardiac symptoms of intoxication include AV block, asystole, sinus arrest, and hypotension. Central nervous symptoms of intoxication are confusion, sedation, coma, and respiratory arrest and can be due to toxic accumulation of the metabolites of lidocaine. Methemoglobinemia and nausea may also occur.

6. *Doses*

For infants or children, a loading dose of 1 mg/kg is given I.V. or I.O. (intraosseous), followed by a continuous infusion of 20–50 mcg/kg/min. A repeat loading dose of 0.5–1 mg/kg may be given if there is a delay starting the continuous infusion of greater than 15 min. Patients with shock, hepatic disease, or CHF may require one-half of the loading dose and lower infusion rates. For doses administered via a tracheal tube, 2–3 mg/kg/dose may be used followed by a flush of 5 ml normal saline.

Adults should be given an I.V. loading dose of 1–1.5 mg/kg. Doses of 0.5–0.75 mg/kg every 5–10 min may be repeated to a total of 3 mg/kg. The continuous infusion should be run at a rate of 1–4 mg/min. Consider decreasing the initial bolus of 0.5–0.75 mg/kg in patients with CHF or hepatic disease. For doses given via tracheal tube, 2–2.5 times the I.V. bolus dose is recommended [3].

Mexiletine

1. *General Aspects/Comments, Classifications, Definitions, and General Uses*

Mexiletine is used for treatment of ventricular arrhythmias and is only available for oral administration [12]. Thus, it is not suitable for use in the acute management of VT/VF.

2. *Mechanism of Action*

Mexiletine blocks the fast sodium channels and shortens the duration of action potentials as well as the repolarization. The effects are positively correlated to the heart rate. Mexiletine has no significant negative inotropic effect but may increase systemic vascular resistance resulting in decreased cardiac output.

3. *Pharmacokinetics/Pharmacodynamics*

Mexiletine has a high bioavailability of about 90 % and is quickly absorbed. It is metabolized in the liver and has a half-life of 10–14 h. Because of its high liver metabolism, half-life is increased with hepatic or heart disease, and accordingly, serum concentration should be monitored. Mexiletine is excreted in the urine, and its elimination can be increased with urine acidification. Dosage must be adjusted as well in hepatic impairment and severe renal failure [3].

4. *Clinical Indication/Uses*

Mexiletine is used for treatment of life-threatening ventricular arrhythmias and suppressions of premature ventricular contractions. Nevertheless, its prolonged half-life and narrow therapeutic index have precluded its widespread usage in the acute care setting [1]. It has been proposed as an alternative treatment for long QTc type 3, depending on specific mutation response [31].

5. *Contraindications/Side effects*

Contraindications to mexiletine use include cardiogenic shock, second- or third-degree AV block without a functioning pacemaker, and hypersensitivity to mexiletine. Mexiletine should be used with caution in hepatic dysfunction, congestive heart failure, and in patients with seizure disorders or hypotension. The most common adverse effects include those that affect the central nervous system (confusion, dizziness, blurred vision, ataxia) and gastrointestinal tract (nausea, vomiting, diarrhea). Less frequent but more serious adverse effects include arrhythmias, worsening congestive heart failure, hepatitis, and hypotension. Intoxication from elevated levels of mexiletine can result in sedation, confusion, seizures, respiratory arrest, AV block, sinus arrest, asystole, paresthesias, tremor, ataxia, and GI disturbances. Treatment is primarily supportive. In case of hypotension with bradyarrhythmias and prolonged QRS, sodium bicarbonate to increase renal elimination is a therapeutic option.

6. *Doses*
Oral dosing for infants and children ranges from 1.4 to 5 mg/kg/dose, with a mean of 3.3 mg/kg/dose, administered every 8 h. Initiate dosing with a lower dose and adjust dosing according to effect and drug levels. In adults, oral dosing should begin with 200 mg every 8 h (may load with 400 mg, if necessary). Adjust the dose every 2–3 days. The usual maintenance dose is 200–300 mg every 8 h, with a maximum dose of 1.2 g/day. Dosing adjustment in renal impairment in children and adults with ClCr less than 10 mL/min is accomplished by administering 50–75 % of the normal dose. In hepatic impairment, administer 25–30 % of the normal dose.

IC Agents

Flecainide

1. *General Aspects/Comments, Classifications, Definitions, and General Uses*
Flecainide is used for atrial, junctional, and ventricular arrhythmias [4, 32].
2. Mechanism of Action
Flecainide is a potent inhibitor of slow sodium channels in the heart but has also some blocking effects on potassium channels. The main effect of flecainide is on the ventricular myocardium and His-Purkinje system. The blocking effect of flecainide on the cardiac sodium channels is voltage and cycle-length dependent [33] with a decreased conduction and prolongation of refractory period in ventricular myocardium and a shorter duration of the Purkinje fiber action potential [4].
3. Pharmacokinetics/Pharmacodynamics
Flecainide is almost completely absorbed (>90 %) in the gastrointestinal tract and then metabolized in the liver. Its peak plasma concentration occurs in 2–3 h. The half-life is dependent on age, in adults 12–27 h, in children 8 h, in infants 11–12 h, and newborns 29 h. An increased half-life can be found in patients with congestive heart failure and renal impairment. The elimination of flecainide occurs via the urine, but it is not dialyzable.
4. Clinical Indication/Uses
Flecainide is used for treatment of paroxysmal atrial fibrillation, junctional arrhythmias, and life-threatening ventricular tachyarrhythmias. It has been suggested as an alternative treatment for long QTc type 3 syndrome, pending on specific mutation response [34]. Furthermore, it may be used in catecholaminergic polymorphic ventricular tachycardia and as a diagnostic tool for Brugada syndrome, as it may produce the characteristic ST elevation in lead V1.
5. Contraindications/Side Effects/Interactions
Contraindications to flecainide use include AV block (second/third degree), complete right bundle branch block with left hemiblock or trifascicular block, cardiogenic shock, and coronary artery disease [2]. Because flecainide has proarrhythmic effects, it may cause worsening of ventricular arrhythmias. Use cautiously in patients with congestive heart failure, conduction abnormalities, and myocardial dysfunction, as well as in patients with renal or hepatic dysfunction [35].

The most common noncardiac adverse effects involve the central nervous system (dizziness, fatigue, blurred vision, nervousness, headache, hypoesthesia) and gastrointestinal tract (nausea, abdominal pain). Some patients may report dyspnea. Less frequent but serious adverse effects include ventricular arrhythmias, AV block, bradycardia, and hepatotoxicity.

Flecainide levels should be monitored, with the therapeutic range for a trough concentration being 0.2–1 mcg/mL. Because of its narrow therapeutic index, intoxication can be seen with flecainide, especially in combination with other antiarrhythmics. Amiodarone or cimetidine may increase the concentration of flecainide. Intoxication may lead to increased PR, QRS, and QT intervals, AV block, bradycardia, ventricular arrhythmias, asystole, and hypotension. Patients may notice blurred vision, dizziness, headache, and GI disturbances. Treatment is symptomatic and may include sodium bicarbonate and fluids for QRS prolongation, bradycardia, and hypotension [3].
6. Doses
For children, the initial oral dose is 1–3 mg/kg/day in three divided doses. Increase the dose every few days to a usual maintenance dose of

3–6 mg/kg/day, with a maximum dose of 8 mg/kg/day. Alternatively begin dosing with 50–100 mg/m^2/day and increase gradually to a usual maintenance dose of 100–150 mg/m^2/day, with a maximum dose of 200 mg/m^2/day.

For adults, the initial oral dose is 50–100 mg every 12 h. The dose may be increased by 100 mg/day every 4 days. The usual effective dose is 300 mg/day, and the maximum dose is 400 mg/day.

Propafenone

1. *General Aspects/Comments, Classifications, Definitions, and General Uses*

Propafenone has a therapeutic profile similar to flecainide. It is used for treatment of atrial, junctional, and ventricular arrhythmias [1].

2. *Mechanism of Action*

Propafenone blocks the fast sodium influx in the Purkinje fibers as well as in the ventricular myocardium. Moreover, it has mild beta-blocker activity and calcium-antagonistic properties. Those mechanisms result in a decreased excitability and spontaneous automaticity. Further, ventricular myocardial refractoriness and conduction are prolonged [4].

3. *Pharmacokinetics/Pharmacodynamics*

Propafenone is almost completely absorbed in the gastrointestinal tract (>95 %), but due to a significant first-pass effect, systemic bioavailability averages only 12 % and is dependent on dose and dosage form. It is then further metabolized in the liver, with both slow (10 % of Caucasians) and fast metabolizer groups identified. Its pharmacokinetics is nonlinear. The half-life for most patients is 2–10 h, but for slow metabolizers, it can be 10–32 h.

4. *Clinical Indication/Uses*

Propafenone is indicated for treatment of life-threatening ventricular tachyarrhythmias and non-sustained ventricular tachycardia [1], atrial fibrillation, and paroxysmal supraventricular tachycardias.

5. *Contraindications/Side Effects/Interactions*

Contraindications to propafenone use include hypersensitivity to the drug, sinoatrial/atrioventricular/intraventricular conduction disorders (without functioning pacemaker), sinus bradycardia, cardiogenic shock, uncompensated heart failure, hypotension, bronchoconstrictive disorders, and concomitant use of ritonavir which can increase propafenone levels.

Propafenone has significant proarrhythmic properties, requiring vigilant monitoring of the ECG for new or worsening arrhythmias. Use cautiously in patients with congestive heart failure and in hepatic dysfunction because of reduced hepatic metabolism. Concurrent use with cimetidine, quinidine, fluoxetine, and miconazole may increase propafenone levels, while phenobarbital and rifampin decrease propafenone levels.

The most common adverse effects involve the central nervous system (dizziness, ataxia, insomnia, fatigue, blurred vision, lightheadedness, anxiety) and gastrointestinal tract (nausea, constipation, metallic taste). Dyspnea may also occur.

Less frequently more serious adverse events occur and include exacerbation of congestive heart failure, proarrhythmia including ventricular tachycardia, AV block, and agranulocytosis. A lupus-like syndrome may also develop [3, 4].

Propafenone has a narrow therapeutic index, and intoxications are seen, especially with concurrent use of other antiarrhythmics. Symptoms include an increased PR, QRS, and QTc intervals, AV block, bradycardia, ventricular arrhythmia, asystole, and hypotension. Patients may notice blurred vision, dizziness, headache, and GI disturbances. Treatment is symptomatic. QRS prolongation, bradycardia, and hypotension may be treated with sodium bicarbonate and fluids.

6. *Doses*

Oral dosing in infants and children begins at 150–200 mg/m^2/day divided every 8 h, with a maximum dose of 600 mg/m^2/day. In adults, initial oral dosing with immediate-release tablets is 150 mg every 8 h. It may be increased every 3–4 days up to 300 mg every 8 h if needed. Using extended-release capsules, the initial dose is 225 mg every 12 h, with increases after at least 5 days to 325 mg every 12 h and then 425 mg every 12 h if needed.

Class II Agents: Beta-Blockers

Esmolol

1. *General Aspects/Comments, Classifications, Definitions, and General Uses*

Esmolol is a short half-life, fast-acting beta-adrenergic blocker suitable for use in the Intensive Care setting [36].

2. *Mechanism of Action*

Esmolol mainly blocks beta-1 adrenergic receptors in the AV and SA nodes. It is short acting and has only minimal effects on beta-2 receptors [30] unless high doses are used.

3. *Pharmacokinetics/Pharmacodynamics*

The beta-blockage appears within 2–10 min after administration, and its effects last only for 10–30 min. Esmolol is metabolized in the blood by esterases. Its half-life is short and dependent on age and is 3–10 min [3].

4. *Clinical Indication/Uses*

Esmolol is indicated for treatment of supraventricular tachycardia, mainly to control ventricular rate in atrial flutter and fibrillation. Moreover, it is used for ventricular tachycardia, non-compensatory sinus tachycardia, as well as perioperative hypertension.

5. *Contraindication/Side effects*

Contraindications to esmolol use include hypersensitivity to esmolol and other beta-blocker, sinus bradycardia, heart block, uncompensated congestive heart failure, and cardiogenic shock. Use esmolol only with caution in patients with hyperreactive airway disease, renal failure (reduced elimination of active metabolite), diabetes mellitus, hypoglycemia, or hypotension. Extravasation can cause skin necrosis and should be avoided. Abrupt discontinuation may cause withdrawal effects of tachycardia and hypertension. In patients with Raynaud's phenomena, monitor for worsening arterial insufficiency. Esmolol can blunt the response to hypoglycemia in diabetic patients.

The most common adverse effects are hypotension, headache, nausea, and injection site pain. Less frequent but more serious complications include myocardial depression, bradyarrhythmia, and bronchoconstriction.

Symptoms of esmolol intoxication include hypotension, bradycardia, heart block, congestive heart failure, and bronchospasm. Treatment is with sympathomimetics and judicious fluid administration.

6. *Doses*

Esmolol therapy is initiated in infants and children with an I.V. loading dose of 100–500 mcg/kg administered over 1 min, followed by a continuous infusion of 50–250 mcg/kg/min. The dose can be titrated in 50–100 mcg/kg/min increments every 5–10 min, with a maximum infusion rate of 1,000 mcg/kg/min.

In adults, an I.V. loading dose of 500 mcg/kg is administered over 1 min, followed by a 50 mcg/kg/min continuous infusion for 4 min. If needed, caregivers may re-bolus and increase the continuous infusion by 50 mcg/kg/min to 100 mcg/kg/min. These steps may be repeated until the desired therapeutic effect is achieved or a maximum maintenance dose of 200 mcg/kg/min is reached.

Propranolol

1. *General Aspects/Comments, Classifications, Definitions, and General Uses*

Propranolol is a nonselective beta-adrenergic blocker with no intrinsic sympathomimetic properties [37].

2. *Mechanism of Action*

Propranolol is a beta-blocker with equal effects on beta-1 and beta-2 adrenergic receptors [30].

3. *Pharmacokinetics/Pharmacodynamics*

After oral administration, effects occur within 1–2 h and last for 6–8 h, whereas after I.V. administration, the effects start in 2 min and last for 3–6 h. Propranolol is almost fully absorbed from the gastrointestinal tract. However, due to a significant first-pass effect, systemic bioavailability is only about 30 %. It is metabolized in the liver, and the metabolites are eliminated in the urine. Its half-life for children and adults is about 4–6 h; however, for neonates and infants, it can be increased.

4. *Clinical Indication/Uses*

Propranolol is indicated for treatment of atrial fibrillation/flutter, AV reentrant tachycardia,

catecholamine-induced tachycardia, cyanotic spells in tetralogy of Fallot, as well as hypertrophic subaortic stenosis. It is used also for therapy of hypertension, angina pectoris, migraine headache, and prevention of myocardial infarction.

5. *Contraindications/Side Effects*

Contraindications to propranolol use include hypersensitivity to propranolol, sinus bradycardia, heart block, sick sinus syndrome, uncompensated congestive heart failure, cardiogenic shock, and asthma. Propranolol must be used with caution in patients with hyper-reactive airway disease, renal or hepatic disease, diabetes mellitus (may block signs of hypoglycemia such as tachycardia and blood pressure changes), or hypoglycemia. Therapy should not be discontinued abruptly to avoid acute tachycardia and hypertension. In patients with Raynaud's phenomena, it is important to monitor for worsening arterial insufficiency.

The most common adverse effects are hypotension, headache, and nausea. Less frequent but more serious complications include myocardial depression, bradyarrhythmia, congestive heart failure, agranulocytosis, and bronchoconstriction.

Intoxication symptoms include hypotension, bradycardia, heart block, congestive heart failure, and bronchospasm. Treatment consists of sympathomimetics and fluid administration.

6. *Doses*

Oral and I.V. doses of propranolol are significantly different and must be chosen carefully.

For neonates, the initial I.V. dose should be 0.01 mg/kg slow I.V. push over 10 min, and it may be repeated every 6–8 h as needed. The dose may be increased slowly to maximum of 0.15 mg/kg/dose every 6–8 h. For infants and children, the I.V. dose is 0.01–0.1 mg/kg given slow I.V. push over 10 min, with a maximum dose of 1 mg in infants and 3 mg in children.

Oral dosing in neonates should be initiated at 0.25 mg/kg/dose every 6–8 h. It can be gradually increased to a maximum of 5 mg/kg/day. In children, 0.5–1 mg/kg/day in divided doses every 6–8 h is given initially, with titration over 3–5 days to a usual effective dose of 2–4 mg/kg/day. Do not exceed 16 mg/kg/day or 240 mg/day.

Adult I.V. dosing is 1 mg/dose given slow I.V. push and repeated every 5 min up to 5 mg total. Oral therapy is initiated at 10–20 mg/dose every 6–8 h and increased gradually to a range of 40–320 mg/day.

Atenolol

1. *General Aspects/Comments, Classifications, Definitions, and General Uses*

Atenolol is indicated for the treatment of supraventricular and ventricular tachyarrhythmias, as well as systemic hypertension [3, 38].

2. *Mechanism of Action*

Atenolol is a cardioselective beta-blocker with predominant effects on beta-1 receptors and minimal effects on beta-2 receptors with high doses. Atenolol does not have any intrinsic sympathomimetic properties.

3. *Pharmacokinetics/Pharmacodynamics*

After oral administration, atenolol effects occur in less than 1 h, reaching its maximum effects between 2 and 4 h. The duration of beta-blocking and antihypertensive effects lasts for approximately 24 h. Atenolol is incompletely absorbed from the GI tract and has little hepatic transformation without formation of active metabolites. It does not cross the blood-brain barrier. Half-life is different for age: in neonates, 16–35 h; in children, 5–16 years, mean 4.6 h with a range of 3.5–7 h; and in adults, 6–7 h. Atenolol is eliminated in urine and feces. Thus, a prolonged half-life can be seen in renal impairment [39, 40].

4. *Clinical Indication/Uses*

Atenolol is indicated for treatment of various types of supraventricular tachyarrhythmias (atrioventricular reciprocating tachycardia, atrioventricular nodal reentrant tachycardia, junctional ectopic tachycardia, atrial flutter) [39]. Furthermore, it is used for ventricular tachycardias, for hypertension, and in adults, for management of angina pectoris and post-myocardial infarction.

5. *Contraindication/Side Effects*

Contraindications to atenolol use include hypersensitivity to atenolol, sinus bradycardia, heart block, uncompensated congestive heart failure, cardiogenic shock, and pulmonary edema. Use with

caution in patients with renal dysfunction (modify dose) and reactive airway disease. Administer cautiously in diabetes mellitus (may block signs of hypoglycemia such as tachycardia and blood pressure changes), hypoglycemia, and congestive heart failure. Atenolol has additive effects when used with other antihypertensive agents, and it may reduce the effects of theophylline. Discontinuation should be progressive to avoid withdrawal. In patients with Raynaud's phenomena, it is important to monitor for worsening arterial insufficiency.

The most common adverse effects are hypotension, bradycardia, dizziness, depression, and fatigue. Less frequent but more serious complications include myocardial depression, congestive heart failure, pulmonary embolism, and thyrotoxicosis.

Side effects can also be dermatologic and appear as a psoriasiform rash or psoriasis exacerbation.

With atenolol intoxication, cardiac symptoms include bradycardia, cardiogenic shock, asystole, and hypotension. CNS effects of toxicity include convulsion, coma, and respiratory arrest. Treatment is symptomatic. One may consider atropine, isoproterenol, or glucagon [40].

6. *Doses*

In infants and children, initial oral dosing is 0.8–1 mg/kg/dose given once daily, with a maximum dose of 2 mg/kg/day, not to exceed the adult maximum dose of 100 mg/day. In adults, the initial oral dose is 25–50 mg/dose administered daily, with a usual dose of 50–100 mg/dose administered daily. The maximum dose is 100 mg/day. In renal impairment, the dose should be adjusted. If the ClCr is 15–35 mL/min, use a maximum dose of 50 mg or 1 mg/kg/dose daily. If the ClCr is less than 15 mL/min, use a maximum dose of 50 mg or a 1 mg/kg/dose every other day [2].

Metoprolol

1. *General Aspects/Comments, Classifications, Definitions, and General Uses*

Metoprolol is indicated for the treatment of atrial and ventricular tachyarrhythmias, as well as hypertension and chronic heart failure [40].

2. *Mechanism of Action*

Metoprolol is a second-generation, beta-1 selective blocker with negative inotropic and negative chronotropic effects and slows the AV node conduction velocity. Metoprolol has no intrinsic sympathomimetic activity.

3. *Pharmacokinetics/Pharmacodynamics*

Orally, metoprolol is almost completely absorbed in the gastrointestinal tract. Because of a significant first-pass metabolism in the liver, the bioavailability of metoprolol is just around 50–70 %. Its half-life is 5–10 h in neonates and 3–7 h in adults [3]. Metoprolol is metabolized in the liver to inactive metabolites that are eliminated in the urine.

4. *Clinical Indication/Uses*

Metoprolol is indicated for treatment of atrial and ventricular arrhythmias. Furthermore, it is used for therapy of hypertension and chronic heart failure, as it improves the ventricular function [41]. In adults, metoprolol administration demonstrated an improved outcome in acute myocardial infarction and as a post-myocardial infarct prophylaxis.

5. *Contraindications/Side Effects*

Contraindications to metoprolol use include hypersensitivity to metoprolol, sinus bradycardia, second-/third-degree AV block (without pacemaker), cardiogenic shock, and uncompensated congestive heart failure. Use with caution in patients with renal dysfunction (modify dose) and reactive airway disease. Administer cautiously in diabetes mellitus (may block signs of hypoglycemia such as tachycardia and blood pressure changes), hypoglycemia, and congestive heart failure. Metoprolol should not be withdrawn abruptly because of rebound tachycardia, hypertension, and ischemia. Expect additive hypotensive effects with reserpine, monoamine oxidase inhibitors, other antihypertensive agents, inhibitors of cytochrome P450 inhibitor, and anesthetics. Nonsteroidal anti-inflammatory drugs may decrease the antihypertensive effects of metoprolol. In patients with Raynaud's phenomena, it is recommended to monitor for worsening arterial insufficiency.

The most common adverse effects are hypotension, bradycardia, dizziness, depression, and

fatigue. Less frequent but more serious complications include myocardial depression, congestive heart failure, pulmonary embolism, and thyrotoxicosis.

Intoxication with metoprolol produces typical cardiac symptoms of excess beta blockade including hypotension, bradycardia, cardiogenic shock, and asystole. Effects on the central nervous systems include convulsions, coma, and respiratory arrest. Treatment of bradycardia may be attempted with atropine, isoproterenol, or glucagon [24, 42].

6. *Doses*

Antihypertensive dosing for children and adolescents 1–17 years old is 1–2 mg/kg/day in two divided doses initially. If necessary, it can be increased to 6 mg/kg/day or no more than 200 mg per day.

In the treatment of adults, an I.V. dose of 1.25–5 mg every 6–12 h can be given to achieve ventricular rate control, with titration of the dose to response. The maximum dose is 15 mg given every 3–6 h. Oral dosing begins at 100 mg/day in one to two doses a day. The dose may be increased at weekly intervals to a usual dosage of 100–450 mg/day [3].

Nadolol

1. *General Aspects/Comments, Classifications, Definitions, and General Uses*

Nadolol is used for treatment of supraventricular and ventricular tachyarrhythmias and hypertension [3].

2. *Mechanism of Action*

Nadolol is a nonselective, long-acting beta-receptor-blocking agent. Nadolol does not have any intrinsic sympathomimetic activities or membrane-stabilizing properties [43].

3. *Pharmacokinetics/Pharmacodynamics*

Nadolol is poorly absorbed (30–40 % in adults) without any hepatic first-pass effect. Because of its low lipid solubility, it rarely causes central nervous system side effects. Its maximum plasma levels occur 3–4 h after administration. Nadolol half-life is age dependent: in infants (3–22 months) 3.2–4.3 h, in children 7.3–15.7 h, and in adults 10–24 h. The half-life of nadolol is increased in renal impairment, and it is moderately dialyzable [24, 43].

4. *Clinical Indication/Uses*

Nadolol is indicated for treatment of various atrial and ventricular tachyarrhythmias. Furthermore, it is used for hypertension and in adults for management of angina pectoris as well as prophylaxis for migraine [44].

5. *Contraindications/Side Effects*

Contraindications to nadolol use include hypersensitivity to nadolol, sinus bradycardia, second-/third-degree AV block (without pacemaker), cardiogenic shock, and uncompensated congestive heart failure. Use with caution in patients with renal dysfunction (modify dose) and reactive airway disease. Administer cautiously in diabetes mellitus (may block signs of hypoglycemia such as tachycardia and blood pressure changes), hypoglycemia, and congestive heart failure. Nadolol should not be withdrawn abruptly because of rebound tachycardia, hypertension, and ischemia. Increased antihypertensive effects may be seen with concurrent use of diuretics and phenothiazines. Nadolol may increase the effects of neuromuscular blocking agents.

The most common adverse effects are hypotension, bradycardia, drowsiness, depression, and fatigue. Less frequent but more serious complications include myocardial depression and congestive heart failure.

Nadolol intoxication may produce cardiac symptoms including bradycardia, AV block, cardiogenic shock, asystole, and hypotension. Associated CNS effects are convulsion, coma, and respiratory arrest. Symptomatic treatment with atropine, isoproterenol, or pacing for bradycardia and hypotension may be tried [24, 44].

6. *Doses*

Limited information is available for dosing in pediatric patients. Initial oral dose for infants and children is 0.5–1 mg/kg/dose given once daily. The dose can be gradually increased to a maximum of 2.5 mg/kg/day.

In adults, the initial oral dose is 40 mg once daily, with gradual increases of 40–80 mg/day up to 240–320 mg/day if needed.

Dosage adjustment is required in renal impairment. If the ClCr is 10–50 mL/min, administer 50 % of the normal dose, and if the ClCr is less than 10 mL/min, administer 25 % of the normal dose [3].

Class III Agents

Amiodarone

1. *General Aspects/Comments, Classifications, Definitions, and General Uses*

Amiodarone is a class III antiarrhythmic agent, and it is used to treat life-threatening and difficult to treat ventricular and atrial tachyarrhythmias, as well as junctional ectopic tachycardia [45].

2. *Mechanism of Action*

Amiodarone is a benzofuran derivative, and it has blocking effects on potassium channels, leading to prolonged action potential and myocardial repolarization. Furthermore, it blocks potassium channels in the SA node, atria, and ventricles and accordingly prolongs the refractory period with increasing heart rates. Additionally, amiodarone has class I properties resulting in decreased AV conduction, class II effects producing noncompetitive beta blockade, as well as class IV effects caused by decreased calcium influx [24, 46].

3. *Pharmacokinetics/Pharmacodynamics*

Orally, amiodarone is slowly and incompletely absorbed. The oral bioavailability is between 35 % and 65 % with an average of about 50 %. The onset of action occurs approximately 2–3 days to 1–3 weeks with oral therapy. In contrast, electrophysiologic effects start within minutes after intravenous administration, whereas antiarrhythmic effects begin within 2–3 days to 1–3 weeks. Amiodarone is 96 % protein bound. It is metabolized in the liver by the CYP3A4 and CYP2C8 enzymes and produces the active metabolite desethylamiodarone. Amiodarone has a very extended half-life. In adults with chronic oral administration, the mean is 40–55 days, and with intravenous therapy, between 9 and 36 days. Desethylamiodarone has an average half-life of 61 days. The half-life of amiodarone in children is shorter. The duration of effects after discontinuation varies between 2 weeks and months. Amiodarone is eliminated primarily via bile with less than 1 % via urine. It is not dialyzable [3, 46].

4. *Clinical Indication/Uses*

Amiodarone is used to treat a variety of ventricular and atrial tachyarrhythmias (cardiac arrest, hemodynamically stable VT, secondary prevention of sudden cardiac death, atrial fibrillation, atrial flutter, AV junctional tachycardia, multifocal atrial tachycardia), although it is only approved by the FDA for patients with hemodynamically unstable ventricular tachycardia or recurrent ventricular tachycardia and poor response to other less toxic antiarrhythmic drugs. Additionally, amiodarone is used for treatment of postoperative junctional ectopic tachycardia [47, 48].

5. *Contraindications/Side Effects*

Contraindications to amiodarone use include hypersensitivity to amiodarone, severe sinus node dysfunction, second- or third-degree AV block (without pacemaker), or cardiogenic shock.

Because of its severe and frequent adverse effects (approximately 75 %), patients should be hospitalized for first and loading dose administration. Both pulmonary and hepatic toxicities have been reported and can be fatal. New or worsening arrhythmias may develop including torsades de pointes – correct hypokalemia and hypomagnesemia before initiating therapy. Monitor for QTc prolongation, especially if other QTc-prolonging drugs are being used. Hypotension (refractory), AV block, and MI have occurred with I.V. administration. Optic neuropathy/neuritis can cause visual impairment and may lead to blindness. Amiodarone contains 37 % iodine and may cause hypothyroidism or hyperthyroidism. Caution should be used with intravenous administration in neonates, as it may contain benzyl alcohol, which is associated with potentially fatal "gasping" syndrome. Exercise caution with concomitant use of digoxin (decrease digoxin dose 50 %), cyclosporine, warfarin (decrease warfarin dose 30–50 %), theophylline, procainamide, flecainide (decrease flecainide dose 30 %), lidocaine, quinidine,

methotrexate, and phenytoin because of increased plasma concentrations. Drug interactions may occur when used in combination with class I antiarrhythmics (ventricular arrhythmia), class II beta-blockers, digoxin, and calcium channel blocker (bradycardia, heart block, sinus arrest), and lovastatin or simvastatin (rhabdomyolysis, myopathy). St. John's wort can decrease amiodarone level.

The most common side effects are gastrointestinal (nausea, vomiting, constipation), elevated liver enzymes, hyper-/hypothyroidism, photosensitivity, skin discoloration (face), and ocular (corneal microdeposits, poor night vision, halos).

More serious side effects include pulmonary fibrosis, interstitial lung disease, acute respiratory distress syndrome, pneumonitis, ventricular arrhythmias, torsades de pointes, and congestive heart failure.

Intoxication with amiodarone produces mainly cardiac symptoms, including bradycardia (sometimes atropine resistant), heart block, hypotension, and QTc prolongation. Serial ECG monitoring is essential [49].

6. *Doses*

For infants and children, an I.V. loading dose of 5 mg/kg can be administered as a rapid bolus for pulseless VT/ventricular fibrillation (VF) or over 20–60 min for perfusing tachycardias. The dose may be repeated for a total load of 20 mg/kg in 5 mg/kg increments. A maintenance infusion may be started at 5 mcg/kg/min and may be increased to as high as 15 mcg/kg/min if needed.

Oral therapy is begun with a loading dose of 10–15 mg/kg/day or 600–800 mg/1.73 m^2/day in two divided doses for 4–14 days. The dosage is then decreased to 5 mg/kg/day or 200–400 mg/1.73 m^2/day for several weeks. For children younger than 1 year, use body surface area to calculate the dose. Keep decreasing the dose to the lowest effective dosage possible, usually 1–2.5 mg/kg/day.

Adult I.V. dosing for pulseless VT/VF is 300 mg diluted in 20–30 mL of 5 % dextrose in water (D5W) or NS administered rapid I.V. push. Supplemental bolus doses of 150 mg by rapid I.V. infusion for recurrent pulseless VT/VF may be used up to a maximum total dose of 2.2 g/24 h [3, 13]. In patients with perfusing tachycardias, the loading dose is 1,000 mg given over 24 h as follows: 150 mg administered over 10 min (15 mg/min), followed by 360 mg over 6 h (at a rate of 1 mg/min), and followed with a maintenance dose of 540 mg over 18 h (0.5 mg/min). After the first 24 h, the maintenance dose is continued at 0.5 mg/min. Additional supplemental boluses of 150 mg over 10–20 min may be administered for breakthrough arrhythmia, with a maximum daily dose of 2 g.

Oral therapy in adults is begun with a loading dose of 800–1,600 mg/day in one to two doses for 1–3 weeks, then reduced 600–800 mg/day in one to two doses for 1 month, and gradually lowered to 100–200 mg/day for atrial arrhythmias or 400 mg/day for ventricular arrhythmias.

Sotalol

1. *General Aspects/Comments, Classifications, Definitions, and General Uses*

Sotalol is a class III antiarrhythmic agent, but it has also class II effects. It is indicated for treatment of ventricular and atrial tachyarrhythmias [50].

2. *Mechanism of Action*

Sotalol has both class II antiarrhythmic and class III antiarrhythmic properties.

Class II antiarrhythmic effect of sotalol is a nonselective beta-adrenergic blockade, resulting in decreased heart rate, AV node conduction, and increased AV nodal refractoriness. The beta blockade is mainly seen with lower doses (children: $\geq$90 mg/m^2/day; adults: $\geq$25 mg/day). The class III effects of sotalol consist in prolonging atrial and ventricular monophasic action potential, increasing the refractory period of atrial and ventricular muscle, and prolonging AV accessory pathways (antegrade and retrograde). Those effects are more prominent with higher doses (children: 210 mg/m^2/day; adults: $\geq$160 mg/day) [24].

3. *Pharmacokinetics/Pharmacodynamics*

Sotalol is rapidly absorbed following oral administration, and its bioavailability is between 90 % and 100 %. The onset of action occurs within 1–2 h after administration with

a duration of 8–16 h. Its half-life is dependent on age: in neonates 8.4 h, in infants/children under 2 years old 7.4 h, in children 2–7 years old 9.1 h, in children between 7 and 12 years 9.2 h, and in adults 12 h. Sotalol is not metabolized but is excreted without any changes via the urine, and it can be partially eliminated with dialysis [24, 51].

4. *Clinical Indication/Uses*

As a class III antiarrhythmic agent with beta-blocking properties, sotalol is used for treatment of ventricular (sustained ventricular tachyarrhythmia) and atrial tachyarrhythmias (atrial flutter, symptomatic atrial fibrillation, supraventricular reentrant tachycardia) [52, 53].

5. *Contraindications/Side Effects*

Contraindications to sotalol use include hypersensitivity to sotalol, sinus bradycardia, second- or third-degree AV block (without pacemaker), cardiogenic shock, baseline QTc interval >450 ms, asthma, impaired renal function (<40 mL/min), and hypokalemia (<4 mEq/L).

Because of the possibility of life-threatening arrhythmias, initiation of sotalol requires a minimum of 3 days in a hospital setting and continuous ECG monitoring. Correct hypokalemia and hypomagnesemia before initiating therapy. Sotalol therapy may cause or worsen heart failure and should be used with caution in renal impairment and diabetes mellitus. Concomitant use of beta-blocker or calcium channel blocker may have additive effects on AV conduction and with drugs that prolong QT interval may increase cardiovascular effects. Class I or III antiarrhythmics should be discontinued for at least three half-lives before starting sotalol. Avoid abrupt discontinuation or use in bronchospastic disease.

The most common side effects are typical of beta-blockers (bradyarrhythmia, negative inotropy, asthma) but also include rash, nausea, dizziness, headache, fatigue, and dyspnea. More serious adverse effects include arrhythmias (torsades de pointes, ventricular) and heart failure.

Cardiac symptoms of intoxication include bradycardia, arrhythmia, and hypotension. CNS symptoms are convulsions, coma, and respiratory arrest. Other common symptoms include hypoglycemia and hyperkalemia. Treatment is symptomatic [52].

6. *Doses*

Dosing should be initiated and adjusted in the hospital secondary to possible proarrhythmia. Impaired renal function can increase half-life, and sotalol dosage should be reduced.

In children older than 2 years old, begin oral dosing at 90 mg/m^2/day in three divided doses. The dose may be incrementally increased every 36–72 h to 180 mg/m^2/day divided in three doses.

In children younger than 2 years, the dose should be reduced by an age-related factor. More gradual dose adjustments in younger patients are necessary [3].

Adults begin oral sotalol with 80 mg twice a day. The dose should be increased gradually to 240–320 mg/day if needed, allowing 3 days between dosing increments. The usual maintenance dosage range is 160–320 mg/day.

Class IV Agents: Calcium Channel Blockers

Diltiazem

1. *General Aspects/Comments, Classifications, Definitions, and General Uses*

Diltiazem is a slow inward calcium channel blocker used mainly for AV node conduction modulation for treatment of supraventricular arrhythmias [54].

2. *Mechanism of Action*

Diltiazem is a calcium channel blocker (voltage-operated and receptor-operated calcium channel). It inhibits the calcium influx into smooth muscle and myocardium as well as the SA and AV nodes. It has negative chronotropic and dromotropic properties. Because it decreases peripheral vascular resistance, it is a potent vasodilator [4], especially of the coronary vasculature.

3. *Pharmacokinetics/Pharmacodynamics*

The oral bioavailability of diltiazem is very good with almost complete absorption of a dose. The onset of action is dependent on the administration route: after I.V. administration, the effects occur within 2–5 min, whereas for extended-release capsule is 2–3 h and for immediate-release tablet is 30–60 min. The duration of action is

approximately 1–3 h for I.V. administration, 12 h for extended-release capsules, and 4–8 h for tablets. Diltiazem is metabolized in the liver with an extensive first-pass effect. Its half-life is 3–4.5 h, and it is eliminated in urine and bile, predominantly as metabolites [24].

4. *Clinical Indication/Uses*

Diltiazem is indicated for treatment of atrial fibrillation or flutter and paroxysmal supraventricular tachycardias. It is used orally for management of hypertension and angina pectoris.

5. *Contraindications/Side Effects*

Contraindications include hypersensitivity to diltiazem, second- or third-degree heart block, sick sinus syndrome, severe hypotension, acute myocardial infarction with pulmonary congestion, cardiogenic shock, and I.V. administration within a few hours of I.V. beta-blocker administration.

Use with caution in patients with renal/hepatic disease or congestive heart failure. Diltiazem may cause bradycardia, 2nd- or 3rd-degree heart block, hypotension, or hepatic injury. Use in combination with beta-blockers or digoxin may cause conduction abnormalities.

The most common side effects include hypotension, bradycardia, AV block (especially in concomitant use with beta-blockers), dizziness, headache, weakness, dermatitis, peripheral edema, and cough.

More serious adverse effects include arrhythmia, CHF, and hepatotoxicity.

Intoxication with diltiazem is characterized by hypotension, bradycardia, heart block, confusion, nausea, vomiting, hyperglycemia, and metabolic acidosis. Treatment with calcium may increase cardiac contractility, and glucagon and epinephrine may be tried to increase blood pressure and heart rate.

6. *Doses*

In infants and children, an I.V. bolus of 0.15–0.45 mg/kg has been given slowly over 5 min, followed by a continuous infusion of 2 mcg/kg/min (0.125 mg/kg/h). Oral dosing begins with 1.5–2 mg/kg/day divided into three to four doses and may be increased to a maximum of 3.5 mg/kg/day.

In adults, an initial I.V. bolus of 0.25 mg/kg is administered over 2 min (average dose 20 mg), and a repeat bolus of 0.35 mg/kg after 15 min (average dose 25 mg) may be given if needed. Then initiate a continuous infusion of 10 mg/h and increase by 5 mg/h if necessary to 15 mg/h. It is recommended to administer the infusion for less than 24 h at a rate not greater than 15 mg/h. Start oral dosing 3 h after a bolus dose. The oral dose (mg/day) is equal to [(I.V. rate in mg/h $\times$ 3) + 3] $\times$ 10, and the range for dosing for atrial fibrillation or flutter is 120–360 mg/day [3]. Careful attention to the availability of both extended- and immediate-release dosage forms is necessary to prescribe the correct dosage interval.

Verapamil

1. *General Aspects/Comments, Classifications, Definitions, and General Uses*

Verapamil depresses automaticity, slows conduction, and increases refractoriness in both the SA and AV nodes, being particularly useful in the control of supraventricular tachyarrhythmias that utilize the AV node as part of the reentrant circuit [1]. It is generally not recommended in pediatric patients, especially infants and those with myocardial dysfunction due to its negative inotropic effects.

2. *Mechanism of Action*

Verapamil is a calcium channel blocker that slows phase 4 of depolarization in the SA and AV node, with slowing of conduction velocity. It exerts no significant effect on atrial, ventricular, or His-Purkinje refractory periods or conduction velocity; therefore, verapamil is unlikely to be a potent antiarrhythmic agent in most types of ventricular tachyarrhythmias. As with diltiazem, it has negative chronotropic and dromotropic properties; however, it is believed that diltiazem may exert somewhat less negative inotropic action [21]. Verapamil is also a potent vasodilator, being used in the treatment of hypertension and angina pectoris [4].

3. *Pharmacokinetics/Pharmacodynamics*

Verapamil can be administrated orally or intravenously, as a bolus. When verapamil is

administered intravenously, the peak effects on the AV node occur in 1–5 min, and the effects last for 10–20 min. After oral administration of the immediate-release formulation, the onset of action is at 1–2 h, with peak effects occurring at 6–8 h. More than 90 % is absorbed, but first-pass hepatic metabolism reduces bioavailability to 20–35 %. Approximately 90 % of the drug is protein bound. Further hepatic metabolism results in an elimination half-life of 3–7 h, with the metabolites eliminated in urine and stools. Verapamil is also available in long-acting forms that can be given once a day [24].

4. *Clinical Indication/Uses*

Verapamil can be very useful in the management of supraventricular tachyarrhythmias for acute termination of paroxistic supraventricular tachycardia. By intravenous bolus, it terminates reentrant arrhythmias in 90 % of the cases, and it is also effective in prevention of its recurrences and modulation of fast ventricular rates in atrial flutter and fibrillation. Although verapamil is not efficacious in treating typical reentrant ventricular tachyarrhythmia, it has been effective in treating repetitive monomorphic ventricular tachycardia (which seems to be due to a channelopathy) and idiopathic left ventricular tachycardia (which may be a form of reentrant tachycardia involving abnormal, verapamil-sensitive Purkinje fibers).

Orally, it is used for management of hypertension and angina pectoris [1].

5. *Contraindications/Side Effects*

Contraindications include hypersensitivity to verapamil, severe left ventricular dysfunction, second- or third-degree AV block, sick sinus syndrome, severe hypotension, severe congestive heart failure, atrial flutter, or fibrillation associated with an accessory bypass tract. Additional contraindications for I.V. administration include concurrent use of I.V. beta-blockers.

Its use must be avoided in neonates and infants due to severe apnea, bradycardia, hypotensive reactions, myocardial depression, and cardiac arrest. ECG and blood pressure should be monitored closely while receiving I.V. infusion. I.V. calcium chloride should be available at bedside.

Caution is also necessary when verapamil is used together with other drugs that reduce SA and AV nodal conduction, as digoxin [24].

Besides significant hypotension, other side effects include constipation, dizziness, nausea, headache, edema, and bradyarrhythmias [1].

6. *Doses*

In infants, an I.V. bolus of 0.1–0.2 mg/kg/dose and, in children, an I.V. bolus of 0.1–0.3 mg/kg/dose with a maximum dose of 5 mg may be given and repeated in 30 min if adequate response is not achieved. Oral dosing is not well established but may begin with 4–8 mg/kg/day divided into three doses.

In adults, initial I.V. bolus of 5–10 mg is administered over 2 min, and a repeat bolus of 10 mg after 30 min may be given if needed. The oral dose is 80–120 mg, 3 or 4 times/day of the immediate-release tablets.

Cautious use and close monitoring is recommended in case of renal or hepatic impairment [24].

Miscellaneous

Adenosine

1. *General Aspects/Comments, Classifications, Definitions, and General Uses*

Adenosine is an endogenous purinergic agent used to terminate paroxysmal supraventricular tachycardias, in particular those in which the atrioventricular (AV) node is involved as part of a reentrant circuit [22, 55].

2. *Mechanism of Action*

Adenosine stimulates adenosine receptors (G-protein bound), and accordingly, it activates potassium channels in sinus and AV nodes, thus inhibiting the calcium influx into the cells. These two mechanisms lead to a hyperpolarization of atrial myocardium, increased conduction time through the AV node, and an interruption of reentry pathways [56]. It has no effect on amplitude or action potential in ventricular myocytes.

3. *Pharmacokinetics/Pharmacodynamics*

Adenosine is rapidly metabolized in the vessels by adenosine kinase and adenosine deaminase

located in erythrocytes and vascular endothelial cells. The half-life of adenosine is extremely short at <10 s [57].

4. *Clinical Indication/Uses*

Adenosine is used for paroxysmal supraventricular tachycardia, especially those in which the AV node is a part of the reentrant circuit [58]. Moreover, adenosine is a useful diagnostic tool for unmasking primary atrial tachycardias by inducing transient AV block. Adenosine has vasodilating properties and has been used as an adjunct for treatment of persistent pulmonary hypertension of the neonate [59].

5. *Contraindication/Side Effects*

Contraindications to adenosine use include hypersensitivity to adenosine, AV block (second/third degree), and sick sinus syndrome without a functioning pacemaker.

Avoid use of adenosine in patients with asthma and obstructive lung disease, as bronchospasm and bronchoconstriction may occur. Heart block or prolonged asystole has been reported with use. Use cautiously in patients with sinus or AV node dysfunction and patients receiving digoxin or verapamil. A dose reduction in concomitant dipyridamole use because of increasing effects of adenosine is recommended [55].

The most common side effects are dyspnea, flushing, chest pressure, dizziness, premature ventricular contraction, AV block, abdominal discomfort, head and neck pain, and headache. More serious adverse effects appear as atrial fibrillation (especially in WPW syndrome), sinus arrest, ventricular arrhythmias, and bronchospasm in asthmatics.

6. *Doses*

For all ages, adenosine must be given by rapid I.V. push, followed by a rapid saline flush. In infants and children, the initial dose is 0.05–0.1 mg/kg. If not effective in 1–2 min, increase dose by 0.1 mg/kg increments to a maximum dose of 0.3 mg/kg. In adults, the initial dose is 6 mg and, if not effective, may be doubled to 12 mg.

Atropine

1. *General Aspects/Comments, Classifications, Definitions, and General Uses*

Atropine is an anticholinergic and antispasmodic agent [60] that is used to treat bradycardia or asystole.

2. *Mechanism of Action*

Atropine is a parasympathetic antagonist, blocking the effects of acetylcholine in smooth muscles, secretory glands, as well as in the central nervous system. Furthermore, it antagonizes histamine and serotonin. Consequently, heart rate and cardiac output increase and glandular secretion are reduced.

3. *Pharmacokinetics/Pharmacodynamics*

Atropine is well absorbed and metabolized in the liver. Its half-life is in children younger than 2 years is 7 h, children >3 years 2.5 h, and in adults 3 h [24]. There is urinary elimination of the drug and its metabolites.

4. *Clinical Indication/Uses*

Atropine is indicated for bradycardia and asystole. Furthermore, it is used preoperatively to inhibit salivation and secretion as well as to neutralize the muscarinic effects of cholinergic agents.

5. *Contraindications/Side Effects*

Contraindications to atropine use include hypersensitivity to atropine, narrow-angle glaucoma, pyloric stenosis, and prostatic hypertrophy. Use atropine with caution in patients with spastic paralysis and brain damage, hyperthyroidism, heart failure, tachyarrhythmia, hypertension, and children with Down syndrome (increased sensitivity to cardiac effects and mydriasis).

The most common side effects are dry mouth, blurred vision, constipation, cardiac conduction abnormalities, fever, and urinary retention. More serious adverse effects include arrhythmia and glaucoma.

Intoxication with atropine presents with the usual anticholinergic symptoms of dry, hot skin, dry mucous membranes, decreased GI movement, urinary retention, tachycardia, hyperthermia, hypertension, and dilated and unreactive pupils. Treatment is with physostigmine (0.02 mg/kg; adults 1–2 mg) subcutaneous or slow I.V.

6. *Doses*

For infants, children, or adolescents with bradycardia, atropine may be given in a dose of

0.02 mg/kg either I.V. or I.O., with a minimum dose of 0.1 mg and a maximum single dose of 0.5 mg. The dose may be repeated in 5 min, and the maximum total dose should not exceed 1 mg.

Atropine may be given via endotracheal tube. However, absorption pharmacokinetics is not well established. The recommended dose is 0.04–0.06 mg/kg, and the dose may be repeated once in 5 min if needed. Atropine must be diluted if administered via endotracheal tube; mix with NS to a total volume of 1–5 mL [61].

Adults with bradycardia are administered 0.5 mg per dose I.V., which may be repeated in 3–5 min to a total dose of 3 mg or 0.04 mg/kg. For endotracheal tube administration, 2–2.5 times the usual I.V. dose is used diluted in 10 mL of NS [3].

Digoxin

1. *General Aspects/Comments, Classifications, Definitions, and General Uses*

Digoxin is a cardiac glycoside and it is used for treatment of arrhythmia by decreasing the ventricular rate in atrial tachycardias and for supraventricular tachycardia. Furthermore, it is indicated for treatment of congestive heart failure [1].

2. *Mechanism of Action*

Digoxin blocks the Na+ -K+ adenosine triphosphatase pump. Accordingly, intracellular sodium and calcium are increased, and the potassium influx is inhibited. Increased calcium leads to a positive inotropic effect. Further, it inhibits adenosine triphosphatase with a consequently decreased conduction through the SA and AV nodes. Additionally, digoxin has central nervous system effects, resulting in a lower sympathetic tone [62].

3. *Pharmacokinetics/Pharmacodynamics*

Bioavailability of digoxin varies with dosage form (tablets 60–80 %, elixir 70–85 %, capsules 90–100 %). The onset of action/maximum effects occurs after oral administration within 0.5–2 h/2–8 h and after intravenous administration within 5–30 min/1–4 h. Only a small part is metabolized in the liver and gut, and the main amount of digoxin is eliminated unchanged by the kidney. Digoxin is not dialyzable. Its half-life is dependent on age, in preterm neonates 60–170 h, in full-term neonates 35–45 h, in toddlers 18–25 h, and in children 35 h, as well as in adults 38–48 h [24].

4. *Clinical Indication/Uses*

Digoxin is used as combination therapy, usually with a beta-blocker, for long-term treatment of supraventricular tachycardia. It should not be used as monotherapy in atrial flutter/fibrillation in addition to an accessory pathway with potential antegrade conduction due to the risk of increased atrioventricular conduction ratio and potentially fatal ventricular arrhythmias. Digoxin reduces ventricular rate and accordingly, hemodynamics are improved. Moreover, it is used in the therapy of congestive heart failure by increasing the cardiac output that results from the positive inotropic effects [62].

5. *Contraindication/Side Effects*

Contraindications to digoxin use include hypersensitivity to digoxin/digitoxin, ventricular fibrillation, patients with severe subaortic obstruction or hypertrophic cardiomyopathy, hypokalemia, alkalosis, or hypothyroidism.

Use with caution in patients with renal impairment due to reduced clearance. Avoid use in patients with 2nd- or 3rd-degree heart block. Correct electrolyte imbalances prior to starting therapy, especially hypokalemia, hypomagnesemia, or hypercalcemia. Increased effects or concentration of digoxin can occur during concurrent use of other antiarrhythmic agents, diuretics, calcium antagonists, atorvastatin, ketoconazole, itraconazole, cyclosporine, NSAIDs, and macrolide antibiotics. Concentration and effects of digoxin can be decreased with use of rifampin, cholestyramine, and antacids.

The most common side effects are gastrointestinal (nausea, vomiting, diarrhea, cramps), headache, yellow/green vision, and dizziness. More serious adverse effects include sinus bradycardia, sinus arrest, AV block, atrial or nodal ectopic beats, and ventricular tachycardia or fibrillation.

Digoxin has a narrow therapeutic index. Signs of intoxication are nausea, vomiting, diarrhea, visual changes, and arrhythmias. Children usually exhibit cardiac arrhythmias as a sign of toxicity rather than GI or CNS effects. With suspicion of

poisoning, digoxin levels should be monitored (therapeutic range 0.8–2 ng/mL). Digoxin levels above 2 ng/mL are toxic. Additionally to digoxin levels and laboratory (potassium, calcium, magnesium, renal function), patients with suspicion of intoxication should be monitored by ECG. Common ECG changes are supraventricular tachycardia, AV block, premature ventricular contractions, ventricular bigeminy, as well as junctional tachycardia. The treatment of severe digoxin intoxication is digoxin immune Fab (dosage (in mg): [serum digoxin (ng/mL) × kilograms/100] * 40 mg/vial or by calculating total body load in milligrams and divide by 0.5 * 40 mg/vial). Other therapeutic options include ipecac and charcoal after oral ingestion, phenytoin or lidocaine for ventricular tachyarrhythmias, propranolol in ventricular and supraventricular arrhythmia, and atropine or phenytoin in sinus bradycardia and AV block, transvenous pacing, and cardioversion [24].

6. *Doses*

	Total digitalizing dose[a] (mcg/kg)		Daily maintenance dose[b] (mcg/kg)	
Age	P.O.	I.V. or I.M.	P.O.	I.V. or I.M.
Preterm infant	20–30	15–25	5–7.5	4–6
Full-term infant	25–35	20–30	6–10	5–8
1 month–2 year	35–60	30–50	10–15	7.5–12
2–5 year	30–40	25–35	7.5–10	6–9
5–10 year	20–35	15–30	5–10	4–8
>10 year	10–15	8–12	2.5–5	2–3
Adults	0.75–1.5 mg (total dose)	0.5–1 mg (total dose)	0.125–0.5 mg (total dose)	0.1–0.4 mg (total dose)

Recommendations based on lean body weight and normal renal function for age. Decrease dose in patients with decreased renal function
[a]Do not give full total digitalizing dose at once. Give one-half of the total digitalizing dose (TDD) in the initial dose, then give one-quarter of the TDD in each of two subsequent doses at 6- to 12-h intervals Obtain ECG 6 h after each dose to assess potential toxicity
[b]Divided every 12 h in infants and children <10 years of age. Given once daily to children >10 years of age and adults [3, 24]

Magnesium Sulfate

1. *General Aspects/Comments, Classifications, Definitions, and General Uses*

Magnesium sulfate is indicated for treatment of torsades de pointes in congenital or acquired long QT syndrome and ventricular arrhythmias, especially postoperative [63].

2. *Mechanism of Action*

The mechanism of the antiarrhythmic effect of magnesium in ventricular arrhythmia is based on a reduced calcium influx via L-type calcium channels and increased potassium entry into the cells. Accordingly, magnesium increases the negative membrane resting potential resulting in reduced myocardial excitability. Moreover, in supraventricular tachycardia, magnesium increases the relative refractory period and suppresses early afterdepolarization, which reduces risk for reentry tachycardia [64, 65].

3. *Pharmacokinetics/Pharmacodynamics*

Intravenous magnesium sulfate has an instant onset of action and duration of action of approximately 30 min [3]. Elimination is by renal excretion.

4. *Clinical Indication/Uses*

The main clinical use of magnesium sulfate in cardiac arrhythmia is treatment of torsades de pointes tachycardia in acquired or congenital long QT syndrome. Further, it is used for treatment and prevention of ventricular arrhythmia. Especially, in the perioperative period of cardiac surgery, supplementation of magnesium sulfate seems to have positive preventive effects on junctional ectopic tachycardia [3, 63, 65].

5. *Contraindications/Side Effects*

Contraindications to use include hypersensitivity to magnesium salts, heart block, myocardial damage, serious renal impairment, patients with colostomy or ileostomy, intestinal obstruction, impaction or perforation, and appendicitis.

Use with caution in patients with renal dysfunction and concomitant digoxin therapy. Try to avoid use of magnesium in myasthenia gravis.

The most common side effects are muscle weakness, decreased tendon reflex, diarrhea, and abdominal cramps. With I.V. use flushing, hypotension and vasodilation are common with rapid infusion rates or high doses. More serious adverse effects include complete heart block, asystole, and respiratory depression.

Intoxication symptoms are dependent on serum magnesium levels. Serum levels over 3 mg/dL can lead to blocked peripheral

neuromuscular transmission and depressed CNS. Serum levels over 5 mg/dL result in depressed deep tendon reflexes, flushing, and somnolence, and serum levels over 12 mg/dL may be associated with complete heart block and respiratory paralysis. Thus, serum levels of magnesium should be monitored. A therapeutic option for severe hypermagnesemia is intravenous calcium [24].

6. *Doses*

In infants and children, magnesium sulfate can be given I.V. at 25–50 mg/kg per dose, with a maximum of 2 g/dose and a maximum infusion rate of 125 mg/kg/h.

Adults are administered 1–2 g I.V. bolus over 15 min in torsades de pointes, but hypotension can occur with rates faster than 2 g/h.

Catheter-Based Interventions on Right Ventricular Outflow Tract

61

Gianfranco Butera, Alessandra Frigiola, and Philipp Bonhoeffer

Abstract

The dilemma of when to treat patients who have right ventricular outflow tract (RVOT) dysfunction presenting late after repair of various congenital heart diseases, such as those with repaired tetralogy of Fallot, is one that faces all congenital heart disease clinicians. Surgical pulmonary valve replacement lacks longevity as conduit dysfunction usually occurs within 10–15 years and exposes patients to multiple risky operations over their lifetime. The recent availability of a percutaneous approach to treat RVOT dysfunction, therefore, offers an attractive solution, as it permits earlier intervention without the problems associated with surgery and cardiopulmonary bypass. Initial midterm results are promising and the technique has been proven safe and has provided efficacious relief of pressure and/or volume overload. Following percutaneous pulmonary valve implantation (PPVI), there is a significant remodeling of biventricular volumes with improvement in biventricular systolic function. These results are associated with improvement of symptoms and objective exercise capacity. However, PPVI is not free from possible complications. These have been reduced by improving the implantation technique (learning curve) and the valve design (hammock effect). Due to anatomical (size and morphology) and dynamic reasons, with the current device, only 15 % of patients with RVOT dysfunction are eligible for such a treatment, but future valve design and advances in four-dimensional imaging techniques will most likely broaden its applica bility, thus making PPVI an even better alternative to surgery.

Introduction

A great deal of progress in surgical management of complex congenital heart defects has led to a situation in which over 85 % of patients can now reach adulthood [1]. In fact, the prevalence of congenital heart disease in the adult population is currently equal to and will soon be greater than that in the pediatric population [2, 3]. However surgery often cannot offer a permanent cure, and patients may be left with residual hemodynamic lesions, one of the most common of which is right ventricular outflow tract (RVOT) dysfunction in the form of pulmonary stenosis and/or regurgitation. This may occur following initial repair of tetralogy of Fallot (TOF), pulmonary atresia, double outlet right ventricle, pulmonary stenosis, common arterial trunk, arterial switch for transposition of the great arteries, Ross operation for aortic valve disease, and any repair that involves insertion of a right ventricle (RV) to pulmonary artery (PA) conduit. In these cases, the initial surgical repair or repeat surgery for RVOT dysfunction often includes the creation of an artificial RV to PA connection. With time, these conduits may develop valvular incompetence or obstruction [4–6]. Pulmonary stenosis and regurgitation may be associated with exercise intolerance, arrhythmias, and increased risk of sudden death [7–9]. Timely pulmonary valve replacement may halt and even reverse such unfavorable outcomes. However this inevitably exposes the patients to re-interventions each time with an increased procedural risk, hence the efforts to develop alternative nonsurgical strategies to treat RVOT dysfunction. Bare metal stenting (BMS) of stenotic conduits has been performed since 1994, with a significant decrease of RV pressure, but at the expense of free pulmonary regurgitation [10]. In 2000, with the introduction of a percutaneously deliverable valved stent, it became possible to treat conduit dysfunction without creating valvular incompetence. Percutaneous pulmonary valve implantation (PPVI) represents the first-in-man application of these techniques and is a nonsurgical option for treating right ventricular outflow tract/pulmonary trunk dysfunction. With increasing numbers of patients with right ventricle to pulmonary artery conduit dysfunction after repair of congenital heart disease, the importance of a technique with lower morbidity and mortality, good patient acceptance, and efficacy, which is comparable to surgery, cannot be underestimated. Over the last 11 years, more than 2000 patients have been treated in several centers all over the world, and PPVI has become a feasible, safe, and effective treatment for conduit stenosis and regurgitation.

This chapter presents a detailed description of the technical aspects of PPVI, the current clinical indications and midterm results, the limitations, and finally the possible future directions.

History

Melody valve (Medtronic, Minneapolis, MN) is a major advance in the history of congenital cardiology. Transcatheter replacement of the pulmonary valve was first described by Bonhoeffer et al. in 2000 [11]. After initial success with experiments on lambs, Bonhoeffer [11] performed the first-in-man transcatheter bovine jugular valve implantation in a 12-year-old boy with stenotic and regurgitant prosthetic RV-PA conduit. Transcatheter pulmonary valve (Medtronic, Minneapolis, MN) consists of a bovine jugular venous valve and a balloon-expandable Cheatham-Platinum stent (Fig. 61.1). The stent is made of a platinum-iridium wire welded together with gold (Fig. 61.2). The length of the stent is 34 mm, and it can be crimped to a diameter of 6 mm. When expanded, the competence of the tri-leaflet valve is maintained at a large range of diameters, from 12 to 22 mm. For implantation, the valve stent is crimped on a balloon-in-balloon front-loading delivery system (Ensemble; Medtronic) (Fig. 61.3). The body is made of Teflon containing a braided-wire reinforced lumen. The stent is covered by a retractable sheath during delivery and is uncovered prior to implantation by withdrawing the sheath. While there is only one device size, the device system is available with an outer balloon of 18, 20, or

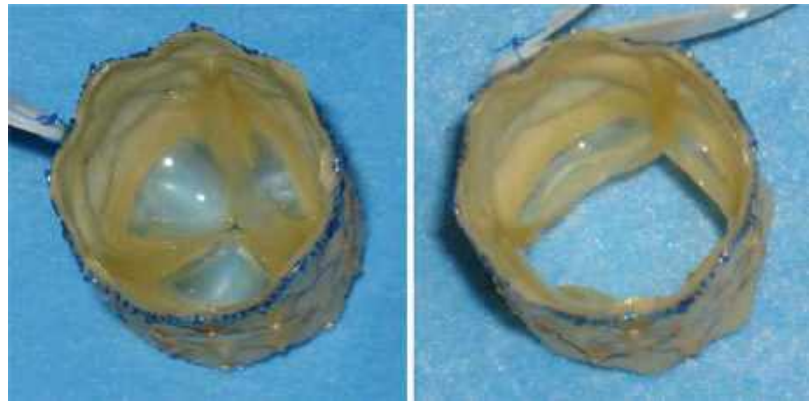

Fig. 61.1 Melody™ percutaneous pulmonary valve, in the close (*left*) and open (*right*) position, mounted on a platinum-iridium stent

Fig. 61.2 Platinum-10 % iridium stent and the gold reinforced current device

Fig. 61.3 Loading of the PPVI stent onto the delivery catheter (Courtesy of Dr Philipp Lurz)

22 mm [12]. In the early design of the device, the venous wall was sutured to the stent only at its two extremities, which, in early experience, led to an important device-related adverse event called the "hammock effect," in which the valve did not appose to the stent because of the failure of these sutures. There was probably a dynamic component to this mechanism, which was seen better during angiography and could be accentuated by a "Venturi" effect. The hammock effect was not observed after a change in the device design, when the whole length of the venous wall was sutured along the length of the stent [3]. The clinical program of PPVI started at Hôpital Necker Enfants Malades (Paris, France) and continued at Great Ormond Street Hospital for Children and The Heart Hospital (London, UK). This group has the longest and largest single-operator experience in PPVI with more than 250 implantation and several published papers [13–15]. PPVI has been accepted by the regulatory agencies for use in Europe and Canada since 2006 and received FDA final approval in 2010. Up to now, 11 years after the pioneering case, PPVI has been performed in more than 150 centers worldwide with over 2000 patients treated and has the potential to become the standard procedure in the treatment of dysfunctional conduits.

Furthermore, a new valve for PPVI has been developed by Edwards Lifesciences (SAPIEN valve), and the initial experience with this is also encouraging.

Indications

Anatomic Conditions

The typical anatomic conditions where pulmonary valve replacement is generally required for residual RVOT lesions after surgical repair are:

1. Tetralogy of Fallot
2. Double outlet right ventricle
3. Pulmonary stenosis
4. Pulmonary atresia
5. Absent pulmonary valve syndrome
6. Common arterial trunk (truncus arteriosus)
7. Rastelli-type repair of transposition, ventricular septal defect, and pulmonary stenosis (TGA + VSD + PS) or pulmonary atresia
8. RV to PA conduits in the subpulmonary outflow (Ross operation)

RVOT dysfunction may be characterized by predominant pulmonary stenosis or regurgitation. Stenosis is often the result of outgrowing the conduit size, residual narrowing due to angulation, kinking or twisting of the conduit, intimal proliferation, and degenerative calcification. Pulmonary valve regurgitation may be due to resection of the valve leaflets during surgery in the native pulmonary trunk, to patch enlargement of the RVOT, or degeneration of the valvular mechanism, for example, homograft degeneration.

Clinical Indications

Clinical indications for the treatment of pulmonary regurgitation and/or stenosis, whether surgical or percutaneous, are subject to ongoing discussions and there are no unifying guidelines [5].

In spite of this, the consensus indications are:

1. RV systolic pressure > 2/3 systemic with clinical symptoms
2. RV systolic pressure > 3/4 systemic without clinical symptoms
3. Severe pulmonary valve regurgitation associated with one or more of the following:
   - RV dysfunction and/or dilatation (assessed on echocardiography and/or cardiovascular magnetic resonance imaging (cMRI))
   - Decreased exercise capacity (peak VO_2 < 65–70 % predicted for normal)
   - Arrhythmias: atrial or ventricular sustained arrhythmias

Table 61.1 shows the reported recommendations regarding pulmonary valve replacement in adult patients with repaired tetralogy of Fallot or similar physiology according to the current American, Canadian, and European guidelines [3, 16, 17].

Imaging Evaluation: The Role of the cMRI

Cardiac magnetic resonance imaging (cMRI) helps in the clinical decision-making in patients with repaired tetralogy of Fallot and/or other RVOT anomalies by providing comprehensive anatomic and functional information [18–21].

Especially important in these patients is the quantitative information on RV size, global and regional RV function, left ventricular size and function, myocardial scar, RVOT aneurysm or obstruction, valve dysfunction (especially helpful in quantifying the amount of pulmonary regurgitation), residual intracardiac shunts, and anatomic abnormalities of the pulmonary arteries and aorta [18, 19].

Although standard echocardiography remains the first diagnostic and follow-up technique, cMRI is increasingly being incorporated into the clinical surveillance protocols once this patient population reaches adolescence.

The goals of cMRI in patients with repaired tetralogy of Fallot, or other congenital heart defects characterized by RVOT dysfunction, include [18–20]:

- Quantitative assessment of left and right ventricular volumes, mass, and parameters of systolic function (effective stroke volumes, ejection fraction, and cardiac output)
- Evaluation of regional wall motion abnormalities
- Imaging the anatomy of the RVOT, pulmonary arteries, aorta, and aortopulmonary collaterals

Table 61.1 Recommendations regarding pulmonary valve replacement

ACC/AHA Guidelines (2008) [3]	– Pulmonary valve replacement is indicated for severe pulmonary regurgitation and symptoms or decreases exercise tolerance – Pulmonary valve replacement is reasonable in adults with previous tetralogy of Fallot, severe pulmonary regurgitation, and any of the following: • Moderate to severe RV dysfunction • Moderate to severe RV enlargement • Development of symptomatic or sustained atrial and/or ventricular arrhythmias • Moderate to severe tricuspid regurgitation
Canadian guidelines (2009) [16]	The following situations may warrant intervention following surgical repair: Free pulmonary regurgitation associated with: • Progressive or moderate to severe RV enlargement (RV end-diastolic volume of greater than 170 ml/m^2) • Moderate to severe RV dysfunction • Important tricuspid regurgitation • Atrial or ventricular arrhythmias • Symptoms such as deteriorating exercise performance
European guidelines (2010) [17]	– PPVI should be performed in symptomatic patients with severe pulmonary regurgitation and/or stenosis (RV systolic pressure >60 mmHg, tricuspid regurgitation velocity > 3.5 m/s) – PPVI should be considered in asymptomatic patients with severe pulmonary regurgitation and/or pulmonary stenosis when at least one of the following criteria is present: • Decrease in objective exercise capacity • Progressive RV dilation • Progressive RV systolic dysfunction • Progressive tricuspid regurgitation (at least moderate) • RVOT obstruction with RV systolic pressure > 80 mmHg (tricuspid regurgitation velocity > 4.3 m/s) • Sustained atrial/ventricular arrhythmias

- Quantification of pulmonary regurgitation, tricuspid regurgitation, or any other valvular abnormality and calculation of pulmonary-to-systemic flow ratio
- Assessment of myocardial viability with particular attention to the scar tissue in the ventricular myocardium apart from the sites of previous surgery (e.g., ventricular septal defect and RVOT patches)

For many years, most centers have referred patients with severe chronic pulmonary regurgitation for pulmonary valve replacement based on symptoms, such as progressive exercise intolerance, heart failure, syncope, or ventricular tachycardia [18–22]. Recent evidence clearly demonstrates that relying on symptoms as the major criteria for pulmonary valve regurgitation results in patients receiving a pulmonary valve when the RV is markedly dilated (mean RV end-diastolic volume 201 ± 37 ml/m^2 in one study), and RV and/or left ventricle dysfunction is present. Several studies have identified prepulmonary valve regurgitation threshold values of RV end-diastolic and end-systolic volumes that are associated with postoperative normalization of RV size. Therrien et al. [23] reported that RV size did not return to normal in any of the 7 patients whose preoperative end-diastolic volume index was >170 ml/m^2, whereas RV size normalized in 9 of 10 patients with preoperative end-diastolic volume ≤170 ml/m^2. Oosterhof et al. [24] identified RV end-diastolic volume <160 ml/m^2 and end-systolic volume <82 ml/m^2 as being associated with normal postoperative RV size. Buechel et al. [25] identified RV end-diastolic volume <150 ml/m^2 as the threshold value below which the RV size returns to the normal range after pulmonary valve regurgitation. In a recent study [26], Frigiola et al. reported on patients who underwent surgical pulmonary valve regurgitation with an average preoperative RV end-diastolic

volume of 142 ± 43 ml/m^2 and RV end-systolic volume of 91 ± 18 ml/m^2. By using this rather aggressive strategy, normalization of RV volumes occurred in the majority of patients and improvement of biventricular systolic function as well as improvement in the submaximal exercise capacity, especially in the patients younger than 17.5 years. These results suggest that the shorter the exposure to pulmonary regurgitation, the better the surgical outcome, probably reflecting a less damaged myocardium. Geva et al. [18] analyzed prepulmonary valve replacement predictors of normal postpulmonary valve regurgitation RV size (end-diastolic volume index ≤114 ml/m^2) and function (ejection fraction ≥48 %) in 64 patients with severe chronic pulmonary regurgitation. The independent predictors of normal RV size and function were preoperative RV end-systolic volume index <90 ml/m^2 and QRS duration <140 ms. Another important element that emerges from the last study is the superiority of pulmonary regurgitation volume to pulmonary regurgitant fraction in evaluating the influence of pulmonary regurgitation on RV dilation and dysfunction in both patients with or without right ventricular tract obstruction [18, 27].

Technical Aspects

The system currently used in clinical practice is the Medtronic Melody valve and Ensemble. Recently a new PPVI system has been introduced but it is still under investigation (SAPIEN valve). Therefore, this chapter will report in detail on the Melody valve and discuss briefly the available data on the SAPIEN valve.

Device

The Melody transcatheter pulmonary valve is composed of a segment of bovine jugular vein with a thinned down wall and a central valve. The vein is sutured inside an expanded platinum-iridium stent with a length of 28 mm and a diameter of 18 mm that can be crimped to a size of 6 mm and re-expanded from 18 mm up to 22 mm (Figs. 61.1 and 61.2). The current stent design, which has an eight-crown zig pattern with six segments along its length, is reinforced at each strut insertion with gold weld. The venous segment is attached to the stent by continuous 5-0 polypropylene sutures around the entire circumference at the inflow and outflow portion as well as discretely at each strut insertion. The suture is clear colored for all the points except the outflow line, which is blue to signify the outflow end of the device. The venous segment is fixed in a buffered glutaraldehyde solution in a concentration low enough to preserve the flexibility of the venous valve leaflets. A final sterilization step is performed on the combined device using a sterilizing solution containing glutaraldehyde and isopropyl alcohol, in which it is then packaged [12, 28].

The Delivery System

The delivery system, Ensemble, also manufactured by Medtronic, MN, includes a balloon-in-balloon (BiB) design onto which the valved stent is front-loaded and crimped (Fig. 61.3). The system is available with three outer balloon diameters: 18 mm, 20 mm, and 22 mm. The tip of the system is blue to correspond with the blue outflow suture on the device to help with correct orientation. The body of the Ensemble system consists of a one-piece Teflon sheath containing a braided-wire reinforced elastomer lumen. The design minimizes the risk of kinking while optimizing flexibility and retaining the pushability required for the procedure. There is a retractable sheath which covers the stented valve during delivery and is withdrawn just prior to deployment. Proximally, there are three ports, one for the guidewire (green), one to deploy the inner balloon (indigo), and one to deploy the outer balloon (orange) [2, 28].

The Procedure

The procedure is usually carried out under general anesthesia. Vascular access is obtained in the

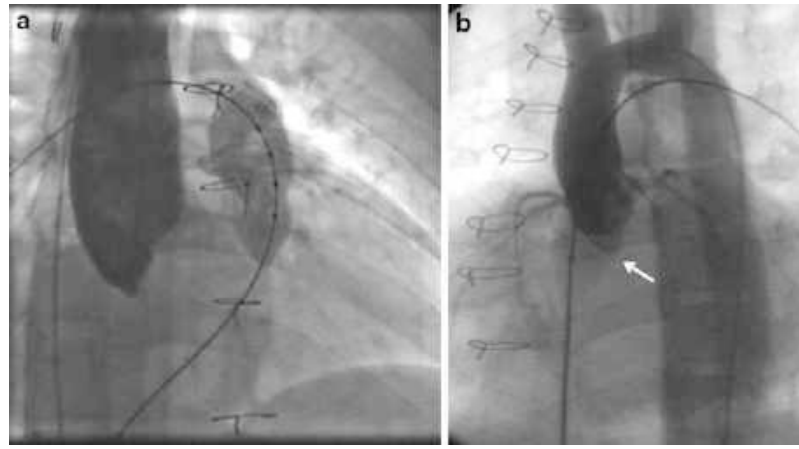

Fig. 61.4 (**a**) Coronary angiography performed with simultaneously inflated angioplasty balloon in the pulmonary conduit (**b**) Coronary angiography performed with simultaneously inflated angioplasty balloon (*arrow*) in the pulmonary conduit. The balloon is inflated with little contrast to avoid masking the potential coronary compression

femoral vein and the femoral artery. A single dose of broad-spectrum intravenous antibiotics is usually given for endocarditis prophylaxis. Heparin is administrated routinely at the beginning of the procedure and repeated hourly thereafter, as required to maintain an activated clotting time greater than 250 s. Right heart catheterization is performed by the standard techniques to assess pressures and saturations with a right coronary catheter, JR 3.5, or any other catheter with a curved tip. Routinely, pressure measurements are obtained in the right ventricle, pulmonary artery, and aorta with additional measurements, for example, in the branch pulmonary arteries. A 0.035" super-stiff guidewire is then positioned in a distal branch pulmonary artery to provide an anchor on which the delivery system can be advanced. Angiography is performed using a Multi-Track catheter (NuMED Inc., Hopkinton, NY) or through an 8-Fr Mullins long-sheath with the tip placed just beyond the pulmonary valve, to allow more detailed assessment of the proposed site for device implantation. Angiograms are performed in multiple planes including lateral and anteroposterior projections with cranial angulation, as well as the aortic root. If there is a possibility that a coronary artery is at risk of compression from valve implantation, coronary angiography is performed with an angioplasty balloon (18–20-mm Mullins balloon, NuMed Inc., Hopkinton, NY) inflated simultaneously in the right ventricle to pulmonary artery conduit (Fig. 61.4a and b). If there is a high risk of coronary arterial compression, valve implantation should not be attempted and the patient should be referred for surgery. Conduit predilatation should be performed using a balloon 2 mm larger than the narrowest diameter of the conduit and less than 110 % of the original conduit diameter in order to reduce the risk of conduit rupture. If the balloon waist measures between 14 and 20 mm on subsequent low-pressure (< 8 atm) balloon sizing, the conduit may be considered anatomically suitable and the procedure may continue (Fig. 61.5). The valved stent is prepared in three sequential saline baths (5 min in each) to wash off the glutaraldehyde, in which it is stored. The size of the valved stent is reduced by crimping it to increasingly smaller sizes prior to front-loading onto the delivery system. It is recommended to use a 2.5-ml syringe for crimping to an intermediate size prior to the final crimping onto the balloon catheter. The blue stitching on the distal portion of the device is matched to the blue portion of the delivery system and verified by an independent observer to guarantee correct orientation of the valve. Further hand crimping of the device onto the balloon is performed, following which the sheath is advanced to cover the stent while a saline flush is administered via the side port to remove air bubbles from the system. The femoral vein is dilated with a 24-Fr dilator and the front-loaded delivery system is advanced into the RVOT over the stiff guidewire, under fluoroscopic guidance. Once in position, the sheath is retracted from the

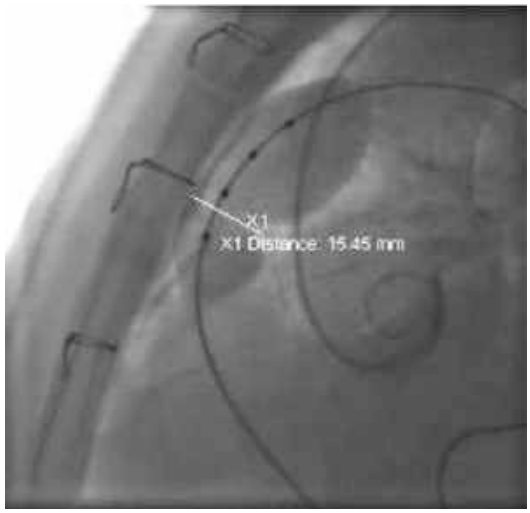

Fig. 61.5 Balloon sizing prior to PPV implantation

valved stent and contrast is injected via the side port to confirm its position. Partial deployment of the stent is achieved by hand inflation of the inner balloon, and after final confirmation of the position, the outer balloon is also hand inflated to complete the deployment. The balloons are deflated and the delivery system withdrawn. Repeat angiography and pressure measurements are obtained to confirm the result (Fig. 61.6). Post-dilatation of the valve may be needed in the presence of a residual gradient and incomplete expansion of the valved stent [12, 28].

Modification of the Technique

The nature and position of right ventricle to pulmonary artery conduits may be heterogeneous, and cannulation with a large delivery system can be challenging. Pre-dilation with high-pressure balloons (Mullins balloon) and in some cases bare metal stent implantation in conduits that are heavily calcified or tortuous can facilitate passage of the delivery system, in addition to optimizing the final result. It may also have the additional benefit of reducing the risk of future stent fractures [29]. Further maneuvers that can be used to advance the delivery system, when it is at the entrance to the conduit, include looping the guidewire/delivery system within the right atrium, partial retraction of the sheath, and repositioning of the guidewire in the contralateral branch pulmonary artery. The first two actions generate a forward force often overcoming any resistance and may aid passage through the conduit. Another useful trick is to pull on the guidewire while pushing the delivery system to help with forward motion. Once the balloon is deflated, the delivery system is withdrawn. If further dilation of the valved stent is required, this is performed using a high-pressure Mullins balloon or other high-pressure balloons. Care is taken not to dilate conduits beyond their original documented size to minimize the risk of rupture. Post-dilation of the device does not appear to cause any damage to the valve leaflets or affect valve competency. Although the preferred approach is via the right femoral vein, successful valve implantation has also been achieved via the left femoral, right and left internal jugular, and left subclavian veins. A transhepatic route is neither used nor recommended in view of the size of the delivery system [30, 31].

Complications

The most important reported procedural complications are [28, 30–33]:

1. Device instability and migration/embolization: This is a very rare event. If it occurs, surgery is usually needed.
2. Homograft rupture: Homograft rupture remains the most difficult complication to predict and therefore avoid. Aggressive post-dilation after deployment of the valved stent may reduce the risk of severe bleeding. If bleeding occurs, autotransfusion should be initiated as soon as possible to reestablish a sufficient circulation for further intervention or "watchful waiting." Acute thoracotomy is not usually advised, since decompression of the chest may exacerbate bleeding and lead to later difficulty in locating the source of bleeding.
3. Compression of the coronary artery [33]: Accurate measurement of the implantation

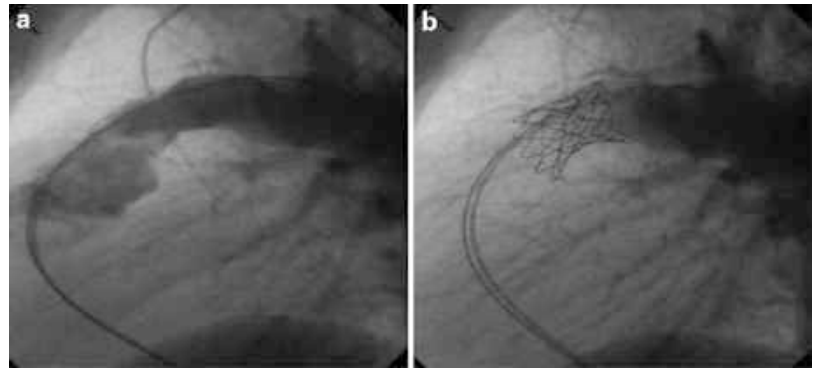

Fig. 61.6 (**a**) Pre- and (**b**) post-PPVI angiograms

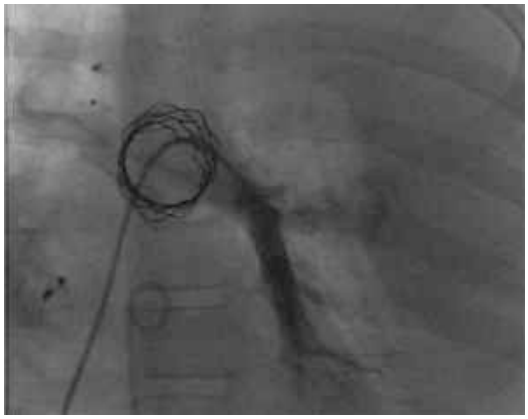

Fig. 61.7 Injury of the distal left pulmonary artery

site, assessment of outflow tract distensibility, and assessment of coronary artery anatomy are now routinely performed prior to Melody valve implantation. This is usually with cMRI or CT scanning study and by performing balloon testing of the RVOT simultaneously with coronary angiography (Figs. 61.4a and b); in rare cases, this assessment has not been sufficient to avoid complications [31, 33].

4. Injury to a distal branch pulmonary artery (Fig. 61.7) or tricuspid valve. Damage to distal pulmonary artery branches can be minimized by ensuring stable guidewire positioning at all times, and avoidance of damage of the tricuspid valve can be achieved by use a balloon flotation catheter for the initial maneuvering of the catheter through the right heart.
5. The "hammock effect," as reported above, describes an in-stent stenosis resulting from partial collapse of the wall of the jugular vein away from the stent within the recipient outflow tract (Fig. 61.8). This problem predominantly affected the initial cohort of patients undergoing valve implantation and led to a revision of the suturing within the device. In theory it may still occur in the context of stent fractures or suture rupture, where adherence of the venous wall to the stent and the surrounding tissues becomes disrupted.
6. Stent fractures (Fig. 61.9): They are a potential complication of all cardiovascular stent applications. In PPVI procedure the prevalence of stent fractures was 21 %. Implantation in a native RVOT, absence of RVOT calcification, and qualitative recoil of the valved stent just after implantation may be predictors of stent fracture. A classification that can guide management has been formulated by Nordemeyer [32], whereby type I fractures (no loss of stent integrity) can be managed conservatively, type II fractures (loss of stent integrity with echocardiographic signs of restenosis) should be considered for repeated PPVI (valve-in-valve procedure) or surgery, and type III fractures (separation of fragments/embolization) necessitates surgery. Pre-stenting with a bare metal or covered stent may reduce the risk of stent fractures (Figs. 61.10 and 61.11). Serial radiographic and echocardiographic follow-up is essential

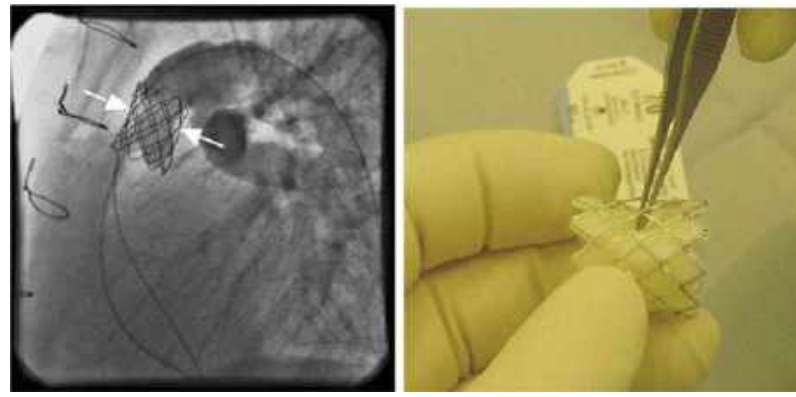

Fig. 61.8 Hammock effect (Courtesy of Dr Louise Coates)

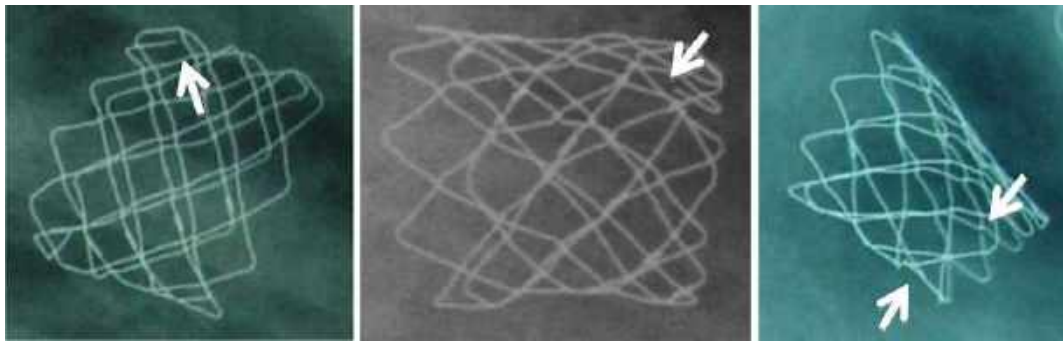

Fig. 61.9 Stent fracture as seen on X-ray

to detect and monitor stent fractures and facilitate timely intervention. Fluoroscopy is a useful adjunct to assess fractures and stent stability. Repeat Melody implantation has been performed for the "hammock effect," stent fracture, and residual stenosis. The procedure is feasible and has excellent and sustained hemodynamic results. In the future, it is to be expected that repeat Melody procedures will be performed for late valvular degeneration in the initial valved stent.

7. Hemolysis is rare, having occurred in only one reported case with unrelieved obstruction in a small conduit, which subsequently underwent surgical explantation of the device. Routine screening is not needed for this.
8. Endocarditis has been documented on both the venous wall and the valve itself. It may or not result in device dysfunction and surgical or medical management strategies should be employed accordingly. Isolation of various bacteria has been reported.
9. Residual stenosis: This is easily solved by post-dilation of the valved stent or, if necessary, with a valve-in-valve implantation.

Outcomes

Technical Outcomes

The combined London/Paris experience (155 patients between September 2000 and February 2007) [31, 34] and the United States experience (136 patients from five centers between January 2007 and August 2009) [35, 36] are currently the largest reported series in the literature. Recently,

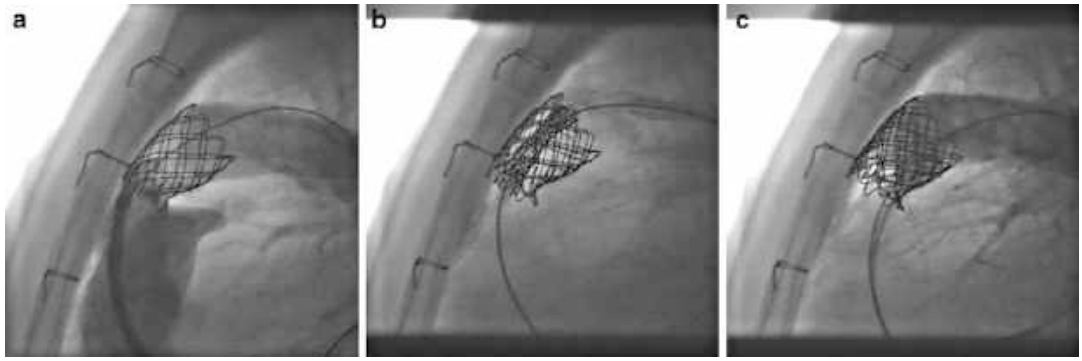

Fig. 61.10 Bare metal stenting (**a**) prior to PPV implantation (**b**, **c**)

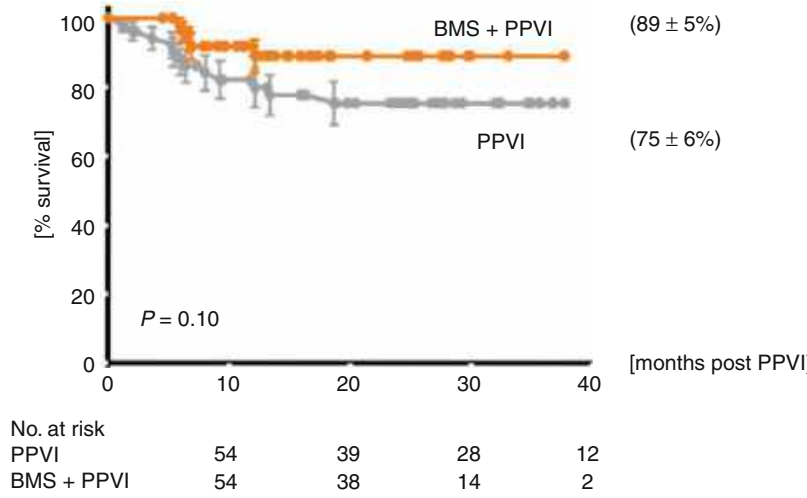

Fig. 61.11 Probability of stent fractures free survival of PPVI with (*orange*) and without (*light grey*) bare metal stenting (*BMS*) (Courtesy of Dr Johannes Nordmeyer)

new data confirming the feasibility and effectiveness of PPVI has been reported from several centers: the German experience is of 102 patients from two centers of Munich and Berlin between December 2006 and July 2010 [37], and the Canadian experience is of 30 patients from the single center of Toronto between October 2005 and December 2008 with 2-year follow-up [38]. Furthermore, recently an Italia registry reported data on 63 patients followed-up for a median of 30 months (range 12–48 months) [39]. The follow-up data show good freedom from reoperation and repeat catheterization and demonstrate that PPVI can postpone open-heart surgery, thereby potentially reducing the number of operations needed by the patients during their lifetime. Moreover, from the London/Paris experience, the importance of the effect of learning curve is highlighted, which has led to identifying, avoiding, or at least reducing early and late complications causing device failure by improving the device design and the technical aspects of the procedure. Indeed, comparing the first 50 patients and the subsequent 105 patients of their series, freedom from reoperation was significantly longer in the second cohort of patients, because of better selection of patients and important reduction of major problems, such as stent fractures or residual gradient of RVOT, both of which correlated with device failure [31].

Clinical Outcomes

PPVI has been shown to impact acutely on biventricular function and exercise performance [13, 30]. Valve implantation significantly reduced the gradient across the RVOT and the RV pressures, increased diastolic pulmonary arterial pressure by restoring valvular competence, and improved symptoms. Cardiovascular MRI showed a reduction in the RV end-diastolic volume and an improvement in RV ejection fraction. However, the potential for further late functional remodeling is unknown. But there is a difference in the acute and late responses of the patients affected by a predominant pressure overload compared with a predominant volume overload [15]. Lurz et al. [34] observed significant early improvement in RV systolic function and exercise capacity in patients with predominant pressure overload, but with no further remodeling at 1-year follow-up. In contrast, patients with predominant volume overload had neither improvement in RV systolic function or in exercise capacity. For many years, pulmonary regurgitation after repair of tetralogy of Fallot or other congenital conditions has been considered a benign lesion, because free pulmonary regurgitation from a transannular patch can be tolerated for decades without any overt symptoms [22, 40–43]. In the last few years, cMRI has allowed accurate measurement of pulmonary regurgitation and its effects on right ventricular volumes and systolic function. Response of the RV to severe chronic volume load is variable: at a compensated stage, the RV end-diastolic volume and compliance increases. Despite initial ventricular dilatation, the compensatory eccentric hypertrophy maintains a normal mass-volume ratio and therefore a normal end-systolic wall stress and global systolic function. When these compensatory mechanisms fail, dilation of the RV, not associated with adequate hypertrophy, may lead to progressive increase of afterload (end-systolic stress), global systolic dysfunction, and reduced contractility. By this stage, irreversible myocardial injury has taken place, with fibrosis, increased interstitial collagen, and fibronectin. Although valve replacement may still be tolerated and associated with clinical benefits, myocardial function will not return to normal. This is associated with right heart dilation and deterioration of exercise performance, development of congestive heart failure, and ventricular arrhythmias and sudden death. The determinants of the degree of pulmonary regurgitation are multifactorial, including functional integrity of the pulmonary valve, right ventricular compliance, ventriculo-arterial coupling, and ventriculo-ventricular interaction. The trend towards the need of earlier treatment of pulmonary regurgitation is supported by the Canadian experience [38]. It offers encouraging results on the clinical outcome of early and 2-year post-PPVI implantation, describing a population of adolescents with significantly enlarged RV chambers, poor exercise performance, and dysfunctional conduits. There was a significant acute decrease in RV hypertension, relief of RVOT obstruction, and near-elimination of pulmonary regurgitation, in both stenotic and mixed lesion groups. Follow-up echocardiographic data demonstrated sustained reduction in RV to PA gradients and RV pressures, in those with pressure-overloaded and/or volume-overloaded ventricles. Furthermore, there was a decrease in RV end-diastolic dimensions sustained during follow-up. Patients treated in this experience were younger. While the median age in the London/Paris series was 21 years (age range from 5 years to 58 years), the median age in the Canadian series was 14 years (age range from 10 years to 19 years). This supports the idea that regurgitation and/or outflow tract obstruction should be treated earlier. Another important goal is the electrical remodeling following PPVI. It is known that sudden cardiac death in congenital heart disease is related to increased right ventricular end-diastolic volumes as well as abnormalities of QRS duration (QRS $>$ 180 ms), and QRS, JT, and QT dispersion. Plymen et al. [44] have published some interesting results: ECGs were performed before, immediately after, and 1 year after PPVI in 99 patients between 2001 and 2007 and observed a significant decrease in QRS duration (135 $\pm$ 27 msec to 128 $\pm$ 29 msec;

$p = 0.007$) in those with predominantly PR and a significant decrease in QRS, QT, correct QT interval, and JT dispersion in all patients.

In future years, it is imperative to optimize the indications, the patient selection, and the device design in order to treat the majority of patients.

Future Directions

With the current valve design, only selected patients with adequate RVOT dimensions (between 14 and 22 mm), appropriate morphology and dynamics of the RVOT/pulmonary trunk, can be treated, leaving the vast majority of patients (85 %) to be treated surgically. This is particularly the case in native outflow tracts, especially if these have been enlarged with a patch. To broaden the application of PPVI to all RVOT morphologies, a number of strategies have been proposed.

1. Device design: the Edwards SAPIEN valve [45], which is a pericardial valve mounted inside a balloon-expandable stainless steel stent, originally designed for aortic valve replacement via an anterograde and retrograde approach, has been proposed for use in the RVOT position, as it is currently available in diameters of 23 mm and 26 mm. 20 mm and 29 mm prototypes are also under development. Early feasibility data are encouraging with the outcome of the COMPASSION (COngenital Multicenter trial of Pulmonic valve regurgitation Studying the SAPIEN InterventiONal transcatheter heart valve) safety and efficacy trial awaited. One further benefit of this device is the lower incidence of stent fractures in the stainless steel frame; however, because of its balloon-expandable nature, it cannot be retrieved once deployed and a degree of obstruction is still required for anchorage this valve, making it possibly unsuitable for patients with transannular patches. Various experimental models have been proposed and can broadly be categorized in two groups: Firstly, the two-step procedure whereby implantation of a conventional device is facilitated by placement of a stent that downsizes the RVOT [46] and secondly, the development of a novel stand-alone device that can be anchored within the dilated RVOT [47].
2. Customized device: advances in 4-dimensional imaging techniques and the use of rapid prototyping models and finite element (FE) analysis have made possible computer testing of new devices based on anatomical 3D information obtained with cardiac computed tomography (CT) imaging (Fig. 61.12) [48]. Patients with congenital heart disease present important variations in RVOT/PA anatomy and dynamics as a result of structural and functional changes secondary to the initial anatomy and multiple surgical operations. Detection of 3D deformation of the implantation site is relevant to identify those patients at a higher risk of stent fracture. This is even more important for future technology, which should target those patients, who cannot currently benefit from this procedure, presenting native RVOT/PAs with actively contracting components. This approach offers an opportunity to tailor device construction using patient-specific data and overcomes an important limitation of the development of new devices: the lack of animal models that encompass the wide variation seen in patients.
3. Hybrid procedure: experimental work has demonstrated the feasibility of a hybrid procedure combining banding of the RVOT via a left thoracotomy with subsequent valve implantation. Implantation of the Shelhigh Injectable Stented Pulmonic Valve has been reported in humans as a hybrid procedure [49]. After deployment, the valve is secured in position with several transmural sutures placed at the proximal and distal rims. While this approach avoids cardiopulmonary bypass and its adverse effects, it still requires re-sternotomy, which is associated with an increased risk.
4. The substrate: the deleterious effects of pulmonary regurgitation on right ventricular function are now well documented. Surgeons have moved towards placing smaller transannular patches and, where possible, valved conduits

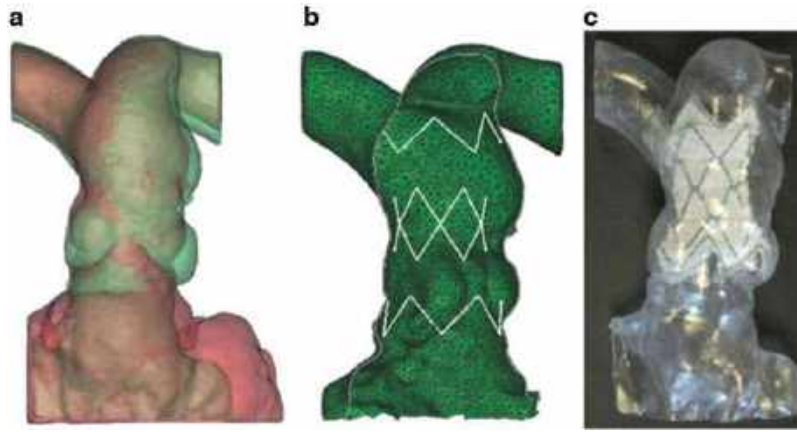

Fig. 61.12 Modeling. (**a**) Superimposed diastolic (*red*) and systolic (*green*) 3D volume reconstructions of the patient anatomy from 4D CT. (**c**) Plastic rapid prototype model of the patient anatomy with the final device design inserted (Courtesy of Dr Silvia Schievano)

as part of the primary repair to try and minimize this complication. In patients, the RVOT anatomy is often tortuous following repair of complex congenital heart disease. Deployment of self-expandable valved stents could potentially be a problem. Insertion of the present devices into a dilated RVOT may, however, be facilitated by a surgical modification in order to prepare the patient for future percutaneous rather than surgical intervention. Additionally, the availability of PPVI may influence the popularity of operations such as Ross procedure. A novel concept being currently tested is the insertion of an expandable, valved conduit for reconstruction of the RVOT. The principle of this approach is that a conduit could be balloon-dilated to keep pace with somatic growth, and when valve failure occurs, percutaneous valve implantation can be safely performed. This approach has been reported for mitral valve replacement in children by Abdullah et al. [50]. Clinical experiences are currently underway for RVOT reconstruction by the same authors.

5. Other issues: despite the potential for repeat percutaneous valve implantation with the currently available device, the durability of biological valves remains an important issue both for surgeons and interventionists. The mechanisms of degeneration of the valve are multifactorial and include immunologic rejection, mechanical deterioration, calcification, and enzyme digestion. There is much interest in developing valves with infinite durability, comparable function, and avoidance of anticoagulation. In the percutaneous field, low-profile biodegradable pulmonary valves made of small intestinal submucosa have been tested experimentally [51]. These valves provide a de-cellularized matrix that is repopulated following implantation by the adjacent host tissue and does not invoke significant immunologic rejection. The development of progressive leaflet thickening in the animal model, however, currently precludes human application [51]. An alternative approach could be the preimplantation seeding of the matrix by means of tissue engineering. Experimental transcatheter implantations of such valves in the pulmonary position are ongoing.

Abstract

Branch pulmonary artery stenosis is a common lesion in congenital heart disease. It occurs as an isolated lesion or in association with other defects such as pulmonary atresia, transposition of the great arteries, and tetralogy of Fallot. It occurs congenitally or acquired postoperatively. This chapter discusses the anatomy, the decision-making process, the technical details, the outcomes, and further developments of catheter-based interventions on pulmonary arteries.

Keywords

Angioplasty • Congenital heart disease • Cutting balloons • Pulmonary artery stenosis • Stent • Ultrahigh-pressure angioplasty

Introduction

Branch pulmonary artery stenosis is a common lesion in congenital heart disease. It occurs as an isolated lesion or in association with other defects such as pulmonary atresia, transposition of the great arteries, and tetralogy of Fallot. It occurs congenitally or acquired postoperatively. There are several classifications reported in the literature [1, 2].

Anatomy-Heterogeneity of Lesion

Branch pulmonary artery stenosis is a heterogeneous lesion (Fig. 62.1), which can occur on any or all segments of the pulmonary arterial tree from the main trunk to the main branches, lobar branches, segmental branches, and the subsegmental branches. It may range from a single isolated lesion to complex and severe hypoplasia of the entire tree and from discrete to long-segment involvement. It may present as a unilateral or bilateral lesion. Morphology of the stenosis is varied. Causes include congenital, postsurgical, external compression, folds, or kinks. The latter are usually found at the junction of the main and branch pulmonary artery. Severe congenital lesions may be associated with Rubella syndrome, Williams syndrome, Alagille

syndrome, and Noonan syndrome (Fig. 62.2). There are also rare cases of pulmonary arteriopathy not identified with any syndromes, but probably related to connective tissue disorders.

Pathophysiology

Branch pulmonary artery stenosis may result in increased pressure loading and hypertrophy of the right ventricle. As the ventricle thickens, it becomes less compliant, leading to diastolic dysfunction. Depending on the severity and duration of the pulmonary arterial stenosis and right ventricular hypertrophy, arrhythmias, right ventricular failure, and death may ensue. Increased systolic pressure can cause pulmonary and/or tricuspid valve insufficiency, leading to an increased volume load in addition to the pressure load. Right atrial and/or ventricular dilation may result in atrial/ventricular arrhythmias. Recent animal studies show that the regurgitant volume is increased with branch pulmonary artery stenosis and is improved once the stenosis is relieved [3]. The hemodynamics of unilateral stenosis is different from bilateral stenoses. Not uncommonly, unilateral stenosis that develops during infancy and childhood is well tolerated as the contralateral pulmonary artery branch dilates to accommodate more flow. Gradients found across such unilateral stenosis may also be underestimated due to decreased flow across the stenosis. In unilateral hypoplasia, the contralateral pulmonary arterial tree may enlarge to accommodate the increased flow such that the right ventricle pressure may be only mildly increased. Hence, it may be difficult to interpret the hemodynamics of the unilateral stenosis without assessment of the bilateral pulmonary blood flow. In this scenario, a pulmonary perfusion scan may be helpful to assess the percentage flow to both lung fields. Significant bilateral stenoses are invariably associated with increased right ventricle pressure, and the gradients are most congruent to the severity of the stenosis. Pulmonary artery stenosis in single-ventricle physiology will have only subtle hemodynamic derangements due to the lack of the pumping chamber to force blood across the stenosis. A high index of suspicion and aggressive assessment are necessary to evaluate the severity of stenosis, especially in the single-ventricle patient with unexplained pleural and/or pericardial effusions or protein-losing enteropathy.

Indications for Treatment

Recent AHA guidelines have been published [4]. Significant stenosis is thought to exist when there are measureable gradients of 20–30 mmHg across the narrowing, when there is RV or proximal main pulmonary artery hypertension at $>1/2$ to 2/3 of the systemic pressure, or when there is relative flow discrepancy between the two lungs of 35 %/65 % or worse. In some stenoses, especially in unilateral lesions, the anatomic obstruction may be out of proportion to the gradients found due to decreased flow across the vessel. In such cases, subjective anatomic evaluation is needed to determine the need for intervention. Branch pulmonary stenosis may also exacerbate pulmonary valve regurgitation requiring more aggressive treatment with stents. Branch pulmonary arterial stenosis in single-ventricle patients may often be underestimated due to the low-pressure venous system and/or the development of venovenous collaterals bypassing and decompressing the pulmonary circuit. In these patients, even mild stenosis should be treated

Table 62.1

Recommendations for pulmonary angioplasty
Class I
1. Pulmonary angioplasty is indicated for the treatment of significant peripheral branch pulmonary artery stenosis or for pulmonary artery stenosis in very small patients in whom primary stent implantation is not an option (level of evidence: B)
Class IIa
1. Pulmonary angioplasty is reasonable to consider for treatment of significant distal arterial stenosis or for stenosis in larger, more proximal branch pulmonary arteries that do not appear to be amenable to primary stent implantation (level of evidence: B)
Class IIb
1. Pulmonary angioplasty may be considered for treatment of significant main pulmonary artery stenosis that results in an elevation of pressure to more than two thirds of systemic pressure in the proximal pulmonary artery segment or in the RV (in the absence of pulmonary valve stenosis). This stenosis is usually a form of supravalvar pulmonic stenosis, which is not particularly responsive to balloon dilation alone (level of evidence: C)
Recommendations for pulmonary artery stent placement
Class I
1. Primary intravascular stent implantation is indicated for the treatment of significant proximal or distal branch pulmonary artery stenosis when the vessel/patient is large enough to accommodate a stent that is capable of being dilated to the adult diameter of that vessel (level of evidence: B)
Class IIa
1. It is reasonable to consider pulmonary artery stent implantation in critically ill postoperative cardiac patients when it has been determined that significant branch pulmonary artery stenosis is resulting in a definite hemodynamic compromise in a patient/vessel of any size, particularly if balloon dilation is unsuccessful (level of evidence: B)
2. Primary intravascular stent implantation is reasonable in the treatment of significant stenosis of the main pulmonary artery segment that results in elevation of the RV pressure, provided that the stent definitely will not compromise a functioning pulmonary valve and will not impinge on the pulmonary artery bifurcation (level of evidence: B)
Class IIb
1. It may be reasonable to implant small pulmonary artery stents that lack the potential to achieve adult size in small children as part of a cooperative surgical strategy to palliate severe branch pulmonary artery stenosis. These stents may need to be enlarged surgically or removed during a future planned operation (e.g., conduit replacement, Fontan completion) (level of evidence: C)

aggressively, especially in the presence of pleural effusions, pericardial effusions, protein-losing enteropathy, and low-output states. Table 62.1 lists the AHA guideline for pulmonary angioplasty and stenting.

Intervention Options and Outcome Data

Balloon Angioplasty

Interventional options include balloon angioplasty alone or augmented with cutting balloons and stent implantation. Angioplasty was first reported in the late1980s to 1990s [5–8]. Early reports showed immediate effectiveness in increasing the minimum diameters by 50 % and decreasing the gradients by 50 % [6]. However, medium and long-term results were less than optimal with recurrence of obstruction due to elastic recoil of the stenotic segment [5–8].

Recent introduction of ultrahigh-pressure balloons and cutting balloons has improved the efficacy of angioplasty, especially for distal and resistant lesions. Cutting balloons available in the US market (Boston Scientific, Natick, MA) are available in sizes up to 8 mm diameter and have several microblades which longitudinally "score" the vessel intima permitting further dilation with a subsequent larger balloon or stent implantation [9–11] (Fig. 62.3). Ultrahigh-pressure balloons offer another angioplasty option if avoidance of stents is preferred [12]. However, only small increments of larger balloons should be used successively in order to avoid vascular ruptures and dissections.

Stents

Stent implantation for the treatment of branch pulmonary artery stenosis was first reported by Mullins in 1989 [13]. Over the last two decades, this modality of treatment has become the primary and most effective method of treating branch pulmonary artery stenosis. Numerous papers have been published to confirm its safety

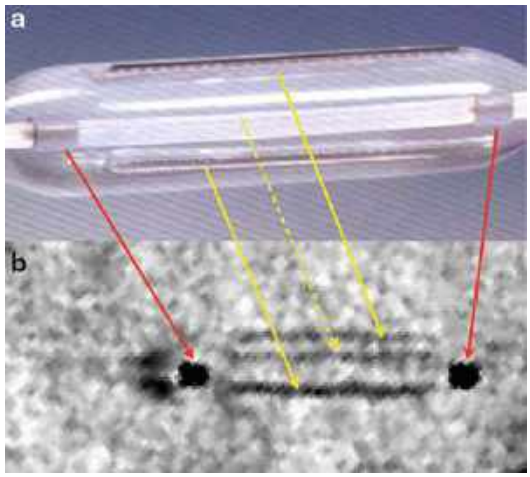

Fig. 62.3 (**a**) 3 longitudinal blades (*yellow arrows*) on the cutting balloon score the intima of the resistant stenosis. Radio-opaque markers of both ends of the balloon define the length of the blades (*red arrows*). (**b**) Magnified fluoroscopy of a cutting balloon. The blades are not easily seen during the actual dilation

and efficacy from immediate – to long-term follow-up [8, 14–23]. However, there are technical limitations including, but not limited to, requirement of a larger delivery system, risk of stent malposition and embolization, steeper and longer learning curve for the interventionist, and the need for further dilation when implanted in a growing child.

With the introduction of newer and smaller profile balloons, more flexible long sheaths, and stents with improved designs, as well as improvement in the delivery techniques, many of these limitations have been overcome. Currently, stents can be implanted in the catheterization laboratory in infants as small as 4–5 kg [20, 24]. When combined with hybrid techniques, large stents, dilatable to adult-size pulmonary arteries (up to 18 mm), can be implanted in even smaller infants [25–30].

Stent Selection and Delivery Techniques

Initial reports of stent implantation for pulmonary arteries used Palmaz stents (Johnson & Johnson Medical, Warren, NJ) on PEMT balloons through 11 Fr long sheaths (Cook Inc, Bloomington, IN). Over the past two decades, the combination of newer and lower profile balloons and stents introduced into the market and improved delivery techniques have allowed the delivery of large stent through smaller sheaths. In the mid-1990s, a technique of adding a dilator tip to the delivery balloon and front-loading the stent into the long sheath before advancing into the femoral veins permitted delivery of the large Palmaz stent through a 7 Fr Mullins sheath. This technique allowed delivery through the right heart in infants as small as 4.5 kg [24].

The introduction of the Genesis stent (Cordis Johnson & Johnson Medical, Warren, NJ) and Maxi LD stents (EV3 Medical Plymouth, MN) later advanced the field further [18, 31, 32]. These stents added the features of flexibility and smoother edges to decrease the risk of balloon rupture during implantation (Fig. 62.4). The "open-cell" design of the Maxi LD stent allowed implantation and covering across side branches, whereby angioplasty of the side branches can be performed through the side cells of the stent [33]. In vivo testing indicates that these side cells can be dilated up to 10 mm diameter (Fig. 62.5). When stenoses are found at closely related orifices of the main or lobar branches, the technique of simultaneously implanting two stents has been reported [21]. Some authors have reported the use of pre-mounted stents in branch pulmonary arteries, but most of these stents are medium sized and cannot be dilated to adult-size pulmonary arteries of up to 18 mm [17, 20]. The advantage of using these pre-mounted stents is that they are convenient and ready for delivery without any crimping and can be delivered through smaller (4–7 Fr) sheaths, but as the child grows, surgery will be required to open the intrinsic limited diameters of the stent [17, 20]. Some authors have advocated this strategy as a reasonable approach for patients, who will require additional future surgery, such as right ventricle to pulmonary artery conduit replacements or Fontan completion [17, 20]. A recent report discusses the pre-mounted Valeo stent, which can be dilated up to 20 mm [34]. However, it should be borne in mind that only those Valeo stents that are pre-mounted on

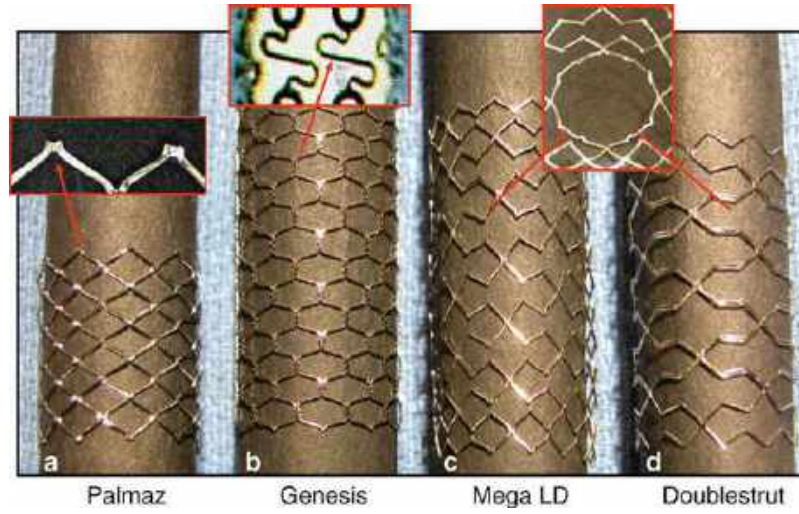

Fig. 62.4 Comparison of large stents. (**a**) First available stent, Palmaz stent with sharp edges, (**b**) newer Genesis XD stent with flexible sigmoidal hinges, (**c**) Mega LD and (**d**) DoubleStrut, both with an "open-cell" design designed for flexibility, for minimal foreshortening, and to allow side cell dilation

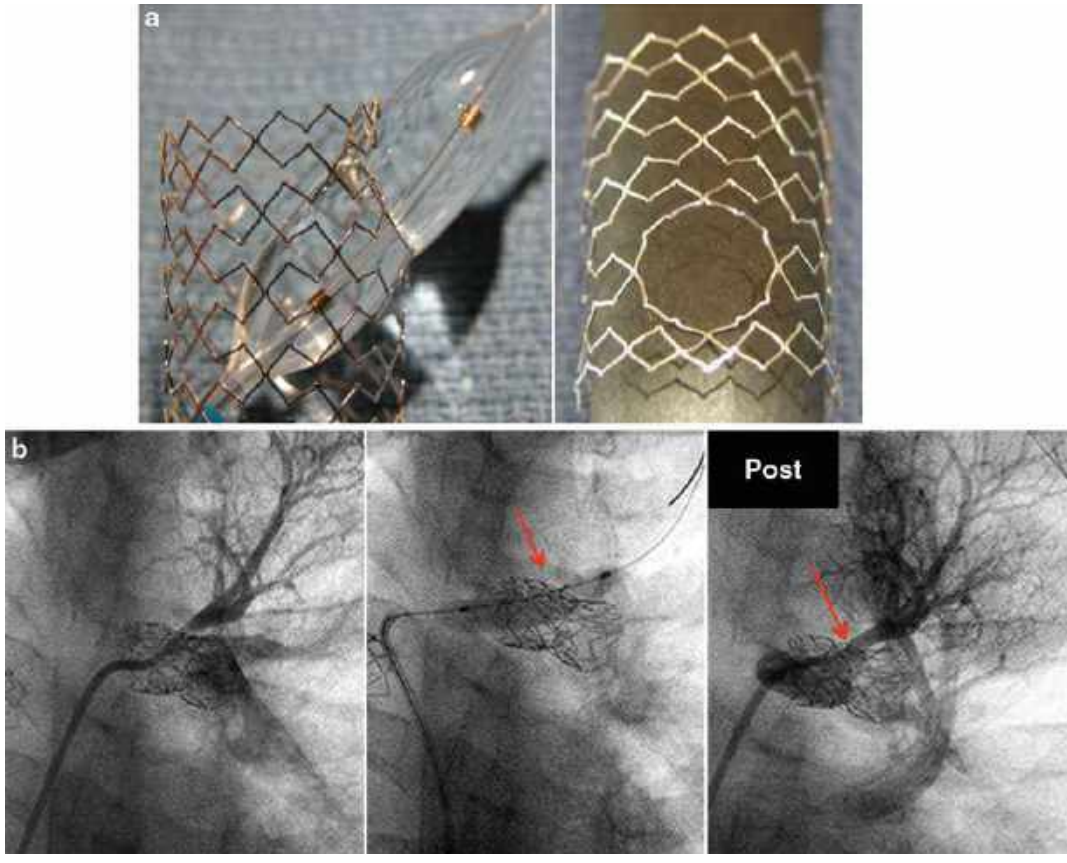

Fig. 62.5 (**a**) Mega LD stent with an "open-cell" design that permits dilation through a side cell with a 10 mm diameter balloon. (**b**) Example of a Mega LD stent implanted in the LPA jailing the LUL. Side-cell dilation improved flow to LUL

9–10 mm balloons and implantable via 7 Fr sheaths can be dilated up to 20 mm, and at such diameters, these stents have very little structural support and radial strength and so are prone to recoil or stent distortion [35].

The general strategy should be to employ a stent in the pulmonary artery segment, whose final diameter matches the final adult size of the vessel.

Two new techniques have particular use in infants and small children. Hybrid or intraoperative techniques were first described by Mendelsohn et al. in 1993 [25]. Recent reports advocate this technique as particularly advantageous in infants and small children. While this requires an operation, it can be performed using transcatheter methods off bypass on a beating heart assisted by fluoroscopy or by direct vision on bypass. In each case, the delivery size is not an issue and a large stent can be implanted quite easily [26–30]. This technique is useful in early postoperative stenoses, where there is a higher risk of suture line disruption, if treated in the catheter laboratory. In the operating room, such complications can be treated quickly with an open-heart strategy.

Tailoring the stent to fit the pulmonary artery anatomy is another recently described useful technique, especially for infants and small children in whom the distance between the branch ostia and the takeoff of the upper lobe branch is short. Since most large stents are available in limited lengths, operators can trim the length to match the infant's anatomy. In the operating room, additional trimming and adjustment of the stent may be useful to fit stents in ostial lesions to avoid jailing of the contralateral branch orifice and to facilitate future catheterizations and further dilations. These techniques may be particularly useful in the complex hypoplastic pulmonary arterial tree occurring in congenital pulmonary arterial stenoses, such as Williams or Alagille syndrome.

Complications

Stenting of the branch pulmonary arteries is one of the more technically challenging procedures for the pediatric interventionist. Pulmonary arteries have diverse morphology and varying shapes, lengths, and degrees of compliance to stent dilation. The stenosis may occur anywhere from the ostium of the branch to the lobar, segmental, and subsegmental level. The stent and delivery system has to traverse the entire right heart, crossing the tricuspid and pulmonary valves before reaching its target. The most common adverse events associated with this procedure are balloon rupture and stent malposition [15]. The first stents used (Palmaz stents) were rigid and had sharp edges, resulting in an increased risk of balloon rupture during inflation (Fig. 62.4). Newer stents are more flexible and have smoother edges, thus reducing but not eliminating this risk. If balloon rupture occurs, the partially dilated stent needs to be stabilized while the ruptured balloon is exchanged for a new balloon. Learning the techniques to prevent stent malposition and stent embolization is of crucial importance. Techniques to reposition stents need to be considered carefully to avoid further complications, such as stent embolization into unsafe places such as within the right ventricle. Stent malposition can occur at any time during its delivery, implantation, and the balloon and wire removal phase of the procedure, so careful attention to minor details is important for a successful stent implant. Other significant complications include vascular injury such as dissection, aneurysm formation or rupture, reperfusion injury, jailing of the side branches, cardiac arrest, and rarely death. Specific techniques of how to avoid and manage such complications are beyond the scope of this chapter but are well described in the literature [36, 37]. More recently, dissections and aneurysms have been treated successfully with covered stents [16, 38, 39]. Reperfusion injury has also been reported, although more commonly with congenital branch pulmonary stenosis or severely obstructed vessels, where successful stenting may result in significant improvement of flow to the lung parenchyma supplied by the stented vessel (Fig. 62.6). Such injury may present with pulmonary edema in the affected segments occasionally requiring prolonged intubation and ventilation. In general, reperfusion injury resolves after 2–3 days. When a stenosis is adjacent to a

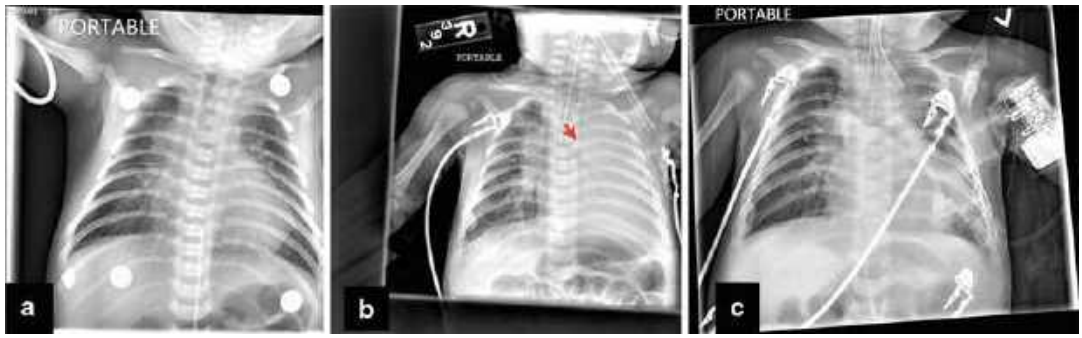

Fig. 62.6 Example of reperfusion injury of the left lung following successful stenting of a severe chronic obstructed LPA followed by resolution of edema over 2–3 days. (**a**) Initial pre-stent CXR showing clear lung fields bilaterally. (**b**) (6 hours) post-stent implantation in a hypoplastic LPA (*red arrow*) shows severe reperfusion edema of the left lung. (**c**) (48 hours) post-stent CXR now shows clearing of the edema

side branch, such as an upper lobe, placement of a stent necessitates jailing of that side branch. The degree of flow obstruction by the stent depends on the size and angle of the takeoff of the side branch and other factors. Judgment has to be exercised regarding the risks of losing flow to the side branch and the benefits of improving flow to the stented vessel. In general, the benefits of stenting a main branch to improve flow to the middle and lower lobes usually outweigh the risk of compromising flow to the upper lobes. This is demonstrated in overall reduction of right ventricular pressures after stenting in spite of flow obstruction to the side branches, during long-term follow-up [40] (Fig. 62.7). Overall, complications associated with stenting remain low. A multi-institutional study of 584 stent implants reported an incidence of 5.5 % (32/584) adverse events [22].

Fig. 62.7 Bilateral stents implanted in proximal branch pulmonary artery stenoses that spanned across the upper lobes resulted in jailed and compromised flow to upper lobes bilaterally (*red arrows*). Nevertheless, overall improvement in flow to lower lobes resulted in significant decrease in RV systolic pressures

Medium- and long-term complications include in-stent restenosis due to thrombosis or intimal proliferation. Although the causes of such complications are unclear, they can be successfully treated with further dilation or additional stenting. Restenosis rates range from 3 % to 9 % in the literature [41, 42]. To date, stent redilation due to restenosis and further dilation to accommodate somatic growth has been reported to be successful [41–43]. Stent fractures have also been reported ranging from 3 % to 21 % [44, 45] and may occur longitudinally or circumferentially (Fig. 62.8). Fortunately, no serious sequelae have been reported with this complication. Many fractures are thought to be caused by repetitive compression

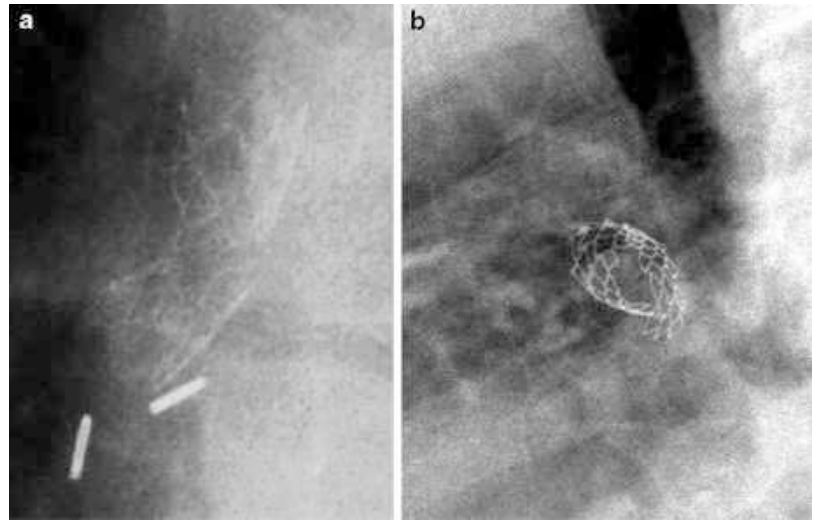

Fig. 62.8 (**a**) Circumferential stent fracture in AP projection. (**b**) Longitudinal stent fracture seen in lateral projection

by a dilated pulsating ascending aorta. Such fractures can result in restenosis which is easily treated with additional stenting to reinforce the pulmonary artery.

Outcome Data

Angioplasty

An early landmark paper by Rothman et al. reported criteria for success as (1) an increase of the predilation diameter by $\geq$50 %, (2) an increase of flow to the affected lung by $\geq$20 %, or (3) a decrease of >20 % in the ratio of the right ventricular to aortic systolic pressure [6]. Based on these criteria, there was 58 % (127/218) immediate success with vessel diameters increasing from 3.8 $\pm$ 1.7 mm to 5.5 $\pm$ 2.1 mm. The gradient decreased from 43 $\pm$ 20 mmHg to 13 $\pm$ 14 mmHg. However, the right ventricular to femoral artery systolic pressure ratio decreased only marginally from 84 $\pm$ 22 % to 72 $\pm$ 21 %. At follow-up, there was an incidence of restenosis of 16 % (5/32). Interestingly, in spite of the author's admission that the criteria were defined "arbitrarily," these have been used for success in most subsequent pulmonary artery angioplasty and stenting studies. Other studies have reported success ranging from 58 % to 64 % [5, 46].

High-Pressure Angioplasty

The introduction of high-pressure and ultrahigh-pressure angioplasty balloons has permitted another option of treating highly resistant stenoses in the pulmonary arterial tree. One report demonstrated 91 % success at relieving stenoses that were resistant to angioplasty with standard balloons as well as in eight cases of residual stenosis within a stented segment [12]. The diameters increased by a median of 36 %. In five cases, the ultrahigh-pressure balloon fractured the stent allowing further vessel expansion. There were no associated complications. The ability to fracture a maximally expanded stent may extend the use of smaller size stents in the pediatric age group.

Cutting Balloon

The largest multicenter trial reported experience of 73 patients who underwent angioplasty with

cutting balloons on 107 vessels compared with high-pressure angioplasty in 66 vessels [9]. Cutting balloon angioplasty therapy resulted in 85 % increase in lumen diameter compared with 52 % in the high-pressure angioplasty cohort. Furthermore, 26 of those vessels treated with high-pressure angioplasty crossed over to cutting balloon therapy experienced an additional 48 % increase in lumen diameter. The final diameter in the cutting balloon cohort was 99 % greater than the initial diameter with no serious adverse events related to the treatment in a study vessel.

Stent Implantation

Many reports have shown excellent immediate outcomes with up to 100 % success rates [25, 47–49]. In general, two-ventricle patients showed a decrease in the right ventricular systolic pressure from a mean of 2/3 systemic to 1/2 systemic pressures. The mean gradients decreased from about 40 to 14 mmHg, while the mean vessel diameters increased from 4.4 to 9.2 mm.

Long-term data of up to 15 years follow-up among the first cohort of patients, who received pulmonary artery stents at Texas Children's Hospital, report that the majority of these patients remained asymptomatic with acceptable right ventricular pressures (<50 % systemic), and 91 % of the patients were in NYHA class I–II as adults [40]. Seven patients, who underwent subsequent surgery to treat associated lesions, did not require surgery on the pulmonary arterial tree.

Comparing Angioplasty and Stent Implantation

In general, angioplasty papers report success rate ranging from 53 % to 72 % and restenosis rates ranging from 16 % to 35 % [5, 6, 46, 50]. Stent papers report higher success rates of 95–100 % with lower restenosis rates of 3–12 % [25, 41, 42, 47–49].

Future Developments

A major disadvantage of implanting stent in a growing child is the need to dilate the stent further as the patient grows to adult size. While this is achievable with currently available large stents, additional procedures may be needed, which carry intrinsic risks. Biodegradable stents are still under development and may obviate the need for further dilation in the future. It will be possible to implant these stents to relieve obstruction and cause remodeling to normalize the caliber of the pulmonary arteries during infancy. Subsequently, the stents dissolve and the need for additional dilation or surgical removal is avoided. Prototypes for coronary vessels have been developed, but none are available commercially nor in the sizes needed for the pulmonary arteries at the present time. Rare case reports of the use of these stents in preterm infants have been published [51, 52]. Other strategies have been reported for infants and small children. Both the "open-ring" stent and the "growth" stent utilize the principle that longitudinally cut stents that are sewn back together with absorbable sutures can be implanted in infancy. Over time, these sutures dissolve leaving an "open ring" and permitting further dilation to a much larger diameter after somatic growth of the child [53, 54]. The use of these experimental stents has been reported, but long-term data are still lacking. Recently, there have been case reports of using ultrahigh-pressure balloons to intentionally fracture an implanted small stent in children [12]. Again, there is no long-term data to demonstrate that these vessels can be dilated to adult size currently.

Conclusion

Angioplasty and stent implantation are important treatment strategies for branch pulmonary arterial stenoses, which began in the 1980s. Improvement in balloon technology has resulted in the availability of high-pressure, ultrahigh-pressure, and cutting balloons with increasingly smaller

profiles, enabling their use in infants and small children as well as rendering more effective dilations in the distal branches. Improvements in stent design along with smaller delivery systems and hybrid techniques have extended their use to the neonates and in early postoperative stenoses. Innovative strategies to "tailor" the stent to fit ever increasingly complex anatomy have been used to permit further rehabilitation of the hypoplastic pulmonary arterial tree over time. At present, there are very few instances of branch pulmonary artery stenosis that cannot be improved with currently available technology. However, the learning curve of these procedures is steep, and the pediatric interventionist must be familiar with all the available equipment and techniques as well as how to anticipate and manage complications. The clinician should also be familiar with these procedures in order to make appropriate referrals.

Catheter-Based Interventions on Left Ventricular Outflow Tract

63

Otto Rahkonen and Lee Benson

Abstract

Left ventricular outflow tract obstruction can occur below, at, or above the aortic valve or as mid-muscular subvalvar obstruction. In children, the most common level of obstruction is aortic valve stenosis and comprises a heterogeneous anatomic spectrum, from an atretic valve (with or without a hypoplastic left ventricle) to an isolated lesion with normal sized but stenotic valve leaflets.

Supravalvar aortic stenosis is rarely suitable for a percutaneous intervention due to its diffuse nature and there is limited experience with the discrete fibrous expression of obstruction. Efficacy of percutaneous aortic valve dilation has been clearly demonstrated in literature and is the therapeutic procedure of choice in most centers in children, however; secondary aortic valve surgery seems to be inevitable for a significant number of the patients in long-term follow-up due to acquired regurgitation. Despite advances in catheter technology and procedural techniques, aortic valve dilation continues to be associated with a higher complications risk than other standard percutaneous interventions, ranging from 10 % to 30 % in the current era. Fetal aortic valve dilation has also been shown as an alternative intervention in selected fetuses to avoid the development of hypoplastic left heart syndrome; however, experience is limited and more studies are needed.

Introduction

Left ventricular outflow tract (LVOT) obstruction can occur at valvar, subvalvar, or supravalvar levels, or at more than one site in the same patient. Supravalvar aortic stenosis is rarely suitable for a percutaneous intervention, and there is limited experience with discrete fibrous subaortic stenosis (see below). The obstruction due to hypertrophic cardiomyopathy and rarer forms of LVOT due to a restrictive ventricular septal defect in the setting of obstructive systemic ventricular anomalies (e.g., left atrioventricular valve atresia and a normal aortic root) will not be addressed in this chapter. Interventions for valvar aortic stenosis are reviewed in detail while other lesions of LVOT tract are briefly overviewed. Percutaneous aortic valve dilation has become the therapeutic procedure of choice in most centers for congenital aortic valve stenosis in infants, children, and adolescents, with valve surgery reserved for non-dilatable or poorly responsive lesions or those with hemodynamically significant aortic regurgitation.

Balloon Dilation of the Aortic Valve

Anatomy

Congenital aortic valve stenosis (AVS) accounts for 3–6 % of all congenital cardiac lesions [1] and males are affected 2–3 times as often as females [1–3]. In the pediatric population, AVS comprises a heterogeneous anatomical spectrum, from the nearly atretic valve with a small annulus, often in association with a hypoplastic left ventricle, to the isolated lesion with a normal sized annulus (often with a bicuspid valve) (Fig. 63.1). In the neonate, the aortic annulus is often hypoplastic and associated non-valvar lesions are frequently present, such as left ventricular fibroelastosis and hypoplasia, mitral valve anomalies, and aortic arch obstruction. Additional left-sided congenital heart defects are found in about 25–30 % of children treated for aortic stenosis [3–5]. The valve leaflets are invariably thickened and the commissures are fused to varying degrees (Fig. 63.2). The anatomical subtypes of stenotic valves include unicuspid, bicuspid, tricuspid, quadricuspid, and undifferentiated valve leaflets. The majority of such valves are bicuspid (BAV) [6, 7], although, functionally normal BAVs are also a common anomaly. Fusion of the right and noncoronary leaflets are associated with a twofold increased risk of stenosis and/or regurgitation compared with other forms of BAV [8, 9]. A recent single center study of 981 patients with or without stenosis demonstrated that only 4 % required an aortic valve intervention during childhood [10]. This study excluded those with neonatal critical aortic stenosis, so the conclusions are not applicable to the entire BAV cohort. Unicuspid and bicuspid dysplastic valves are seen more commonly in infants. Conversely, a tricuspid aortic valve is more likely seen in older children and adults with AVS (40 %).

Pathophysiology

Neonatal presentations can vary from those with few if any symptoms and good left ventricular performance to cardiovascular collapse, ductal-dependent systemic blood flow, and poor myocardial function in part due to an elevated end-diastolic pressure limiting coronary blood flow with resulting myocardial ischemia. ECG changes are common in severe neonatal AVS and are a risk factor for sudden cardiac death [1]. Most patients with severe AVS may die suddenly [1, 11]. Outside the neonatal period, infants and children are

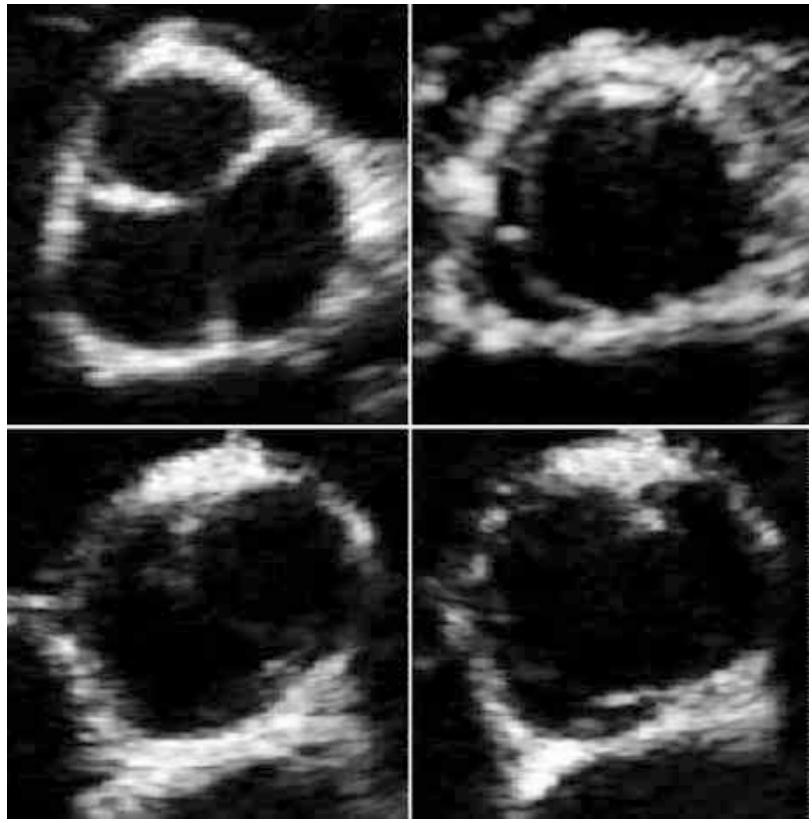

Fig. 63.1 Echocardiographic views (short axis at the base) of a normal tricuspid aortic valve (*top panels*: *left* – during diastole; *right* – during systole) and in the *lower panels*, a dysplastic bicuspid aortic valve (systole – *left panel*, diastole – *right panel*)

generally asymptomatic in the early stages of the disease. The valvar obstruction causes left ventricular pressure overload, resulting in an increased left ventricular wall thickness and, in later stages, chamber dilation. Relaxation is abnormal due to the chamber hypertrophy and as a compensatory mechanism for prolongation of the ejection time. As the disease progresses, the elevated filling pressure and compromised coronary filling can result in ischemia especially during exercise when increased oxygen demands of the myocardium are not adequately met. Inability to increase cardiac output during exercise can be a manifestation of the severity of the outflow obstruction. This can be seen as inadequate blood pressure response during the exercise. Common symptoms include fatigue, decreased exercise capacity, failure to thrive, arrhythmias, and syncope.

The severity of the lesion is graded as mild, moderate, severe, or critical on the basis of hemodynamic and natural history data. In adolescents and adults, the AHA/ACC consensus guidelines for grading the severity of stenosis include: aortic jet velocity, mean pressure gradient, and valve opening area [12]. In severe stenosis, the valve area is <1 cm^2, mean gradient is >40 mmHg, and jet velocity is >4 m/s. Moderate stenosis is defined as valve area 1.0–1.5 cm^2, mean gradient 25–40 mmHg, or jet velocity 3.0–4.0 m/s, and mild as a valve area >1.5 cm^2, mean gradient <25 mmHg, or jet velocity <3.0 m/s. Critical AVS is characterized by severe stenosis with ductal-dependent systemic circulation or depressed left ventricular systolic function regardless of the gradient. In children, the resting peak-to-peak gradient (peak left ventricular

systolic to peak aortic systolic pressure) is used to grade severity [5, 13, 14]. Management strategies in children were studied by Khalid et al. in a study that included 25 centers (15 from the United States and 10 from Europe, Australia, and Asia) [14] noting that most centers use the following criteria for grading of severity: peak-to-peak gradient <25 mmHg (mean <25–40 mmHg) for mild stenosis and peak-to-peak gradient >50–60 mmHg (mean >45–64 mmHg) for severe stenosis, which is in general agreement with the AHA/ACC consensus guidelines for children and adolescents [5].

Balloon Dilation

Aortic valve balloon dilation was first performed in older children in 1984 [15], and in 1986, the first procedure was reported in a newborn [16]. With improved catheter technology and technique, balloon dilation has proven an effective initial palliation in all age groups with a 1–14 % early mortality, 65–90 % survival at 10–15 years and 48–54 % freedom from re-interventions at 10 years [2–5, 17–20] (Table 63.1). Circa 2011, in most major pediatric centers, balloon dilation is a treatment of choice in childhood [14, 21]. Risk factors for death include patient age <1 month, additional left-sided obstructive lesions, depressed pre-dilation left ventricular function, need of mechanical ventilation prior to the procedure, and infants with a small aortic valve [2–5, 17–20].

One of the largest European series on balloon dilation for congenital AVS reviewed 1,004 infants and children (median age 3.6 months), with one third being neonates [2] and a median

[a] = at 12 years; [b] = acute post-dilation aortic regurgitation (moderate to severe); [c] = study included only neonates; [d] = early <30 day mortality was excluded; [e] = at 10 years; [f] = for <1 month/>1 month age groups; [g] = early mortality

follow-up 32 months (range 0 days–17.5 years). The pressure gradient decreased acutely from 65 to 26 mmHg and significant (moderate to severe) regurgitation was present in 1 %. The reported peri-procedural mortality (within 30 days of the procedure) was 9 % in neonates and 0.3 % in infants and children. All peri-procedural deaths occurred in infants <1 year of age. Independent of age, freedom from surgery at 5 and 10 years was 70 % and 50 %, respectively.

Boston Children's Hospital reported their single center results of intermediate and longer-term follow-up in 563 children [5], a quarter (22 %) treated as neonates with a median follow-up of 9.3 years (0.1–23.6 years) for the cohort. Two-thirds (320 of 563) had isolated AVS. After the procedure, the peak outflow gradient decreased from 65 to 28 mmHg with significant (moderate to severe) regurgitation present in 14 %. Freedom from all re-interventions (surgical or percutaneous), 5 and 10 years after the procedure, was 72 % and 54 %, respectively. Overall survival was 93 % at 19 years, but those children converted to a univentricular circulation and/or died under 30 days after the procedure were excluded ($n = 19$; 3.4 %). In this series, factors associated with longer freedom from any aortic valve surgery were lower outflow gradient and degree of aortic regurgitation after the procedure, but age and pre-dilation gradient were not. These risk factors are concordant with previously published data, however; neonates have been shown to have higher re-interventions rates in other studies [4, 5, 19, 22, 23]. Additional risk factors for re-intervention identified in other series included a smaller aortic annulus diameter, younger age at the time of the initial procedure, presence of a symmetric valve opening, and a bicuspid aortic valve [3, 7, 24]. A 2011 study by Maskatia et al. from Texas Children's Hospital found an association between depressed left ventricular function before the procedure and the risk of re-intervention [20].

While these studies have validated the use of balloon dilation in AVS, there are no prospective randomized studies comparing outcomes between surgical and percutaneous approaches. Retrospective studies comparing the outcome of surgical and percutaneous procedures have been published showing comparable results [21, 25–27]. Freedom from death and re-operation are similar for the two groups; however, such

Table 63.2 Indications for transcatheter treatment of aortic valve stenosis [12, 13]

	Indications	
	Neonates	Children and adolescents
Symptomatic with critical AVS[a]	Regardless of gradient: presentation with low cardiac output, severe left ventricular dysfunction, or a ductal-dependent systemic circulation	Depressed left ventricular systolic function
Symptomatic[a] (children presenting with ischemia, syncope, or ST-T changes on ECG at rest or with exercise)	Resting peak systolic gradient >40 mmHg at catheterization or Doppler peak-to-peak gradient >40 mmHg (mean Doppler gradient >40 mmHg)	
Asymptomatic[a]	Resting peak systolic gradient >50 mmHg at catheterization[b] or Doppler peak-to-peak gradient >50 mmHg (mean Doppler gradient >40–50 mmHg)	

[a] = Balloon dilation is not indicated if significant AR is present (surgical intervention); [b] = Valve dilation may be considered even with peak systolic gradient <50 mmHg (by catheter) if patient is anesthetized and non-sedated Doppler study demonstrates Doppler peak-to-peak gradient >50 mmHg (mean Doppler gradient >50 mmHg)

studies are limited (as all retrospective reviews) as being nonrandomized, and have nonhomogeneous (age and morphology) groupings. As such, the long-term outcomes either percutaneous or surgical are palliative, and many of these children will ultimately need further interventions. An additional observation after balloon dilation is in the case of a small aortic annulus, where successful dilation has been shown in some, to lead to normalization of the valve diameter and left-sided structures within 2–3 years of the procedure [28, 29]. With the application of balloon dilation as the initial intervention, surgery can often be delayed for many years and most often only to address significant regurgitation rather than recurrent stenosis.

Indications for Intervention

Echocardiography confirms and complements the clinical observations to provide pertinent morphological and hemodynamic information defining severity of the lesion, and indications for the intervention. MRI is rarely required to obtain additional anatomical views of the ascending aorta, coronary arteries, determine gradients, or regurgitant fraction in older children and adolescents. The central question to be considered in the setting of neonatal critical AVS is whether a biventricular repair can be achieved or should a child undergo univentricular palliation. Several studies have shown a correlation between various left-sided structures or hemodynamic findings and survival after a biventricular repair [26, 30–32] and include left ventricular size, degree of endocardial fibroelastosis, aortic root and mitral valve diameters, direction of flow in the ascending aorta, and left ventricular mass. A study addressing this issue by Hickey et al. [33] was based on the Congenital Heart Surgeon´s Society Data and included 362 neonates with critical LVOT obstruction (139 neonates in the biventricular group) and found risk factors for death after a biventricular repair being the minimum left ventricular outflow tract diameter, presence or absence of endocardial fibroelastosis, left ventricular dysfunction, and a small mid-aortic arch. The study established a Univentricular Survival Advantage Prediction Tool, which calculates the advantages for patient selection in borderline cases (http://www.ctsnet.org/aortic_stenosis_calc/). Such published treatment algorithms are useful guides, but as they are based on retrospective data, they are limited and should be applied with care [32].

Indications for aortic valve balloon dilation are the same as for surgery (Table 63.2) [13]. In the neonate, intervention is indicated for AVS with left ventricular dysfunction, a low cardiac output state, or a ductal-dependent systemic circulation regardless of the aortic valve gradient. In addition, asymptomatic neonates with left ventricular hypertrophy and ECG changes of myocardial ischemia (LVH with strain) are at risk of sudden death [1, 11] and balloon dilation should

be considered even if the gradient is at the lower limits for intervention. Outside the neonatal period, widely accepted indications in the asymptomatic child include an estimated peak-to-peak echocardiographic gradient of >50 mmHg (see below), a mean gradient >40 mmHg, or peak resting systolic valve gradient >50 mmHg measured by catheter [13, 14, 30, 34–36]. Associated clinical findings include left ventricular hypertrophy with strain, ST-T wave changes indicative of myocardial ischemia at rest or with exercise, and reduced exercise tolerance. When these later findings are present with a resting valvar gradient (by catheter) >40 mmHg, balloon dilation can be considered [13]. Peak instantaneous pressure gradients measured using Doppler echocardiography overestimate the so-called peak-to-peak gradient [37, 38], the latter being a measure of a nonsimultaneous cardiac event. As such, peak-to-peak gradients can be noninvasively estimated by echocardiography from the following formula: peak-to-peak systolic gradient = 6.02 + 1.49 × (mean gradient)−0.44 × (pulse pressure). The mean gradient can be measured by echocardiography and the pulse pressure measured by blood pressure cuff. This kind of assessment has been found very useful in grading AVS severity and guiding the timing of intervention. When evaluating echocardiographically derived variables, it should be remembered that the results are flow dependent and in the setting of a low cardiac output, a low transvalvar peak velocity may be obtained. In pediatrics, valve areas are rarely employed to determine lesion severity as in the adult, primarily due to the inherent measurement errors when applied to small structures [12, 13]. In the presence of aortic valve regurgitation, Doppler echocardiography will overestimate the degree of obstruction. In children with moderate or more than moderate aortic regurgitation, surgical treatment is preferred to balloon dilation.

Newborns with critical AVS frequently present in cardiogenic shock. If a fetal diagnosis of critical AVS is suspected, these babies should be delivered in hospitals where cardiovascular surgery and catheter interventions are available. Newborns with critical stenosis should be mechanically ventilated and sedated to decrease oxygen consumption, and prostaglandin should be started to provide systemic blood flow through a patent arterial duct.

Technique

General anesthesia is normally used in the pediatric age group. Biplane imaging systems can streamline the procedure, but single plane rooms are frequently used as well. The F_i0_2 should be increased to 1.0 before the dilation (after hemodynamic measurements are obtained). The goal of the procedure is to decrease the gradient as low as possible without inducing significant aortic valve regurgitation. In general, a final aortic valve gradient of <50 % of that before dilation is considered successful. Choosing the correct balloon size is critical for a successful procedure. In an experimental animal model and in autopsy series, it has been shown that balloon dilated stenotic aortic valves rupture along the lines of least resistance, not necessarily along the natural commissures and depending on the direction of the force vector generated by the balloon [39, 40]. In the late 1980s, the impact of the balloon size compared to the annulus diameter was studied in the animal model [39] and demonstrated that a balloon to annulus ratio of >1.1 could result in damage to the valve leaflets and tears or hematomas of the interventricular septum, valve annulus, and mitral valve. The incidence of aortic regurgitation and complications after the procedure have been shown to correlate with ratios >1.0 in several patient series [17, 29, 39]. Other studies, however, have not shown that correlation [2, 3, 7, 41]. That may be due to the use of smaller initial balloons or because the initial balloon to annulus ratio did not exceed 1.0 and larger balloons were chosen only if the first dilation was ineffective. Current clinical practice is to choose a balloon with a diameter that is approximately 90 % of the annulus. If the aortic valve gradient is not reduced sufficiently and significant regurgitation has not developed, the balloon diameter can be increased up to a ratio of 1.1. If a double-balloon technique is used, the combined major diameter of the two balloons is not more than 1.3 times the diameter of the valve annulus [42, 43]. The double-balloon technique has been

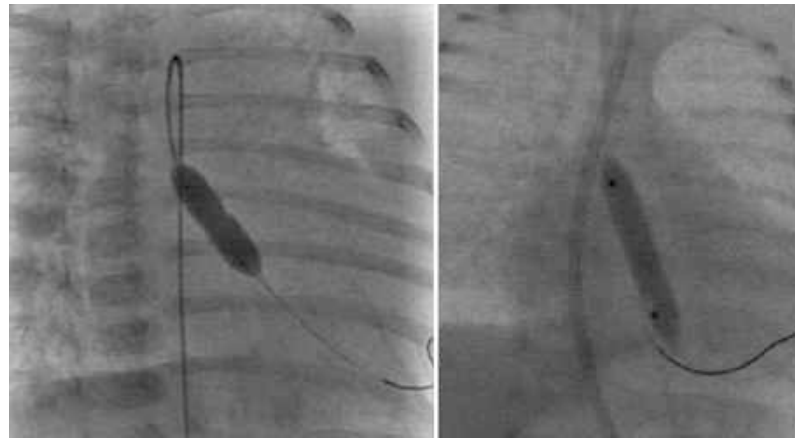

Fig. 63.3 Balloon dilation of the aortic valve from a retrograde (*left panel*) and trans-carotid (*right panel*) approach, anteroposterior projections. In each case, a coronary wire is used to guide the balloon catheter

suggested to have several technical advantages including use of smaller introducers (decrease femoral artery complications), avoidance of complete LVOT obstruction, decreased balloon movement and dislocation during the procedure, and better anatomical positioning in bicuspid aortic valve orifice, but numbers are limited in published series [4, 43, 44]. In older children and adolescent with larger valve annuli, the double-balloon technique allows avoidance of very large single balloons, which may be unwieldy. The aortic valve annulus diameter may be obtained from cross-sectional echocardiographic imaging (short axis and parasternal long axis views) or angiographically at the time of the procedure, either from an aortogram or left ventriculogram. Current advances in catheter and balloon technique have reduced the sheath size used in single balloon techniques; however, no publications comparing double and single balloon techniques in the current era exist.

Access

Various sites have been used to approach the aortic valve including the right common carotid or axillary arteries, umbilical artery or vein, or transvenous antegrade or transfemoral retrograde access (Fig. 63.3). All have their own advantages and disadvantages. Currently, the transfemoral arterial retrograde technique is the most widely used and is the preferred technique in most centers. In the neonate, an antegrade transatrial approach may be associated with a lower risk of aortic regurgitation [29, 45].

Femoral artery and vein access are generally obtained, the latter for insertion of a temporary pacemaker (Fig. 63.3). A 4 Fr. introducer is placed in the femoral artery for neonates and small babies, and 5 or 6 Fr. introducers are used for older children and adolescents. Sometimes a small introducer is placed in the contralateral artery for monitoring purposes. A 5 Fr. venous introducer is all that is required for the pacing wire. In the sick neonate, arterial access can sometimes be the most difficult part of the procedure; and there is always the risk of an arterial complication (thrombosis or laceration). As such, alternative sites, e.g., carotid artery cut down, has become a reliable access point with few complications or an umbilical approach can potentially be used [46, 47]. Vascular complications are the most frequent (discussed below).

Retrograde Approach

Once access is obtained, heparin sulfate (50–150 IU/kg) can be administered with monitoring of the ACT level. There are a variety of approaches to the conduct of the procedure. A pigtail catheter can be placed in the ascending aorta just above the aortic sinuses for aortography to: (1) orient the operator to the plane of the valve (the hemodynamic orifice) from the jet of unopacified blood exiting the ventricle and assists in crossing the lesion, (2) document the presence

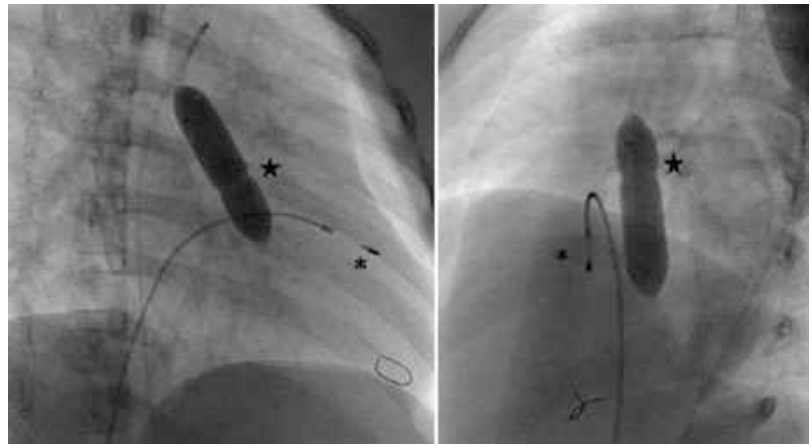

Fig. 63.4 Balloon dilation of the aortic valve, note the typical waist seen during inflation (*star*), *left* and *right panels* same projections as in Fig. 63.2. A pacing wire is in the right ventricular apex (*asterisk*)

of aortic regurgitation, and (3) to measure the valve annulus (see above). Some operators will not obtain an ascending aortogram and cross the valve, perform a left ventriculogram (LAO-cranial; RAO), and measure the valve annulus from the ventricular injection in either angiographic projection as the hinge point to opposite hinge point of the leaflet attachments. For critically ill and unstable neonates, balloon dilation could be performed without angiography, the procedure and the decision of balloon size based on real-time echocardiography [48]. A variety of catheters may be required to cross the valve (Judkins or Amplatz right coronary catheters, Cobra or multipurpose catheters, just to name a few). The valve is crossed by using soft-tipped wire (0.018″–0.035″), such as a 0.035″ glide wire. In small neonates, a 0.014″ coronary guide wire can be used. Most commonly, the hemodynamic orifice is situated between the left and noncoronary cusps, with the orifice pointing posterior and from left to right. Before the catheter is advanced over the wire, correct wire position in the left ventricle should be confirmed, as wire can be easily pass into the left coronary artery. There are several options for obtaining outflow gradients: nonsimultaneous, as the operator goes from aorta to left ventricle, a method most often used, or advancing a balloon tipped catheter into the left ventricle across the atrial septum and measuring simultaneous pressures with a catheter in the ascending aorta, or crossing the valve with a pressure wire. After the gradient is defined, a pigtail catheter may be advanced into the left ventricle over the wire for angiography. Subsequently, a J-shaped stiff wire is placed in the left ventricle, the selection of which depends on the size of balloon catheter which will be used. A low profile balloon is normally chosen with a diameter approximately 90 % of the annulus (as discussed above). Ideally, such balloons should have short inflation/deflation times. In neonates, balloon catheters with a length of 2 cm are normally used, and in older children and adolescents, 3–5 cm balloons selected. Rapid right ventricular pacing is normally used during inflation (see section below), but may not be necessary in those neonates with critical stenosis and profoundly reduced ventricular performance. Inflation is by hand, until the waist is abolished and the balloon is fully inflated using as short an inflation/deflation cycle (<5 s) as possible (Fig. 63.4). In neonates, a waist may not be seen. When the balloon is deflated, it should be pulled back to the descending aorta, not left in the ascending aorta or across the valve, with hemodynamic measurements repeated. If the hemodynamics are acceptable (usually ~50 % gradient reduction expected), aortography may be obtained to grade the degree of and to exclude vascular wall complications [49] or the assessment may be left to transthoracic echocardiography after the procedure. Left ventriculography is not routinely performed. If the gradient reduction is not sufficient and there is no significant regurgitation, a 1–2 mm

larger balloon can be tried or if the balloon did not straddle the valve, dilation should be repeated with the same diameter balloon. In critically ill neonates, with low cardiac output, the gradient is often low before the dilation. In these children, the aortic valve gradient can remain the same after a successful dilation and the operator can often see an increase in the gradient days after the procedure due to improved left ventricular function.

Balloon Stability During Dilation

To improve balloon stability during dilation, rapid right ventricular (RV) pacing or intravenous adenosine administration can be tried, although rarely required in the critically ill neonate. Pacing reduces the stroke volume and adenosine induces profound bradycardia by transient atrioventricular block, both of which decrease the likelihood of the balloon being forcefully ejected from the left ventricle during inflation. RV pacing, first suggested by Frank Ing [50], and the use of adenosine are effective [51, 52]; however, the reliability of pacing has supplanted the use of adenosine in most procedures. A recent paper by Navarini et al. from Turkey described a technique where the guide wire was used for pacing from the left ventricle during the procedure, thus avoiding femoral vein access [53]. During the procedure, pacing is begun just before inflation and stopped once the balloon is deflated. Some have suggested that RV pacing reduces the severity of aortic insufficiency, reducing the trauma to the valve, as there is little movement of the balloon at full inflation.

Antegrade Approach

A variety of approaches can be used to perform the dilation from an antegrade entry to the LVOT. This technique is generally used in the critically ill neonate to avoid arterial access, and to assure that the hemodynamic orifice is crossed (avoiding perforation of the valve leaflets). Early experience in the older child resulted in damage to the mitral valve due to difficulty in balloon stability; although techniques to secure balloon position (see above) were not used at the time. An angiographic catheter is placed across the atrial septum into the left ventricle for pressure measurements and angiography. Any number of end-hole catheters can then be used to cross the mitral valve (e.g., Judkins right or cobra shaped) and a coronary wire advanced through the left ventricle, across the aortic valve and secured in descending aorta preferably at the level of the femoral artery, where it can be compressed externally to achieve wire stability. After wire position is achieved, a balloon catheter (coronary balloon or very low profile balloon such as a Tyshak Mini®; Numed, Cornwall NY) is advanced across the atrial septum and mitral valve to the level of aortic valve and dilated.

Aortic Valve Dilation in the Fetus

Aortic valve dilation has been suggested as a technique in selected fetuses to avoid development of hypoplastic left heart syndrome (HLHS), to encourage the growth and development of the left ventricle. This followed from data which documented some fetuses with critical AVS (and a near-normal sized left ventricle) may have arrested left heart development and develop the HLHS [54–56]. The therapeutic goal therefore in this setting is to alter the "natural history" of critical AVS in utero. Only those fetuses at risk for the development of HLHS, a patent mitral and aortic valve, and near-normal sized left ventricle are suitable for this fetal intervention anticipating a biventricular circulation. The anatomical features are heterogeneous, with some of the manifestations due to the consequences of abnormal myocyte function (i.e., cardiomyopathy), further complicating and challenging proper selection for the procedure [36, 55]. To date, experience is limited with few centers publishing follow-up data; however, results are promising [57, 58]. Indications are not well established, but critical AVS with the potential for evolving into the HLHS has been suggested and includes a left ventricular long and short axis length Z-score >0 SD, mitral valve diameter Z-score > -2, aortic valve diameter Z-score > -3.5, a mitral valve or aortic valve maximum gradient >20 mmHg [59].

Additionally, fetuses with critical AVS demonstrate left to right atrial shunting, retrograde aortic arch flow, monophasic mitral valve flow, and left ventricular dysfunction. The largest study thus far originates from Boston Children's Hospital [58] and included 70 fetuses with a median gestational age of 23 weeks (range 20–31 weeks). Technical success was achieved in 74 % of the cases while only a quarter achieved a biventricular circulation after birth (a third of the fetuses with a technically successful procedure). Two-third of the fetuses required single ventricle palliation after birth. All of the neonates with biventricular circulation at birth needed subsequent re-intervention, but only one child needed surgical aortic valve replacement. In the biventricular group, the most common (80 %) re-intervention after birth was aortic valve balloon dilation. In the fetal procedure, the median balloon to annulus ratio was 1.11, with aortic regurgitation (AR) observed in two-thirds of the fetuses after a technically successfully intervention. Similar to postnatal valve dilation, a larger balloon to annulus ratio was associated with a higher incidence of aortic regurgitation, however and most interestingly, it was well tolerated, and resolved in all but one child during follow-up [58, 60]. A recent paper from Europe included 23 fetuses in whom procedures were performed at median gestational age of 26 weeks [57]. In 70 % of the fetuses, the procedure was successful with only one intrauterine death. Two-thirds of fetuses with a technically successful intervention achieved a biventricular circulation. However, 60 % of those required surgical outflow tract reconstruction, in contrast to the Boston data. Proper indications for this procedure are not clear at this time, due to the varied manifestations of the syndrome, difficult selection, and technical challenges.

Technical details are only briefly overviewed here. A specific chapter is available in the section dedicated to fetal cardiology in this book. In no small part, the key to success is the creation of a team approach to management, involving an interventional obstetrician, fetal echocardiologist, and interventional cardiologist, in addition to a supporting environment for care of the mother and family. The mothers are positioned to achieve an ideal position of the fetus, such that the fetal chest is anterior and there is a clear path for the needle. This can take some time and requires considerable patience and often postponement of the procedure until the fetus is in the correct position. Occasionally, manual positioning is required. If satisfactory positioning of the fetus is not achieved, some have advocated a limited laparotomy to allow direct uterine manipulation. A fetal analgesic and paralytic agent is administered. Under ultrasound guidance, an 18 or 19 gauge needle with trocar is advanced through the fetal chest wall and into the LV cavity. A coronary guide wire is inserted through the needle and maneuvered across the aortic valve. A low profile coronary balloon catheter is then inserted through the needle lumen across the valve and inflated. Use of a pressure wire during the procedure has been recently been reported which may improve understanding of fetal hemodynamics before and after the intervention [61]. Contrary to pediatric aortic valve dilation (see above), a higher balloon to annulus ratio has been used in the most recent reports (1–1.2) [57, 58, 60].

Complications

Despite advances in catheter technology and procedural techniques, aortic valve dilation continues to expose the child to a variety of complications occurring in 10–39 % of cases in the current era [2, 4, 19, 62]. Early periprocedural mortality has been reported in 4–9 % of neonates [2, 4, 29] and as a group, associated with a higher complication rate risk than in older children. In the largest European series of 1,004 cases [2], the complication risk in newborns was 15 % compared to that of 6 % outside the neonatal period, with the most common complication being arrhythmias or vascular. In the European series, the risk for developing moderate to severe aortic regurgitation immediately after the procedure was low (1 %) compared to other published results, with that degree of regurgitation developing in one third

of those who subsequently required surgical intervention in follow-up.

Vascular arterial complications (femoral) are of concern especially in neonates, and alternative approaches (see above) have been investigated (antegrade transvenous, or retrograde by umbilical, axillary, or carotid approaches). The development of smaller French sized catheters and balloons have reduced such risk and so, the retrograde femoral artery approach remains the most common technique applied today. In contemporary series, arterial complications have been reported in 2.6–35 % of cases [2, 4, 19, 62]. Careful surveillance and early detection of arterial compromise is essential and should lead to interventions to recannulate the vessel (e.g., heparin sulfate infusion, thrombolytic therapy, or long-term anticoagulation) to prevent permanent vessel injury and limb vascular insufficiency. Another issue, particularly in the critically ill newborn, is the development of ventricular arrhythmias, where a wire or catheter can trigger a life-threatening rhythm. The overall risk for significant (moderate to severe) aortic regurgitation is 1–29 % [2, 4, 19, 29], and seems to increase over time even when not present after the procedure [19, 20, 25, 29]. Identified risk factors for aortic regurgitation are a balloon to annulus ratio >1.1, preexisting regurgitation (more than mild), depressed left ventricular function (before dilation), older age, and larger annulus diameter [5, 7, 17, 20]. In addition, Maskatia et al. reported that AR was inversely related to a gradient after the procedure [20]. In older children and adolescents, the increased risk for aortic regurgitation may be explained by a more unstable balloon during inflation and/or degenerative changes of the aortic valve. Correct balloon sizing and avoidance of balloon movement during inflation may help to decrease its incidence. A relatively common finding ($\sim$15 %) when sought after balloon dilation is aortic wall injury; the most common expression is an intimal flap, but its long-term clinical significance is unknown [49]. Rare, but potentially life-threatening complications also include embolization, mitral valve damage, coronary ostial lesions, and tamponade due to chamber perforation. Nevertheless, balloon dilation carries no higher risk of complications than primary surgery and should be favored as the first-line palliation.

Post-catheterization Management

Generally, the children remain in hospital overnight for observation, although the older child and adolescents may be discharged after 6–8 h of observation. Careful observation of the access sites is important and any weak or absent pulse should be treated aggressively. Echocardiography is generally performed prior to discharge.

Balloon Dilation of Subaortic Stenosis

Anatomy

The pathological anatomy of subaortic stenosis (SAS), at first glance a simple discrete obstruction in the LVOT, is in fact complex involving additional structures in the outflow tract and can be very heterogeneous. As in AVS, subaortic stenosis can be associated with other left-sided anomalies and/or ventricular septal defects in 25–30 % of cases [63, 64] and commonly associated with a BAV [65]. If a ventricular septal defect is present, obstruction is often caused by posterocaudal deviation of the outlet septum, with anomalous attachment(s) to the left atrioventricular valve or anomalous tissue tags. In the setting of hypertrophic cardiomyopathy, basal septal hypertrophy causes dynamic stenosis with the anterior leaflet of the mitral valve drawn into the outflow, resulting in outflow obstruction. When the ventricular septum is intact, SAS is commonly discrete, and occurs in three general subtypes: a so-called membranous type (although it is not a true membrane), a fibromuscular collar, or a tunnel-like obstruction. The membranous lesion is the most commonly encountered [66, 67]. Recently, Suarez de Lezo and colleagues from Spain reported their experience with percutaneous therapy [68], for the thin membranous type lesion, an approach that was originally reported several decades ago, and may be useful in certain unique clinical situations.

Discrete SAS

The mechanism leading to the development of discrete SAS is unknown, but the lesion can be acquired as well as congenital [63, 69, 70]. The most frequently observed form is that of a thin muscular "membranous-like" (1–2 mm in thickness) circumferential or crescent-shaped fixed obstruction within the LVOT. Abnormal flow conditions, due to differential alignment of the ventricular septum and aortic annulus, have been suggested as possible mechanisms for formation of the obstruction [71]. Although classified as a congenital heart defect, discrete SAS can present at any age, is rarely diagnosed in newborns but often manifests in the first decade of life with features of a progressive disease. Additionally, it can present after surgical interventions such as after repair of some forms of partial atrioventricular septal defect, further indicating its acquired nature. The high velocity subaortic jet may damage the aortic valve and lead to aortic regurgitation. The distance between the lesion and aortic valve cusps varies and may affect the risk of aortic regurgitation, the greater the distance the less likely the chance of the latter developing. Aortic regurgitation is commonly associated with acquired SAS and its progression may be rapid [72, 73]. The presence of aortic regurgitation is an indication for repair regardless of type or mode of presentation, although regurgitation may progress even after successful surgical resection [55, 73]. Treatment is surgical for all forms of the disease when significant aortic regurgitation is present.

In the early stages of the disease, most children are asymptomatic. Indications for intervention include an instantaneous Doppler gradient of >40–50 mmHg (mean gradient >30–35 mmHg) with or without ECG changes or symptoms (such as exercise intolerance or chest pain) [74]. Surgical relief is effective, with low mortality, but despite an adequate resection, there is a recurrence rate ranging from 0 % to 37 % [73–76].

Balloon dilation of discrete SAS was first reported in 1986 by Suarez de Lezo and shortly thereafter by Lababidi et al. [77, 78]. Short-term obstruction relief after balloon dilation has been well characterized in older children and adolescents [77, 79, 80]; however, few mid- or long-term follow-up studies are available. The most recent experience from a single center [68] included 76 patients with an isolated so-called thin discrete lesion, at a mean age of 19 years (range 2–67 years), about half under 13 years of age, with a mean follow-up of 16 years. Immediately after the procedure, the subvalvar gradient decreased from 70 to 18 mmHg, and no patient developed acute aortic regurgitation. Only one patient died of a procedural complication and no deaths related to the lesion occurred in the long-term. Freedom from surgery or re-dilation at 10 and 15 years after the procedure was 92 % and 75 %, respectively. Good clinical outcomes were predicated on the presence of a thin membrane-like obstruction (<2 mm). Risk factors for recurrence included age <13 years, body surface area <1.3 m^2, aortic annulus <20 mm, and valve to membrane distance of <9 mm; however, multivariable analysis identified larger annulus size and thinner membranes as the only independent factors associated with better long-term results. Twenty years recurrence-free probability was 42 % in the younger patients and 35 % in those with an aortic annulus <20 mm. As such, balloon dilation of isolated discrete membranous lesion in adolescents and adults may be as effective as surgical treatment with low mortality and a high recurrence rate in children <13 years of age.

Supravalvar Aortic Stenosis

Supravalvar aortic stenosis (SVAS) is the least common of the LVOT obstructions, accounting for <7 % of all such lesions [81, 82]. SVAS presents as a fixed form and may be a localized or diffuse narrowing in the ascending aorta above the aortic valve. It can be either isolated or a component of the Williams syndrome [83, 84] where it may be associated with elastin gene mutations. The latter occurs in two defined populations: either a familial or a sporadic elastin arteriopathy [85], with the sporadic form the most common. Other vascular sites affected include

the pulmonary arteries, aortic arch branches, the abdominal aorta, and renal arteries. Surgical treatment is well established with low mortality and good long-term results with 90–94 % 10-year survival [82, 86, 87]. The presence of diffuse vascular involvement is associated with a poor outcome [82]. Percutaneous treatment of the supravalvar lesion has been suggested, particularly in cases of long segment narrowing; however, only case reports have been published [88, 89]. Percutaneous catheter-based treatment of SVAS has to be balanced against the risks of potential damage to the aortic valve, aortic root, compromise to the coronary artery ostia, and potential risk of dissection.

Conclusions

Treatment of left ventricular outflow tract obstruction in children remains a significant clinical challenge. Efficacy of percutaneous aortic valve dilation has been validated in literature, and is the therapeutic procedure of choice for congenital stenosis in children at any age, and not associated with significant aortic insufficiency. For those patients with subvalvular aortic stenosis, balloon dilation is not generally considered a first-line treatment, but may be considered if there is a thin subvalvular membrane in older children. Supravalvular stenosis is rarely suitable for percutaneous treatment. Fetal aortic valve dilation has been shown a promising technique in selected cases to achieve a biventricular circulation, although it is too early to determine the impact on long-term treatment algorithms.

Balloon dilation of the aortic valve is a palliative procedure and many of the patients will ultimately need further interventions. However, surgery can often be postponed for many years and is most often only needed to address significant insufficiency rather than recurrent obstruction. Published series have shown approximately 50 % freedom from re-intervention at 10 years. A retrograde approach is most often used. Current clinical practice is to choose a balloon with a diameter that is approximately 90 % of the annulus diameter and rapid pacing is used to secure balloon stability during inflation. Despite advances in catheter technology and procedural techniques, aortic valve dilation continues to carry relatively high risk of complications, especially the risk of femoral arterial compromise in neonates and small children. Nevertheless, balloon dilation carries no higher risk of complications than primary surgery and should be favored as the first-line palliation.

Catheter-Based Interventions of the Aorta

64

Marc Gewillig, Derize Boshoff, and Werner Budts

Abstract

Coarctation of the aorta includes a wide array of anatomic and pathophysiologic variations, which may cause important long-term morbidity and mortality. Percutaneous techniques such as balloon dilation and stenting allow safe decrease or abolition of most of the gradients along the aorta; however, there are some limitations. Interventional techniques allow adequate stretch or therapeutic tear of the vessel wall while keeping complications such as an excessive tear, dissection, aneurysm formation, or rupture to a minimum. The interventional techniques are determined by characteristics of the patient such as age, size, and growth potential and the lesion such as degree of narrowing, length, and angulation and by local regulations and facilities.

Introduction

Diseases of the aorta include predominantly abnormal narrowing and hypoplasia, but also dilation and aneurysm formation. Coarctation of the aorta consists of a wide array of anatomic and pathophysiologic variations. It occurs with a frequency of 0.04 % of live births and comprises about 7 % of known congenital heart disease [1]. Narrowing of the aortic arch predisposes patients to high blood pressure and subsequent development of premature atherosclerosis, which may lead to myocardial infarction and stroke at a younger age. Long-term follow-up studies, even after successful coarctectomy, have shown significant morbidity and mortality beyond the fourth decade, usually secondary to or associated with arterial hypertension [2]. The aim of treatment should always aim for an aortic arch free of any gradient in order to avoid arterial hypertension and should improve long-term outcome in these patients. A blood pressure gradient at rest of greater than 20 mmHg between upper and lower extremities generally indicates the need for intervention. Additionally, pressure differences of less than 20 mmHg may warrant intervention if there is hypertension at rest and, especially, if there is left ventricular dysfunction or progressive hypertrophy. Lastly, exercise-induced hypertension is increasingly being recognized as another indication, as late outcome is also suboptimal [3].

Mechanism of Pressure Loss Along the Aorta

Several lesions, either isolated or in combination, may cause a gradient in the aorta, each with specific opportunities and limitations for transcatheter treatment:

- Discrete narrowing, typically a coarctation
- Tubular hypoplasia at:
  - The isthmus, distal to the left subclavian artery
  - The distal cross, between left carotid artery and left subclavian artery
  - The proximal cross, between brachiocephalic trunk and left carotid artery
  - The lower thoracic or abdominal coarctation (middle aortic syndrome)
- Steep angulation of the arch as seen in a cervical arch (between ascending aorta and proximal transverse segment)
- Any tortuous course of the arch
- An atretic segment, when acquired later in life, typically at the isthmus between the left subclavian artery and the coarctation site
- A postsurgical narrowing, which may consist of residual hypoplasia or stenosis, lack of (catch-up) growth of bordering segments, excessive scar tissue, a circular nonresorbable wire, or a tube interposition graft
- A residual, recurrent, or growth-induced narrowing after catheter intervention

Treatment of Coarctation

In 1944, Dr. Clarence Crafoord and Dr. Robert Gross performed the first successful surgical repair of coarctation of the aorta [4, 5]. During the ensuing four decades, surgery remained the only treatment for coarctation. In the late 1970s, percutaneous balloon angioplasty was described as an alternative to surgical repair [6]. Since then, transcatheter interventions have become increasingly popular and in many cases have emerged as the treatment of choice [7, 8].

Percutaneous Options and Mechanism of Action

Transcatheter options now include simple balloon angioplasty, angioplasty followed by stenting, primary stenting using bare or covered stents, and rescue stenting with a covered stent. The mechanism of relief involves stretching and tearing of the vessel wall.

By *simple balloon angioplasty*, the minimum a balloon will do is *stretch* the target lesion; however, this may be followed by early and late recoil of the lesion, making this technique less

satisfactory. A sustained result of balloon dilation typically involves a *tear* of the intima and partially the media while keeping the adventitia intact; such a therapeutic tear should be contained to the narrowed zone [9–11]. In order to obtain a sustained result, some degree of overdilation with the balloon is frequently required. After dilation, some mechanisms will limit or improve the long-term result: recoil and retraction of nongrowing scar tissue will result in recurrence of the narrowing or stenosis, but catch-up growth and remodeling may occur by release of the stenotic ring and enhanced anterograde flow. However, such tears may predispose to possible complications. These include dissection, false aneurysm, and rupture [12]. A *dissection* is a tear that extends beyond the coarcted segment in the axial dimension, permitting contrast to track extraluminally in a proximal or distal direction. The false lumen of such dissection may be progressive and cause distal tearing of the vessel wall or even occlusion of side vessels. A *false aneurysm* may result from a defect in the aortic wall, with contrast extravasation beyond the adventitial plane with a discrete length; such a false aneurysm may "grow" over time and eventually rupture. An *aortic rupture* is a frank disruption of the aortic wall, which appears angiographically as extravasation of contrast beyond the confines of the aorta into the mediastinum or pleural space. A relatively high incidence of aneurysm formation of between 2 % and 20 % has been reported after balloon dilation [7, 13]. Several techniques have been described to improve the hemodynamic result and reducing the risk for these complications: these involve low-pressure balloon dilation and interrogation of the stenosed site, progressive and/or stepwise dilation with noncompliant balloons in one or more sessions, and limiting the size of the balloon based on the narrowing itself or adjacent segments.

Since 1989, *bare metal stents* have been used to treat narrowing in the aorta [14–18]. Stents will overcome many of the shortcomings of simple balloon dilation. A stent will expand and scaffold the target region, thereby avoiding recoil and residual or recurrent stenosis. A good result can be obtained by simple stretching of the wall without a tear as there is no need for overdilation. Stenting may therefore result in lower vessel wall complications: fewer aneurysms, no dissections within the stent as they are automatically contained by sealing the intimal flap, and less rupture. Where intimal tears occur, the stent provides a surface for formation of neointima over the tear and reinforces the weakened areas within the aortic wall reducing the risk of a false aneurysm. However, stent implantation has some shortcomings: the technique is technically more demanding and requires a bigger sheath causing more vascular trauma at sheath insertion point, the foreign metal may induce interactions with surrounding tissues such as coagulation, wall hyperplasia, sharp edges of the stents may protrude and damage the vessel, the stents alter local vascular compliance and impede vessel growth, and stents may fracture and collapse [19]. Overall, the use of bare stents has improved results while lowering the complication rate of vessel wall trauma to 1–5 % [20].

Initially, stent implantation was used only for cases where surgery and balloon angioplasty had failed. However, as experience increased, stenting gradually became the treatment of choice in selected patients with aortic coarctation [21]. This is especially the case when coarctation coexists with hypoplasia of the isthmus or transverse arch, or when balloon dilation has a high failure rate such as in a tortuous coarctation, a long segment coarctation, or mild discrete coarctation. Stents are particularly helpful in some postsurgical patients [22] where a nonresorbable wire was used: balloon dilation alone may only tear the intima from the vessel with possible major dissection before breaking the wire. In adult patients, stenting is now considered as the treatment of choice in any variant of aortic coarctation. At the other end of the scale, in children less than 10 years of age, it is preferable to avoid stenting, as several redilations may be required until the child is fully grown.

The availability of *covered stents* has further reduced the incidence of aneurysm formation and vessel rupture to less than 1 % as the covering

will seal any tear in the vessel wall [23]. Covered stents can also exclude an unwanted passage to vessels such as an arterial duct or an existing aneurysm [24–26] and allow creating a new vessel segment as in aortic arch atresia [27]. Covered stents typically will require a larger sheath of more than 1 F than the size needed for bare stents, may cover origins of side vessels, may cause flow obstruction if incompletely opened or partially collapsed, and if they migrate to an unwanted location, may be more hazardous than bare stents. Currently, the discussion is still open as to whether covered stents should be used as a routine or only in case of a complication or specific indication. In countries where covered stents are available, there is a clear shift towards more routine use of covered stents in order to reduce the early and late complication rates [28]. Having covered stents available in the catheter laboratory adds to the safety of any aortic procedure: bleeding due to excessive vessel damage can usually be controlled with a covered stent as bail-out procedure.

Equipment

Balloons for Angioplasty

Many balloons are currently available for angioplasty of the aorta. The differences between balloons include availability in different sizes and lengths; tapering of balloons (the shorter the better, as the nose of the balloon may cause unwanted lesions in the arch); compliance; profile which determines sheath size for vessel entry; mode of refolding, which determines sheath size for removal of the balloon and the extent of damage at distal point of sheath; nominal pressure; burst pressure; inflation and deflation time; resistance to puncturing (stent or calcium); mode of rupture such as a point, longitudinal, and transverse; coating of balloon and shaft properties, and stretchability on retrieval. It is not uncommon to have different types of balloons available on the shelf at all times.

Balloons for Stent Delivery

Many balloons are available for stenting of the aorta. Although the same balloon as the ones used for angioplasty may be used, each technique will determine different ideal requirements of the balloon. For stent delivery, additional features such as the balloon size, material, surface, and mode of inflation are important. A shorter balloon will avoid excessive shoulders on inflation which may cause flaring of stent and puncture of the balloon and will enhance stability of the balloon during inflation with reduced inflation time, and less hemodynamic effects, but may make slipping of the stent off the balloon more likely. The balloon material should be non-slippery and puncture resistant, especially when used with stents with "sharp" edges of the crimped stent; sufficient lumen should remain to allow symmetric inflation of the balloon as asymmetric inflation may result in "milking-off" the stent from the balloon during expansion. Several balloons are currently available from different manufacturers: Powerflex® and Opta Pro® (Cordis, USA), Z-Med® and BIB® (NuMED, USA), Cristal® (Balt, France), and many others.

In the early days, all stents were hand-crimped on single large diameter balloons for expansion and delivery within the coarctation. Large diameter single-balloon catheters tend to expand first at their ends and thereby evert the stent ends such that they protrude radially into the vessel wall, which predisposes to aneurysm or dissection at the edges of the stent. An important development of equipment for delivery of large diameter stents has been the Balloon-in-Balloon (BIB®) catheter (NuMED, USA). These catheters have a small inner balloon and a 1 cm longer outer balloon that is twice the diameter of the inner balloon. The BIB catheters offer the important advantage of opening the stent more uniformly along its length. They do, however, require a larger arterial sheath for introduction: the profile of BIB catheters with outer balloon diameters of 8–14 mm is 9 Fr, of 16 mm is 10 Fr, of 18–20 mm is 11 Fr, and of 24 mm is 12 Fr sheath. Thus, while BIB catheters prevent stent flaring, cause less stent

Table 64.1 Characteristics of currently available stents: crimpability, distensibility, foreshortening

	Min inner diameter (Fr)	Stent thickness (Fr)	Min outer profile (Fr)	Balloon premounted	Stent maximal diameter	% shortening at 20 mm
Bare stent						
Genesis XD	5	1	6		18.5	57
Valeo	P		6	≤10	20	50
AndraStent XL	8	1	9		25	25
AndraStent XXL	9	1	10		32	5
IntraStent LD Max	9	1	11		26	3
Cheatham-Platinum	7	2	9		28	18
Mounted CP	P	2	10 12	12–24	28	18
Covered stent						
CCP	7	2–3	10		26	18
Covered Mounted CP	P		12 14	12–24	26	18
V12 Advanta	P		10	≤16	20(22)	17

Legend: P = premounted; V12 Advanta can be dilated up to 22 mm, but recoils to <20 mm

foreshortening, allow repositioning after inflation of the inner balloon, and offer more precise control over stent placement without danger of "milking-off" the stent during inflation, single-balloon catheters are preferable in smaller patients to reduce the risk of injury to the femoral artery at the access site. In order to keep the sheath size as small as possible in smaller children, a single low-profile balloon may be used to deliver the stent and anchor it across the lesion and then further dilate the stent with another noncompliant high-pressure balloon.

Stents

Many stents are available for stenting the aorta. Differences between the stents include crimpability with low profile, distensibility, the pressure required to open and deploy the stent, conformability over the full length, foreshortening and radial strength at different diameters, flaring at the ends, open or closed cell design which determines longitudinal grip and side branch accessibility, sharpness of the edges and the wire within the stent, collapse resistance, wire fracture resistance by metal fatigue or intentional by balloon dilation, membrane covering, radiolucency, and MR compatibility. Less important stent features for aortic application are flexibility and cell area which determines tissue prolapse through the cells. The following balloon dilatable stents are available to treat congenital lesions in different parts of the world: Palmaz® XL 10-series and Genesis® XD (Johnson & Johnson, USA), AndraStent® XL and XXL (Andramed, Germany), IntraStent® LD Mega and Max (ev3, USA), and the Cheatham-Platinum® (CP) stent (NuMED, USA). The Valeo® stent (Bard, USA) and Mounted CP stent® (NuMED, USA) are premounted, the latter within a sheath. Covered stents are available as the Covered CP® (CCP stent) or the Covered Mounted CP® stent (NuMED, USA), the V12 Advanta® stent (Atrium, USA), or can be handmade [29]. Some comparisons between stents are summarized in Table 64.1. Occasionally, self-expanding stents may be used, but these have a limited role in pediatric cardiology practice when treating narrowed segments. Such stent grafts typically require 22–24 Fr sheaths and are used to treat true aneurysms in adults.

Crimpability of the stent to a low profile determines the minimum sheath size, but this is inversely related to its distensibility, foreshortening, radial strength, and fracture resistance (Table 64.1). The Genesis and the

premounted Valeo stent have a low profile of 6 Fr when mounted on a balloon up to 10 mm, and can be dilated up to 18–22 mm, however, with significant foreshortening (>60 %) and fracture rate. Most other stents will require a minimal sheath size of 9–10 Fr, depending on the type of balloon used. The size of an adult aorta varies between 16 and 20 (and may be up to 22 mm), and so sheath size may be up to 14 Fr. In very premature infants, coronary stents can be introduced through a 4 Fr sheath and can eventually be dilated up to 5 mm and so currently these need subsequent surgical removal. The pressure required to open and deploy the stent and the sharpness of the stent wire will determine the required thickness and pressure resistance of the balloon, which determines the profile of the balloon and thus the final profile for insertion. Some conformability is desirable to allow the stent to conform to the curvature of the arch to reduce the likelihood of stent damaging the vessel wall. When partly covering the origin of a head and neck vessel, flaring the end of the stent into the side vessel may be desirable, especially when using a covered stent. Stents may have an open or closed cell design, which determines the maximal size of opening to a neck vessel.

A stent ending with a stiff thin circular wire will offer more grip, but this is not required in the aorta as the stent is usually well fixed by the stenosis, but the wire may cause more vessel damage, both at placement and at redilation, resulting in dissection or aneurysm formation at the ends of the stent.

Guidewires

Most operators use a long stiff 0.035″ guidewire with a soft tip. The guidewire may be positioned in the ascending aorta or the left ventricle; but in order to avoid damage to the left ventricular apex, the aortic valve or a coronary artery, the tip of the guidewire should be curled. Positioning the guidewire in the right subclavian artery may offer more stability during stent deployment, but with some risk of dissection of the brachiocephalic trunk [30]. The left subclavian artery is rarely used due to insufficient space for balloon inflation.

Sheaths

Hand-crimped balloon mounted stents should be delivered through a long sheath, keeping the stent covered until positioned across the stenosis. There are several appropriate types of sheath, the most popular being the straight Cook RB-Mullins design sheath (COOK, Denmark), which has a competent hemostatic valve, a radiopaque tip, and a side arm, allowing hand contrast injections during stent positioning. Some covering or a short, cutoff piece of sheath tubing placed over the stent is usually required to pass the stent safely through the valve.

Inflation: Speed by Hand or by Indeflator

Early in everyone's experience, it was felt that the balloon should be inflated as fast as possible to keep the hemodynamic burden on the heart as short as possible. However, this has often resulted in asymmetric expansion and migration of the stent during inflation. Most operators now recommend slow balloon inflation initially, allowing both shoulders of the balloon to rise around the stent, preventing the stent from being "milked" off the balloon. Once in satisfactory position, further balloon inflation may be much faster. The use of a BIB balloon has nearly abolished the risk for asymmetric stent opening and stent dislodgement.

The balloon can be inflated by hand, allowing the operator to continuously observe the stent and the coarctation site, and thus control the dilation, when opening the stent inside the lesion and stretching and tearing the stenotic region. The operator should know by experience the level of pressure that can be achieved with different syringes, keeping in mind that the larger the syringe size, the lower the maximal pressure that can be

achieved by manual inflation. For example, a 10 cc syringe typically will allow 6–10 atm pressure to be achieved while a 20 cc syringe allows pressure of 4–6 atm. An indeflator device may help achieve better control of the pressure, but ideally one operator should focus on the manometer while another operator focuses on the stent expansion. Most lesions will open with inflation pressures below 6 atm, but when higher pressures are required, an indeflator is necessary.

Stability of Stent

Adequate stability of the stent on positioning depends on the delivery ensemble such as stiff guidewire, stiff balloon shaft, and long stiff introducer sheath placed just below the balloon. Guidewire position may influence stability such as ascending aorta versus subclavian artery position of the guidewire. Often rapid right ventricular pacing at a rate of 180–240 bpm is used [31]. Rapid pacing may be of importance in adults with a high stroke volume and in particular in the presence of aortic regurgitation, or when deploying a stent in the transverse aortic arch closer to the heart. In exceptional cases, additional stability can be achieved by snaring and externalizing the distal end of the guidewire from the right radial or brachial artery to form a stable circuit for stent deployment [32].

Technique of Balloon Angioplasty

The procedure is performed under general anesthesia or heavy sedation as stretching or tearing the aorta is extremely painful for the patient. Vascular access is obtained via the femoral artery. An aortogram is performed with maximal elongation and profiling of the aortic arch. Initially, the plane of the aortic arch is determined. With the catheter in the ascending aorta, the frontal camera is placed in RAO projection until perfect alignment of the ascending and descending arch is obtained. Subsequently, the lateral camera is rotated in LAO projection at exactly 90° to the RAO camera. From this angle, the aortogram will be perpendicular with maximal elongation of the arch. Angiography can be performed using a pigtail catheter with 1 cm radiopaque markers, allowing accurate calibration and exact measurements of the aorta. Alternatively, a Multi-Track® catheter (NuMED, USA) advanced over a 0.035″ exchange guidewire can be used. This catheter has a 1 cm marker for accurate calibration and a monorail system allowing pullback gradients to be measured across the coarctation without losing guidewire position. The measurements of the aorta include systolic diameters of the distal transverse arch just proximal to the origin of the Ieft subclavian artery, the aortic isthmus just distal to the origin of the left subclavian artery, the site of the coarctation, and the descending aorta above the diaphragm.

Different protocols have been reported to select the appropriate balloon size for safe dilation of the coarctation. Balloon size is limited by the neighboring segments such as the transverse aortic arch, the proximal isthmus, or the thoracic aorta at the diaphragm level and/or by the coarcted segment itself. The balloon should be no more than 300 % of the minimal diameter, provided this is well visualized by the aortogram. A low-pressure inflation is recommended to interrogate the compliance and narrowing of the vessel. If the stenosis was underestimated, a smaller balloon may be preferred for initial dilation. Progressive dilation can be performed, each time preceded by measurement of the residual gradient and a repeat aortogram to assess the result (Fig. 64.1). Not surprisingly, a bigger balloon will yield a better gradient relief, but may increase the complication rate.

For a patient younger than 1 year of age, balloon angioplasty is frequently only palliative as the rate of recoarctation has been reported to be more than 50 % [14]. For a patient older than 1 year of age, balloon angioplasty has reasonable immediate results, but the rates of recoarctation are still about 26 % [15].

Late false aneurysms have been reported in 1.5 % of cases after balloon dilation of a postsurgical coarctation [7], whereas they seem to occur

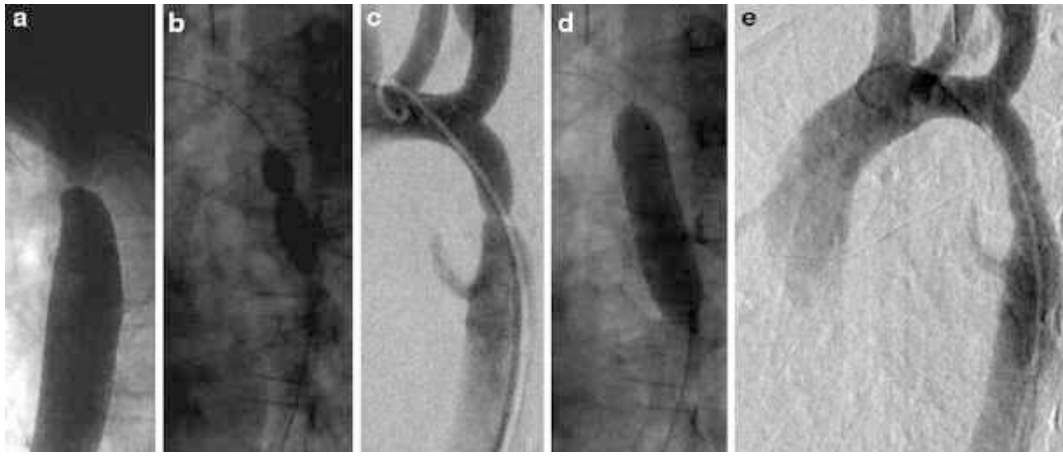

Fig. 64.1 Balloon dilation of native aortic coarctation. Six-year-old patient with a tight aortic coarctation: (**a**) Aortogram in the descending aorta shows narrow discrete coarctation. (**b**) Through a 5 F sheath, balloon dilation shown with an 8 mm balloon. (**c**) Repeat angiogram shows residual discrete narrowing. (**d**) Further dilation with 10 mm balloon. (**e**) Final angiographic result with gradient reduction from 30–8 mmHg. At latest evaluation 2 years later, satisfactory growth of the distal arch without clinical gradient

more frequently (8–35 %) [13] in patients with a native coarctation. The lower incidence of aneurysms in postsurgical coarctation patients may be due to the fact that the aorta is surrounded by postoperative fibrosis and that most of the abnormal aortic wall tissue is removed at the time of surgery.

Technique of Stenting

The procedure is similar to balloon dilation in many aspects (Fig. 64.2). In the presence of a very tight or nearly atretic aortic segment, access may be needed via the right or left radial or brachial artery, allowing a catheter or guidewire to be passed from above through the coarctation site into the descending aorta. Rarely, transcardiac or a carotid arterial access via a surgical arteriotomy may be required. Heparin at a dose of 100 IU/kg is given after access is obtained; the activated clotting time is maintained above 220–250 s throughout the procedure, particularly due to the risk of long clots developing in the long introducer sheath. A Perclose (Abbott Vascular) suture can be inserted at this stage for rapid and lasting hemostasis at the end of the procedure. However, in adolescents and young adults, good hemostasis can be achieved by prolonged manual compression under anesthesia even after removing a 14 Fr sheath. A 5 or 6 Fr end-hole catheter is passed through the aortic coarctation and positioned in the ascending aorta. In a tight or tortuous coarctation, it is preferable to cross the lesion with a straight tipped guidewire from below. Adequate angiography and accurate measurements are even more important than for simple balloon dilation. Small errors may lead to selection of a wrong balloon size and stent and therefore increase the complication rate significantly. The length of the stent is based on the length of the hypoplastic segment, typically from the left subclavian artery or the left common carotid artery depending on previous surgical technique and/or site of coarctation to about 15 mm beyond the site of the coarctation.

To reduce the small risk of vascular complications with bare stents, it is reasonable to test the compliance of the coarctation lesion. A balloon of similar size or even bigger than the intended stent is inflated at low pressure. This maneuver is intended as a diagnostic measure, not as an angioplasty prior to stent placement [33]. If there is a significant residual waist on the balloon, a slightly smaller balloon is chosen for stenting

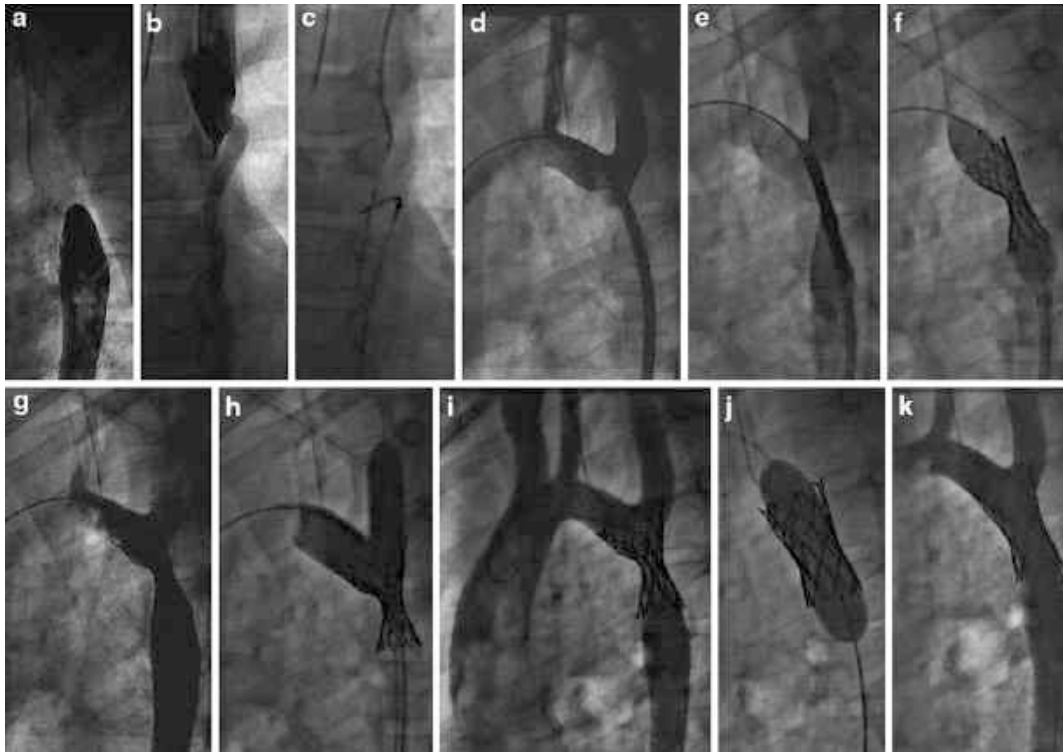

Fig. 64.2 Stenting of near atresia of the aortic arch. Ten-year-old boy with near atresia of the aorta: (**a**) Aortogram showing no retrograde flow. (**b**) Aortogram in distal isthmus showing tiny passage of contrast to thoracic aorta. (**c**) Snaring of 0.014″ coronary wire. (**d**) After arterio-arterial circuit was made, retrograde passage of 11 F sheath and hand injection of contrast through the sheath. (**e**) 34 mm CCP stent in position on 14 mm BIB balloon. The large origin of left subclavian artery is partly covered but remains accessible after deployment of the stent. (**f**) Hand inflation of balloon with subtotal opening of stent sufficient for stent anchoring. (**g**) Flaring of upper end of stent with 10 and 14 mm balloon to open passage to the left subclavian artery and appose the stent maximally to the wall. (**h**) Stent nicely apposed to the vessel wall, thereby sealing the zone of expected vessel tear at the end of first procedure. (**i**) After 2 months, dilation with 12 mm high-pressure balloon at 10 atm. (**j**) Final result with no residual gradient and excellent patency of stent

and complete expansion of the stent is postponed until a second catheterization 2–6 months later. However, a test interrogation of the coarctation site is usually not indicated if a covered stent is used.

The maximum balloon diameter on which the stent is mounted is based on either the transverse or the distal arch diameter, whichever is the larger, and on occasions 1–2 mm larger. A long Mullins sheath is passed over the 0.035″ stiff exchange guidewire. The sheath size ranges between 10 and 14 Fr and is generally 2–3 Fr larger than that required for introduction of the balloon catheter alone (Table 64.1). The stent is manually crimped tight on to the selected balloon, so as to ensure that it does not slip off the balloon. To facilitate introduction of the stent/balloon assembly through the diaphragm of the sheath, to prevent the stent from slipping off the balloon, and to protect the covering of the stent from being removed inadvertently, a cutoff short sheath tubing of similar size and sufficient length or a dedicated introducer is placed over the stent.

The stent/balloon assembly is advanced through the long sheath and positioned across the site of the coarctation. OptimaI positioning is confirmed by small hand injections of contrast through the side arm of the Mullins sheath. Alternatively, injections can be made through a second catheter placed in the transverse aortic arch.

While maintaining the balloon catheter and guidewire position, the Mullins sheath is withdrawn to expose the stent/balloon assembly in position at the site of the coarctation. Keeping the sheath just below the balloon will enhance the stability during inflation. Care must be taken to withdraw the sheath sufficiently below the balloon to allow the balloon inflation in an unrestrained manner. Failure to do so may cause the balloon/stent assembly to move during inflation, or milk the stent off the balloon because of asymmetric inflation. Rapid right ventricular pacing is used if desired. The balloon is initially inflated slowly to allow the shoulders of the balloon to distend and to immobilize the stent on the balloon, and then faster inflation is performed until the stent is anchored at the stenosis site with both ends of the stent widely open and the stenosis sufficiently relieved, or the maximal balloon pressure reached. Once the stent is deployed, the balloon is deflated and pacing is stopped. If a BIB balloon is used, the inner balloon is inflated first, followed by the outer balloon, and for fast deflation, both balloons can be deflated simultaneously. A bare stent can be expanded to the diameter of the normal vessel at either side of the coarctation; however, in case of a tight coarctation, an undersized balloon should be chosen or the balloon not fully expanded in order to reduce the likelihood of aortic wall damage. After deflation, the balloon is withdrawn carefully so as not to dislodge the stent. The gradient across the stent is then measured and an aortogram is repeated to exclude dissection or aneurysm formation.

Further dilation with a larger balloon is performed in some cases until satisfactory relief of the stenotic waist is obtained. Flaring of the ends of a bare stent to achieve contact with the aortic wall at all points is not usually performed. In contrast, flaring of the ends of a covered stent allows adhesion and sealing of the wall, which will prevent a tear from creating an aneurysm or extravasation of contrast. In complex lesions in small patients, it is not uncommon to use one low-profile balloon to deliver a stent across a stenosis through a small sheath, another larger balloon to flare and appose the ends of the covered stent to the wall to obtain maximal sealing, and one or more high-pressure noncompliant balloons to progressively dilate the stenotic region.

Patients are usually discharged the day after the procedure and reevaluated clinically and echocardiographically 4 weeks, 6 months, and 1 year after the procedure. Spiral CT scanning is performed 4–6 weeks after the intervention to exclude aneurysm formation, dissection, and stent thrombosis.

Anticoagulation and Antiplatelet: Follow-Up

A large diameter stent with high flow is unlikely to thrombose. Many interventionalists neutralize the heparin with protamine at the end of the procedure when removing the sheath and give no further antithrombotic treatment. Several other regimes have been advocated, but no trial has been reported to prove the need or superiority of any anticoagulation or antiplatelet protocol.

Re-catheterization is performed only if there is clinical evidence of recoarctation, residual arterial hypertension, or CT evidence of aneurysm formation. In patients in whom the stent was initially intentionally underinflated, elective re-catheterization is performed after 2–6 months to relieve residual stenosis.

Bare or Covered Stents

An aneurysm or aortic wall rupture can occur unexpectedly; therefore, the procedure with a covered stent is safer than with a bare stent, as the lesion is automatically contained. A covered stent offers a bigger margin of safety to expand the stent more at the initial procedure and much more at subsequent interventions, if indicated. The use of covered stents is necessary to safely treat patients with atretic or severely hypoplastic segments, as a transmural tear may occur. Not all problems are abolished as tears at the edges of the covered stent [34] or at a distance, bleeding from the vessel wall or the side vessels such as intercostal arteries may still occur, but these complications are usually less dramatic. Stenting techniques are slightly different

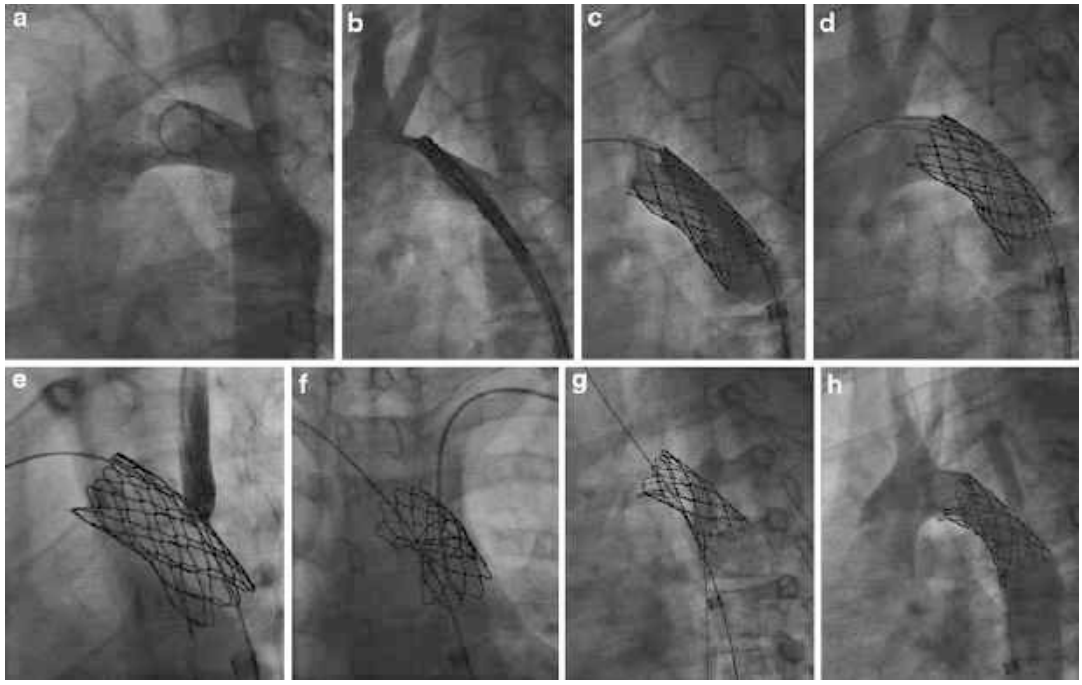

Fig. 64.3 Retrograde puncture of covered stent to establish antegrade flow in the neck vessel. A 14-year-old girl with postoperative residual coarctation at the distal aortic arch: (**a**) Aortogram showing complex recoarctation: residual hypoplasia of distal arch at the origin of the left subclavian artery. (**b**) 45 mm CCP® stent mounted on a 16 mm BIB® balloon through a 13 Fr Mullins sheath. Hand injection through side arm of the sheath demonstrates correct position of the stent. A 4 F end-hole catheter is positioned in the left subclavian artery to perform the retrograde puncture. (**c**) Stent is deployed with the 16 mm BIB® balloon. (**d**) Aortogram through sheath demonstrates correct deployment of the stent. (**e**) Injection in the left subclavian artery through the 4 F catheter. (**f**) After retrograde perforation with stiff end of 0.035″ guidewire, the 4 Fr catheter is advanced into the thoracic aorta. (**g**) Balloon dilation of stent covering at the origin of the left subclavian artery with a 10 mm balloon. (**h**) Final result with no gradient across the aortic arch and antegrade flow into the left subclavian artery

when using covered stents compared with bare stents. Balloon interrogation prior to stenting is rarely performed and the stent is fully approximated against the wall at deployment in order to obtain maximal sealing around the hypoplastic segment. The combination of a CCP stent with a slightly oversized BIB balloon allows the stent to be apposed fully to the aortic wall at the site of the coarctation. Progressive dilation of the coarctation site is performed either immediately or at a later procedure, depending on the operator's estimation on how well the expected tear will be sealed off. The ends of the stent can be flared into the side vessels such as the subclavian or left carotid artery, if required.

Experience with stent grafts for thoracic aortic aneurysms suggests that the origin of the left subclavian artery can be covered with a covered stent without any acute effects although it is preferable to avoid this. However, arm claudication can rarely occur. Additional techniques such as retrograde perforation [35] and double wire technique [36] may therefore be required to avoid excluding side vessels. *Retrograde perforation* is an elegant technique which allows stenting of a narrowing at or near the origin of a side vessel such as the subclavian artery and the carotid artery. The stent is deployed in the arch and the covering is perforated retrogradely from the excluded vessel that has been covered, thereby restoring antegrade flow (Fig. 64.3).

The double wire technique allows a stent to be delivered across a stenosis or aneurysm just distal to a side branch (Figs. 64.4, 64.5 and 64.6).

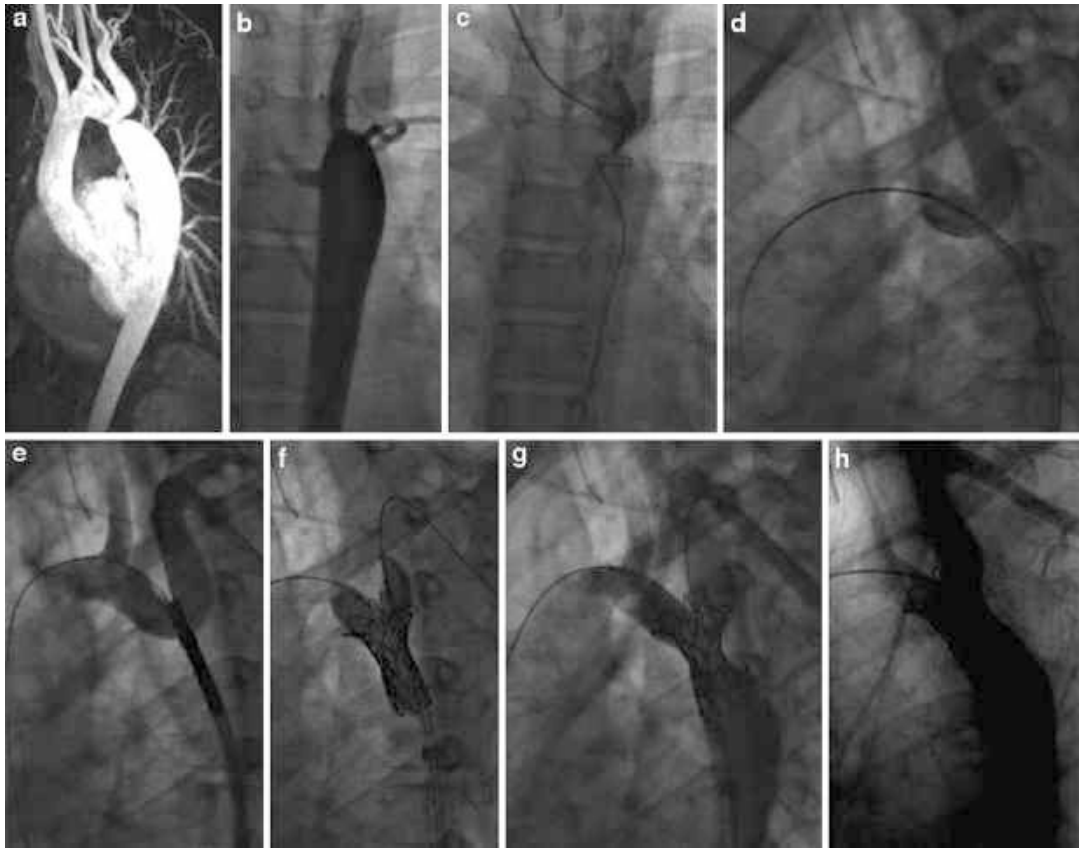

Fig. 64.4 Double balloon technique. A 13-year-old girl presented with a near aortic arch atresia. (**a**) MR demonstrates the near atresia. The left subclavian artery originates just proximal to the coarcted segment. (**b**) Aortogram in the descending aorta demonstrates large collateral vessels, but no connection with the arch. (**c**) Antegrade passage from the right brachial artery as the angle from the left subclavian artery was assessed to be too acute. A coronary guidewire is captured with a 10 mm snare in the descending aorta to form an arterio-arterial circuit. (**d**) Aortogram in the distal arch. Note a 0.035″ guidewire placed in the ascending aorta. (**e**) After predilation with a 3 mm balloon, a 11 Fr long Mullins sheath is positioned in the distal arch. Two 0.025″ guidewires are positioned in the ascending aorta and left subclavian artery. A 34 mm CCP® stent mounted on a 12 and 10 mm Tyshak® balloon is positioned as cranial as possible. (**f**) The stent is opened and delivered by gentle inflation of both balloons. Dilation of the coarctation site at this point is no issue. (**g**) The stent is apposed to the wall thereby sealing the expected zone of vessel tear at the end of first procedure (**h**) 2 months later, the stent was expanded with a 14 mm high-pressure balloon and there was no residual gradient

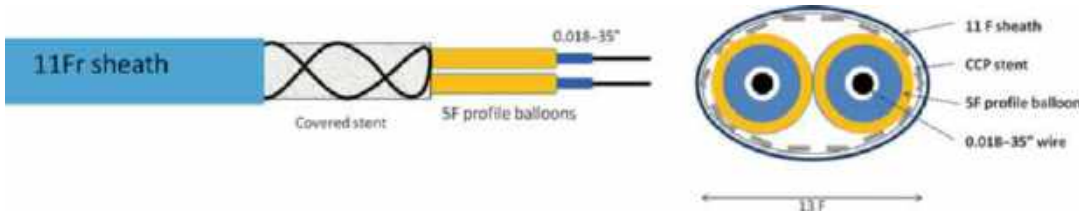

Fig. 64.5 Double balloon technique: sheath size. The smallest sheath must be determined for any selection of balloons and stent. A CCP stent mounted on two balloons each with a 5 Fr profile has an oval shape and can be delivered through an 11 Fr Mullins sheath

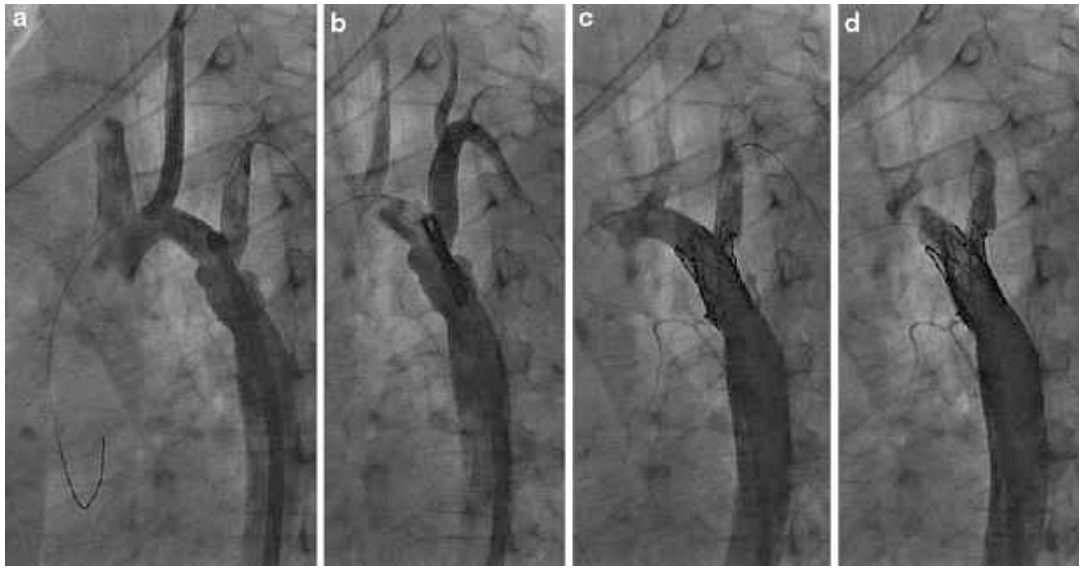

Fig. 64.6 Double balloon technique to exclude post-dilation aneurysm. A 10-year-old boy weighing 28 kg presented 5 years after balloon dilation of coarctation with a complex aneurysm at the dilation site, involving the origin of the left subclavian artery. (**a**) Aortogram through a 11 Fr sheath after two 0.018″ guidewires have been positioned (**b**) 22 mm CCP stent, mounted on two 10 mm Tyshak® balloons, is positioned as cranially as possible to cover the aneurysm. (**c**) The stent is deployed but there is still a small opening into the aneurysm distally. (**d**) After further expansion with a 14 mm balloon, the stent seals off the aneurysm completely

The second wire maintains access to the side vessel after deployment of the stent and allows flaring of the stent into the side branch. In order to reduce the required sheath size, the lowest profile balloons to get the stent anchored are selected, without the aim of dilating the lesion at delivery. After anchoring the stent, it is subsequently expanded as needed. Once balloons are selected, sheath size is determined by bench testing. Theoretically, one would add the profile of the two balloons to the necessary upsizing for a bare or covered stent. However, the whole unit becomes oval in shape instead of the normal round configuration, allowing a decrease in the final sheath size from the mathematical prediction (Fig. 64.5).

If sheath size is critical, both CCP and V12 covered stents can be delivered through a 10 Fr sheath, followed by additional dilation with a larger balloon as indicated.

In many centers, a gradual shift from using bare stents to using covered stents has occurred due to the additional therapeutic and safety margins. Disadvantages of covered stents are the slightly bigger profile and potential hemodynamic problems if the stent migrates inadvertently. This complication can be avoided by correct technique and attention to detail.

Measures of Success

The main measures of success of treating coarctation should be abolition of the gradient, control of blood pressure, and absence of complications from the treatment. While treatment with balloon-expandable endovascular stents is a technically challenging procedure, it is an extremely successful one [17, 22, 37–39]. A multicenter retrospective series of 588 procedures performed between 1989 and 2005 was conducted by the Congenital Cardiovascular Interventional Study Consortium (CCISC) [40]. Of the 588 procedures, 580 (98.6 %) were successful in reducing the gradient to less than 20 mmHg or increasing the coarctation to descending aortic diameter ratio to at least 0.8. Two patients developed an aortic dissection with

rupture and the procedures had to be terminated and emergency surgery undertaken with a bad outcome. In retrospect, such complications were probably avoidable and treatable with the use of covered stents.

In the adult population, the initial gradient across the coarctation may not reflect its severity as there may be extensive collateral vessels decompressing the aorta proximal to the stenosis. Resolution of hypertension cannot necessarily be used as a measure of efficacy because the incidence of hypertension may be masked by antihypertensive treatment. Some adult patients without residual stenosis at the coarctation site will continue to be hypertensive with persistent abnormal endothelium [41, 42]. However, control of their blood pressure usually becomes easier after stenting. Stenting appears to be effective in reducing resting blood pressure to normal levels in the majority of children and adults.

Little information is available on how stenting affects exercise tolerance or how well the stented coarctation segment responds to the increased cardiac output in pregnancy.

Complications

Some complications of coarctation stenting have already been discussed. In general, they can be classified into technical, aortic wall or peripheral vascular complications, or post-procedural hypertension and pain.

Technical complications include stent migration on the balloon in the sheath, during deployment on the balloon, migration after deployment, stent fracture, balloon rupture, and covering of the brachiocephalic vessels [43]. While passing the stent/balloon assembly through the valve or the sheath, the stent may migrate off the balloon; radiopaque markers on the balloon allow confirmation of correct position of the stent on the balloon before withdrawal of the sheath to uncover the stent in the aorta. If the stent has moved, the stent-balloon sheath can be removed leaving the guidewire in place, remove the stent from the front of the sheath and start the procedure again.

Stent migration off the balloon during inflation can occur if the balloon is inflated asymmetrically. This can be avoided by minimal inflation of the balloon before introduction through the sheath, creating small shoulders on both sides of the stent. This is relatively easily done with an indeflator. During stent deployment, balloon inflation should be started slowly, allowing both shoulders of the balloon to expand, thereby immobilizing the stent on the balloon. Stent migration can be avoided further by using a BIB balloon, especially when using the bigger sized balloons of >15 mm, the inner balloon is typically within the stent and cannot milk the stent off the balloon and the outer balloon will inflate symmetrically after the inner balloon has been inflated. During or after deployment, the stent may migrate more proximally or distally. Often the stent can be recaptured with a balloon and repositioned. If it cannot be repositioned safely within the coarctation, it should be expanded in the safest location available, away from side branches if possible. *Balloon rupture* may be avoided by using an appropriate balloon for a given stent. Stents with sharp edges require thicker, puncture-resistant balloons. Balloon rupture occurred in 13/588 (2.2 %) of cases in the CCISC cohort predominantly when using older stents such as the now-abandoned Palmaz 8-series stents. Balloon rupture may result in other complications involving the aortic wall, or embolization of balloon fragments, and if the balloon ruptures prior to full expansion, it will carry a high risk of stent migration.

Whether stent placement over the *origin of the brachiocephalic vessels* constitutes a complication is debatable. There have been no demonstrated harmful sequelae from doing so, except at redilation (see below [44]). A late *stent fracture* may occur at the transition of the mobile segment of the aortic arch to the fixed retropleural thoracic aorta. Currently, stent fractures may occur in stents with thinner metal, e.g., Genesis and Valeo stents, when expanded to larger diameters.

Aortic wall complications at or around the site of the coarctation include *intimal tears, dissection, aneurysm formation, and rupture* either

within the stent or at the edges or at a distance [45–47]. Vascular complications are more prone to develop in patients with connective tissue disease such as Turner syndrome [48]. Most of these complications can be treated, or are better avoided, by using covered stents [49, 50]. The general rule of "it is easier to stay out of trouble than get out of trouble" certainly applies to these situations.

It is important to have large diameter covered stents available for use in emergency situations as the covered CP stent can be dilated up to 24 mm and Atrium stent up to 20–22 mm, but for some emergencies, larger self-expanding excluder stent grafts (from Boston Scientific, Gore, Medtronic) should be available.

Aortic aneurysm is infrequently encountered, but it may be a harbinger of aortic rupture and is therefore a potentially dangerous complication. It may be seen at the time of the procedure or on follow-up. If a large or growing aneurysm occurs at the time of the stent placement, it must be excluded with a covered stent to prevent progression and possible rupture [51–53].

Peripheral vascular complications include cerebrovascular accidents, peripheral emboli, and injury to access vessels. Neurologic events including cerebrovascular accidents occurred in the CCISC group in 6/588 procedures. Adequate anticoagulation during the procedure is essential as the head and neck vessels are crossed with wires for a prolonged time and long sheaths are used where clots may form. Horner syndrome was reported due to a carotid artery dissection by the guidewire [30].

Significant femoral vessel injury was reported in the CCISC study in 15/588 (2.6 %) procedures. One patient had placement of the arterial sheath above the inguinal ligament and developed a retroperitoneal hematoma. Vessel thrombosis is more frequent in small children. It is current practice to institute heparin therapy for 24 h when there is loss of pulse after catheterization. If the pulse has not returned after 24 h, or if the viability of the leg is a concern at any point, thrombolytic therapy or surgery may be indicated.

Post-procedural rebound hypertension is sometimes observed in adult patients immediately after the procedure. Patients with systolic blood pressures greater than 99th centile for age should be monitored carefully, and infusions of nitroprusside or esmolol or both should be used, if there is severe rebound hypertension. These patients can generally be switched to oral antihypertensive medications within 24 h after the procedure.

Thoracic pain and abdominal discomfort can occur early after the procedure. This pain may only become evident when the analgesics from the anesthesia fade away. Thoracic pain remains an alarming symptom, so dissection, aneurysm formation, bleeding from the aorta, or torn intercostal arteries must be excluded by observing peripheral pulses and assessing by echocardiography and CT scan. Such pain is most likely due to stretching of the aorta and requires adequate analgesia in the form of opiates and is usually relieved after some hours. Some adult patients may complain of abdominal discomfort early after the procedure because better pulsatile flow may cause bowel irritability within the first few hours after the intervention.

Special Situations: Bail-Out Stenting in Premature Babies

A coarctation in newborns is typically treated by surgery. However, there may be occasions when a clinician may prefer to defer the surgery. These include extreme prematurity, a critically ill neonate with multi-organ failure shock, or complex syndromic patients. Stenting a coarctation may be performed as an emergency in such patients and may acutely improve the newborn, deferring surgery to a later period after adequate weight gain or hemodynamic stability. This strategy compares favorably to a surgical treatment strategy, when applied in critically ill or vulnerable newborns [54].

The technique in these premature infants is slightly different from that previously described. Puncture of the femoral artery is performed with a 21 gauge needle allowing a 0.014″ wire to be introduced into the artery. A 4 Fr smooth tapered introducer sheath is placed in the artery. A 4 Fr

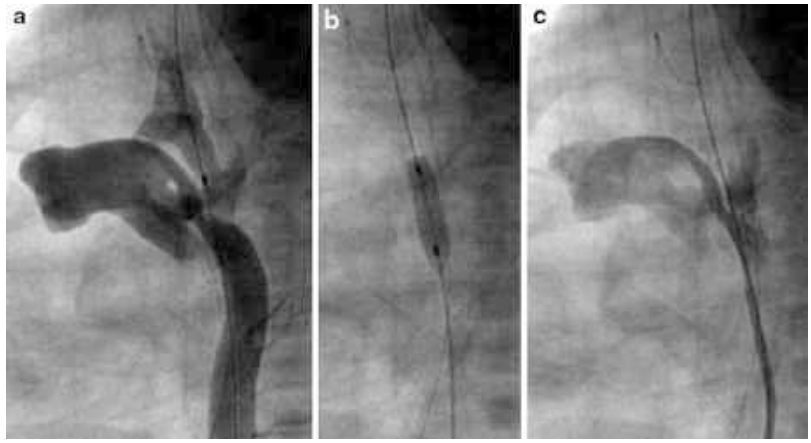

Fig. 64.7 Bail-out stenting in a premature infant. A 1,500 g infant presented with critical aortic coarctation. (**a**) Retrograde aortogram by hand injection of layered contrast-saline through a short 4 F sheath. A 4/8 mm coronary stent is positioned for deployment. Points of reference are the cranial end just beyond take-off of left subclavian artery and caudal end beyond coarctation site within the thoracic aorta. (**b**) Inflated balloon has expanded the stent. (**c**) Hand injection of contrast through 4 F catheter to confirm adequate position of stent

end-hole vertebral catheter is advanced up to the coarctation site where a small volume of 1 cc of contrast is injected by hand. The coarctation is crossed using an atraumatic 0.014″ coronary wire. If the isthmus cannot be entered retrogradely, a transvenous antegrade approach may be used. Another hand injection is performed in the aortic arch to delineate the anatomy and the origin of the left subclavian artery. A low-profile, premounted coronary stent is chosen on the basis of the pre-catheter echocardiographic measurements as well as angiography. The stent should ideally cover the arch from just distal to the origin of the left subclavian artery up to and beyond the coarctation site, the typical length being 8–12 mm. The stent diameter should equal the aortic arch diameter, which is usually about 3–5 mm. Such diameter allows a significant increase in size at the coarctation site, without risk of vessel tear because "fetal tissue" may allow significant stretch.

The stent is passed "unprotected" through the valve of the introducer sheath. Stent position is checked with retrograde aortogram hand injections through the short femoral sheath. A useful method is using sequential gentle aspiration of 5 cc of saline into a 10 cc syringe held vertically, followed by aspiration of 1 cc of contrast, keeping contrast and saline layered (Fig. 64.7). The stent is deployed using an indeflator device at a pressure recommended by the manufacturer. In premature babies and neonates with primary coarctation, the prostaglandin E-1 infusion is stopped immediately after deployment of the stent. Stent position is assessed with an aortogram through the 4 F catheter placed just below the stent. Such stents usually produce a satisfactory result for several weeks to months. In very small premature babies below 1,000 g weight, vascular complications may be avoided by accessing the aorta directly during a hybrid procedure. After sternotomy, a 4 F sheath is inserted in the ascending aorta, allowing the stenting procedure to be performed. Such an approach also allows for closure of the patent arterial duct [55] (Fig. 64.8).

The timing of surgical removal of the stent may vary. After some days when the neonate has recovered sufficiently from the initial cardiogenic shock, or after some weeks or months when adequate body weight has been reached to perform surgery safely, or when additional surgery is planned. If during follow-up more time is required, any coronary stent can be further dilated up to 5 mm as this also reduces the stent length if this were an issue for safe resection.

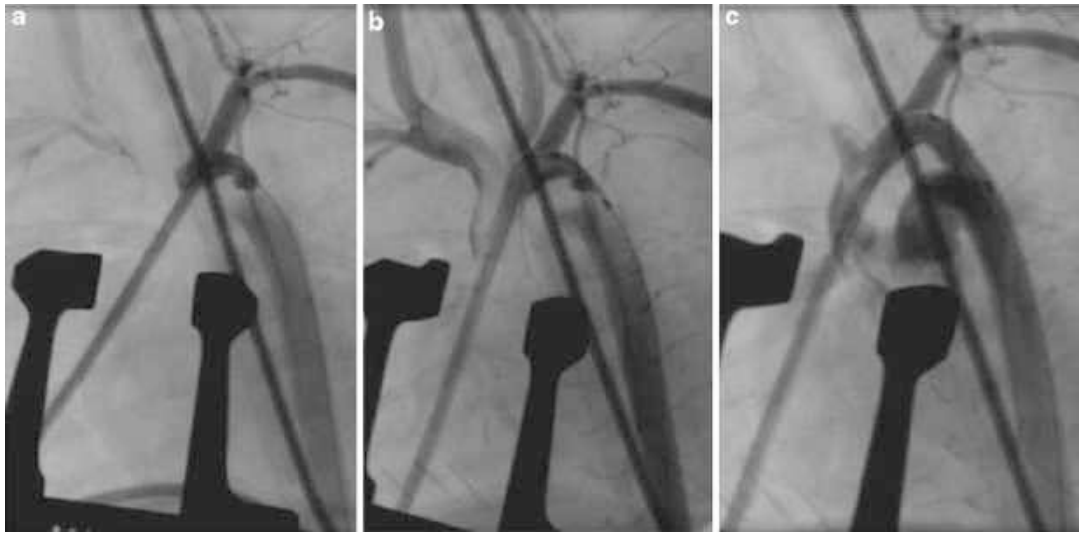

Fig. 64.8 Antegrade bail-out stenting in 850 g premature infant through sternotomy An 850 g infant presented with critical aortic coarctation. (**a**) After sternotomy, a 4 Fr sheath was inserted in the ascending aorta through a purse string. Aortogram is performed by hand injection. (**b**) A 3/8 mm coronary stent is positioned for deployment. Points of reference are cranial end just beyond take-off of the left subclavian artery and caudal end beyond coarctation site within the descending aorta. (**c**) Hand injection of small volume of contrast through 4 F catheter to confirm correct position of stent. The duct was then clipped surgically and the sternum closed. The stent was surgically removed 4 months later.

Dilation: Redilation

Staged dilation, in which stents are expanded to a diameter less than the adjacent aorta and redilated a few months later, may overcome the possible risks of excessive wall damage. A controlled injury is allowed time for healing of the arterial wall before full expansion is attempted. However, even with this approach, aneurysm formation may occur.

If stents are implanted in smaller patients, somatic growth of the patient will require further redilation. In this age group, stenting should be reserved for exceptional clinical indications rather than routine use because excellent surgical results can be obtained with extended arch repair.

Redilation of a stent is generally a straightforward procedure. However, such procedure may still be associated with complications. Within a bare stent, an aneurysm may develop and embolization of intimal peal may occur; dissection and aneurysms may develop at the stent ends, but also at a distance. Most stents shorten when dilated to larger diameter, causing longitudinal stress on the vessel wall. Theoretically, it is safer to dilate gradually in small steps and with short balloons. An excessive shoulder of a big long balloon may tear the vessel wall from the stent before effective dilation. Such complication has been reported with late dissection of the thoracic aorta and fatal outcome [48]. An aortogram should therefore be performed at least at the end of any procedure, and if such complication is observed or suspected, implantation of an additional covered stent may be lifesaving.

When using covered stents, the operator should aim for adequate apposition of the stent to the wall, thereby allowing maximal adherence of the stent around the narrowed segment. Such safety zone will seal the expected tear at further dilation.

Arch Atresia

A long standing critical coarctation may occlude completely, creating an atretic segment by the

time treatment is initiated. The pre-catheterization evaluation should attempt to determine whether there is critical stenosis or atresia. Careful Doppler examination may show a tiny connection on color flow or a typical saw-tooth pattern. If atresia or critical stenosis is expected, access through both the brachial/radial and femoral arteries must be obtained. Angiography is performed proximal and distal to the interrupted segment. In some patients, a minute connection may be found when actively looked for. This can be crossed with the use of a 0.014″ coronary guidewire or a 0.018″ guidewire in a 2 F tracking microcatheter system [56]. When no connection is found, recanalization may be performed by puncturing with a stiff end of a guidewire of 0.035″ caliber or a 0.014″ guidewire or a Brockenbrough needle or by radiofrequency perforation using a Nykanen 0.024″ wire through a coaxial system (Baylis Medcomp, Montreal, Canada) or a PT2 coronary wire through a 2 Fr Progreat catheter passed through a 4 Fr catheter [57]. The anatomy of each patient will determine how the atretic portion is best crossed. Usually, this is from the arch to the thoracic aorta, with an opened snare in the descending aorta as target. Once the guidewire is snared, an arterio-arterial circuit is established. Predilation may be required to allow crossing the defect with the delivery sheath. A covered stent is implanted with sufficient overlap proximal and distal to the atretic segment. Full stent expansion may be performed a few weeks after the initial stenting procedure.

Stenting of Transverse Aortic Arch

Many patients with a coarctation may have associated hypoplasia of the transverse arch, which can leave a residual gradient. The surgical treatment option for transverse arch hypoplasia is to perform an extended arch repair, which frequently requires cardiopulmonary bypass and is not risk free, or insertion of a bypass graft.

Percutaneous treatment of arch hypoplasia is slightly different from coarctation treatment [58, 59]. Balloon dilation is likely to be unsuccessful, and so stenting may be necessary. The margin between a therapeutic tear and a catastrophic rupture is very small. The adventitia is adherent to the media in the transverse arch, which is not the case in a typical coarctation where the adventitia "jumps" from the isthmus over the coarctation to the thoracic aorta. Therefore, when stenting the transverse arch, the aim is to stretch the wall without creating a tear. In the proximal transverse arch, bare metal stents are almost exclusively used, while in the distal arch, a covered stent may be used. Such stents may be positioned across the origin of the left subclavian artery and exclude it. This can then be reopened easily by retrograde perforation of the covering and balloon dilation of the orifice (Fig. 64.3).

An ascending angiogram is performed in two planes perpendicular to each other with the aim of defining the arch anatomy as well as the origins of the innominate, the left common carotid, and the left subclavian arteries. Balloon interrogation of the hypoplastic segments of the arch with a low pressure, mildly oversized balloon such as Tyshak balloon (NuMed) is essential. The stretchability of the segments can be assessed, which determines the balloon size and the desired stent conformation during deployment (Fig. 64.9). This technique allows the operator to avoid deployment of an undersized stent which will anchor itself insufficiently in the wall and possibly migrate, or to tear a narrow, unstretchable segment. The balloon diameter is chosen based on the largest stretched diameter of the aortic segment to be stented. The stent needs to be about 3–5 mm longer than the distance between the origins of the vessels where the aorta is to be stented. Stents partially protruding over the origin of the left common carotid artery can be flared into the vessel, whereas struts covering the origin of the left subclavian artery are of less concern. During inflation, the stent will shorten asymmetrically, typically around the point where the stent touches and anchors itself in the aortic wall.

Angiograms are performed through the side arm of the Mullins sheath to check for accurate positioning of the stent. The Mullins sheath is withdrawn while keeping the stent/balloon

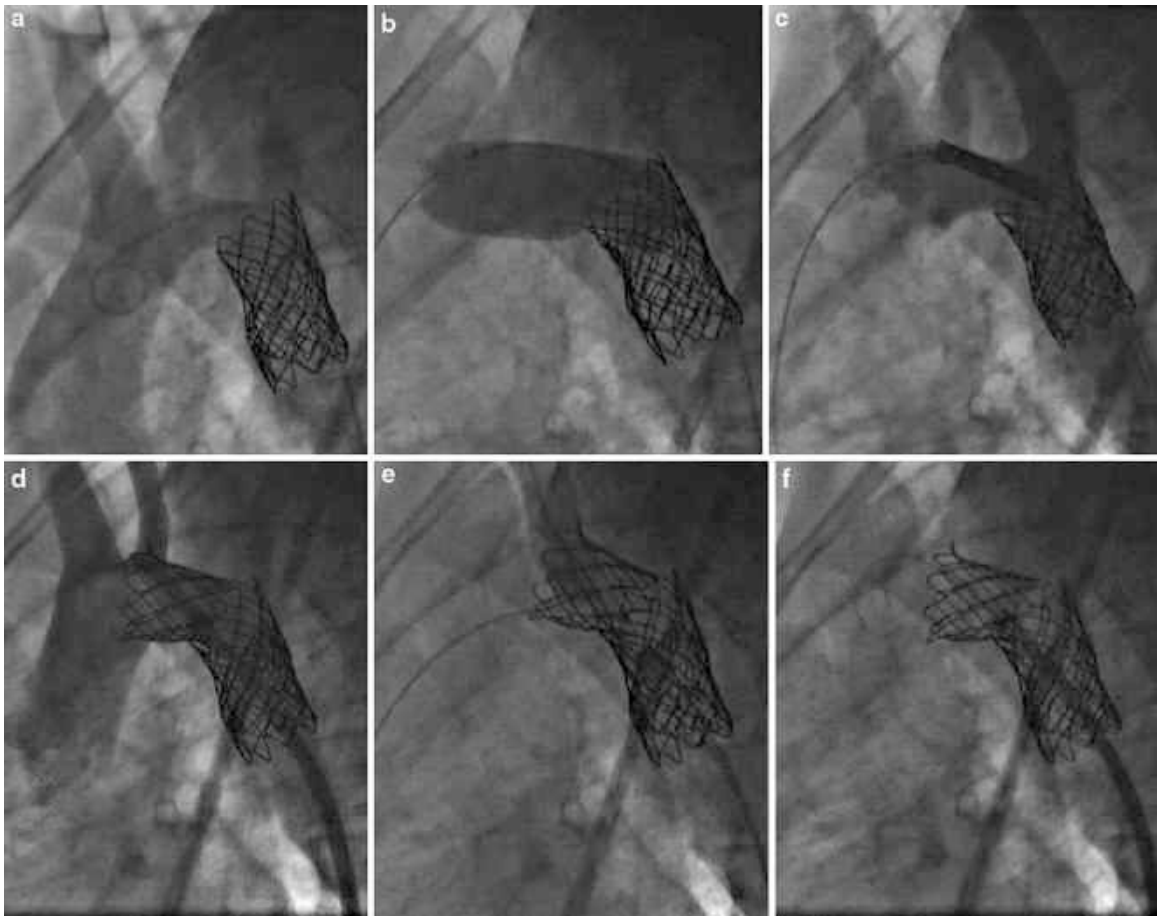

Fig. 64.9 Stenting of the hypoplastic transverse arch. A 19-year-old boy with previous stenting of coarctation and residual hypertension: (**a**) Aortogram shows 12 mm diameter hypoplasia of distal arch between the left common carotid and the left subclavian arteries. There was a gradient of 15 mmHg. Coarctation was previously stented with 20 mm diameter stent. (**b**) Low-pressure balloon interrogation with 20 mm Tyshak® balloon to determine compliance of hypoplastic segment. (**c**) Deployment of 28 mm bare CP stent on 20 mm BIB® balloon at low pressure through 13 F sheath. (**d**) Stent in transverse arch. (**e**) Flaring of stent into left carotid artery with 16 mm balloon. (**f**) Final result with no residual gradient

assembly in position so as to expose the stent. The balloon is inflated manually at low pressure. A BIB balloon allows deploying the stent as accurately as possible. The expansion of the stent is usually symmetrical during inflation of the inner balloon, and asymmetric shortening only occurs when the stent anchors itself in the aortic wall. The stent is apposed to the wall under low pressure, aiming to stretch and not tear the wall. On balloon inflation, the stent shortens and so may clear off the origin of the carotid artery, or the end of the stent can be flared into it.

Middle Aortic Syndrome

Middle aortic syndrome is an uncommon lesion presenting with physical signs of coarctation of the aorta, hypertension, renal insufficiency, and/or mesenteric ischemia. The etiologies are multiple, but Takayasu's arteritis is a leading cause. Variable involvement of diverse systemic arterial systems requires individualized management strategies. The aortic wall becomes very thick and pressure resistant, and balloon dilation alone yields poor results. Stenting using high-pressure balloons is required, with a significant risk of vessel tear and stent thrombosis [60]!

What if a Residual Gradient Persists After Percutaneous Stenting

Despite percutaneous stenting and an optimum result, a significant residual gradient may persist due to residual hypoplasia of the aorta, which cannot be dilated safely, or due to angulation in a high cervical Gothic arch, restrictive stents, or conduits. Surgery in an arch with gradients at different levels can be difficult, even more so when some segments are stented. Adequate gradient relief can then be obtained with an extra-anatomic bypass [61]. Two types of approaches can be applied. A repair through a median sternotomy consisting of creating a "right arch," with the insertion of a bypass from the right lateral wall of the ascending aorta, routed around the right margin of the heart, to the supra-celiac abdominal aorta. A second approach is through a left thoracotomy with interposition of a graft between the ascending and descending aorta or interposition of a graft between the left subclavian artery and the descending thoracic aorta.

True Aneurysms

A true aneurysm consists of dilation of all layers of the vessel wall. Small aneurysms can be treated very effectively with a covered stent as described above. However, several treatment strategies, both surgical and interventional, can be complicated later with large and long thoracic aneurysm formation. Such aneurysms are associated with a high rate of rupture within 15 years after detection [62]. Traditionally, these aneurysms are treated by repeat surgery including interposition graft placement under cardiopulmonary bypass, hypothermic circulatory arrest, or other methods of distal circulatory support. Postoperative mortality may be as high as 13 % and morbidity may include paresis of the left recurrent laryngeal nerve and bleeding requiring repeat thoracotomy. Thoracic endovascular aneurysm repair (TEVAR) has emerged as a minimally invasive alternative for repeat surgery after coarctation repair [63–65]. These techniques however involve self-expanding systems requiring large sheaths of 22–24 Fr, which necessitate a surgical cutdown.

Pre-interventional imaging is usually performed with magnetic resonance and/or computed tomography imaging, including 3-D reconstructions. The diameter of a thoracic aortic stent graft should be oversized by 10–15 % compared with the nominal diameter of the proximal and distal landing zones. The length of the stent graft should include the length of the aneurysm and the length of the proximal and distal landing zones, which are at least 2 cm each. Typical contraindications for conventional TEVAR are too small proximal luminal diameter, too short length of the landing zone, and an acute angle of the thoracic arch such as Gothic arch. These cases should be considered for open surgical or hybrid repair.

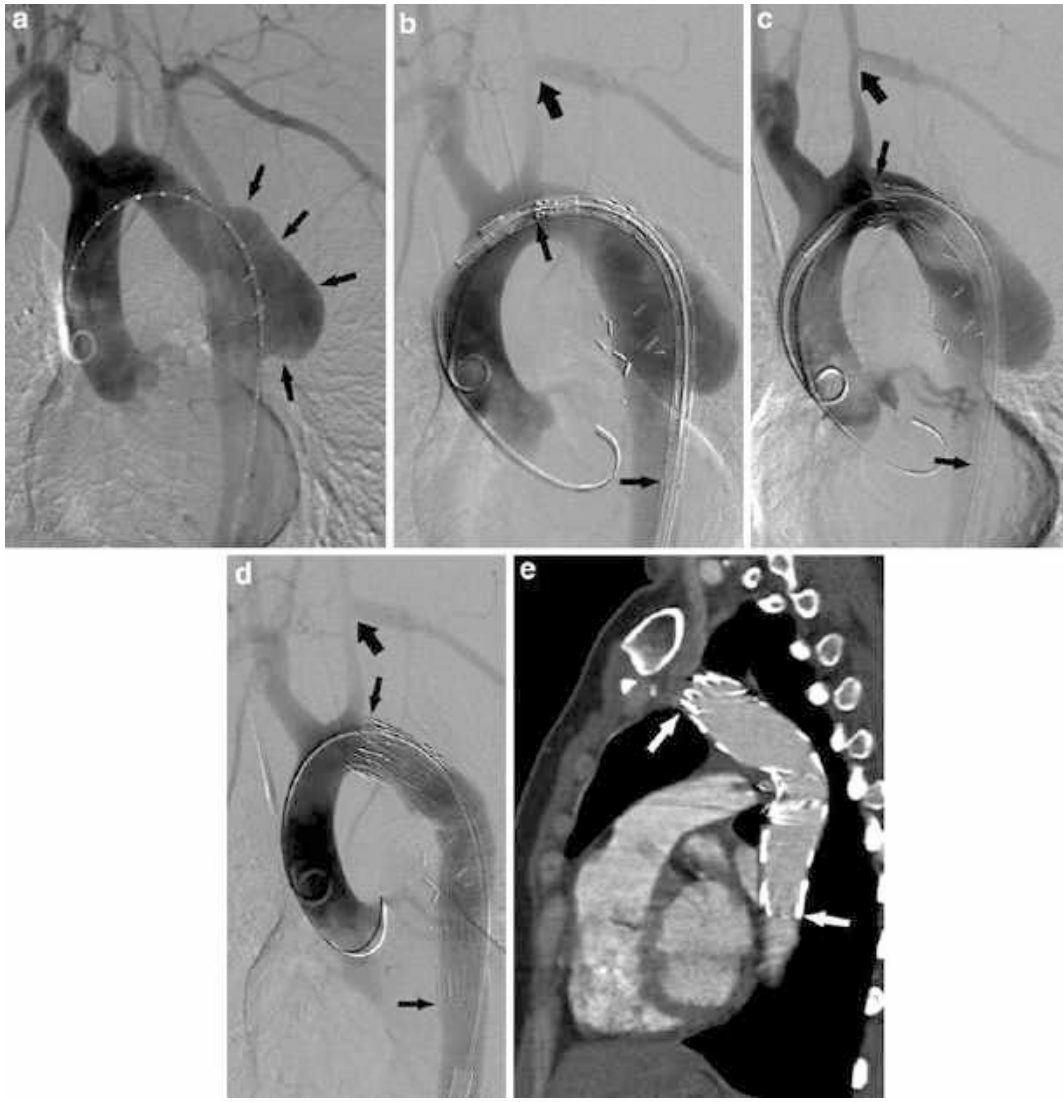

Fig. 64.10 Exclusion of aneurysm by stent graft. A 32-year-old woman presented with an asymptomatic aortic aneurysm, 28 years after Dacron patch aortic arch repair. (**a**) Calibrated catheter flush aortography revealed an aneurysm of 50 mm (*arrows*) distal to the origin of the left subclavian artery. (**b**–**d**) Transfemoral insertion of a Zenith TX2® (Cook) stent graft (*small arrows*) loaded in a 20 F sheath after carotid to subclavian artery transposition (*large arrow*). (**e**) Repeat CT scan 6 months after the stent-graft procedure shows the stent graft (*white arrows*) completely excluding the aneurysmal sac

The stent graft is positioned over the aneurysm and carefully deployed under hypotension induced by rapid right ventricular pacing to reduce the systolic blood pressure to less than 80 mmHg and angiographic and transesophageal echocardiographic imaging control (Fig. 64.10). In case of a small diameter arch and a normal diameter descending thoracic aorta, a reversed and tapered custom-made device is preferred [66]. Following deployment, the device can be further conformed and approximated using a large, compliant balloon, therefore obtaining optimal proximal and distal sealing.

During the last decade, several small case series, mostly consisting of less than ten patients, have been published [67–69], all demonstrating

that TEVAR is relatively safe and effective for endovascular repair of aneurysms associated with coarctation surgery. Major complications seem to be rare, although perioperative and postoperative mortality may occur [70, 71]. Procedure- and device-related complications encountered after TEVAR for coarctation aneurysms include left-sided arm claudication due to intentional covering of the left subclavian artery, endoleaks, infolding, and collapse of the stent graft, graft infection, stent migration.

Conclusions and Recommendations

Although treatment of coarctation of the aorta with balloon-expandable endovascular stents is technically challenging, it is a relatively safe and extremely effective treatment modality when used carefully in selected patients. The shift from simple balloon angioplasty to implantation of bare stents and eventually covered stents has significantly improved results while decreasing complications. Further research is necessary to determine the incidence of various complications and identify risk factors, allowing refinement of guidelines for even safer and more successful procedures.

With current knowledge and experience, the following recommendations can be made:

(a) In infants and children less than a year of age, surgery is the treatment of choice for all native coarctation, and balloon angioplasty is the treatment of choice for most recurrent coarctations. In very premature and critically ill neonates, bail-out stenting may be considered, and later surgical stent removal may avoid many complications typically observed in this difficult age group.

(b) Between the ages of 1 year and the time when the child reaches a weight of 30–35 kg, usually 9–11 years, there is insufficient data to determine whether surgical intervention or balloon angioplasty is preferable for native lesions. Percutaneous treatment usually involves several interventions during growth, while surgical results in a single procedure are very good. Balloon angioplasty is the treatment of choice for recurrent coarctation in this age group.

(c) In children weighing more than 35 kg who have not reached adult size yet, it is likely that the treatment of choice for native and recurrent lesions could be endovascular stent placement, as it has been demonstrated that stents can be enlarged safely at a later time to accommodate somatic growth.

(d) In adolescent and adult patients, stent placement is the treatment of choice for all lesions, whether native or recurrent.

(e) In many situations, the use of covered stents is emerging as the safer option, especially in adults of advanced age and in patients with known vasculitis or other conditions associated with vasculopathy.

(f) TEVAR is a good option to treat large thoracic aneurysms.

(g) All patients require long-term follow-up for timely detection of aortic aneurysms or dilation, as well as arterial hypertension.

Mazeni Alwi and Ming Chern Leong

Abstract

Ventricular and atrial septal defects are the commonest congenital cardiac defects. Though surgical closure of these defects can be performed with very low mortality and morbidity, the option of transcatheter closure, which obviates the surgical scar, the need to undergo painful surgery, and ICU stay, is desirable to many patients. Transcatheter closure of atrial septal defects, which is currently limited to secundum defect with good surrounding rims, has proven safety and efficacy. This chapter will discuss the evolution of ASD devices, the different device designs, as well as the closure procedure and complications. Patent foramen ovale closure, though controversial, may be indicated in selected patients who have a history of cryptogenic stroke, decompression illness or migraine. The chapter discusses these controversies and the methods of device closure. Transcatheter VSD closure, which is technically more challenging, has a well-established role in muscular VSDs. However, worrisome complications associated with closure of membranous VSD makes conventional surgery the preferred method of closure of this type of VSD. The chapter will elaborate on both percutaneous and perventricular closure of muscular VSDs, as isolated lesions and those following repair of complex malformation.

Introduction

Ventricular septal defect (VSD) and atrial septal defect (ASD) were among the commonest congenital cardiac defects, in various population-based studies ([1]). Closure of these defects, when indicated, is also the commonest procedure performed for the treatment of congenital heart disease (CHD). As patients with ASD tend to be asymptomatic and may only be diagnosed in adult life due to lack of obvious clinical signs, they tend to be referred for closure at a later age than patients with VSD. Surgical closure for both ASD and VSD in the modern era has excellent results, with low morbidity and a mortality that approaches zero. However, conventional surgery requires cardiopulmonary bypass, an ICU stay, and generally a hospital stay of a few days. An efficacious alternative method of closure that avoids a sternotomy scar and is associated with minimal pain and a short hospital stay is desirable to patients. The last two decades have seen a proliferation of devices that have been designed for closure of secundum ASD. Today, device closure is the treatment of choice for closure of secundum ASD when the defect size and morphology do not preclude it.

Compared with ASD, device closure of VSD has a more limited clinical application because of the morphologic characteristics of these defects in relation to important structures of the heart, the complexity of procedure, and the complications. However, device closure has a well-established application for muscular VSDs and those VSDs that become apparent following repair of complex lesions, either from previously undiagnosed defects or those that result from patch dehiscence. Acquired muscular VSD from acute myocardial infarction or chest trauma will not be discussed.

Patent foramen ovale (PFO), found in approximately 20 % of post-mortem specimens, has received much clinical attention over the last decade due to its association with cryptogenic stroke, migraine and decompression illness in adult patients. One section in this chapter discusses the clinical relevance of PFO, the controversies surrounding the need to close it, and the methods of percutaneous closure. As the devices and the procedure for PFO closure is fairly similar to that ASD closure, this section follows that of ASD.

The principles of device closure, current available devices, and complications are discussed. Crucial to the success of these procedures is the imaging support by echocardiography, either transesophageal or intracardiac for a detailed pre-procedure evaluation, to guide device implantation, and postimplantation assessment, including detection of serious complications.

Closure of Atrial Septal Defect

ASDs are among the commonest congenital heart defects in children and in adults with CHD. They are classified according to the location and the proposed embryogenesis of the defect: (a) primum ASD involves the atrioventricular junction of the heart. It is part of the spectrum of endocardial cushion defects, and frequently the mitral valve is involved by having a cleft at the anterior leaflet; (b) secundum ASD is a true defect which lies in the central aspect of the septal wall; (c) sinus venosus ASD is located adjacent to the systemic venous circulation of the atrium. The defect is frequently associated with anomalous drainage of the right pulmonary vein, and (d) unroofed coronary sinus where there is a persistent left superior vena cava

draining into the coronary sinus which is unroofed.

Although surgical closure of ASD can be performed with a low mortality, percutaneous ASD closure, which is currently limited to secundum ASDs, offers patients with a suitable anatomy an attractive alternative.

ASD Device Concept and Design

The quest for this alternative treatment began in 1976 when King et al. first reported their clinical success in ASD closure in a 17-year-old girl using a device made up of double umbrella device which was connected by a stalk [2]. The King-Mills device was used to close a total of seven patients but two of the devices could not sit properly, and the patients required surgical repair. A recent 27-year follow-up showed that four of the five patients were alive and well with no residual shunt or long-term sequelae [3]. The method of device closure described has been the cornerstone of transcatheter ASD closure used in the modern era. The use of general anesthesia, heparin to reduce the occurrence of thromboembolism and a balloon for sizing of the defect, was described then and is still very much in use by interventionalists today. The principle behind device closure involved the use of a self-expanding double umbrella in which each of the umbrellas sits in the atria on either side of the defect. The umbrella was made up of radially extending struts which have membranes sewn onto them. The metal struts gave the device its support while the membranes provided the occlusion. The device could be folded and loaded in a sheath, which was then introduced into the patient and manipulated by a delivery cable. The major drawback of the procedure was the high profile of the delivery system, a 22-French sheath, which required a venous cutdown. Nevertheless the double umbrella has inspired further refinements in devices and closure techniques.

In 1990 Lock and associates reported the use of the first Lock Clamshell device, which has the same radially arranged stainless steel struts leading from the center with two facing polyester membranes sewn onto them [4]. The struts were finer than the ones originally designed by King et al., and they could be further folded to allow for a delivery system of a smaller profile. The device was widely used to close ASDs, PFOs, and even in patients with residual ASD postcardiac transplantation. However, concerns were raised when the device, especially the larger ones, sustained fatigue fractures of the struts and there was a potential for myocardial injury from the radially extended struts and device embolization.

In 1990 Sideris et al. designed a device which consisted of an occluder (the left atrial disc) and the counter-occluder (the right atrial disc) [5]. The left atrial disc was a polyurethane foam supported by a wire skeleton which opened up into an X shape with a knot in the center. The counter-occluder was a foam in rhomboid shape which had a rubber piece sewn in its center. When pieced together, they formed a "button." It fell out of favor due to the complication of spontaneous "unbuttoning." The subsequent devices such as the ASDOS (ASD occluding system) [6], Das Angel Wings [7], CardioSEAL [8] and its modification, the STARFlex device utilized a similar concept. Although there have been modifications to the design and the structure of devices, with the exception of the Das Angel Wings, they retained the concept of a membrane attached to the radially extended struts in the occluder. The disadvantages of this design are the issues of possible strut fracture; trauma to the adjacent structures by the rigid struts, particularly with attempts at retrieval; and their non-self-centering features which may displace the device postimplantation. Such complications have also been attributed to the latest incarnation of this design concept, the Atriasept device [9].

In the 1990s Amplatz introduced the Amplatzer septal occluder, which revolutionized the device design [10]. This device consists of two basket type weaving of nitinol wires. Nitinol is a nickel alloy with a laden memory which springs into its original shape when unconstrained. The soft pliable nature of this device allows it to be loaded into a small profile

Table 65.1 Comparison of characteristics among the three major ASD devices

Characteristics	Amplatzer ®	CardioSEAL ®	Gore Helex ®
Manufacturer	AGA medical	NMT medical	WL Gore & Assoc
Device design	Double disc with a 3–4 mm connecting waist Self-centering	Two square-shaped umbrella connected in the center with coil springs at either arm	Non-self-centering, double spiral disc
Skeleton	Nitinol wire mesh	Nonferromagnetic alloy, Mp35n in radial extension	Wound nitinol
Fabric	Dacron polyester	Woven Dacron	Hydrophilic Gore-Tex fabric
Conformity	Highly	Less compared to the others	Highly
Sizes available	4–40 mm	23–44 mm	15–35 mm
Delivery sheath	6–14 French	10–11F sheath	9F integral delivery catheter
Remarks	Larger LA disc	Not suitable for defect > 20 mm	Biocompatible and low profile

[a]For ease of description, the cardioSEAL device and the newer generation STARflex device are collectively referred to as the cardioSEAL device in this review. Both cardioSEAL and STARflex are no longer available, but they were included in the table for comparison of different types of device designs

sheath, and it is self- expandable on delivery. Each of the discs grips on either side of the atrial wall giving stability to the device while the inlaying polyester fibers attract clotting elements, occluding the defect over time. The device "waist" gives it a self-centering advantage over the other devices. Moreover, this device is easily retrievable and repositionable, allowing operators to adjust and readjust the device if it is not properly positioned, as long as the device is still connected to its delivery cable. These properties made it overwhelmingly the most widely used device for ASD closure over more than a decade (Table 65.1).

The Helex septal occluder is another device that addresses the problems faced by the double umbrella design by having several desirable features, namely soft, atraumatic shape, flexibility, and retrievability. It consists of a helical coil with attached PTFE, which occludes the defect. This device has a small profile delivery system but is suitable mainly for small- and medium-size ASDs.

In the United States, currently only the Amplatzer septal occluder and the Helex septal occluder are approved for clinical use. There are other ASD occluders which may not be registered with the FDA but are being used in other parts of the world.

Indications

Due to the design of these devices, only secundum ASDs with adequate surrounding septal rims to allow a good grip of the device are suitable for device closure. Transcatheter secundum ASD closure is performed in children with significant left-to-right shunting, evidenced

by right heart chamber volume overload or a Qp: Qs > 1.5:1. In children, the indication for closure is relatively straightforward and is usually performed after the child attains a weight of 15–20 kg, when the procedure is better tolerated and technically simpler, especially if larger device sizes are used. On the other hand, the indications for closure in adults are less well defined. In 2008, the American Heart Association Guideline Task Force published the indications for ASDs closure in adults [11], which included (a) presence of left-to-right shunting with right chamber dilatation (Class I, level of evidence: B); (b) presence of paradoxical embolism (Class IIb, level of evidence: C); (c) documented orthodeoxia-platypnea (Class IIb, level of evidence: B); and (d) presence of nett left-to-right shunting, pulmonary arterial pressure less than two-third systemic levels, pulmonary vascular resistance less than two-third systemic vascular resistance, or when responsive to either pulmonary vasodilator therapy or test occlusion of the defect (Class IIb, level of evidence: C).

Small ASDs less than 5 mm generally do not cause right heart chamber dilatation and are at negligible risk for pulmonary arterial hypertension. Nevertheless they should be kept under vigilance as the shunt may increase with decreased left ventricular compliance with age [12]. For small ASDs with history of paradoxical embolism resulting in stroke or transient ischemic attack, closure is recommended. Larger ASDs are associated with the risk of developing pulmonary arterial hypertension, irreversible arrhythmias, and reduction in effort tolerance in the long term due to long-standing shunt via the defect. Closure should therefore be performed during childhood before these complications set in. This is supported by data from adult patients, in whom closure by surgery can provide symptomatic relief and survival benefit [13], improvement in the cardiopulmonary exercise capacity [14], and measureable cardiac function [15]. A recent meta-analysis showed that ASD closure reduces the prevalence of preexisting atrial tachyarrhythmias in the short and medium term [16]. However, a significant proportion of these adult patients have persistent atrial tachyarrhythmias following closure. Gatzoulis et al. showed that age above 40 years at the time of repair and the presence of preexisting atrial arrhythmias were at risk of late postoperative arrhythmias [17]. Prolonged shunting and stretching of the right atrial chamber secondary to volume overload may have caused fibrotic remodeling, which may not be reversible post closure. The initial reversion to sinus rhythm may be short-lived in many patients with long-standing atrial arrhythmias post closure. Hence, the decision for closure of ASDs in the elderly and patients with established atrial arrhythmias should be individualized. Several studies have shown outcomes from transcatheter device closure of secundum ASD to be comparable to surgical outcome in carefully selected adult and pediatric patients [11, 18–21]. It is associated with low complication rates, short anesthetic times, and short hospitalization, and has become the treatment of choice in many institutions.

Contraindications

In patients who have established pulmonary vascular occlusive disease and Eisenmenger disease, ASD closure is contraindicated as the defect offers a physiological pop-off mechanism to the pressure-loaded right ventricle. Closing the ASD in this situation may worsen the right ventricular function and offset the hemodynamic balance. ASDs with unsuitable anatomy or other concomitant anomaly, such as partial anomalous pulmonary venous drainage, which may warrant surgical intervention, are best treated surgically where the concomitant surgical lesion is dealt with during the same operation. ASDs with deficient posterior or inferior rim are likely to be technically difficult for device implantation and are at risk of device embolization. Large ASDs may pose difficulty in device closure as these are typically insufficient in the surrounding rim to hold onto the device. They are at higher risk of embolization early postprocedure should the device not be securely held by the rim or an

incorrect device size is used. Additionally, balloon sizing, if employed, may be inaccurate with larger defects.

Procedure

General anesthesia is usually employed in all children and most adults to allow for the uncomfortable transesophageal echocardiography (TEE). Intracardiac echocardiography (ICE) offers images comparable to the TEE and has obviated the use of general anesthesia, allowing ASD closure to be performed on a day-care basis [22]. However, the benefit of this technology has been offset by the prohibitive price of the ICE catheter and hence may not be available in all centers. If ICE is used, an additional venous sheath of 8F will be needed for introduction of the probe, which can be operated by the same operator. During TEE, assessment of the size and shape of the ASD as well as the number of ASD is performed. The rims of the ASD should be at least 7 mm from adjacent structures, namely the superior and inferior vena cava, pulmonary veins, coronary sinus, and the atrioventricular valves (AV) (Fig. 65.1). A deficiency in the anterior (aortic) rim is not a contraindication if the other surrounding rims are adequate. The drainage of pulmonary veins, best viewed on TEE, is assessed. The mobility and competence of the atrioventricular valves are recorded for comparison as infrequently, impingement of the device onto these valves may interfere with their function. 3D TEE is not mandatory (Fig. 65.2) but is useful in the evaluation of septum with multiple defects.

It is good practice to perform an initial hemodynamic study to estimate the shunt size and pulmonary vascular resistance. The technical detail of device closure, such as using the Amplatzer septal occluder, has been described elsewhere [23] (Fig. 65.3). Care should be taken to minimize traumatic injury to cardiac structures and vessels by the stiff wires and delivery systems, and air embolism, especially with large sheaths required for the larger devices. Balloon sizing to select appropriate device size was rigorously followed at the beginning of the device closure era, but this is not considered an essential step nowadays [24]. However, in defects with thin floppy rims, balloon sizing is advisable to minimize undersizing of the device, which may lead to inadvertent embolization.

Tackling Difficult ASDs

Occasionally there may be two or more ASDs in a patient. The treatment for these ASDs depends on the distance of the one defect from the other. As the LA disc of the Amplatzer device is 14 mm wider than the waist, putting two devices in two closely approximated ASDs may cause overcrowding of the devices. As a general rule, if the ASDs are at least 7 mm apart, two devices may be safely placed. However, if the ASDs are closely related, as in the event of a fenestrated ASD, a cribriform ASD device can be used. The disc should cover all of the lesions, and with endothelialization, the fenestrated ASDs may be occluded. Otherwise, surgery should be considered.

The Amplatzer device and other similar design of devices are suitable for large ASDs as the device sizes are available up to 40 mm. Occluding large ASD is challenging as the delivery cable, approaching from the inferior vena cava, is at an angle with the atrial septum. The anterior aspect of the LA disc tends to prolapse into the RA in this situation. Several techniques have been proposed. Varma reported successful closure of large defects by rapid deployment of RA disc while the LA disc is still in the left or right upper pulmonary vein [25]. The principle is to prevent the LA disc from prolapsing into the RA. In another technical modification, Wahab used a stiff dilator to hold the LA disc in the LA [26]. The use of balloon-assisted technique by Dalvi has also accomplished a similar objective [27]. All of these techniques help in maintaining the left atrial disc within the left atrium while the right atrial disc is delivered in the right atrium. The balloon is then deflated and withdrawn carefully while ensuring by imaging that the device has remained in correct position across the defect.

(**c**) 15 mm central defect with good surrounding rims. (**d**, **e**) A small 8 mm ASD with a thin and flimsy rim. (**f**) A large defect with deficient posterior rim. A small pericardial effusion is noted. (**g**) 18 mm ASD with absent anterior-superior rim (aortic rim)

Postprocedural Care

The patient is extubated in the catheter laboratory and transferred to the ward with standard groin care instructions. Prophylactic antibiotic is given for 1 day, but this depends on individualized unit policy. ECG, chest x-ray (anteroposterior and lateral), and echocardiography are performed to look for new onset of atrial arrhythmias and pericardial effusion, the position of the device, and the presence of residual shunt. Depending on individual institutional practice, patients are generally discharged the next day with 6 months of aspirin (3–5 mg/kg/day) to prevent thrombus formation onto the device surface and its associated neurologic sequelae while allowing endothelialization of the device. Subacute bacterial endocarditis precautions are observed for the first 6-month post-occlusion, as there may be residual shunting across the defect and

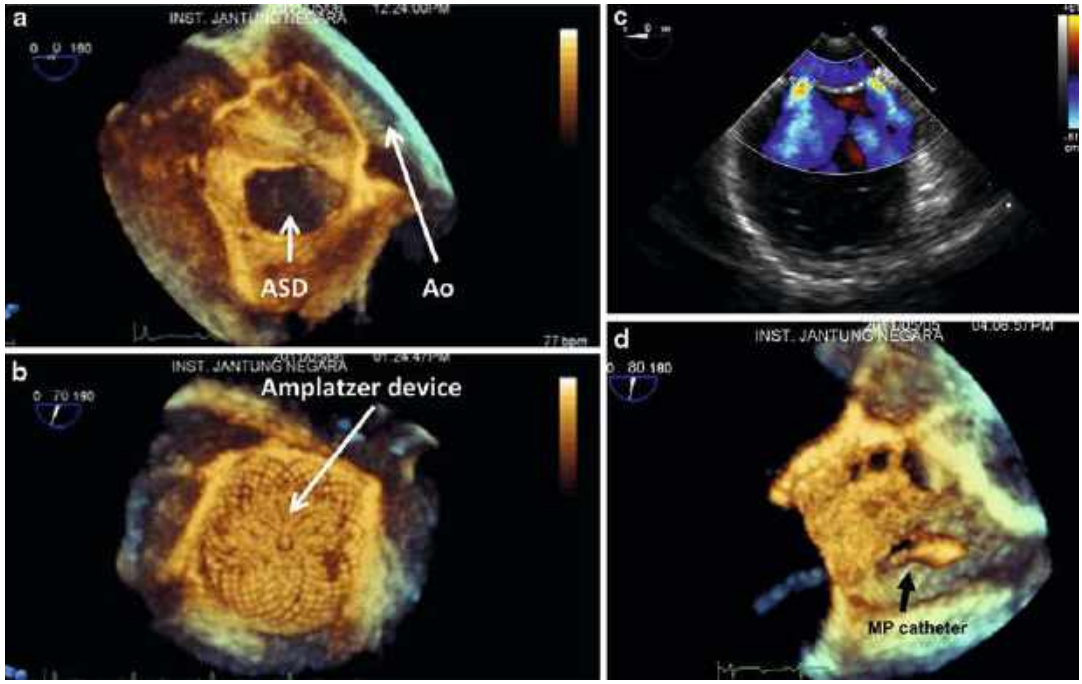

Fig. 65.2 *3D TEE*. (**a**) An oval shaped moderate secundum ASD with deficient anterior-superior rims as seen from the LA. (**b**) Device implanted. (**c**, **d**) 2D image showing two ASDs. However on the 3D image, there are four ASDs and one of the defects crossed by a multipurpose catheter

insufficient endothelialization of the device. Eventual endothelialization will seal off the residual defect and further stabilize the device.

Complications

In well-selected cases, transcatheter ASD closure has been shown to have excellent results with few procedural complications [18, 20, 21]. However, a few serious complications have been recognized. Atrial arrhythmias have been reported postprocedure. Commonly these arrhythmias are short-lived and resolve within 24 hours. They are believed to be secondary to compression of the device onto the septal wall. Usually the arrhythmias settle spontaneously, but occasionally appropriate antiarrhythmic treatment may be needed for 6–12 months. If the arrhythmia persists, the device may need to be explanted or retrieved to avoid permanent arrhythmias. Device embolization is a rare complication which may occur in large ASDs and those with deficient rims. Should embolization occur, it is usually within 24–48 hours post-occlusion, although later embolization has been reported. The embolized device is usually to the right heart, frequently in the pulmonary arteries. Embolization to the left heart has also occurred (Fig. 65.4). Embolized device should be retrieved as soon as possible either by transcatheter means or surgically. The thrombogenic nature of the device can cause disastrous thrombus formation, which may occlude the pulmonary artery or cause pulmonary embolism. The Amplatzer and Helex devices may be retrieved atraumatically using snares and large long sheaths. However, retrieval of the umbrella type devices is technically difficult and may cause injury due to its rigid metallic arms. The most serious complication is erosion which may lead to pericardial effusion and tamponade. Several reports have been published on this complication by the Amplatzer device [28, 29]. The Amplatzer-related erosion typically involves the superior-anterior rim of the atrial septum especially when the rim is deficient or

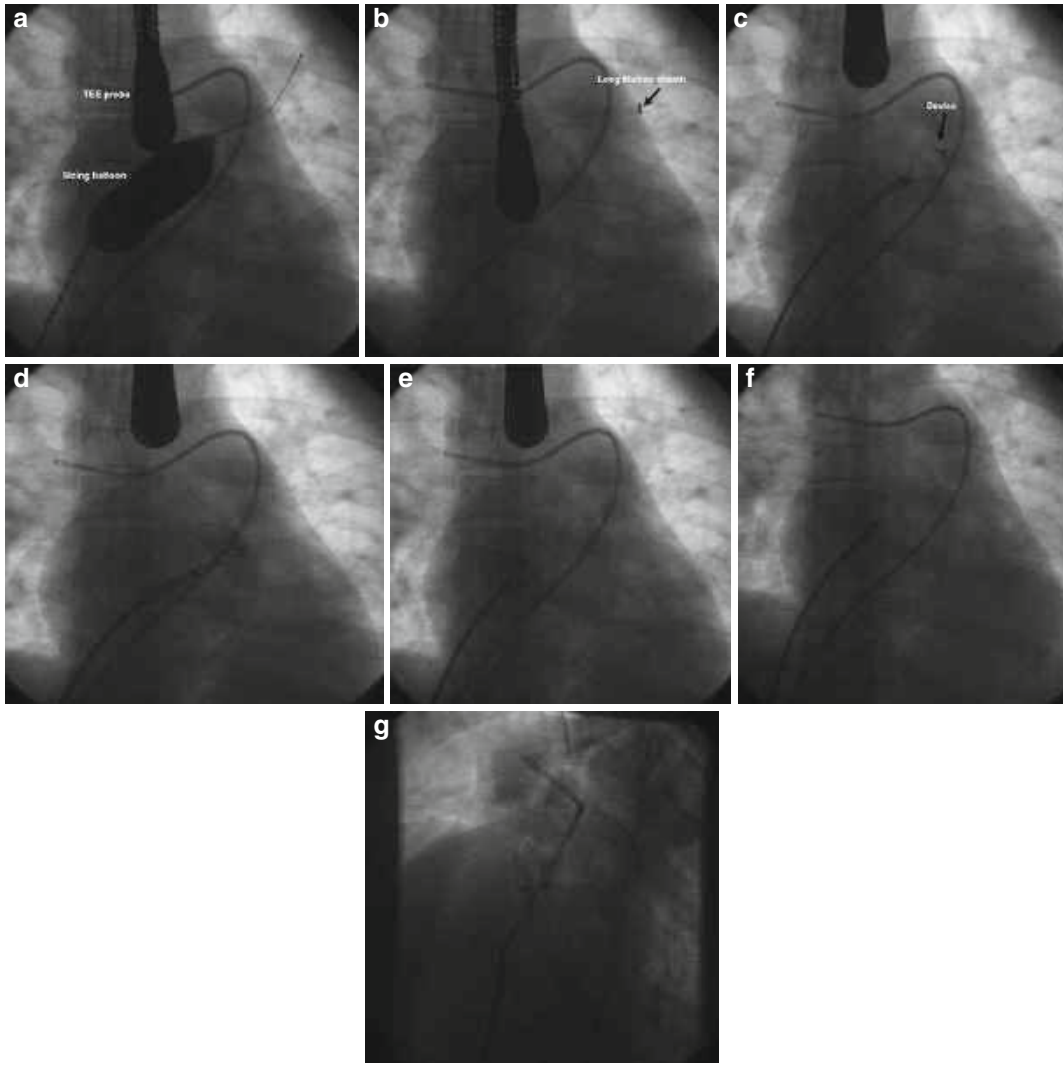

Fig. 65.3 *Step by step implantation of Amplatzer Septal Occluder*. (**a**) A super stiff exchange length guidewire is positioned at the left upper pulmonary vein. A sizing balloon is monorailed onto the stiff wire and inflated to size the ASD. (**b**) After determining the size of the defect, the long Mullins sheath is advanced into the left upper pulmonary vein with the tip of the sheath sitting just at the border of the cardiac silhouette (*arrow*). The stiff wire and the dilator of the long sheath are then removed gently. (**c**) The device is then loaded into the long sheath, thoroughly flushed and advanced to the tip of the long Mullins sheath. *Arrow* shows LA disc partially opened in the left atrium. (**d**) The left atrial disk is seen open in full in the left atrium and pulled as a whole towards the right septum. (**e**) Once the device approaches the ASD, under the guidance of the TEE or ICE, the right atrial disk is opened. Note that the device sits at the lateral border of the spine and appears flat. (**f**) The device position and possible residual shunt are interrogated by the TEE or ICE. Stability testing is then performed by gently pushing and pulling the delivery cable. If the device dislodges easily during testing, it needs to be up sized. (**g**) The delivery cable is turned anticlockwise to release the device. Post release, the device fits snugly onto the defect and appears flat

the selected device is too large. The exact mechanism of the erosion is unknown but is believed to be due to the compression effect of the device in a beating heart (Fig. 65.5). In patients with deficient anterosuperior rim, it has been recommended that the device splays open to hug the aorta rather than having the edge of the disc abutting onto the aorta (Fig. 65.6). Careful

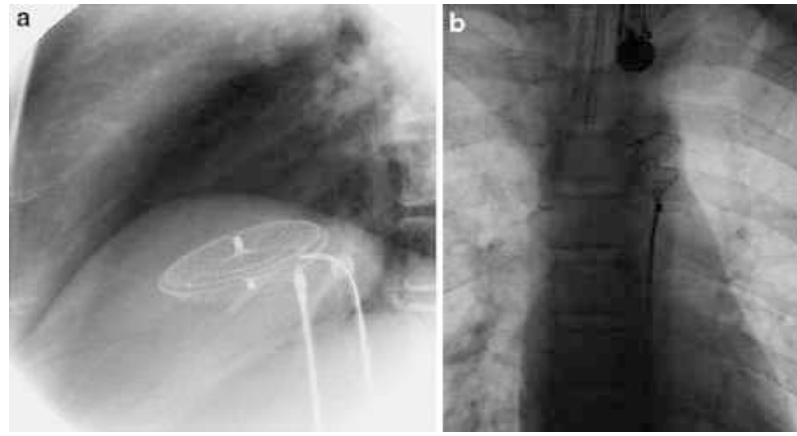

Fig. 65.4 *Complication of ASD closure – embolization of device*. (**a**) A large Amplatzer Septal Occluder embolized to the left atrium. (**b**) A small Amplatzer Septal Occluder embolized to the aorta. Both devices were retrieved percutaneously and appropriate size devices were later implanted

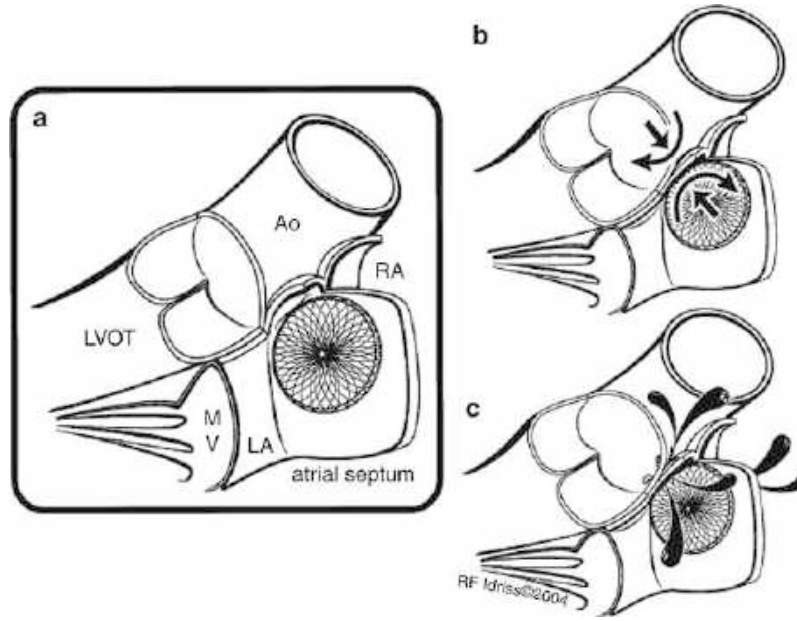

Fig. 65.5 *Amplatzer Septal Occluder*: *purported mechanism of erosion*. (**a**) The device is at close proximity to the aorta anteriorly and to the free wall of both atria laterally. (**b**) With every cardiac cycle, the edge of the device acts like a blade saw, bruising the aorta and the atria. (**c**) Over time, the device may erode into the atria and the aorta causing hemodynamic compromise (With permission from Wiley Periodical Inc.)

surveillance is required for this group of patients as the risk for erosion is higher. Serious cases of cardiac perforation may occur early or late after discharge [28]. One should have high index of suspicion when a patient presents with a new onset of pericardial effusion post-procedure, especially if the device used is large. In institutions where balloon sizing is employed, balloon stretching the defect is no longer practiced as a larger device size than necessary tends to be used. The size at which balloon inflation stops the shunt is used (stop-flow technique). Acute left heart decompensation may occur shortly after ASD occlusion in elderly patients. The less compliant left ventricle (LV) secondary to diastolic dysfunction causes generous left-to-right shunting via the ASD. Occlusion of the ASD eliminates the pressure pop-off from the ASD and causes a sudden increase in the LV inflow, which the poorly compliant LV cannot handle. This causes elevation of LA pressure and in turn a variable degree of pulmonary edema. Elderly patients with hypertension and coronary arterial disease are particularly at risk of this complication. The patient typically develops respiratory distress post-ASD closure, and the CXR reveals

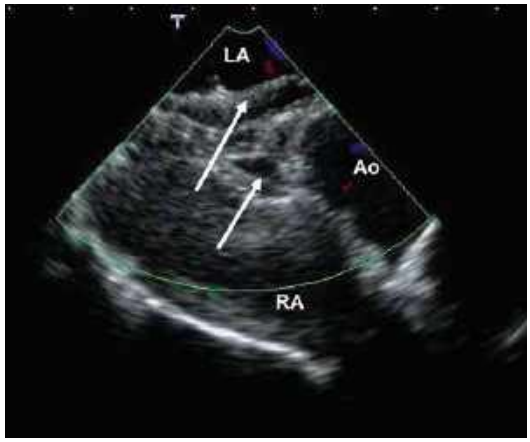

Fig. 65.6 The disks of the Amplatzer Septal Occluder splay open (*arrow*) to hug the aorta

pulmonary edema. Supportive measures and diuretics post-procedure are usually adequate to help these patients overcome the transient pulmonary edema. Not uncommonly, high-risk patients are started with diuretics 2 days prior to occlusion to reduce the effect of this complication, and occasionally pretreatment with afterload reduction may be needed for 3–6 months prior to attempting device closure.

Conclusion

Device closure of secundum ASD in well-selected cases in children and adults is safe and efficacious. It is the treatment of choice in many institutions today. Early closure reduces the risk of future irreversible atrial arrhythmias and pulmonary hypertension and should be recommended for patients with significant left-to-right shunt. Patient selection is paramount in ensuring a smooth and near complication-free procedure. The unique design and features of the Amplatzer septal occluder, ease of implantation, and retrievability have made it the most widely used device today. Other devices with similar designs are also being used. Late erosions leading to tamponade is a serious, major complication, and care should be taken not to oversize the device.

Closure of Patent Foramen Ovale

Patent foramen ovale (PFO) is found in 20–27 % of the adult population [30]. It is a communication formed when the septum primum and septum secundum fail to fuse during embryogenesis. The secundum septum of the PFO is typically thicker and more stable, whereas the primum septum is the thin flimsy partition. The two flaps are kept open by the higher LA pressure during atrial contraction while closed during atrial relaxation. Depending on the degree of overlap between the primum and secundum flaps, the PFO can be simple or tunnel shaped. If the overlap is significant, it forms a long tunnel which extends supero-inferiorly, whereas if the overlap is minimal, it forms a small simple hole (Fig. 65.7). The lesion is commonly present in young children, but as the septal wall toughens with growth, the prevalence of PFO decreases from 33 % in those $<$30 years old to 20 % in those $>$ 80years old [31]. Though the lesion is fairly common in adults, the pathological ones are rare. Shunting across the PFO is classically not generous and does not cause volume loading of the right heart. There are, therefore, no potential long-term complications of arrhythmias and pulmonary hypertension, as may be the case with atrial septal defects. However, transient reversal of flow with right-to-left shunting does occur when the right atrial pressure increases during Valsalva maneuver. The possibility of right-to-left shunting through the defect has caused concerns over the probable undesirable cerebral consequences and hence the notion to close it. Of particular concern are those patients with atrial septal aneurysm (ASA) (Fig. 65.8a, b). ASA is a redundant aneurysmal highly mobile tissue. The saccular bulge flips between the two atria from the imaginary midline and has been linked to septal fenestration or PFO with increased risk of shunting. For decades, physicians and surgeons have been closing PFOs, but the real benefit of treatment remains debatable. The devices for PFO occlusion currently in use include the Amplatzer PFO occluder, Helex septal occluder, PFO STAR, and the Premere devices, but none has FDA approval

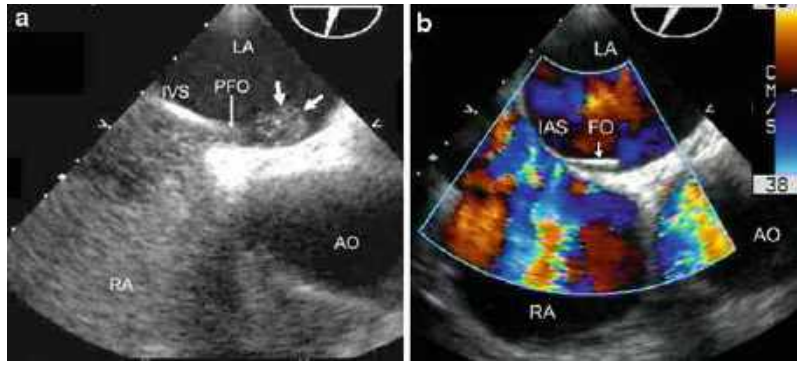

Fig. 65.7 *Right to left shunting*. (**a**) PFO with minimal overlap between the septum primum and septum secundum. Bubbles test showing right → left shunt following release of Vasalva (*arrow*). (**a**, **b**) TEE shows atrial septal aneurysm with multiple fenestrations with excursion into the *LA* during release of Valsava maneuver. Bubble test was positive grade 2 (not shown). (**c**) Blade septostomy converted a small fenestration in the ASA into ASD. This was further enlarged by a static non-compliant balloon. (**d**) A 26 mm Amplatzer septal occluder implanted

for this purpose in the USA [30, 32]. Among these, the Amplatzer PFO occluder is the most widely used.

Indications

Cryptogenic stroke, i.e., a stroke that occurs in young adults below 55 years of age with no apparent cause is the major indication for PFO closure. PFO has been incriminated in causing cerebral and systemic thromboembolism. The pathophysiological explanation is that paradoxical embolism of venous thrombus crosses the PFO into the left-sided systemic circulation, causing an ischemic stroke or distal systemic embolism. Most of the studies incriminating PFO to cryptogenic strokes are observational in nature. However, prospective studies, have not convincingly show cause and effect relationship. In a recently concluded CLOSURE I study, a randomized controlled trial involving 909 patients with previous strokes and transient ischemic attacks, looking at the risk of mortaliy and recurrent stroke, there was no difference between the medically treated group and the closure group [33]. In 2006, the American Stroke Association published the guidelines with regard to PFO and cryptogenic stroke, stating that there was insufficient data to recommend PFO closure in patients with first stroke and a PFO [34]. PFO closure may be considered in patients with recurrent strokes, despite medical therapy (Class IIb, Level C – consisting of consensus opinions of experts and case studies). To date, there is still no clear definition of what constitutes "adequate medical therapy" – aspirin or warfarin or both? In the midst of these controversies, most centers would subject a patient with one cryptogenic stroke to undergo a bubble contrast study to assess the amount of right-to-left shunt, and if it is significant, the PFO will be closed. The interpretation of "adequate medical therapy" prior to occlusion may differ from center to center.

Bubble Contrast Study

This study is performed to assess the amount of right-to-left shunting through the interatrial defect during Valsalva maneuver. The patient is preferably anesthetized and a TEE or an ICE catheter is introduced to visualize the PFO and the two atria. Agitated saline is injected into the vein rapidly, and continuous echocardiography is performed with simultaneous Valsalva maneuver. For optimal effect, the Valsalva maneuver is performed for 15–20 s. The grading of right-to-left shunt focuses on the number of bubbles seen in the left atrium during Valsalva maneuver [35]: Grade 1, <5 bubbles; Grade 2, 5–25 bubbles; Grade 3, >25 bubbles; and Grade 4, opacification of the left chamber. There is no single widely accepted grade at which the PFO is closed, but in the authors' institution, the decision is made if there is Grade 2 or greater right-to-left shunting during contrast study.

Another indication for PFO closure is migraine with aura. Migraine is a debilitating clinical symptom with unknown cause. Migraine may be so intense that it leaves the patient with a poor quality of life. PFO with right-to-left shunting has been linked to migraine, especially those with aura [36]. The reason behind this link is postulated to be due to the presence of venous chemokines or microemboli, which were supposed to be filtered in the lungs, escaping into the systemic circulation via the PFO. These chemokines travel up into the brain and trigger a cascade mechanism, which eventually leads to migraine. The relationship between PFO and migraine has been studied bidirectionally. The odds of PFO being found in patient with migraine is 2.5 (95 % CI 2.01, 3.08) while the odds of having migraine with aura in the presence of PFO is 3.2 (95 % CI 2.38, 4.17) in a meta-analysis study [37]. The link is stronger in patients with migraine and aura because as high as 60 % of patients were found to have a PFO [36]. However, a recent population-based study [38] showed no statistical correlation between PFO and migraine.

In terms of intervention outcome, a nonrandomized trial [39] showed some benefit in PFO occlusion in patients with migraine with and without aura. On the other hand, in the recently concluded MIST (Migraine Intervention with StarFLEX® Technology) trial, which was a randomized controlled trial comparing medical therapy with PFO occlusion, there was no

significant difference in terms of abolition of symptoms between the two groups [40]. Some of the arguments behind the difference in primary end point, especially in the MIST trial, were the recruitment of patients with different severity of migraine and the different methodology among studies that may have contributed to the difference in the outcome. Nevertheless, currently available data demonstrate only a weak link between PFO and migraine.

A less established indication of PFO closure is decompression sickness, a complex formed when spontaneous air bubbles form in the blood circulation during a decrease in barometric pressure, typically occurring in divers during ascent from deep depths. The resultant air bubbles are hypothesized to have crossed from right to left via the PFO into the systemic circulation. The spectrum of effects may vary from an asymptomatic neurological event (ANE) to that of stroke or spinal myelitis. One study has shown that the risk of decompression illness among divers is low, though divers with PFO are at a higher risk of decompression illness [41]. However, another study has suggested that diving itself and the frequency of diving are attributed to the sickness and the presence of PFO does not increase the risk [42].

Contraindications to PFO Closure

PFOs classically do have sufficient surrounding rims to hold the commonly used available devices. Also, there is usually no concern about the pulmonary arterial pressure, unless the patient has primary pulmonary arterial hypertension, which is a contraindication for PFO occlusion. The absolute contraindication, however, is the presence of thrombus at the PFO. Catheter manipulation of PFO in the presence of thrombus may dislodge this, causing devastating distal embolism.

Procedure

The procedure is almost similar to ASD occlusion, with some additional measures to consider. The procedure is performed preferably under general anesthesia, unless ICE is employed. Good imaging is required to assess the PFO, its size and the number of shunts, the presence of thrombus in the septal aneurysm, the rims of the PFO, and the distance to the adjacent structures. Valsalva maneuver is performed, as described previously, to assess the presence and the grade of right-to-left shunting.

In PFOs with Tunnel-liked morphology and ASA, balloon sizing is recommended. This aids in profiling the tunnel and defines the exact defect, which may not be apparent previously. Occasionally, in patients with fenestrated PFO, an option is to convert the fenestration to a single defect with a blade and balloon dilation, hence allowing a single device to occlude all the defects (Fig. 65.8) or use a PFO device that covers all the defects.

Postprocedural Care

After extubation, the patient can be transferred to the ward for recuperation with standard post-procedure care. Aspirin is started at 75 mg dly for 6 months, as per ASD closure. Aspirin may need to be continued on a long-term basis in patients who had previous thromboembolic stroke to prevent occurrence of future strokes even after device occlusion. Some operators may add in an extra antiplatelet agent or even warfarin. Chest x-ray and echocardiography are performed the next day to rule out device embolization, pericardial effusion, and residual shunt. Patients are usually discharged the day after the procedure. In patients in whom general anesthesia is not employed, discharge from the hospital may be on the same day and chest x-ray and echocardiography are repeated either the next day or a few days later, depending on local protocol. Total occlusion has been reported ranging from 68 % to 95 % [39, 42]. The difference in the rate of complete occlusion differs widely with different devices, the presence of ASA, and the sensitivity of the imaging modality in detecting residual shunting. Smaller PFOs, which need a device size less than 25 mm, tend to have higher rate of total occlusion. Among the devices, Amplatzer devices generally offer faster total occlusion in the short and medium term,

presumably due to the rigid nitinol scaffolding and the ability to grasp the interatrial wall better, encouraging better endothelialization of the device [33]. Residual shunting poses residual risk for future cerebral event, depending on the size of the shunt. Small residual PFO may close spontaneously over time and one may adopt a watchful approach, whereas larger residual defects with significant residual shunt, which is rare, may warrant placement of another device.

Complications

PFO occlusion generally has a brief learning curve and complications are uncommon. Nevertheless studies have reported complications ranging from 2.4 % to 6.8 % [33, 40]. As in ASD closure, erosions and device migration are the more serious ones but are fortunately rare.

Conclusion

Although PFO is a common defect, the pathological ones are uncommon. Routine closure of PFO is not warranted. PFO has been implicated with cryptogenic stroke, migraine, and decompression illness. The pathogenesis is thought to be due to paradoxical embolism from the venous to the systemic circulation through the PFO during sudden increase in the RA pressure, especially in a PFO with a large flap. Nevertheless, existing evidence is not able to link these pathologies to PFO beyond doubt. While PFO closure can be safely performed nowadays, the risks for these pathologies are not totally eliminated by closing the PFO alone. Bearing in mind the inconclusive cause and effect, the decision for PFO closure in patients should be individually made.

Closure of Ventricular Septal Defect

Isolated VSD is the most common congenital heart defect. However, device closure of VSD has a shorter history, more limited applicable devices, and far smaller accumulated clinical experience compared with that of ASD closure. Given the location of VSD within the heart, the technique for transcatheter closure of VSD is far more complex than that of ASD closure with the current or even historical devices. The technique requires the creation of an arteriovenous circuit and the passage of catheters, wires, and stiff delivery sheaths across the tricuspid and aortic valves, maneuvers that may be deleterious in the small symptomatic infant. On the other hand in the modern era of pediatric cardiac surgery, VSD closure, particularly for perimembranous VSD (PMVSD) has a very low mortality even in very small symptomatic infants, and the incidence of complete heart block has been sharply reduced [43, 44]. Thus, surgery is likely to remain the treatment of choice for the majority of patients in whom VSD closure is indicated. Its designation as a simple lesion and yet the most common surgical procedure for congenital heart disease, finding an effective, safe, and less invasive method such as transcatheter device closure is a challenge. Furthermore the limitations of the conventional surgical approach in the closure of the less common and difficult to approach muscular VSDs are well recognized [45, 46]. This is one area, where device closure has made a significant impact in the management of CHD.

Closure of Muscular VSD

About 10–15 % of VSDs are located entirely within the muscular part of the ventricular septum [47]. These defects may be single or multiple, and the size ranges from very small to large. Small defects, unless multiple, are of no hemodynamic consequence and do not require closure. Patients with large muscular VSDs, either single or multiple, are often severely symptomatic early in life and require intervention in the first few weeks or months. Because of high morbidity and mortality associated with primary surgical closure of these defects in small infants, the favored management is for an initial pulmonary artery band, until the patient has gained enough weight to undergo surgical closure and debanding of the

pulmonary artery [47, 48], or sequentially percutaneous device closure followed by pulmonary artery debanding. Primary closure by the hybrid, periventricular method is increasingly favored in many institutions today.

Even when patients with muscular VSD are not severely symptomatic and the surgery may be performed electively at a later age, surgical closure still poses a significant challenge. These defects are frequently hidden within the coarse right ventricular trabeculations and therefore, are difficult to localize through the standard surgical approach. Various different surgical approaches have been proposed. However the overall mortality and the rate of residual VSDs remain higher than with isolated PMVSD [45, 46]. It is in the closure of muscular defects that device closure perhaps has an edge over surgery.

Percutaneous device closure of VSD was first reported by Lock in 1988 [49], and since then various attempts have been made to close these by using the Rashkind umbrella [50], variations of the Clamshell, Sideris buttoned device [51], and Gianturco coils [52]. With the exception of the Gianturco coils, these devices were specifically designed for closure of either ASD or PDA. A major drawback of the double umbrella devices is that they lack the self-centering feature, one which is important for stable device position once completely deployed. These devices are not easily retrievable without damaging them should the device embolize or is in a suboptimal position, precluding reimplantation of the same device. The stiff metal spokes that constitute the device frame may traumatize valve leaflets and chordae, and vessel walls in the attempt at retrieval.

The Amplatzer muscular VSD occluder [53] is specifically designed for closure of muscular VSD and the Nit-Occlud coils [54] for both muscular and perimembranous VSD. The Nit-Occlud coil, whose loops are from a single piece of nitinol wire is easily retrievable and atraumatic. It does not require a large long sheath for delivery. However scant data are available in the literature on its efficacy. The Amplatzer muscular VSD occluder is based on the similar design concept of the family of Amplatzer devices, i.e., a self-expanding double disc device made of nitinol wire mesh. The connecting waist of the device, which is usually slightly larger than the VSD size stents the defect and, together with the two discs, keeps it in a stable position. The fabric within the device interferes with shunting and promotes thrombosis. Even if most muscular VSDs do not have a round shape for which the device waist is conceptualized, satisfactory closure with some residual shunt can be generally achieved if a proper-sized device is selected.

Indications for VSD Closure and Initial Assessment

As with surgical closure, the major indication for device closure is significant left-to-right shunt that causes volume overload of the left heart, evident clinically and on echocardiography, with long-term potential for the development of pulmonary hypertension. The other indication is previous episode of endocarditis. Due to the limitations of the technique and the potential for serious complications, percutaneous closure should not be performed in small symptomatic infants with large defects. In the past, such patients were treated initially by pulmonary artery banding, and percutaneous closure was performed by debanding of the pulmonary artery when the patient achieved a reasonable weight. Today, primary closure by conventional surgery or the hybrid perventricular method are preferred (see below).

A small subgroup of patients with muscular VSD includes those with residual or previously undiagnosed defects causing severe cardiac failure following repair of complex cyanotic cardiac lesions. Unaccustomed to increased pulmonary blood flow, these patients tolerate the new left-to-right shunt poorly, often requiring high inotropic and ventilator support and a prolonged stay in the ICU. Uncorrected, these defects may also lead to accelerated development of pulmonary hypertension [55]. These defects, which may be multiple and apically located, in patients with severely hypertrophied RV with previous obstruction to its outflow, pose a major challenge to surgical closure [56]. Though not strictly muscular VSD in

the morphologic sense, significant residual shunt may also occur due to patch dehiscence late after repair of complex malformations where VSD is one of the principal lesions. The patient does not usually present in an ill state but the development of accelerated pulmonary hypertension warrants timely closure. The less invasive percutaneous closure may be the preferred technique in such patients, in whom adhesions from previous operation may pose a major challenge for the surgeon.

Echocardiographic assessment of the size, the number, and the location of the VSDs is important in the planning of the procedure. The four-chamber view demonstrates apical, mid-muscular, and inlet defects, and the parasternal long axis view demonstrates anterior VSDs. Generally defects below the moderator band, i.e., the mid-muscular and apical ones, require the transjugular approach, whereas the higher defects may be closed via the femoral venous approach [57].

In patients with multiple muscular VSDs (Swiss cheese), one may elect to close the largest defect deemed to be causing the significant shunt and leave the smaller ones. If there is more than one large defect, the procedure may be staged or multiple devices can be implanted at the same time.

Devices and the Procedure

The CardioSEAL, the Rashkind umbrella, Nit-Occlud coils, and Gianturco coils have all been used to close muscular VSDs, but the introduction of the Amplatzer muscular VSD occluder has superseded other devices. The US multicenter registry evaluated only the Amplatzer muscular VSD occluder, and the large European registry, which also included PMVSD and residual postsurgery VSD, overwhelmingly employed the Amplatzer device for closing the VSD [58, 59].

Only the Amplatzer muscular VSD occluder is described in this section as this is the most commonly used device in many institutions today. The principles of the technique and the indications for other devices are similar. The procedure should be performed under general anesthesia, as it may be complex and prolonged. Furthermore transesophageal echocardiographic guidance is almost always mandatory. Details of the procedure have been well described elsewhere [53]. As mentioned above, mid-muscular and apical VSDs generally require the transjugular approach, i.e., a long sheath, appropriate for the device size, is inserted into the internal jugular vein and traverses the tricuspid valve, into the RV, and across the VSD, and its tip is placed well into the LV. This is achieved by first crossing the defect with a guidewire from the LV to the RV and then into the pulmonary artery or the systemic veins. The wire is snared with a gooseneck or similar snare and exteriorized out of the internal jugular or the femoral vein. The delivery sheath is passed from the venous approach to the LV over this guidewire. Figure 65.9 shows step-by-step method of device implantation. Often it is possible to discharge the patient the following day, and antiplatelet therapy with low-dose aspirin is given for 6 months.

Results and Complications

There is a steep learning curve to this procedure. The US and European registries have demonstrated the feasibility of closing muscular VSDs using the Amplatzer device with high success and excellent closure rates [58, 59]. However, as expected from the experience of surgical closure, the complication rate is not negligible. Among the more serious complications is hemodynamic instability especially in smaller, symptomatic patients and those with residual VSD post-surgical repair of complex anomalies (Fig. 65.10). The relatively large and stiff delivery sheaths and dilators may impair cardiac output and splint the tricuspid valve open. In the US multicenter registry, hypotensive episodes and/or cardiac arrest, requiring inotropic support, occurred in 12 % [58].

Other complications related to the procedure are cardiac perforation and tamponade, arrhythmias, air embolism, conduction disturbances, and damage to the tricuspid and mitral valves due to

He was successfully weaned off high inotropic and ventilator support following percutaneous closure with two Amplatzer muscular VSD occluders size 6 and 8 mm. *RV* angiogram showing *RV* discs of the devices on the *RV* aspect of ventricular septum (*arrows*). The defects are closed via the femoral vein approach as they are located above the moderator band. *RV* right ventricle. (**b**) Adolescent female, post conduit repair for Tetralogy of Fallot with pulmonary atresia. Residual VSD due to patch dehiscence, pulmonary artery pressure two-third systemic. Device closure with 14 mm Amplatzer membranous VSD occluder (*large arrow*) and 6 mm Amplatzer ASD septal occluder (*small arrow*) at 3 years and 5 years post surgical repair. The patient also has left pulmonary artery stenosis which was stented (*broken arrow*)

impingement of the device on these valves [57, 60]. Deaths related to the procedure were reported in both the US and European registries. The device may embolize to the aorta or the pulmonary artery due to suboptimal implantation, but generally they can be retrieved with snare catheters. Hemolysis may occur when there is a significant residual shunt. Mild left ventricular outflow tract obstruction related to the implanted device may occur. Although patients weighing <5 kg had been subjected to percutaneous closure in the US and European registries, there should be a lower threshold for using the perventricular method in small symptomatic children to minimize the above serious complications.

Perventricular Closure

In the US registry evaluating the Amplatzer muscular VSD occluder, 92.8 % of the defects were closed by the percutaneous method, and a weight of <5 kg significantly correlated with procedure or device-related complications. This was attributed to the arteriovenous loop required for percutaneous delivery, the stiff delivery catheter and cable, the less than ideal angle of device delivery to muscular VSD anatomy, and the necessity of delivery across the tricuspid valve, factors that are magnified in the small infant.

The perventricular approach, first described experimentally by Amin [61], allows a more direct access to the defect by inserting the delivery sheath via a puncture on the RV free wall. A short sheath is then passed over a guidewire across the defect into the LV through which a muscular VSD occluder is implanted (Fig. 65.11). This, however, requires a median sternotomy but without cardiopulmonary bypass, which is a significant advance from previous attempts at open-heart-intraoperative-device closure using the umbrella device.

A few small series reported encouraging results of this technique, and this is today the preferred method in many institutions for the primary closure of large muscular VSDs in severely symptomatic small infants [62–64]. Another group of patients who may benefit from perventricular closure apart from those with no

vascular access, are sick patients following repair of complex anomalies, who have newly discovered residual muscular VSD, causing a large shunt and cardiac failure. These patients may be too unstable to undergo the complex procedure of percutaneous closure. However, the procedure is not always straightforward as some defects are difficult to cross from the RV free wall, especially those that are apically or posteriorly located. An initial percutaneous approach may be required to cross the VSD from the LV, followed by snaring and exteriorizing the guidewire through the catheter in the RV free wall for successful implantation of device. The CardioSEAL has also been successfully used in perventricular closure of muscular VSD [65], but it is no longer available. Interestingly, this technique has also been applied to PMVSD but 6.6 % needed conversion to conventional surgery [66].

Closure of Perimembranous VSD

These defects account for 80 % of all VSDs, and so having a safe and effective device which can be universally applied to closing perimembranous VSDs (PMVSD) will drastically alter the way ICU, OR, and catheter

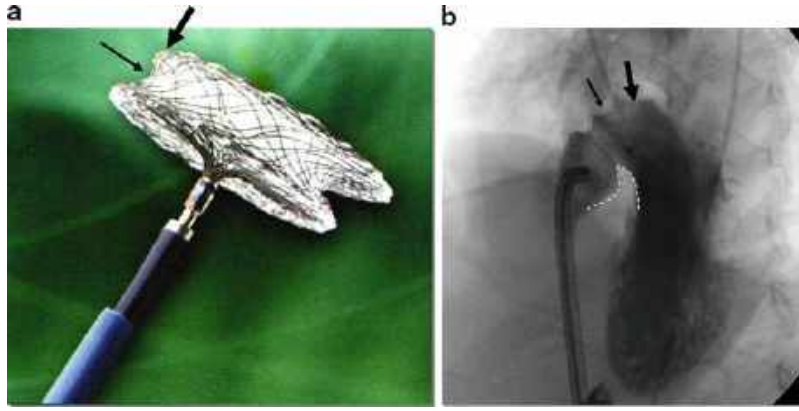

Fig. 65.12 (**a**) Amplatzer membranous VSD occluder device. The eccentrically configured *LV* disc (*large arrow*) forms a small margin on the superior aspect of the waist (*small arrow*) to avoid impingement on the aortic valve cusp. (**b**) Closure of a perimembranous ventricular septal defect with a 12 mm membranous VSD occluder. *LV* angiogram immediately post deployment shows contrast shunting into the *RV* through the device which is not uncommon. The device has not been detached from the delivery cable. *Arrows* showing aortic valve cusps, one of them in close proximity to the superior aspect of the *LV* disc (*small arrow*). This seldom cause significant aortic regurgitation but device contact with the crest of the ventricular septum (*broken line*) may cause complete AV block. *LV* left ventricle, *RV* right ventricle

laboratory resources are utilized. However, the excellent results of conventional surgical closure, even in small infants [43–45] and given the technical complexity of percutaneous procedure in small children and its possible complications, surgery will remain the principal method of closing PMVSD. The proximity of PMVSD to the conduction bundle, and the tricuspid and aortic valves [48] compounds the procedure and device-related risks mentioned in the preceding section on muscular VSD in the percutaneous closure of this type of defect.

Despite the major obstacles, the fact that it is the commonest of all congenital cardiac lesions drives the quest for a suitable device for PMVSD. The few devices which were designed for other lesions have been occasionally used for this purpose but proved unsuitable if not technically difficult and hazardous [67–69]. The Amplatzer membranous VSD occluder, designed specifically for closure of this type VSD, is a self-expanding nitinol mesh with a "waist" that stents the defect as the mechanism to effect closure, and a disc on either side of the defect to hold the device in place. However, the LV disc is eccentrically configured such that the superior rim is only 0.5 mm larger than the waist to avoid impingement of the device on the aortic valve, and the waist thickness conforms to that of the membranous septum (Fig. 65.12).

A multicenter international registry and a European registry have shown that the Amplatzer membranous VSD occluder could be successfully implanted in the majority of patients and achieved good closure rates at 1 and 6 months [59, 70]. However, failure of implantation in 7 % in the multicenter international registry and a residual shunt of 4 % at 6 months, even though graded as mild in the great majority, did not fare well compared with conventional surgery, given that these patients had mild or no symptoms and weighed above 7 kg. More recent large series from Asia have reported higher rates of successful implantation using devices that were similar in material and construction design to the Amplatzer membranous VSD occluder [71, 72]. As expected, new or increased aortic regurgitation was one of the reasons for procedural failure and was observed post-procedure in 9.2 %. Although this resolved in some patients, the long-term outcome on the aortic valve remains to be seen. The most serious adverse outcome however, is the development of complete atrioventricular block (CAVB), particularly those that

occurred several weeks or months after the procedure [73, 74]. Most series have reported this important major complication, with an incidence as high as 5.7 % requiring pacemaker implantation in a large European study [75], and in a smaller series, the incidence was even higher at 22 % [76]. Edema and inflammation were speculated to be the etiology for early onset CAVB, whereas the late onset CAVB has been attributed to ongoing fibrosis. That no predictive factors can be firmly identified for such a complication which can potentially lead to sudden cardiac death, this has led to voluntary discontinuation of this procedure in many major institutions worldwide. Finally, the Nit-Occlud VSD device is theoretically less likely to cause this major complication as it does not stent the defect and the delivery system is less rigid. However, this is yet to be supported by a body of published clinical data [54, 77].

Conclusion

The ability to close muscular VSDs by percutaneous techniques represents a significant advance in the management of CHD as these lesions are challenging, even in the current era of pediatric cardiac surgery. This is also the more effective method in the management of VSDs in the small but significant subgroup of patients who remain in ICU because of residual or undiagnosed muscular VSDs following repair of complex cardiac lesions. The perventricular hybrid technique extends the utility of device closure to muscular VSDs in the small, severely symptomatic infant.

Although PMVSD can generally be performed safely in bigger children with no or mild symptoms, the incidence of late CAVB with no identifiable predictive factors is particularly worrying. A radically different concept, from one that relies on a device stenting the defect to effect closure with retention discs to maintain stability would perhaps be the way forward. Transcatheter patch closure is one of the innovations in this direction, but its safety and efficacy remain to be seen [78].

Catheter-Based Interventions on Extracardiac Arterial and Venous Shunts

66

Jeffrey R. Darst and Thomas E. Fagan

Abstract

Extracardiac shunts can result in deleterious alteration of effective pulmonary or systemic blood flow. The catheterization laboratory has become an environment in which both left-to-right and right-to-left shunts can be addressed with reasonable success in most cases. The development of transcatheter techniques and devices has increased markedly over the past two decades, and increasing experience is being obtained in palliative and curative procedures in these situations. The most common left-to-right shunt is the patent ductus arteriosus, in which transcatheter occlusion has become the standard of care in most infants and children. Various methods of closure have been widely described and employed. Systemic-to-pulmonary collaterals are ubiquitous in single-ventricle patients, and considerations for their closure (or potential benefits) are varied and important. Similarly, previously placed surgical shunts may no longer be necessary due to the development of native cardiac structures, and transcatheter occlusion is preferable over an open surgical approach in some patients. Closure of coronary artery fistulas, aortopulmonary windows, and sinus of Valsalva aneurysms has been successfully performed. Closure is not the only desired result with left-to-right shunts, however, and interventions to maintain surgical or native shunts may also be considered via stent placement. Right-to-left shunts, usually indicated by cyanosis, may also be addressed through transcatheter approach. Pulmonary arteriovenous malformations are the most widely described, and occlusion may be possible with various devices. Arteriovenous

malformations may be of several morphologic types with differing etiologies, each of which requires unique considerations in evaluation and treatment. An unroofed coronary sinus to the left atrium provides a pathway for deoxygenated blood to enter the heart directly, and device placement may redirect flow away from the left atrium. Lastly, systemic vein-to-pulmonary vein collaterals and systemic venous collaterals in Glenn circulation may be amenable to intravascular occlusion, physiology permitting.

Introduction

Efficient circulation is dependent on serial delivery of oxygenated blood flow to the body and deoxygenated blood flow to the lungs. While cardiac malformations are responsible for a large portion of the disruption in this pattern, various extracardiac conditions can result in similarly altered physiology. Blood flow that results in the routing of oxygenated blood back to the lungs is considered a "left-to-right" shunt and may volume-load the heart and the lungs. Desaturated blood that bypasses the lungs or passes through the lungs without obtaining oxygen constitutes a "right-to-left" shunt. This may result in significant systemic desaturation.

Techniques to address these shunts have been developed over time, and many transcatheter modalities are now available to eliminate pathways that prevent effective pulmonary and systemic blood flow from reaching their appropriate destinations. The catheterization laboratory is the ideal site for diagnosis and treatment of these conditions. Angiography can identify many of these shunts, and physiologic parameters, such as oximetry and pressure measurement, can help assess the effect of the shunts on the systemic and pulmonary circulations.

The advent of many new devices over the past 20 years has increased the armamentarium available to an interventional pediatric cardiologist. While FDA-approved devices are still limited due to the difficulty in completing large-scale studies in congenital heart disease patients to prove safety and efficacy, the ever-growing list of available devices provides what is often the best option to benefit patients who are affected by extracardiac shunts.

In this chapter, relatively common, as well as more infrequently encountered, conditions are grouped by the type of shunt that results. Interventional techniques are as numerous as interventional operators; however, commonly accepted or reported techniques are discussed. Devices that have been effective in these types of situations are described, with review of relevant literature.

Left-to-Right Shunt Lesions

Patent Ductus Arteriosus

In patients with normal pulmonary vascular resistance, a persistently patent ductus arteriosus (PDA) results in a left-to-right shunt from the aorta to the pulmonary artery. A common finding in neonates, the ductus usually closes in the first few days of life. If it remains open, a volume load from the systemic to the pulmonary circulation may have several consequences. In the short

term, pulmonary overcirculation may result in tachypnea, poor growth, and left heart enlargement. In a patient with a sufficiently large PDA, pulmonary artery pressure may increase. Even if the shunt is relatively well tolerated, shear stress on the vascular endothelium over time can lead to increased muscularization of the distal vasculature, resulting in elevated pulmonary vascular resistance and, in the most severe cases, Eisenmenger syndrome.

Small PDAs may be pressure restrictive, and the volume load to the lungs and left heart may be physiologically trivial. Historically, all known PDAs were closed due to the risk of endarteritis, thought to be an increased risk due to the turbulent jet of blood flow in the pulmonary artery. More recently, this practice has undergone some reevaluation, and in silent or very small PDAs, intervention may sometimes be deferred [1]. The decision whether to close an inaudible ductus continues to be a matter of debate.

In patients who need PDA closure, two general options exist to eliminate the shunt. A surgical approach, via a left lateral thoracotomy, is generally reserved for the very small patient, such as the premature neonate. In fact, techniques are being developed and are in early use to close the ductus in very small infants [2].

A transcatheter approach is now preferred for ductal occlusion in infants as well as older children. While small children present some technical challenges, even children <6 kg have been shown to undergo successful occlusion by this method [3]. The advantages include the relatively straightforward access to the PDA via the femoral vein and artery. In addition, venotomy and arteriotomy sites are at very low risk of infection, and a thoracotomy is avoided. Most often, fluoroscopy times are kept at a minimum, the efficacy of the procedure is extremely high, and the risk of the procedure is low [4].

While variation in the techniques among various operators exists, both femoral venous and arterial access are obtained. In older children with clear evidence of a very small PDA, venous access may be avoided by some operators. In general though, right heart catheterization is usually performed to assess the cardiac output, the shunt magnitude, and the pulmonary artery pressure and resistance. In a small PDA, a very modest and even occasionally undetectable shunt may be observed, whereas a large PDA may result in a shunt of nearly 3:1 or more. Pulmonary artery pressure may not be elevated, even in a large ductus. As resistance is related to the length, a large ductus with significant length may still be pressure restrictive in the setting of a moderate shunt.

Although classification of the ductus is largely an academic pursuit, some practical considerations exist [5]. Right anterior oblique (30–40°) and straight lateral projections usually profile the vessel reasonably well. A conical-shaped ductus may be best suited for a particular device, whereas a long, tubular vessel may not accommodate the same occluder. In small children with a tubular ductus, standard occluder devices may not be useful at all, requiring the creative use of other devices or referral for surgical ligation. Important measurements include the narrowest portion of the ductus as well as the aortic ampulla diameter in moderate to large PDAs. With some devices (e.g., Amplatzer Ductal Occluder II (ADOII) (St. Jude Medical, St. Paul, Minn)), the midpoint of the PDA is a relevant measurement for device sizing.

Often, several options for closure of the ductus with a device exist, though one is often superior to another depending on the morphology and size of the PDA. In a PDA that measures less than 1.5 mm in nominal diameter, coil occlusion is usually preferred (Fig. 66.1). The approach may be via the pulmonary artery side or the aortic side, though the latter is most straightforward (Fig. 66.2). Coil selection is based on nominal ductal diameter, and the coil diameter should be at least double that diameter. The coil length is best chosen to allow for four total loops so that ½ to 1 full loop can be placed on the pulmonary artery side with three coil loops on the aortic side. Therefore, coil length should be equal to or greater than (coil diameter × Pi × 4). A 3 mm diameter coil should then have a length of at least 4 cm. A 5 mm diameter coil should be at least 6.3 cm long.

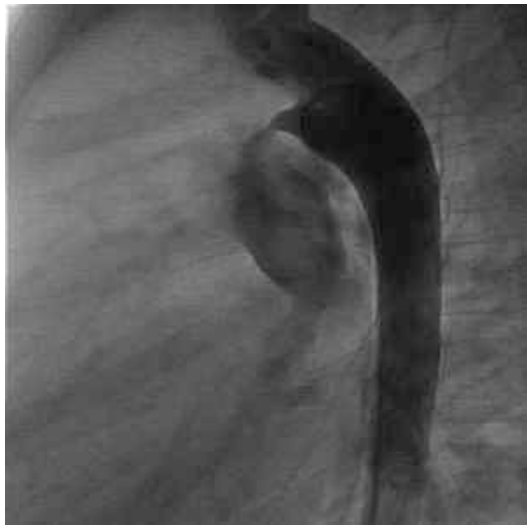

Fig. 66.1 A small, conical PDA allows for a quantifiable left-to-right shunt that requires closure

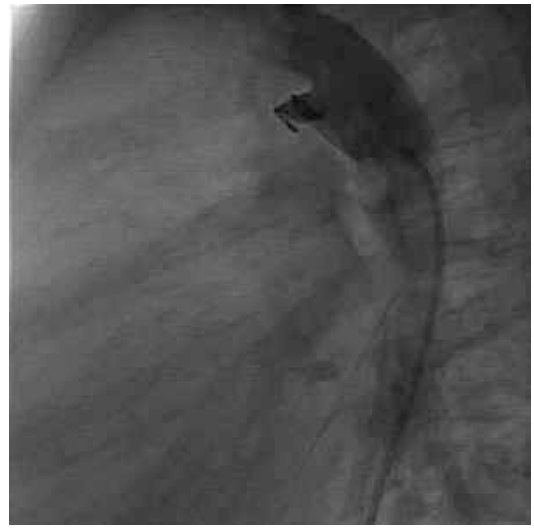

Fig. 66.3 Angiographic occlusion is achieved with a properly configured coil within the ductal ampulla

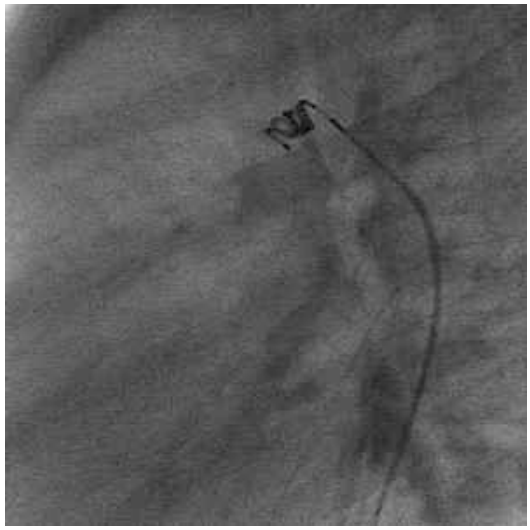

Fig. 66.2 An aortic approach to the ductus with a detachable Flipper coil is fairly straightforward

The diameter of the coil wire is generally at least 0.035–0.038″ and may be up to 0.058″ for larger coils, though these are used with less frequency with the advent of pluglike devices. Finer coils, such as the 0.018″ variety, have little utility even in small PDAs. Coils may be pushable or detachable, with the latter providing increased control to reduce the risk of embolization.

Once the coil is in place, a follow-up angiogram is performed to assess its position and occlusion of the ductus (Fig. 66.3). Often, a trivial wisp of contrast will pass along the coil which will disappear over time. Concern should be raised for the risk of persistent leak when a discrete jet of contrast passes the coil without much alteration in course. Additional coil(s) may be required.

In a larger ductus arteriosus (Fig. 66.4), coil occlusion may still be efficacious, but relatively straightforward use of an Amplatzer Ductal Occluder (ADO) (St. Jude Medical) may be simpler and more successful. Approach from the venous system requires a bit more preparation but allows for controlled delivery. A long delivery sheath is required and is inserted over the wire and advanced well into the descending aorta. The device is partially deployed in the aorta and pulled back into position, with tactile clues and angiograms to assist in its adjustment (Fig. 66.5). A pigtail in the artery is useful for serial angiograms before and after device release (Fig. 66.6).

Other off-label alternatives have been used in certain situations to occlude a particularly tricky ductus. An Amplatzer Vascular Plug II (AVP II) [6] (St. Jude Medical), which consists of two narrow disks which flank a wider central disk, can be useful in a ductus with a relatively small

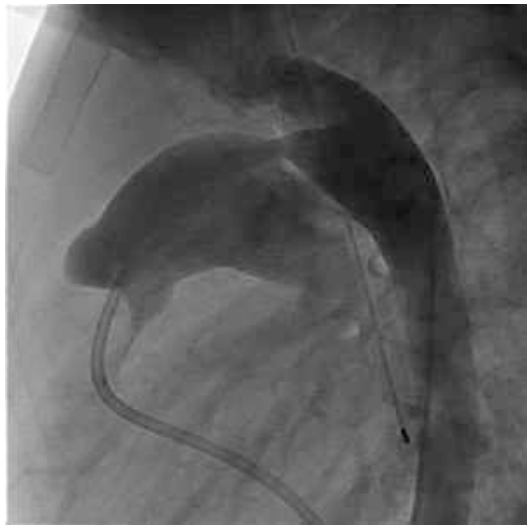

Fig. 66.4 A large PDA may be responsible for a large left-to-right shunt

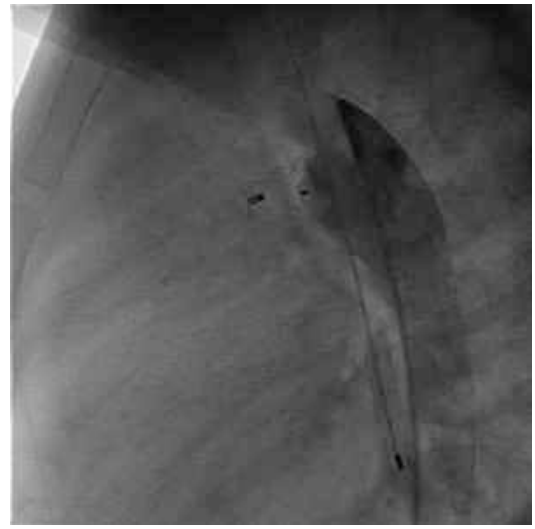

Fig. 66.6 Ductal occlusion is achieved without retention skirt extension into the aorta

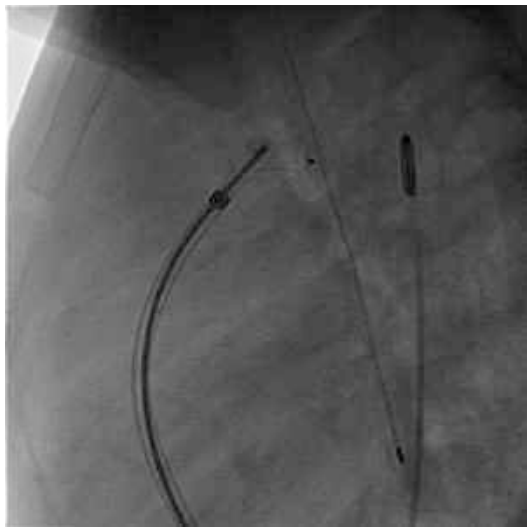

Fig. 66.5 An ADO may be delivered through a long sheath, from a venous approach

aortic ampulla. A long PDA with some tortuosity may be amenable to AVP II placement (Figs. 66.7 and 66.8). The AVP II can be placed via a venous or arterial approach.

The traditional ADO device was designed with a retention skirt on the aortic side, which served to both fill the aortic ampulla and also resist embolization from the higher-pressure aorta to the lower-pressure pulmonary artery. Clearly, however, elevated pulmonary vascular resistance can lead to a higher pressure in the pulmonary vascular circuit, and embolization to the systemic circulation may occur.

The second-generation ADOII consists of a central waist with disks on either side. The pulmonary disk may resist right-to-left embolization. It is currently available outside the United States and is undergoing trial within the USA, and additional advantages include smaller sheath size for delivery and softer shape [7] (Fig. 66.9).

A final off-label device used for closing a PDA is an Amplatzer muscular VSD occluder (mVSD) (St. Jude Medical). This device has a 7 mm long waist of variable diameter bracketed by two disks. This device has been used, particularly in larger children with very-large-diameter PDAs [8].

For obvious reasons, the shape and size of the PDA must be very carefully assessed before proceeding with off-label device use. The risk of off-label device use must also be compared with the former standard, surgical ligation, which remains a viable option. Retrieval in all of these options is a challenging technical endeavor, so release of a device should be thoroughly evaluated by angiography and, sometimes, hemodynamic assessment for obstruction in the aorta or

Fig. 66.7 A long, tubular PDA is less amenable to standard devices

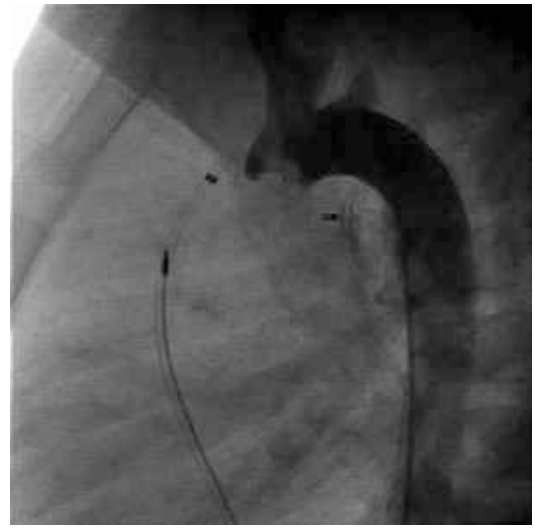

Fig. 66.9 The second-generation ADOII includes a disk on either side of a central waist

Fig. 66.8 Occlusion may be achieved with an AVP II

pulmonary artery, in questionable cases. Abnormal left lung perfusion has been described in a series of patients following device closure, particularly in low-weight infants [9].

As with nearly every device occlusion case, periprocedural considerations include the need for systemic heparinization to reduce the risk of clot formation during device manipulation and placement. Antibiotics are routinely given prior to device delivery. Usually a first-generation cephalosporin is sufficient, though clindamycin or vancomycin may be used in known MRSA positive-colonized patients.

The follow-up for patients with now-occluded PDAs varies. Most often, 1–2 follow-up visits in the first 6 months are sufficient after coil placement, after which discharge from care is routine. In small children with larger PDAs or in patients in whom an off-label device was required, additional follow-up over the short term with extension past 6 months may be reasonable. Subacute bacterial endocarditis prophylaxis is recommended for 6 months after device or coil placement.

In rare cases, a residual leak may remain after more than 6 months of follow-up. Residual shunts are usually quite small and are almost always hemodynamically insignificant. However, closure of these residual leaks is recommended due to the potentially increased risk of endarteritis related to exposed foreign material in the bloodstream. It seems unlikely for endothelialization to be complete in areas adjacent to the jet of flow that constitutes the leak. Fortunately, a single additional coil is often all that is necessary to complete the occlusion. In addition, intravascular hemolysis has been described [10].

Systemic-to-Pulmonary Artery Collaterals

Patients with single-ventricle physiology often develop collateral vessels from the systemic to the pulmonary circulation. These collaterals may have both beneficial and adverse consequences. On the positive side, increased pulmonary flow increases the saturation of blood mixing in the single ventricle and also may prevent arteriovenous malformation in the lungs by providing a route of delivery for hepatic blood flow to the lungs in a stage II-palliated patient [11]. An increased volume load on the single ventricle may be deleterious; however, some studies suggest that pulmonary blood flow in some patients may be augmented in times of increased cardiac output [12]. Because of the perioperative implications, many surgeons and cardiologists prefer to have these collaterals removed from the circulation whenever possible prior surgery.

Systemic-to-pulmonary collaterals may also form in association with other conditions, primarily related to the respiratory system. Pulmonary sequestrations are often supplied by vessels arising from the descending aorta. Scimitar syndrome is another example that may exist in an otherwise normal heart. Isolated systemic-to-pulmonary collaterals have been described and found to be quite harmful, in other congenital cardiac lesions [13]. Hemoptysis has been described in conjunction with collateral presence [14], though many operators have embarked on unsatisfying collateral hunts when presented with this symptom.

Common sites of collateral formation include the aorta (Figs. 66.10 and 66.11) and the brachiocephalic vessels. Intercostal vessels may give rise to collaterals to either lung. Both the right and left internal mammary arteries (IMA) are well situated to give off branches to the pulmonary circulation; either IMA can be readily identified as a collateral source by proximal dilation as it arises from the ipsilateral subclavian artery. Other vessels arising from the subclavian artery, particularly the lateral thoracic arteries, are common sources for collateral origin. The carotid and vertebral arteries will sometimes supply the lung, often via an impressively tortuous course. Some operators will generally avoid the carotid and vertebral arteries due to the obvious proximity to the brain should a vascular disruption or coil embolization occur.

Fig. 66.10 A large collateral of the descending aorta communicates with a large portion of right lung

Fig. 66.11 Coil occlusion eliminates the inefficient left-to-right shunt

Clinical implications of small, scattered collaterals are poorly understood. Two-ventricle patients will tolerate some collateralization

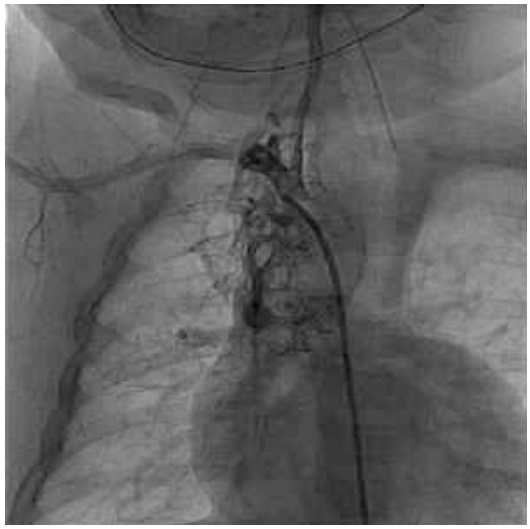

Fig. 66.12 Extensive collateralization is found upon injection of the right subclavian artery in a single-ventricle patient
